(2) Total lesions of the cord are irremediable, because the cells and fibres of the entire cord are destroyed, are never regenerated, and are replaced by cicatricial tissue. The lesion thus is permanent, and requires no treatment.

(3) In hematomyelia the clot is absorbed; its site persists as a cavity or is filled by newly formed tissue; irregularities of circulation in the surrounding portions of the cord adjust themselves. There may be great amelioration of the symptoms. There is, therefore, no therapeutic indication, and no remedial treatment is possible.

(4) In partial contusion of the cord the lesion results in permanent destruction of cells and fibres; disturbances of circulation adjust themselves. Repair is accomplished by cicatricial tissue. No treatment is available.

(5) In open injuries of the cord there are destruction of cells and fibres and disturbances of circulation. In addition, infection may occur or a foreign body be introduced and left in or lodged against the cord, and by its continued presence produces great disturbance of circulation and consequent extensive degeneration and necrosis of cells and fibres. Repair occurs by cicatricial tissue. Here immediate operation is indicated for antiseptics, drainage, and the removal of the foreign body.

OPERATION FOR TUMORS OF THE SPINAL CORD.

Schultze⁸² reports 2 successful cases of tumor of the spinal cord diagnosed and treated surgically, thus adding to the list of 20 similar cases published by Bruns, in which beneficial results had been obtained only in 6.

The first patient, a woman, age forty-nine years,

suffered from hysterical and neurathenic symptoms which were succeeded by signs of spinal disease, symptoms of compression of the spinal cord and paraplegia. The localizing symptoms pointed to the mid-dorsal region, and on operation a tumor was discovered compressing the cord in the region of the fourth to the seventh dorsal segments and lying between the dura mater and the vertebra. This was removed, and for a week after the operation the symptoms grew worse, after which they steadily improved, and in a few months the patient was able to walk and to get about freely.

The second case was that of a man, age twenty-eight years, with symptoms of spastic paraplegia and with an area of anesthesia extending up to the level of the mid-dorsal segment of the cord. On opening the spinal canal a tumor was found at the level of the sixth dorsal vertebra and was removed. The sensory and motor troubles temporarily grew worse during the few days succeeding the operation. After this the patient improved steadily, and was able to walk about and to follow his occupation as a gardener.

Schultze points out that these 2 cases throw a more favorable light on the statistics of operations for spinal tumors, and that in view of the utter hopelessness and futility of expectant and palliative treatment there is every reason why surgical operation should be resorted to when once the diagnosis of intraspinal tumor is confirmed.

POST-ANESTHETIC PARALYSES.

Mally⁸³ cites a number of instances in which paralyzes, central, hysterical, peripheral, or reflex, have been detected after the administration of a general anesthetic.

Regarding the peripheral paralyzes, he says they are generally due to compression. They are more numerous than one might at first suppose, as many of them pass unnoticed, the patient recovering before being able to leave the bed after the operation, so that they are not noticed. If, however, they are carefully questioned, many will admit that they have had a numbness or tingling which has not amounted to much. The anesthetic cannot be considered as the cause of this, except that the unconscious patient has been unable to defend himself against cramped positions and overstretched limbs.

The paralyzes that are reflex and those that are hysterical in their character have nothing to do with the anesthetic. The central paralyzes due to cerebral hemorrhage are very rare where the anesthetic has provoked the arterial rupture in a purely mechanical manner.

The treatment should be preventive, sufficient care being exercised to prevent the patient from receiving injury by pressure through awkward positions during the operation. The cerebral and hysterical should be treated on principles applicable to these conditions. The use of electricity and massage is advised for the others.

THE TREATMENT OF VARICOSE ULCERATIONS BY NERVE STRETCHING.

Chipault⁸⁴ says that the results obtained in cases of malperforant of the foot by the stretching of the

⁸¹ *Annals of Surgery*, August, 1899; *American Journal of the Medical Sciences*, November, 1899, p. 602.

⁸³ *Rev. de Chir.*, July, 1899; *American Journal of the Medical Sciences*, October, 1899, p. 475.

⁸⁴ *Rev. de Chir.*, November, 1899; *American Journal of the Medical Sciences*, March, 1900, p. 348.

plantar nerves led him to attempt the same method of treatment in cases of varicose ulcers.

The method employed consisted of two parts. The first was the stretching of the nerve supplying the skin area in which the ulcer was found. This nerve should be stretched at a point not far from the ulcer, nor too near, lest the wound become infected. The nerves usually involved in these operations are the internal saphenous, either at the ring or in the upper portion of the limb; the sciatic, its popliteal portion either at the head of the peroneal or at its bifurcation. The stretching in these cases is limited to the musculocutaneous branches. This is the more common seat of these varicose ulcerations and generally involves the musculocutaneous branches associated with the internal saphenous. It should be remembered that these nerves, when this condition is present, are more friable than usual.

The second part of the operation consists in curetting the ulcer and getting it aseptic, if the skin and surrounding tissue is much involved, or in excising the skin with the ulcer and then, after gentle traction and complete hemostasis, sewing the edges together. The tightened skin exercises a beneficial influence on the varicose condition.

THE TREATMENT OF VARICOSE ULCERS BY STRETCHING THE PERONEAL NERVE.

Bardescu³⁵ claims priority over Chipault, who, on April 15th of the present year, at a meeting of the Biologic Society of Paris, advocated the treatment of varicose ulcer of the leg by means of nerve stretching. In proof of his claim the author refers to the *Bulletin de la Société des Sciences Médicales de Bucharest*, December, 1897. Chipault's paper confirms the previous claims made by the author. Two cases are reported in which the internal saphenous vein was first resected under cocaine, and in one case nine and in the other ten days later the common peroneal nerve was stretched under chloroform narcosis. Both the resection and the nerve stretching could be done at one sitting. The common peroneal nerve was selected in these cases on account of the extensive character of the ulcers. Naturally the nerve which corresponds in distribution to the site affected should be selected. Both cases made an excellent recovery. Temporary anesthesia following stretching was noticed.

THE HISTOLOGY OF DUPUYTREN'S CONTRACTION OF THE PALMAR FASCIA; REPORT OF MICROSCOPIC EXAMINATION IN TWO ADDITIONAL CASES.

Nichols³⁶ in an article on this subject, states that his observations go toward indicating that in the early or developing period of Dupuytren's contraction the cellular and vascular elements occur in great abundance; while at a later stage, when the lesion is fully developed and stationary, the cells and vessels diminish, leaving the abnormal tissue a dense, fibrous mass; and that the hypertrophied fibrous bands are developed by the activities of the abundant connective-tissue cells, which are proliferated in especial profusion along the course of the small blood vessels. The lesion is essentially a hypertrophy, the new tissue being similar to the pre-existing normal fascia. Any etiological explanation of Dupuytren's contraction would have to take into account the active prolifera-

tion and the fibroplastic action of the connective-tissue cells and their relation to the vascular elements. The presence of Pacinian bodies in all the 3 cases microscopically examined by the author he considers worthy of mention.

A CASE OF ACUTE OSTEOMYELITIS OF THE FEMUR, WITH GENERAL SYSTEMIC STAPHYLOCOCCUS AUREUS INFECTION, TERMINATING IN RECOVERY.

Berg³⁷ gives a history of a case of acute osteomyelitis of the femur in a child eight years old, and gives as the points worthy of notice in his article the following: (1) An infection of the medullary cavity of the femur by the staphylococcus aureus, induced by the traumatism; (2) an early blood infection by the same organism and its toxins; (3) the use of the antistreptococcus serum and the absence of any metastatic focus of suppuration in a staphylococcus infection; (4) the subsequent elimination of the organism by the kidneys; (5) the effects of this organism and its toxins upon the viscera, as shown by the acute degeneration and inflammation of the latter.

A METHOD OF TREATMENT FOR THE RESTORATION OF ENTIRE TIBIÆ NECROTIC FROM ACUTE OSTEOMYELITIS.

Cushing,³⁸ in an article on this subject, gives the following summary as to the indications for treatment in cases of acute osteomyelitis:

(1) To save the patient's life and relieve pain by immediate operation to establish free drainage. The medullary cavity should be opened, pressure relieved and infection checked.

(2) If the bone is killed, as it usually and rapidly is in a few days, it should be removed.

(3) The most favorable time for its removal is when the periosteum and granulation tissue are in their most active regenerative stage, but before the process of calcification of the bone trabeculæ has shut out the sequestrum within a compact, dense shell of involucrum.

(4) This point is to be determined by frequent examinations of sections of the periosteum with the microscope. It is shown by the presence of numerous fibroblasts, osteoblasts and small trabeculæ in which lime salts are beginning to be deposited.

(5) Clinically it can be recognized by the slight crackling sensation as the periosteum is incised, due, probably, to the crushing of the trabeculæ by the knife.

(6) The periosteum at this stage resembles granulation tissue in color, density and vascularity. There is no macroscopic appearance of ossification. Bone will be formed from this elastic, flexible, periosteal layer.

(7) This stage in this case was probably reached in the seventh to eighth week of the disease.

(8) At this stage the necrotic bone should be removed by incising the periosteum in the long axis of the leg and shelling out the sequestrum.

(9) The periosteal sheath remaining should be closed by suture, leaving a solid cord or mass of periosteum buried in the centre of the leg when in its most active bone-producing condition.

(10) If areas of calcification of any extent or thickness are found adherent to the inner surface of the periosteal sheath, they should be dissected off.

³⁵ *Annals of Surgery*, December, 1899, p. 775; *Centrbl. f. Chir.*, 1899, Bd. xxviii, S. 769-771.

³⁶ *Medical News*, October 14, 1899, p. 491.

³⁷ *American Journal of the Medical Sciences*, March, 1900, p. 332.

³⁸ *Annals of Surgery*, October, 1899, p. 486.

(11) The soft parts and skin superjacent can be closed by suture.

(12) The utmost care and most efficient means should be used to render the operation an aseptic one, for primary union is important.

(13) The new bone is formed rapidly, apparently in eighteen to twenty-four days, when the operation is done at the time above indicated. At this time ossification is so advanced that the new bone is rigid.

(14) If the operation is done too early, the growing periosteum is injured, apparently, and its growth interfered with.

(15) If too late, a rigid bony involucrum makes the removal of the sequestrum more difficult and forms a cavity which is very difficult to close.

(16) It is demonstrated by the radiograph that the medullary cavity is reformed in the new bone.

(17) The shaft of the bone is easier to restore than the epiphysis.

TREATMENT OF VARICOSE ULCERS BY TOTAL EXTIRPATION OF THE INTERNAL SAPHENOUS VEIN.

Casati³⁹ states that extirpation of the entire internal saphenous vein from the femoral junction, in case of leg ulcers and varices, has been followed by excellent and permanent results at his hands. In order to avoid the long skin incisions, from 70 and 80 centimetres in length, the author proceeds as follows:

Eight centimetres below the femoral fold he makes a 4-centimetre incision exposing the vessel. The vein is isolated as high up as possible and the proximal end ligated. The vein is then isolated as far downward as possible and traction put upon it. This causes it to become prominent for the whole extent of the thigh. Another 4-centimetre incision is made 4 centimetres above the knee, and the vessel is isolated subcutaneously upward and downward in the same manner. It is then drawn out of the wound. The same procedure is repeated through two incisions below the knee, so that finally the entire vein has been removed. It is not necessary to ligate the lateral branches. One of the advantages of the operation is the placing of the first incision below the fold of the groin; at the latter point a dressing is difficult to hold in place; secondly, the avoidance of a cicatrix at the knee, which is apt to prove painful. The author reports 3 successful cases by this method.

DELAYED SUTURING IN PACKED WOUNDS.

Koppen⁴⁰ calls attention to the fact that it is not good surgery to place stitches in the flaps of the wound which it is necessary to pack with gauze. There are many reasons why this should not be done. If we are uncertain of our asepsis sufficiently to make it necessary to pack the wound, there is no logic in putting in sutures while the wound is septic. They may become infected and lead to stitch abscesses after the gauze packing has been removed and the wound closed; they will frequently become weakened while the surrounding tissues may become the seat of a phlegmonous infiltration. The sutures can be readily inserted at a later period by the use of a eucaine B. solution—eucaine B. .1, salt .8, water 100. This solution anesthetizes the part sufficiently to permit the insertion of the sutures, and in addition

permits the removal with a curette of the granulations that have formed, so that a more nearly primary union will be the result.

(To be continued.)

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

C. H. HARR, M.D., SECRETARY.

REGULAR meeting, Wednesday, March 28, 1900,
DR. E. L. TWOMBLY in the chair.

DR. E. S. BOLAND read a paper on

IMMEDIATE REPAIR OF PERINEAL TEARS.¹

DR. STORER: I think the thanks of the section ought to be given to Dr. Boland for his eminently practical presentation of this subject. I wish every student could have this paper in his hand when he starts in practice. I think the two points of special interest that he emphasized were very well taken—the preparation of the perineum for the passage of the head and the advantages of having a head mirror handy.

DR. CALL: I most certainly think the only right and proper treatment is that every perineum should be examined immediately after labor and any tear that is discovered repaired at once.

DR. DAVENPORT: I have not for a number of years done any obstetrical practice and see very few or almost no tears of the perineum immediately after labor. The tears that I see come months or perhaps years after labor has occurred, and of these the tears which seem to me to be most important are those of the levator ani muscle, and it has been a question in my mind whether they can be detected at the time of labor. Of course if there is a giving way of the levator ani muscle at its attachment in the perineal body and below its lower attachment in the vagina the detection is comparatively easy, but I am of the impression that very often such giving way takes place subcutaneously and there has been in my mind a doubt as to whether such a tear can be recognized and properly sutured at the time of labor. I should be very glad if Dr. Boland would tell whether such tears can be detected. Certainly they give rise to more serious difficulty afterwards than do the tears through the perineal body, even those which extend down to the sphincter ani. They weaken the support of the lower part of the vagina and we have prolapse of the vaginal walls and tendency to pulling down of the uterus, and so there are more symptoms complained of by the patient than in those tears of the external perineum which are readily seen. In the cases that I occasionally see where I have been asked to repair a perineum immediately after labor I have always used silkworm gut and the objection Dr. Boland gave for its use, namely, the ends of the sutures sticking into the patient and causing annoyance, can be avoided by leaving them long and tying them together in a knot and cutting the ends short. I should feel that silkworm gut was better suture material for these tears than silk, which of course becomes more easily infected.

¹ See page 185 of the Journal.

³⁹ Annals of Surgery, December, 1899, p. 776.

⁴⁰ Centrbl. f. Chir., July 1, 1899; American Journal of the Medical Sciences, October, 1899, p. 473.

DR. TWOMBLY: Not long ago a medical gentleman within my hearing remarked that he always sewed up his perineal tears immediately, but he had two-thirds of the number failures, and I imagine if we should ask our brother practitioners if they had observed, after some time, whether the perineum was good and firm, a good many of them would have to confess to these same failures. It is due in part, I have no doubt, to the faulty arrangements at the time, where we have to act so often with few assistants, or with nobody who can help at all. I feel that the head mirror is a distinct advantage which we should mention again and again to the younger men who are taking up this work, for it certainly will throw light on the dark subject, and so often an improper light is the cause of failure. Personally I feel that the silkworm-gut suture is the one to use and I have used it in my cases with good success. You can always boil it ten to fifteen minutes beforehand; it does not string out and run over things; you can take it out of its small basin in which it is boiled over the stove and apply it immediately, and it does not become infected as readily as the plain silk. The scratching of the ends can be avoided by twisting or tying, leaving them outside. If they are slightly irritating, the discomfort is not greater than the gain that we get in closing up the tear. I think it is wise to take two or three—very seldom do we have to take more than three in a moderate tear—rather deep interrupted sutures inside the vagina, getting the patient into position where the torn parts fall into place relatively to the position which they would take in health without trying to coapt very carefully, and we get a pretty good perineum resulting. Where you have plenty of assistants and can perform a more careful operation, it has been the vogue in Vienna for some time to employ the layer suture, using an animal tendon or catgut and in that way sewing the parts from the bottom to the top. For the general practitioner, what we want is something practical and the easiest, quickest, best way to get a good result. Dr. Boland has very kindly pointed out a number of suggestions easy to understand and easy to follow out.

DR. BOLAND: I don't think I have ever seen the injury Dr. Davenport speaks of. I may have overlooked it. I have been fortunate not to have many tears that went down into the rectum. The point I want to urge is the necessity for looking deeper than the perineum. There is one point I trusted some of the gentlemen would take up—the *prevention* of these tears. I have tried supporting the perineum, taking off the instruments, etc. I don't believe they can be prevented if the soft parts do not stretch.

DR. F. H. DAVENPORT read a paper on

THE MORTALITY OF HYSTERECTOMY FOR FIBROIDS.²

DR. CUSHING: I think we have all listened with great interest to this paper, and I am sure that I should cordially agree with what Dr. Davenport has said. In the 2 fatal cases it is very plain it was not the operation, but the long delay that made them fatal; in other words, if they had been operated a good deal earlier they would not have died. The indications for operation in fibroid I have always considered to be pain, growth, bleeding, pressure, and either of these is quite sufficient, since with the modern technique the mortality has become very little.

I don't think it is any worse than in ovarian tumors; hysterectomy is about as safe and nice a procedure as any abdominal operation. There is a reasonable chance of the tumor being malignant. It does not make much difference, except anatomically, whether there is cancerous degeneration of the fibroid or concomitance of the two conditions, there is a certain proportion of fibroids which if left to themselves will turn out malignant. The theories that they are surely going away at the menopause are fallacious. I have found that particularly when a fibroid starts growing in the forties it is apt to keep on growing. The fibroids which have a pedicle or have formed adhesions to the abdominal wall or omentum so that they have an independent source of blood supply do not stop growing at the menopause, but keep on increasing.

Some five years ago I took a good deal of pains for the *Monatsschrift der Geburtshilfe und Gynäkologie* to collect a series of statistics from all the American operators I could reach, and it figured to 1,160 cases or more, including hysterectomy for fibroids, cancer and salpingitis, with a percentage of 13.5% mortality, and that was taking cases running back to the early eighties and including the evolution of the extra-abdominal treatment of the stump. I have not collected the statistics for the last five years, but they have been vastly improved. Personally within that time I have done over 100 fibroids and lost 1, and I have no reason to think that my statistics are better than others. We meet cases in all abdominal surgery where the chances are unfavorable from the beginning. One fatal case was in a middle-aged woman who came with a ventral hernia. She stated just before operation that she had been examined and had a tumor and wished it removed at the same time. It made a long operation. I presume I was not at my best, as I had just done another long operation. She did well three or four days and sank away and died. As far as mortality goes, my friends tell me that their results are so good they have not the least hesitation in recommending the operation while the tumor is young, before it forms adhesions. They have excellent results, do not need drainage. I think that it is the disinfecting of the uterine cavity beforehand that makes all the difference, since the technique involves a very careful cleansing of the vagina and uterine canal, so that when you cut the stump across it is clean and when you lift the uterus up nothing drips out of it. The profession used to wait until they had big tumors, but now the trouble is rather the other way.

DR. CALL: It seems to me the position Dr. Davenport has taken in this paper is the one that would commend itself to all of us who have had any experience. In the early years of my practice I had the opportunity of following the course of a good many fibroid tumors which belonged to patients in the practice of Dr. Lucy Sewall. In those days the danger of operation was so great that nobody advised it except as a last resort; therefore almost all these cases had been allowed to go on with the hope that the menopause would end the troubles. I remember but one in which sooner or later that effect did not come to pass; nevertheless those people went through for years a series of hard times, either with hemorrhage or discomforts of every kind that I have no doubt nowadays they would have been spared by the advice that Dr. Davenport gives. So far as my limited ex-

² See page 181 of the Journal.

perience goes, I do feel that a very large number of fibroid tumors will cease to trouble the patient at the menopause. Of course there are a good many exceptions to this rule, and if the patient cannot be under observation it seems to me the wisest thing is to operate.

Dr. E. W. CUSHING read a paper entitled

HYSTERECTOMY FOR MYOMA IN AMERICA.³

Dr. DAVENPORT: Dr. Cushing's paper seems to me to express the historical facts and the present condition of the operation of hysterectomy very fairly. I have no criticisms to offer.

Dr. TWOMBLY: I think we ought to thank Dr. Davenport for his clear presentation of the reasons why and why not in regard to early operating for fibroids, and for bringing it to our attention. It is something that we are very much interested in, especially in Boston, as we see many of the smaller fibroids and in a great many cases we are rather conservative and do not tell the patients they must immediately have an operation. Dr. Davenport's paper will be of very great help in future counsels.

Dr. MALCOLM STORER and Dr. M. T. THURBER read a paper on

REPEATED ECTOPIC GESTATION IN THE SAME PATIENT, WITH OPERATION IN EACH CASE.⁴

Dr. BOLAND: In regard to leaving the other ovary in case one has been the seat of an ectopic gestation calling for operation, it would seem best to be guided by the same rules that are safe to follow in ovariectomy for any other condition. In 3 extra-uterine cases where the offending tube and ovary on one side had been removed four children have been born subsequently in perfectly normal labor.

Dr. CUSHING: I also can add a case of extra-uterine pregnancy followed by a normal birth.

Dr. HARE: I assisted at an operation for extra-uterine pregnancy two years ago last November, and since then she has had two children.

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

THE OPENING CEREMONY.

The opening general meeting of the congress took place in Paris on Thursday, August 2d, with the official ceremony which entails evening dress, in the vast Salle des Fêtes in the Exhibition. Owing to the assassination of the King of Italy, the President of the French Republic was not present, but he was represented by M. Monis, the Minister of Justice, who arrived punctually at 2.30 p. m. to the strains of the "Marseillaise," played by the band of the Republican Guard. Professor Lannelongue, the president of the congress, dressed in the green embroidered coat and wearing the sword of an academician, had on his right, M. Fallières, the President of the Senate, and on his left the Minister of Justice. On the platform were also seated the members of the Committee of Organization, the members of the Academie de Médecine, the professors of the Faculty of Medicine, the presidents and vice presidents of sections, while behind

and to the right of the chair sat the official foreign delegates, among the representatives of Great Britain being Sir William MacCormac, Bart., K.C.V.O., Sir Dyce Duckworth, Sir Lauder Brunton, Professor Simpson, of Edinburgh, etc. In the body of the circular hall were the members of the congress, the representatives of French and foreign universities, and delegates of learned societies; the ladies were placed in a gallery at the back of the hall, one hundred and fifty yards or so away from the platform, while the press was allotted a gallery in an equally disadvantageous position. As a result, of the president's opening speech only three words penetrated to the far end of the vast auditorium.

PRESIDENT'S ADDRESS.

The president of the congress read the opening peroration welcoming the members of the congress. In terminating, he said: In wishing you welcome I offer you my warmest congratulations. I most heartily thank the committees of all the foreign countries who have helped in the organization of this vast undertaking; the entire press for its active and disinterested aid; the Executive Committee, who have never failed to respond to my call and have given the best of their advice; the University of Paris and the members of the government of the republic, who have understood from the first the importance of our task and have rendered its realization easier. As to myself, my heart filled with the keenest emotions I have ever felt in my life, I can find, in conclusion, no better words than those addressed to you by Bouillaud, the first and one of the most illustrious presidents of this congress: "Thanks to you, my whole life has just received its crowning award. I hold you in the depth of my heart, and you will continue to live there till its last beat." I will only add: Now to work, time is pressing; never since the beginning has there been promise of a richer or more plenteous harvest. May we know how to profit by it and gather in the fruitful grain, which future generations will cause to bear more fruit.

GENERAL SECRETARY'S REPORT.

The Minister of Justice, in the name of the government, then welcomed the members of the congress. M. Chauffard, the general secretary, now read his report, describing the complex work of organization. As a result, 190 delegates, representing the governments of 34 foreign states, were present on the platform; 250 universities, academies, or learned societies have sent delegates, and over 6,000 members of the congress have come to Paris. The programme of the congress includes 260 reports, and more than 1,200 communications.

PRESENTATION OF FOREIGN DELEGATES.

After the termination of the secretary's report, the official delegates of the foreign nations came forward to offer their good wishes to France, and hopes for the success of the congress. Professor von Bergmann led the lengthy procession. Sir William MacCormac, Bart., K.C.V.O., represented Great Britain. Professor Baccelli was absent owing to the mourning of the Italian nation. M. Mandizabal, the delegate of Mexico, made a long and spirited speech, which was greatly applauded. The delegate of Venezuela closed the series.

³ See page 183 of the Journal.

⁴ See page 177 of the Journal.

ADDRESS BY PROFESSOR VIRCHOW.

This terminated the official portion of the programme, and as the audience had heard little or nothing of the speeches the majority left, and it was a very small crowd which gathered round the foot of the platform when Professor Rudolf Virchow rose to give his address on "Traumatism and Infection." The venerated professor, who was in the best of health and spirits, spoke in German. After a historical review of the subject, Professor Virchow expressed the opinion that the present attention to bacteria has withdrawn us too much from other causes of pathological processes. Injuries of bones take place without abrasion of the skin, yet osteomyelitis ensues. Brain abscess results from head trauma. Some surgeons claim that microbes enter even through the slight lacerations of skin. This, however, is mere theory. We know that cells may degenerate without any microbial influence. Trauma may kill them. We know from dead parasites, such as trichina within the body, what happens to dead cells. The changes occurring in extra-uterine fetuses also make this clear. Let us, then, not attribute too much importance to microbes, but let us study carefully the cellular changes as they occur. With the address of Professor Virchow, which was received with great applause, the proceedings terminated, the discourse of Professor Pavlov, which was included in the original programme of proceedings, being postponed to the first general meeting.

THE SECTIONS.

The work in the various sections, twenty-six in number, began generally at nine o'clock on Friday morning, with the exception, however, of the Sections of Neurology, and Dermatology with Syphilography. These sections are perhaps the largest attended. The Section of Neurology is at the same time the second International Neurological Congress, and it is a question which will be decided before the end of the present congress whether the International Neurological Congress as such shall cease to exist, or whether it will arrange its meetings at a different time to the International Medical Congresses. These two sections, owing to the great number of communications promised and the number of subjects for discussion, met on Thursday morning at nine o'clock, and are holding morning and afternoon sittings every day.

RECEPTIONS AND SOIRÉES.

The president of the congress and Madame Lanlongue gave a reception by invitation to the delegates and presidents of sections on Friday evening, August 3d. The programme included minuets and ballets by dancers from the opera, while a Hungarian band played at intervals in the refreshment room.

The Committee of Organization gave a *soirée* in the Palace of the Senate and in the Luxembourg Gardens on Monday, August 6th, at 9 p.m. The programme included dancing and an entertainment in the Salle des Fêtes of the Palace. M. Mounet-Sully, of the Comédie Française, and Madame Sarah Bernhardt recited poetry, while the musical talent was supplied by M. Renaud and Madame Litvinne, of the opera, and M. Fugère, of the Opéra Comique. As all the members of the congress with their wives and families had been invited, the number of guests must have ex-

ceeded 15,000. Owing presumably to faulty organization the enjoyment of some hundreds was spoilt, as the sole entrance into the Palace, a door five feet wide, also served as the popular means of exit, so many guests never succeeded in reaching the door of entrance even, but after a struggle of half an hour or so gave up the attempt and left.

Dinners and *soirées* have been given by the presidents of all the sections, and these smaller *fêtes* have been a very enjoyable feature of the meeting to the fortunate guests.

Excursions were arranged for Sunday, August 5th, to Versailles and to Fontainebleau.

DINNER IN HONOR OF LORD LISTER.

A dinner was given by the scientific society "Scientia," on August 1st, in honor of Lord Lister. The dinner took place in the Restaurant des Congrès, in the Exhibition Grounds. About 60 guests were present, the obstetricians and physiologists turning up in force. At the president's table were Professors Richet, Lucas Championnière, Marey, Bouchard, Guyon, Pinard, Pozzi, Landouzy. Prof. Lucas Championnière recalled how he went to Glasgow, and after seeing and working with the master, returned as an apostle to Paris, and was not listened to. Professor Pinard spoke in the name of the obstetricians and of the *accouchées* of France. Lord Lister replied in French, in his own simple and quiet manner, speaking almost half apologetically, and was received with great applause. He told the story of his early struggles and work, saying, "All my efforts were without result till Pasteur showed a possible way, which I have done my best to follow; that is all, gentlemen. If the result of my work has been as beneficial to humanity as you say, it has been largely due to the happy accident of my epoch." After the dinner, on the invitation of the Medical Club in Paris, Lord Lister and the guests went to a reception in the club in the Avenue de l'Opéra, where Lord Lister was welcomed by Professor Pozzi, the president, and on whose motion it was decided to put up a tablet on the wall in commemoration of the event.

Owing to the death of the King of Italy, the official *fêtes* to the members of the congress have been put off. The evening *fête* in the Town Hall given by the municipality, and the evening *fête* given by the President of the Republic and Madame Loubet at the Elysée, are changed into afternoon receptions; the latter is to take place on Friday, August 10th, at 4.30 p.m. Members of the congress have thus had many evenings free, and have been able to utilize to the utmost the card giving free admittance to the exhibition.

STATISTICS.

Up to August 5th, 6,170 members had registered their names, the nationalities being represented as follows: France, 2,293; Russia, 805; Germany, 572; the United States, 412; Italy, 324; Great Britain, 222; Spain, 219; Belgium, 147; Austria, 141; Argentine Republic, 108; Swiss, 101.

PRESS ARRANGEMENTS.

Owing to the initiative and energy of Dr. Blondel and the French Medical Press Association, a reception room and a work room have been placed at the

disposal of the French and foreign press reporters. Here members of the press find the daily programme and printed summaries of all the communications made in the various sections, and are able to write their articles and post them on the premises. Members of the French Press Association in rotation are always in attendance to give information and advice. It is interesting to note that this is the first occasion at an International Medical Congress when such facilities have been given to medical journalists and correspondents.

(To be continued.)

Recent Literature.

Bacteria. Especially as they are related to the Economy of Nature, to Industrial Processes and to the Public Health. By GEORGE NEWMAN, M.D., F.R.S. (Edin.), D.P.H. (Cantab.), etc., Demonstrator of Bacteriology in King's College, London. Illustrated. New York: G. P. Putnam's Sons; London: John Murray. 1899.

This book is one of a series devoted to popular science. It is an attempt to present a popular scientific statement of our present knowledge of bacteria. It is not designed as a textbook for the laboratory, nor as an exhaustive work on the subject. It is apparently written for the layman rather than for the medical man. In looking over the work we note the statement that the bacillus *icteriodes* of Sanarelli "is now accepted as the causal agent" of yellow fever. This statement is not justified at the present time. In the definition of diphtheria a misprint makes the word "fibrinous" read "fibrous." On the whole the book seems to be well written and to fulfil the purpose of the author to a reasonable extent.

A Blank Book for Autopsy Protocols. By ALDRED SCOTT WARTHIN, M.D., Ph.D., Assistant Professor in Pathology in the University of Michigan. Ann Arbor, Mich.: George Wahr. 1899.

This book is essentially a collection of blank forms which when filled out will constitute the records of autopsies. Their chief purpose seems to be to fix in the student's mind a routine method of autopsy technique. These forms have been used by the author in connection with his work in instructing medical students. We think that they are of doubtful utility for any one else. A table of average weights and measurements of the normal human body accompanies the volume.

Saunders' Question Compend, No. 2. Essentials of Surgery, together with a Full Description of the Handkerchief and Roller Bandage, arranged in the Form of Questions and Answers; prepared especially for Students of Medicine. By EDWARD MARTIN, A.M., M.D., Clinical Professor of Genito-Urinary Diseases in the University of Pennsylvania. Illustrated. Seventh edition, revised and enlarged, with an Appendix. Philadelphia: W. B. Saunders & Co. 1900.

Quiz compends are all of necessity dogmatic and very fragmentary in the information they give. We wish that it were not necessary to have quiz compends, but if they must exist this is a good one.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 23, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE INTRADURAL INJECTION OF COCAINE.

ANESTHESIA by ether or chloroform is occasionally contraindicated by the condition of internal organs, or by the generally weak state of the patient. In such cases, which fortunately are not extremely frequent, there is at times a demand for radical surgical operation and the necessity for an extensive local anesthetic becomes apparent. Cocaine has long been used to this end and with good success. Operations of magnitude and taking a considerable time have been carried to a successful conclusion without material discomfort to the patient. Very recently, however, an attempt has been made to produce a more general insensibility of the lower portion of the body and legs by the introduction of a cocaine solution into the subdural space of the cord, with the object of paralyzing sensation at and below the point of injection. This somewhat radical measure has no doubt been encouraged by the almost complete safety of the operation of lumbar puncture, which has now taken its place as a recognized means of diagnosis and occasionally of treatment. Several European surgeons in 1899 published cases of major operations on the abdomen and legs, anesthesia being produced by cocainization of the spinal cord. Tuffier, of Paris, has given the matter particular attention and has performed in the neighborhood of eighty operations under cocaine anesthesia of the lumbar cord. Cadol, a former house surgeon in Tuffier's wards, has presented in his thesis before the Faculty of Medicine a résumé of twenty-three of these operations, with the technique of the methods. The current number of the *Practitioner* publishes a detailed letter on the subject from a Paris correspondent, to which we would refer our readers for a complete description. The method of introducing the needle between the vertebrae, the precautions to be observed and the difficulties to be avoided are familiar in connection with the similar operation of lumbar puncture. When the point of the needle is in the subdural space, as indicated by the exudation of cerebrospinal fluid, the cocaine solution is introduced. This injection should be

made with scrupulous care as regards rapidity, quality, quantity and temperature of the fluid. It is particularly important to bear in mind that the cocaine must not become immediately diffused throughout the cerebrospinal fluid and that the drug should not be allowed to permeate to higher levels of the cord, the object being to produce a temporary cutting off of sensation below a certain level, with a minimum amount of the cocaine solution. To accomplish this, the injection must be made very slowly, the solution should be freshly prepared and of a temperature corresponding with the body fluids. The quantity injected should never exceed four centigrammes of a one-per-cent. solution, and must naturally be varied below that amount according to circumstances of age and extent of anesthesia desired. After the completion of the injection the point of entrance of the needle is covered with collodion. The physiological action of the cocaine is manifested by subjective sensations of tingling and prickling of the legs, followed by loss of sensibility to pain, temperature and touch respectively. Soon thereafter the motor system also is involved, with a loss of muscle sense. The anesthesia, reaching to about the level of the umbilicus, is complete in eight to ten minutes after the injection. Among the cases operated on by Tuffier in this manner, as described by Cadol, were a sarcoma of the thigh, resection of tibia, resection of knee, suture of patella, amputation of thigh, extirpation of rectum and four vaginal hysterectomies.

An analysis of the cases shows certain fairly constant phenomena, which may be summarized as follows: The extent of the area rendered analgesic and the duration of the anesthesia depend upon the age of the patient and upon the amount of the dose, the duration varying from thirty minutes to an hour and forty minutes. In young adults and children the effect of the injection ensues more rapidly than in adults, varying from an almost instantaneous effect to eight or ten minutes or even more. The onset of analgesia is characterized by subjective sensations, as already described. It begins in the extremities of the legs and progresses upward, and is both superficial and deep. An interesting fact is that there is often a temporary dissociation of sensation, resembling that observed in syringomyelia. The return of sensation is opposite to its loss, the sole of the foot being the first and the last region affected. Symptoms which may occur during the anesthesia, but which are claimed to be so insignificant or transitory as to be of no moment, are sweating of the face, dilatation of the pupil, nausea, tremor, headache, vomiting and tachycardia during the operation. It is, however, urged that some at least of these symptoms may be induced by the emotions incident to grave operations in persons whose consciousness is in no way disturbed. In Tuffier's series of cases no serious accident is recorded.

The method of intraspinal injection of cocaine has also been suggested as a means of easing the pains of labor. Of this, which is said to have been successfully

practised by Dolèris in five cases, the *Medical Press* remarks: "One of the maddest ideas of which it has been our lot to take cognizance is unquestionably that of abolishing the pain of labor by injection of a solution of cocaine into the arachnoid cavity of the spinal cord."

The whole matter seems to us a matter of theoretical rather than practical interest, and one which therefore will find an extremely limited range of usefulness. That pain may be wholly abolished by such means is certainly a fact of great scientific interest; that it is, except in very rare instances, necessary to abolish pain by such a method must be equally evident. Why should a patient be compelled to look on at a severe abdominal operation or at an amputation of one of his members, if such a situation can possibly be avoided? For minor operations cocaine has long since been demonstrated to be an agent of the greatest service to the surgeon, but we suspect that experience will show that its range of usefulness stops there. It is, however, conceivable that circumstances might arise which would warrant its more extended use, and in those rare cases the possibility of anesthetizing large areas of the body as described above must be regarded as a significant addition to our knowledge.

STATE HEALTH INSPECTORS.

IN spite of the fact that we are repeatedly told that typhoid fever is a preventible disease, a year never passes that we do not hear of one or more local epidemics traceable in every case to carelessness. No doubt, so long as we are human, such incidents will occur, but each new experience should at least impress more deeply the necessity of the most painstaking care and watchfulness on the part of those who are charged with the duty of guarding the public health. The present epidemic at Norwood should certainly serve as an object lesson. The question naturally arises as to the possibility of securing a greater immunity than we now have against these annoying and dangerous sporadic outbreaks. It would seem that this might be secured by increased watchfulness on the part of men well trained in the problems of public hygiene. This suggestion has in fact been made by Dr. Henry P. Walcott, chairman of the State Board of Health. Dr. Walcott's idea is that the State should appoint a certain number of expert inspectors, whose function it would be to investigate and report on public nuisances menacing to health, without thereby interfering with the authority or prerogatives of the various local health boards. Such a relation of a State board to a local board should engender no antagonism, but rather a better possibility of working out the various problems of sanitation which are constantly presenting themselves. Without any disparagement whatever, it must be admitted that the men representing the health boards of small towns are often not sufficiently trained in modern scientific methods to grapple successfully

with the difficult problems which the origin and spread of an epidemic disease implies. Furthermore, as a daily contemporary well says: "It should be obvious to every one that in order to prevent the spread of infectious or contagious diseases, it is necessary to have uniform regulations throughout the Commonwealth and to have the different municipalities acting together instead of each proceeding without regard to the others and sometimes in hostility to the others' interests." For these various reasons it is to be hoped that Dr. Walcott's suggestion will be given due consideration and action taken which will result in protecting the community still further from what we cannot help thinking are unnecessary outbreaks of disease.

MEDICAL NOTES.

CONDITIONS IN THE PHILIPPINES.—There are said to be 30,000 lepers in the Philippines. The disease is supposed to have been introduced in 1633 by a vessel from Japan, bringing 150 lepers to be cared for by the Catholic priests. The Manila Board of Health reports that bubonic plague made its appearance at Manila, December 29, 1899. Only one white man died of it. Out of a total of 225 cases there were 167 deaths, 115 being among the Chinese and 51 among the Filipinos. The number of deaths in Manila from October, 1899, to July, 1900, inclusive, was 8,535. The population of the city is estimated at 350,000 to 600,000. Of the number who died 7,591 were Filipinos and 15 Americans (civilians).

RABIES IN PARIS.—According to the *Medical Record*, the annual report on hydrophobia, which has just been presented to the Council of Public Hygiene by Prof. Adrien Proust, inspector-general of the Board of Health, shows by statistics that the number of mad dogs in Paris and the department of the Seine is steadily increasing. The Pasteur Institute treated 294 persons who had been bitten by rabid animals between January 1 and June 8, 1900.

MOSCOW PRIZE CONFERRED ON PROFESSOR RÁMON Y CAJAL.—The prize of \$1,000, established at the Twelfth International Medical Congress at Moscow in 1897, for medical work of the greatest benefit to humanity, has, at the present congress, been awarded to Professor Rámon y Cajal, for his researches on the minute structure of the nervous system.

RETIREMENT OF PROFESSOR GEGENBAUR.—Dr. Carl Gegenbaur, professor of anatomy at the University of Heidelberg, is reported to have retired from the active duties of his professorship.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, August 22, 1900, there were reported to the Board of Health of Boston, the following

cases of acute infectious diseases: diphtheria 85, scarlatina 17, measles 31, typhoid fever 15.

THE ENFORCEMENT OF VACCINATION AT ROCKLAND, ME.—The antivaccinationists of Rockland, organized in an effort to cause the repeal of the non-enforcement of the State law regarding the vaccination of school children have received a check in the form of a refusal by the Board of Health to accede to their demands. The Board of Health, through its secretary, sent a formal reply to the request, thus: "The Board of Health has considered the matter, and can see no reason for modifying its action regarding the enforcement of the State law."

CHELSEA HOSPITAL IMPROVEMENTS.—Extensive improvements, for which the government has appropriated \$45,000, are being made at the United States Naval Hospital at Chelsea, Mass. More commodious buildings are to be provided, the plumbing and ventilation renovated, and other needed changes made.

THE HARVARD INFIRMARY.—Harvard College has bought of the Cambridge Hospital a tract of land on Mount Auburn Street adjoining the hospital, which it intends to use as a site for the new infirmary. The land previously selected was regarded as unsuitable.

TYPHOID FEVER IN NORWOOD, MASS.—An epidemic of typhoid fever of considerable magnitude has appeared in Norwood, and has been traced to the sale of infected milk.

NEW YORK.

WATER SUPPLY OF BROOKLYN.—Chief Engineer Robert Van Buren, of the Brooklyn Water Department, has given out a statement regarding the water supply of the borough, in which he refers to the inadequate amount of water on storage, and expresses the opinion that the great need of the department is increased conduit facilities from the watershed to the reservoirs at Hempstead, Ridgewood and Mount Prospect. From July 1st to August 12th the consumption exceeded the supply by over 6,000,000 gallons a day, and on the latter date the amount of water in storage had fallen to 283,360,100 gallons; showing a loss of 252,323,700 gallons in forty-two days. On August 12th of last year the storage amounted to more than 200,000,000 more than at present. What is most urgently needed, he declares, is an additional pipe conduit from Millburn west, as by this means most of the water which now goes to waste along the watershed east of Millburn could be made available for the borough.

NEW LYING-IN DEPARTMENT FOR BELLEVUE HOSPITAL.—Commissioner Keller, of the Department of Public Charities, has announced that he is about to convert the building on the grounds of Bellevue Hospital which for more than twenty-five years was occupied by the Bellevue Hospital Medical College, and of late has been used as the temporary quarters of the Cornell University Medical School,

into a thoroughly equipped lying-in department for the hospital, to take the place of the inadequate maternity hospital now connected with Bellevue. The fine new building of the Cornell School on First Avenue, just opposite the Bellevue Hospital, is approaching completion, and this old building will no longer be required.

BEQUEST TO A HOSPITAL. — By the will of Judge Francis O. Mason, of Geneva, N. Y., the Geneva City Hospital is made the recipient of a bequest of \$100,000. Of this amount, \$10,000 is immediately available, and the remaining \$90,000 comes to the institution after the death of two sisters of the deceased.

Miscellany.

POWER OF THE EYE.

"We often hear," writes Hiram M. Stanley, "people say that they can merely by a steady gaze affect a person at a distance, who is not looking at them, and some say that they are able to make one sitting in front turn the head in this way. Mr. Bell in his 'Tangweera' mentions this feeling when he says: 'Presently I felt as if some one was looking at me, and raising my head I saw a large puma standing ten yards away.' To the physiologist it may seem uncalled for to investigate a manifest absurdity, but it has at least a practical value to explode a common error by direct experiment. I asked a young man, who is very confident of his powers, to stand unknown to reagent A behind a bookcase and look through a carefully concealed peep hole. I gave him the best opportunity, placing A about four feet from the hole directly facing him, and I engaged A in mechanical writing. To the young man's confessed disgust and irritation he was unable to disturb A. My few experiments were negative in results. However, it may be that telepathic influence is exerted under certain conditions, and experiments with twins and others constantly *en rapport*, especially when under emotional stress and at critical junctures, might be worth trying. If there is nervous telepathy, this is perhaps as simple and common a form as any. If disturbance arose subconsciously the test would be that the tracings from an instrument, to show nervous conditions, should show large fluctuations coincidentally with the times when the agent regards himself as successful." — *New York Medical Record*.

THE DANGERS OF THE RAILROAD.

THAT the arts of peace are not less dangerous than those of war would appear to be amply indicated by the figures of railway accidents for a year. According to the twelfth statistical report of the Interstate Commerce Commission, 1 among every 420 of the 417,508 men engaged in the work of railway transportation was killed, and 1 among every 27 was injured during the year ended June 30, 1899. Of trainmen proper, engineers, firemen, conductors, brakemen, baggagemen, etc., 1 was killed for every 155 employed and 1 injured for every 11 employed. The

total number of accidents among employes was as follows: Killed, 2,216; injured, 34,923. Of 523,000,000 passengers carried only 239 were killed and 3,442 injured. A good deal has been done to reduce to a minimum the dangers attending railway travel, but much remains that can yet be done and the promise seems not extravagant that the time will come when there will be no more risk in travelling by rail than in any other form of progression or locomotion. — *Philadelphia Medical Journal*.

Obituary.

SIR WILLIAM STOKES.

THE death of Sir William Stokes occurred at Durban, South Africa, August 19th. Sir William was one of the eminent men who were appointed consulting surgeons to the British forces in South Africa during the early period of the Boer war. He was born in Dublin, March 10, 1839, studied medicine at the University of Dublin, and became a master of surgery. He was surgeon in ordinary to Her Majesty the Queen in Ireland, and professor of surgery in the Royal College of Surgeons. Other professional honors were the presidency of the Pathological Society, 1881; presidency Royal College of Surgeons, 1887; honorary presidency of the International Medical Congresses of Berlin, 1890; Rome, 1894; Moscow, 1897; and Paris, 1900. He was gold medallist of the Pathological Society of Ireland, surgeon to Meath Hospital and County Dublin Infirmary, and formerly senior surgeon to Richmond Surgical Hospital. He was the author of many surgical addresses and a contributor to the *Lancet*, *British Medical Journal* and other professional publications on topics pertaining to clinical and operative surgery. He was knighted in 1886. His home was in Dublin.

DR. MOSES W. KIDDER.

DR. MOSES WARREN KIDDER, of Lincoln, formerly of Lowell, died at the Waltham Hospital, August 15th, of appendicitis. He was born September 11, 1828, from an old New England stock. His education was chiefly obtained under the instruction of his father; he later attended the Harvard and the Berkshire medical schools, graduating at the latter in 1852, when he entered into practice with his father in Lowell, where he remained until 1870. He served as city physician and as member of the School Board in 1861-1863. He was a member of the Massachusetts Medical Society and his services as chemical expert in law cases were often in demand. During the late years of his life he became interested in mechanical devices and removed to Boston and later to Lincoln. He was in the latter town chairman of the School Committee and of the Board of Health. Dr. Edward H. Kidder, of Fall River, his son, died a few years ago.

Address.

THE SURGEON IN THE NINETEENTH CENTURY.¹

BY FREDERICK TRAVES, F.R.C.S.,

Surgeon Extraordinary to H. M. the Queen; Surgeon in Ordinary to H. R. H. the Duke of York; Consulting Surgeon to the London Hospital.

MR. PRESIDENT, LADIES AND GENTLEMEN:—The honor of being selected to address an association which represents not only in numbers but also in dignity and repute the medical profession of this country is an honor of such a kind that I feel it can only be belittled by any expressions of gratitude I am able to command. I will do no more therefore than sincerely thank you for bestowing upon me a great distinction, and at the same time remind myself of the words of Goethe that "it is easier to bind a wreath than to find a head worthy to wear it."

I am fortunate also in the circumstance that the occasion for the giving of this address should coincide with the concluding year of the nineteenth century. This century has been without a parallel in the history of human culture, and so far as the art of surgery is concerned has embodied an advance in principle and in practice which has been no other than revolutionary. I do not propose to attempt a review of the progress of surgery during the last hundred years. That work has been already done by abler hands. I would venture rather to deal with the progress of the surgeon himself during this period, and with the advancement of the individual as an exponent of a grave profession.

There is little difficulty in fashioning a picture of England as it was one hundred years ago. A sympathetic literature has left us with ample records of the men and women of the time and of the scenes they moved among. These records are rich with the littleness of personal affairs and are made living by the very gossip and petty commentaries of those who constituted society when the century was young. The life in England then was largely life spent in the country, in sleepy villages, and in sober, self-esteeming county towns. The conditions were yet immature which led men to herd together in ever-extending cities and to swarm around oases of blackened chimneys and restless furnaces.

Travelling was a luxury limited to the few. The many were content to live and die within sight of fields and spires which had been familiar from babyhood. They were apparently content to keep to their own stations in life, to take their notions of dignity from the squire and their conceptions of religion from the vicar, and to be satisfied with such excitement as was afforded by harvests and market days, by the movements of the locally great and by the achievements and misdoings of their neighbors. In many a town it was no little event when the coach from London lumbered through the cobbled streets or when a gang of pressed men marched by on their way to the sea, or when some soldier home from the wars made the little ale house lurid with tales of arms and tragic lands. These simple folk were comparatively free from the fever of social ambition, from the almost savage conflict of modern commerce, and from the bewildering hurry of events which compass the peace of later times.

¹ The Address in Surgery delivered at the Annual Meeting of the British Medical Association at Ipswich, August, 1900. By courtesy of the British Medical Journal.

London was then not one-fourth of its present size; the great city ended, towards the west, at Sloane Street, and beyond were quiet fields and meadows intersected by footpaths, certain of which led to the hamlet of Kensington and the little riverside village of Chelsea. The lover of solitude would have found seclusion in the wide open country through which ran the Edgware Road. Paddington was still in the fields. Game could be shot about Westbourne Green and around the isolated farm house which marked the present settlement of St. John's Wood. Few would have cared to venture after dark across the bare fields of Battersea or to traverse the expanse of open land which stretched to the north of Tottenham Court.

No railway terminus flaunted its hideous structure in the city's midst, and neither omnibus nor cab nor tram car invaded the narrow streets. There was no telegraph and no telephone. The postal system was without form and void. The gayest streets were lit by oil lamps, and the gloom by night was only equalled by the dirt by day. It was not until 1829 that the omnipotent policeman appeared upon the scene, and his early experience of the city's traffic was concerned with sedan chairs and cabriolets, with gaudy coaches and creeping wains, with link boys and running footmen. It was not until 1821 that the English Channel was crossed by steamboats and that the picturesque hoys and coasting sloops, the dignified frigates and the stately East Indiamen, began to vanish from the sea.

Education among the mass of the people was a matter of little account, and was to a great extent actually non-existing. The average man of the middle class was quite content with a degree of learning which would do little more than satisfy the demands of a modern school board.

As to the surgeon in those days, he was but a sorry element in social life. In the great towns and cities there were esteemed practitioners of surgery who were eminent by reason of their scientific work and their successful practice, but their numbers were few. At the commencement of the period under notice London was the centre of surgical activity, and the prominent exponents of the art at that time were John Abernethy, Henry Cline, Sir William Blizard, Sir Everard Home, Sir Astley Cooper, William Lawrence and Charles Aston Key. The great John Hunter had died in 1793, having accomplished a work which marks an epoch in British surgery. In the provinces the most conspicuous surgeons were Edward Alanson, of Liverpool, and William Hey, of Leeds, while in Edinburgh the position of the leading operator was held for many years by John Bell. A little later in the century we find among the names of prominent men in England those of Sir Charles Bell, Sir Benjamin Brodie and the ingenious and learned Benjamin Travers.

At the beginning of the century surgery on the Continent was represented by such men as Sabatier, Deschamps, Boyer and Larrey in France, Scarpa in Italy, Langenbeck, Chelius and Diefenbach in Germany, and Warren and Physick in America.

The surgeon or common practitioner in the village and town in these early days has been depicted by many writers. Possibly the most precise of these was Smollet, who was himself in turn an apprentice, an assistant, a surgeon's mate, a practitioner and a graduate in medicine. Smollet died in 1771. The account he has furnished of the leech of his time is tolerably discouraging. We find him an ignorant,

illiterate, sordid creature, not above the allurements of money-grubbing, and not without suspicion of dishonest practices and of a leaning towards the bottle. He was to a large extent a mere retailer of physic, and in the public eye he ranked with the quacks and nostrum sellers with whom he competed. There was probably some excuse for a writer who, in a discourse in the *New Monthly Magazine* for 1828, speaks of the general body of surgeons as a "cringing, pulse-feeling race." Smollet's description could not have been true of all his brethren, and there is no doubt he wrote with the bitterness of an unfortunate experience. Still, there can be little question that Lauecelot Crab represented a type not yet extinct when the century began, and he must be taken as a forerunner of the cultured and esteemed general practitioner of the present day.

1. THE SURGEON AS AN ADVISER.

In noting the advances made by the surgeon during the century, the first matter which may be dealt with concerns his position as an adviser to his patient. In reviewing this subject, one cannot fail to be immediately impressed by the paramount influence which exact knowledge—or *a fortiori* the want of exact knowledge—has had upon the attitude of the medical profession.

It is obvious that the progress of any science is to be measured by the amount of absolute truths which may have been accumulated at a given time. The lack of knowledge, the mass of things unknown, represent merely a void to be filled. In the development of the science of medicine the element of the unknown has not remained so negative a factor, but has, on the contrary, proved to be a stimulus for a very luxuriant invention, the products of which have been tabulated as facts.

There is no science outside our own in which there has been, during the stages of development, such an extreme disproportion between the amount of knowledge professed and the amount proved ultimately to be exact and sound. As an example of this may be cited the "humoral" system of pathology, which, in spite of its ancient origin and its more or less obvious foolishness, held a position in medicine for centuries, and struggled on, as a distorted and dying creed, even into modern times. This system, in its barest features, asserted that four cardinal humors occupied the human body, and that practically all diseases, and certainly all tumors, were due to disorders of certain of these fluids. The pathology of this system was precise, dogmatic, elaborately classified, and full of detail. Upon it all treatment was founded, and yet the whole of this precious system was a mere daring fiction, an ingenious fancy, the product of an impudent and unscrupulous imagery.

The reason for all this lies more with the sick man than with the man of medicine. The sick man requires absolute and exact knowledge from his doctor. He will accept neither possibilities nor doubts nor confessions of ignorance. He will accept such from his lawyer and from his man of business, but not from the man who attends him in illness.

It is no matter of wonder that in the past the physician has made good by fiction what he lacked in fact. The demands of the patient have been hopelessly beyond any powers of supply, and the deficiency has been furnished by the products of invention. It

would seem that the less the man of medicine knew the more he invented, and the more diligently he hid his little light under the bushel of a ceremonious and mystery-making treatment. The judicial wig, the academic ruffe, the gold-headed cane, the reflective snuff box, and the Socratic air, all made an effective covering for the few poor bones which formed the skeleton of his knowledge.

It thus happens that a good deal of the pretence and humbug with which medical practice has been associated in the past has been forced upon the practitioner by the demands of unreasoning people. With such people the surgeon in the early part of the century had more largely to deal than he has to do at the present day, and yet his stock of knowledge could seldom meet the demands even of the reasonable. Hereby it came to pass that the puzzled man of medicine had to repudiate his ignorance, had to concoct such explanations and to construct such pathologies as could meet the sick man's inquisitiveness, and at the same time give a semblance of reason to an empirical and tawdry system of therapeutics. His utterances were tangled and confused by conceits of his own invention. A false attitude towards his patient was unconsciously forced upon him, and the folly of his pretence to an unattainable learning was apparent to all but the simplest. As an adviser, therefore, he spoke not as one having authority, and his position intellectually is well illustrated by the endless lampoons and caricatures to which he was publicly subjected.

The surgeon of the present day, as an adviser, is in a position which is so greatly improved that it could hardly have been imagined by his forbears of one hundred years ago. He has in the first place to deal with a more enlightened public, with patients whose education to a large extent enables them to appreciate the nature of scientific problems, and with whom it is possible to discuss difficulties, and to own to lapses of information.

In the second place, the additions made to surgical lore have been so substantial that in many departments surgery has reached to the status of an exact science. There is indeed no longer need to call upon invention to supply such gaps as still indicate the unknown. An intelligent patient is satisfied with the assurance that practically nothing at present is known of the nature and causes of cancer. Such assurance is at least as valuable as the information provided at the beginning of the century, when the inquirer would have been told that cancer was "a diseased hardness," or a "scirrhous degeneration."²

We have perhaps not quite shaken off the poor vestments of mummery with which ignorance was clad, nor rid ourselves of forms of speech which still pass current for sense, but which are little more than sounding brass and tinkling cymbal. We speak assuredly of the "constitution" and of "states of the system" and of the "supporting of the system." We sanction such terms as "poverty of blood," "diminished vitality," and "sympathetic inflammation." We profess to believe in "tonics," in medicines the swallowing of which will give strength, in "galactagogues," in "alteratives," in "astringents," and in "cooling physic." We profess moreover to "strengthen the lungs" and give "tone to the stomach."

² Samuel Cooper's *First Lines*, London, 1807.

³ South's *Chelius*, 1826-46.

The modern surgeon can well afford to dispense with all this empty verbiage, since he can base his opinion upon demonstrated facts and can express it in plain words, free from any of the embellishments of a literary masquerade. For many reasons this is well.

II. THE SURGEON AS A MAN OF LEARNING.

The surgeon at the commencement of the century appears to have lacked most of what we now consider to be the essentials of the art, and we can only view with amazement the scantiness of his learning and the poverty of his equipment. He knew little more of inflammation than that it was represented by swelling, heat, redness and pain. His knowledge of the causes of inflammation and of those dangers which follow upon open wounds was scarcely in advance of that professed in the days of Hippocrates. He had no glimmer of the possibilities of asepis. He had no anesthetic, no hypodermic syringe, no clinical thermometer and no practical means of investigation in clinical chemistry. The very name "bacteriology" did not exist, and the treatment of disease by prepared serums would have appeared to him as wild as the wildest therapeutic dream of ancient days. Although vaccination had been introduced in the last year of the eighteenth century, the magnitude and nature of the principle it involved had not been appreciated.

The microscope as an aid to diagnosis played no part in the equipment of the surgeon. He had neither laryngoscope nor ophthalmoscope, and his acquaintance with otology, skin affections and the diseases of women was at the best rudimentary and indistinct. He had only rude medieval orthopedic appliances, and he knew nothing of the lithotrite nor of the array of instruments which are now in daily use in connection with ophthalmic, laryngeal, cranial and abdominal surgery. It would seem indeed that there was little for him to do but to open abscesses and sow the seeds of chronic septicemia, to excise tumors of the structure of which he talked much and knew little, to amputate limbs for diseases he could not mend, and to draw blood whenever doubt existed as to what was best to be done.

Conservative surgery was not understood, and was certainly not practised, and plastic methods of operation had no place in treatment.

Lord Thurlow, in speaking against the Surgeons Bill in the House of Lords in 1797, declared, with some basis of truth, that "surgeons in this country are not respectable men, their pretensions are unjust and illegal because they are not a scientific body."

In 1800 a man could practise as a doctor without passing an examination of any kind. Indeed one itinerant practitioner is reported to have assumed the title of assistant surgeon on the ground that he had served an apprenticeship to the crutchmaker of a hospital. The examination for the diploma of the Royal College of Surgeons was by *via voce* only. There was no examination of patients, and no dissection of the subject. Candidates were required to produce evidences of apprenticeship, of attendance upon anatomical and chirurgical lectures, of having performed dissections, and of having attended the practice of a recognized hospital for a period of six months.

In 1813 the period of compulsory attendance at a hospital was raised to one year. The standard of

knowledge, however, does not appear to have risen in corresponding proportion, for in 1822 the then president, Sir William Blizard, felt called upon to address the Court of Examiners on certain "tokens of remissness in teachers, and of inattention in students," which had been forced upon his notice. He regrets that candidates are commonly ignorant of the situation of nerves and blood vessels, of the disposition of the muscular fibres of the heart, gullet and stomach, and of the diameters of the intestine. He further adds that "the deficiency of candidates in physiological information is far more remarkable," and enters into such detail as the following: "Often do we find them," says the president, "ignorant of the reasons why the ribs in inspiration are, from their figure and muscular connection, moved upwards and outwards, of the systole and diastole of the heart, of the process and intention of respiration, of the nature and distinction of the pulse, of the distinct offices of divers muscles, of the figure of the lens and uses of the humors of the eye in vision."

He concludes by deploring that there is a "correspondent darkness of mind relating to the symptoms, seat, causes and rational treatment of diseases and injuries," and furnishes a catalogue of items with which candidates do not appear to have been commonly conversant, although the list presents such matters as the signs of fractures and dislocations, the symptoms of compression and of inflammation of the brain, the consequences of fractured rib, and the *rationale* of the symptoms of hernia.

At the commencement of the century there was, indeed, no systematized medical education. The training of the surgeon was paltry, casual and inefficient. His preliminary education was miserably meagre. It was necessary that he should be able to read and write and pretend to some smattering of Latin. He became an apprentice, and, in that menial capacity, gleaned what he might from his master and from attendance upon sundry lectures. So far as hospital practice was concerned, his attitude as a learner was well expressed by the phrase, "He walked the hospital." The institutions which he thus attended for a period of six months were in a state of rude squalor as regards administration, sanitary arrangements and nursing, and well deserved the abuse which was lavished upon them.

III. THE SURGEON AS AN OPERATOR.

During the nineteenth century the surgeon, as an operator, passed through a rapid metamorphosis, and has now reached at least the level of the unexpected. It may have been supposed that there is little to be learned in the way of using a knife which had not been learned during a period of over eighteen hundred years, for there were surgeons before the Christian era. Yet time has shown that even in 1800 there was a technique in operating which was as little like the technique of today as are the slashes of a cutlass when compared with the studied movements of a foil. It may have been surmised that twenty centuries would have exhausted the methods by which a limb could be cut off. Yet in 1800 modes of amputation were in vogue which are now regarded as uncouth. It cannot even be said that the commencement of the century saw in use a ready and efficient means of checking bleeding, although that measure represents the most elementary of the surgeon's duties.

The operator of olden times certainly possessed many qualities which are now falling into abeyance, and which cannot pass away quite unregretted. The success of his craft depended largely upon his daring, upon the alertness of his eye, the steadiness of his nerve, and the rapidity of his movements. He stepped into the arena of the operating theatre as a matador strides into the ring. Around him was a gaping audience and before him a conscious victim, quivering, terror-stricken, and palsied with expectation. His knife was thrust through living flesh and acutely-feeling tissues, and the sole kindness of his mission was to be quick. In spite of moans for mercy from gagged lips the knife had to move on its way steadily, and, undeterred by struggles and bursts of hemorrhage, the blade must needs pass without faltering or sign of hesitancy.

There is less need for such qualities now. The dramatic element in surgery has gone with the men who unconsciously fostered it. The operating theatre of the present day has lost its horrors, and has changed from a shambles to a chamber of sleep. The surgeon's hand can move with leisurely precision, and theatrical passes of the knife are favored only by those who have not yet learned that mere brilliancy is no measure of success.

It may be that the present-day surgeon is a loser in that he has less need for those dashing qualities which were essential to the operator before the days of anesthetics; but, on the other hand, he has gained much in the direction of the sympathetic handling of his patient and in the culture of gentleness.

It is little wonder if the older surgeon became rough and stern, if his sense of feeling became dulled, and if the sympathetic side of his nature suffered some suppression. Indeed, contemporary accounts are apt to represent the operator of pre-anesthetic times as rough almost to brutality, and as coarse both in his conduct and in his utterances. His language, it would appear, savored of the cockpit, and the hasty flourishing of his knife led occasionally to unintended mutilations.

Within the compass of some thirty years the whole state of affairs has changed. Consideration for the patient and for the patient's sensibilities has become a matter of the first moment, and the operator has learned that his work is best done if done with gentleness and tact, and that haste and bluster, coarseness and coarse handling are out of place around the operating table. A striving after affect at any cost has ceased to be an element in the surgeon's work. Success is no longer measured by the number of minutes occupied in the amputation of a limb, but by the state of the patient many days after the measure has been completed. The triumph of the older surgeon was immediate and scarcely reached beyond the arena of the theatre. The triumph of the modern surgeon is deferred, and is found in the operation ward and in the convalescent home.

Still, the fact remains that it is easier to be a surgeon of some degree at the end of the century than it was at the commencement, since in the earlier days the qualities needed for success in operating were rare and of a kind not readily to be acquired.

On passing more into detail, one notices that beyond these general changes in the attitude of the operator there have been others which owe their existence to special advances in the surgeon's art. Prominent

among these may be named: (1) An improved knowledge of anatomy; (2) a readier method of arresting hemorrhage; (3) the employment of anesthetics, and (4) the introduction of antiseptic measures.

(1) *An improved knowledge of anatomy.*— Among the surgeons of the early part of the century there were many competent anatomists, and not a few who could lay claim to be deeply versed in that science. Among the latter were such men as Astley Cooper and William Lawrence. Still, in the education of the average surgeon the study of anatomy did not play a prominent part. Anatomy was largely taught by means of public demonstrations. The teacher dissected and the student looked on, much as he did in the days when Rembrandt's great picture of Nicolaus Tulp and his pupils was painted. The knowledge required was scant and superficial and had little practical basis, and no methods of teaching existed which can in any way compare with those in vogue at the present day. The science of anatomy was well advanced at the commencement of the century, but it was not taught to the common student. "Quain's Anatomy," first published in 1828, contained a very sound account of the human body, although the whole work was then represented by a single small volume of 700 pages which was without illustrations.

The facilities for acquiring a practical knowledge of anatomy were not only few, but were hampered by many sordid difficulties. Anatomical schools were regarded with disfavor and were actively discouraged. They were viewed with unconcealed suspicion by the public, and were surrounded by a ghoulish romance in which rifled graves and unseemly dealings with the hangman played a pungent part. Indeed, the teacher in an anatomical school found himself involved in a squalid and disreputable traffic, very un congenial to any earnest man of science.

Among the many qualifications needed for success in operating, a practical knowledge of anatomy as acquired by repeated dissection is conspicuous. Such knowledge as the surgeon needs is to be learned not from books but from the patient use of the scalpel and forceps. The dissecting room is the surgeon's nursery. The tissues of the body are the material with which he works, and he must needs know them as the sculptor knows the marble he chisels and the potter the clay he moulds.

It is no matter of surprise that the older surgeon often lacked confidence in operating, that he failed in initiative, and clung only to formulated methods, and that a departure from accepted lines was attended with fear and hesitancy. Ignorance encouraged in the rash heroic passages of the knife and in the timid and over-cautious and dangerous fumbling. And as to this, it is probable that in pre-antiseptic days as much ill attended the nervous fingers which were creeping clumsily into the unknown as followed the reckless operator who essayed to draw his bow at a venture.

(2) *A readier method of arresting hemorrhage.*— At the commencement of the century the means employed for the control of bleeding were numerous, and were represented by such familiar measures as the ligature, the suture, styptics of many kinds, and the actual cautery. In applying the ligature the vessel was picked up by forceps and tied as at the present day. The instruments used were those of Dieffenbach, Assilini and Liston. The older types of instruments were not readily applied, or at least required

time in their adjustment. The bleeding from the vessel was not necessarily controlled by the forceps when in position. The general rule in amputation was to apply a tourniquet and to ligature the individual arteries after the limb had been removed. In the excision of tumors the practice was recommended of securing each vessel as it was divided.

When it is remembered that operations were carried out without anesthetics, it will be understood that the older surgeon had an absolute terror of bleeding, and was driven to undesirable shifts to avoid the need of facing it. He was indeed a coward where hemorrhage was concerned, and there was reason for alarm when a conscious patient was struggling and showing signs of exhaustion, and when the means for staying the stream of blood were slow of application.

We find, then, that hemorrhage was expected, and that a liberal loss of blood was considered to be a necessary adjunct to every major operation. Tourniquets were employed freely and with considerable harshness. Raw surfaces were bathed with styptic solutions which were often destructive in their action or at least opposed to primary healing. The actual cauterium with which to sear the bleeding area was in some request, and every well-equipped operating theatre kept its stove and its cauterium irons in constant readiness.

The least pleasant evidence of the surgeon's dread of hemorrhage and of his inability to deal with it was afforded by the treatment of certain nevi in infants and children. These growths were strangled by ligatures which slowly cut their way through the skin and the neoplasm, assisted by a benevolent process of suppuration. A painful ingenuity was expended upon amplifications of this measure, the cruelty of which was but little mitigated by the introduction of chloroform.

Allied to this procedure was the *écraseur* of later date. Its invention was due to Chassaignac, and it was freely used in England until quite recent times. It was employed for the removal of growths of various kinds, but its most baneful employment was as a means for excising the tongue. It is scarcely to be believed that within the period of the introduction of anesthetics the tongue has been torn out of the mouth by means of a loop of hemp or wire which strangled it at its root.

The *écraseur* will remain in the archives of surgery as the insignium of the incompetent and the timorous, and will stand out as a blot in an otherwise bright period of progress and enlightenment. The shadow of this medieval instrument has been slow to fade, and as the ovarian clamp and the *serrenard*, it clung about the confines of reasonable surgery and hindered the development of the operations of ovariectomy and excision of the uterus.

At the present day the surgeon has little dread of hemorrhage, and the confidence he possesses is based upon good grounds. In the first place, he makes larger use of the precautionary ligature of vessels. It has become a commoner practice to apply a temporary or permanent ligature to a main artery before a part supplied by that vessel is excised. This is carried out frequently in dealing with large and vascular tumors. In removal of the tongue, moreover, an excellent method is that in which a preliminary ligature of both linguals in the neck is carried out. In removing the uterus through an abdominal incision the ques-

tion of hemorrhage is disposed of by an early ligature of the ovarian and uterine vessels. A further example of this mode of anticipating bleeding is afforded by that method of hip amputation which is known as the anterior racket. Here the main vessels and even the main branches are secured before the flaps are cut, whereas by the older plan the vessels were severed with the flaps and were tied after the limb had been removed.

In the second place, the latter-day surgeon is operating upon an anesthetized patient and can proceed with slowness and deliberation. The importance of this fact in connection with the present subject cannot be overstated. In the instances which have been just cited, an incision of the tongue in a conscious patient would be greatly extended by the twofold operation in the neck, and whereas the amputation of the hip by transfexion occupied in able hands but a minute or so, the operation by the anterior racket is tedious and involves relatively much expenditure of time.

Thirdly, the treatment of hemorrhage has been to a remarkable extent simplified, if not indeed rendered complete, by the introduction of the pressure forceps of Sir Spencer Wells. These little instruments represent the most valuable addition which has ever been made to the surgeon's appliances. It is not uncommon in operations of a certain type to have twenty or more pairs of pressure forceps applied to the surface wound at one time. This represents a degree of possible bleeding which in the old days, when every vessel had to be separately tied, would have been replaced by actual bleeding of a fatal type. No instrument has brought with it so great an assurance of security or has done more to extend the area of safe operation.

(3) *The employment of anesthetics.* — The value of the anesthetic and the radical and beneficent transformation it has effected in surgical practice call for no comment in this place. The changes that the discovery has wrought in the personality of the surgeon, in his bearing, in his methods and in his capabilities are as wondrous as the discovery itself. The operator is undisturbed by the harass of alarms and the misery of giving pain. He can afford to be leisurely without fear of being regarded as timorous. To the older surgeon every tick of the clock upon the wall was a mandate for haste, every groan of the patient a call for hurried action, and he alone did best who had the quickest fingers and the hardest heart. Time now counts for little and success is no longer to be measured by the beatings of a watch. The mask of the anesthetist has blotted out the anguished face of the patient and the horror of a vivisection on a fellow man has passed away. Thus it happens that the surgeon has gained dignity, calmness, confidence and, not least of all, the gentle hand.

Anesthetics have, moreover, greatly extended the domain of surgery by rendering possible operations which before could have been only dreamed about, and by allowing elaborate measures to be carried out step by step.

The introduction of anesthetics has not only developed surgery, but it has engendered surgeons. It has opened up the craft to the many, for in the pre-anesthetic days the qualities required for success in operating were qualities to be expected only in the few.

In the technique of established operations chloroform and its allies have led to advantageous changes.

This is well seen in the case of amputations. In the olden days that method of removing a limb was best which was the most speedy. A prominent position was, on this account, given to the cutting of flaps by transfexion, a long, narrow blade being used for the purpose. This rapier-like instrument required great skill in handling and in the grasp of the feeble it was a fearsome weapon. Muscles were sliced through in such a way that the widest possible section of their substance was often made. Vessels and nerves were, in like manner, cut almost in the direction of their long axes, and the resulting incision gave the maximum area of wounding. At the present day transfexion is abandoned and the murderous amputating knife has found its way into the museums of the curious. Muscles can now be severed at right angles to their length, or in such a way as to secure the smallest possible surface of section. Vessels and nerves are cleanly divided in the same manner and the resulting area of the wound is reduced to a minimum. This difference in methods is vividly illustrated by amputation at the hip joint.

(4) *The introduction of antiseptic measures.*—Of the great work of Lister, and of the introducing of the antiseptic treatment, there is no call to speak at this time. When the century was young the touch of the operator was the touch of a tainted hand; the balm he poured into the wound was poisoned and he himself undid the good his science strained to effect. It is sad to think that behind the earnest man with the ready knife there stood a shadow which rendered hopeless his kindest effort and which only too often proved to be the veritable shadow of death. The change has been great, and its greatness lies in its littleness, for it is bound up with no more than this: that the surgeon has learned to be clean.

The operator of days gone by would have turned with some petulance from the grand simplicity of the counsel to be clean. He ever sought some means of mighty bearing to rid him of the incubus of failure and, like Naaman of old, he would have hesitated to dip in the Jordan of antisepticism to be free of his leprosy. The surgeon has not only learned to be clean, but he has become aware of the potency of little things. The demands of the antiseptic treatment have made him minutely careful, distrustful of any aid that he cannot control and suspicious of every semblance of error.

It is possible that the abandonment of the old easy order of things has been followed by a too slavish devotion to mere ceremonial. The remarkable and extravagant preparations with which some surgeons now approach an operation, the cleansings and the washings which precede the laying on of hands, smack a little of fetish worship and foster the cult of the surgical Pharisee. On the other hand, these performances, this "making clean the outside of the cup and platter," seem to give assurance and to render the devotee thankful that he is not as other men.

IV. THE SURGEON OF THE FUTURE.

Circumstances in the tendencies of today foreshadow to some extent what may lie buried in the future. The changes which have swept over the world of surgery have extended the possibilities of the art and have, at the same time, added a host to the ranks of those who practise it. Some thirty years ago the roll of such as could claim to be accomplished operators

was very small. The greater deeds of surgery were limited to cities and the larger towns. The general practitioner seldom took up the scalpel except in minor necessities. Even in London the list of consulting surgeons was meagre. In the hospitals of the metropolis the number of operations performed in the year would be less than is now the quatum for a month.

But here at the close of the century the disposition of affairs is wholly altered. Where there was one surgeon there are now ten, and throughout the breadth of the land and to its utmost limits the work of the operator has extended. The more ambitious performances of surgery are no longer restricted to great centres, but are carried out in the little town, in the cottage hospital and even in the cottage itself. The general practitioner is laying claim to operate upon his own patients and is carrying out his intention in no hesitating manner. The days of the great operator, of the one man to whom all came who could, are rapidly passing away. Indeed, the practice of pure surgery, which was at one time limited to the prominent few, is now becoming common to the many. The man who excels conspicuously as an operator will always attain such eminence as his ability deserves, but the exclusiveness of the practice of operative surgery is quietly vanishing with the century. This change is well. It is a change that is inevitable. The democratic movement is the active power of the day, and that an oligarchy in the community of surgeons should be replaced by an earnest democracy is precisely in accord with the spirit of the times.

In every great change there must—at first at least—be some undesirable developments, and it is impossible to deny that the wider distribution of the practice of operative surgery may lead to the occasional performance of major operations by men who are not justified, either by experience or by training, in undertaking them. Furthermore, there is among the signs of the times some evidence that the reaction in the matter of operative surgery is to some degree extreme, and that we are in danger of passing from the policy of doing too little to the policy of doing too much. Operations we know were too few in the past, but there is some foundation for the impression that they are occasionally too frequent in the present.

One other matter which looms out of the future will suffice to bring this subject to a close. So many have been the artificial aids to clinical investigation which recent science has introduced that it comes to be a question whether the natural acumen of the surgeon will not deteriorate in proportion as he fails to encourage that particular learning which elings to the finger tips of all great diagnosticians. That there will be such a decadence is beyond doubt. The loss is to be deplored, for if there be one point of excellence which stands before all in the qualifications of the perfect surgeon, it is bound up in that refined sensibility, that critical perception, that inestimable cunning, which lies in the surgeon's touch.

Examples of the directions in which this loss will be felt come readily to mind. A considerable amount of skill, for example, is demanded in the examination of complex fractures, of lesions of deep-seated bones, and of injuries about joints. What was to be learned of these troubles once had to be acquired by a tedious manipulation demanding considerable refinement. The surgeon who has now to deal with such con-

ditions can afford to dispense with a prolix examination, and can submit the inquiry to a demonstrator of the Röntgen rays. The skiagraph, although its value is much exaggerated, embodies a substantial gain, but it is to be discounted by the loss of the great element in education which it is slowly replacing.

An obscure tumor—to take another instance—presents itself, and no longer is the surgeon compelled to trust to the acuteness of his inquiry and his patient review of all the physical details of the mass. For what his ready fingers may have learned can be substituted the findings of the exploratory incision, the trochar and the aspirator. Here once more an advantage is minimized by a loss.

Or, again, an abdominal swelling is brought under notice. Its features are obscure, but much of the uncertainty of outline can be dissipated by a cultured hand which, with infinite patience and repetition, has learned to construct a reality out of a shadow. It may be said that it is needless to persist in bringing this much elaborated means of inquiry to further perfection since the problem is at once to be solved by an exploratory laparotomy. By such little operation a great advantage is gained, but an opportunity to add to one of the most refined forms of learning is lost. The value of the exploratory incision is beyond question, but among the signs of the times it is impossible not to notice a tendency to resort too readily to this means of solution. The Gordian knot, according to the legend, was ultimately cut, and it is a question whether the sum of human ingenuity would not have been substantially increased if attempts to untie the noose had been more diligently persisted in.

In another example, let it be supposed that a suspicious ulcer presents itself for diagnosis. In such case is it well to devote time to a precise and tedious inspection of its edges and to a careful tactile examination of its base, and to check what is discovered by results laboriously gained from like inquiries? Is it not simpler to take a scraping of the affected surface and to submit it to a microscopist, and to thus be spared a method of examination which, although it may not give final results, yet represents an opportunity of furthering a priceless accomplishment?

Finally, there are cases which present symptoms hard to interpret at any superficial inquiry. Is it worth while in such to undertake an exhaustive critical research and to submit the whole to a trained judgment? The quest would no doubt develop habits of observation and powers of weighing evidence; but the process is slow, and an inquiry carried out in a bacteriological laboratory will clear up all doubts, and at the same time dispense with the efforts of a cultured sense.

Those, therefore, who are concerned with the education of the surgeon of the future would do well to still cherish this ancient power, and to foster a memory of the fact that surgery is, in its very essence, a handicraft, and that in all that he does the surgeon's great endeavor should be to make his own hands self-sufficing.

It is sad to think that this hardly acquired faculty dies with the possessor of it, and never was this more vividly presented than it has been by the loss which surgery has sustained in the death of Sir James Paget. One can picture the great surgeon composed in his last sleep, and can see the once busy fingers lying lifeless on the white sheet, and then comes the wonder at the

wealth of learning, at the exquisite cunning, at the refined sense which lay dead in the dead hand. No written book can hold a tithe of the dainty knowledge which had been mastered by those subtle fingers, and no record, however labored or however loving, can tell of the power which once rested in that magic touch.

An individual loss does not, however, hinder the general tide of progress. Advance in such a work as ours depends upon the uneventful work of the whole body, and is only accentuated by the achievements of the prominent few. The movement is the movement of a multitude in which individuality is, at a distance of time, little to be distinguished and in which personal eminence contributes a smaller factor than the present is ready to acknowledge. Those who stand forth as the leaders of the advance are merely the elect of the common body and the representatives of a wide intellectual franchise. Even he who startles the world as a discoverer has often done little more than give expression to what was already nascent in the multitude. So as one great surgeon after another drops out of the ranks his place is rapidly and imperceptibly filled, and the advancing line moves on with still the same solid and unbroken front. The continuity of progress is undisturbed by the uncertainties of human life, and, as one writer has well expressed it,

"No work begun shall ever pause for death."

RESULTS OF THE OPERATIVE TREATMENT OF CANCER OF THE BREAST.

BY HOMER GAGE, M.D., WORCESTER, MASS.,
Surgeon to the Worcester City, Memorial and St. Vincent's Hospitals.

THE removal of the cancerous breast has for more than fifty years been one of the commoner of the major operations. When successful it is usually followed by a sense of relief on the part of the patient at being rid of the external manifestations of a loathsome disease, and on the part of the surgeon by a feeling of satisfaction in having at least temporarily relieved his patient, with a probability of having prolonged her life, and a possibility of having permanently eradicated the disease. These feelings of relief and satisfaction are too often of very short duration, and the return of the growth within a few months plunges the patient into a deeper despondency, and leads the surgeon to question the value of his advice and operation. So frequently is the darker side of the picture the more prominent that from almost the beginnings of surgery many of its most distinguished followers have doubted the wisdom of operating at all.

Sir Benjamin Brodie says that the late Mr. Cline, Sr., and Sir Everard Home, both men of great experience and sound judgment, would scarcely ever consent to the removal of a scirrhus tumor of the breast under any circumstances, and states his own belief that in the larger proportion of cases in which the operation is performed the patient is not alive two or three years afterward, and in a great many cases instead of the operation stopping the disease it actually seems to hasten its progress. He thought the number of cases suitable for operation extremely limited. Sir James

Paget thought the utility of the operation very doubtful. Halsted says Agnew operated only for moral effect, and that Sands did not save a single case. The late Dr. Richard M. Hodges, in 1888, wrote that he had only known of but one instance of seemingly prolonged life after the removal of cancer of the breast, and expressed his opinion that there were but three conditions in which removal of the breast for cancer should be or ever has been thought advisable, namely, (1) for extreme pain, a rare occurrence; (2) for the relief of unendurable odor, in the exceptional instances of this popular supposed inevitable accompaniment, a condition now wholly within the control of local treatment; and (3) when the patient, after a statement of the nature and sure return of the disease and small prospect of prolonged life, took upon herself to decide for excision. He believed that in dissuading his patients from operation he had rendered them the greatest service.

The establishment of the aseptic principle in surgery has wholly removed many of the objections which these men have made to the principle of interference, but it has also, in connection with the studies of Heidenheim and others, so materially changed the character of the operation itself that the old discussions seem hardly pertinent, and the whole subject must, in the near future, be thoroughly revised. In 472 pre-antiseptic operations from the clinics of Velpeau and Billroth the mortality was over 17%; in 231 antiseptic operations from the clinics of Volkmann, Lister and Billroth the mortality was 6%; and in 490 operations done at the London Hospital from 1882 to 1890 the mortality was almost 10%. A mortality of 1 in 10 or even 16 is enough, I think, to throw a legitimate doubt upon the advisability of urging the patient to submit to the operation, unless a reasonable assurance can be given that in case she survives she will not only live longer and more comfortably, but have fair chance of permanent relief. This question of mortality, is, however, now practically eliminated. Many observers have now reported long series of consecutively successful cases, and the general mortality would seem to be certainly less than 2%, and probably even less than 1%. Halsted has reported 50 successful operations, with no death; Dobson, 63, with no death; and Cheyne, 64, with 1 death. These with my own 56 consecutively successful cases make 233 cases, with 1 death, or less than one-half of 1%.

At the same time that the dangers of the operation have been reduced to almost nothing, the objections of the tedious convalescence, frequent and painful dressings and subsequently impaired usefulness of the arm, have been practically negated. Indeed, so safe and so simple has the operation for the removal of a cancerous breast become, when performed by what is generally termed the incomplete method, that is, without the removal of the muscle and the axillary contents, that, as Dr. Hodges said, it is or has been "performed with but little hesitation even by those not accustomed to surgical operations of similar importance." Under such circumstances the immediate results are apt to be much more brilliant than the later; the wound heals quickly, but the disease soon returns, and by the patient and her friends the operative treatment of mammary cancer falls into disrepute. In the hands of the experienced surgeon, however, the removal of these objections has simplified very much the choice of operation. Any surgical operation is to

be avoided if possible, and when absolutely necessary the consequent mutilation should be as limited as is consistent with the attainment of the object for which it is undertaken. But if the complete and incomplete methods of operating upon the cancerous breast are equally safe, with an equally short and comfortable convalescence, that method is to be preferred which seems to offer the chance of securing the longer immunity from the extension of the disease.

I have purposely avoided the use of the term cure, because it seems to be absolutely impossible to fix a limit beyond which the disease may not reappear. The three-year limit, which has been quite generally accepted, was proposed by Gross, who believed that after that time local recurrence was so rare that it might be reasonably assumed to be a development independent of the previous disease. But the more careful collection and observation of cases proves that late recurrences are too numerous to be accounted for in any other way than by the latent existence of the local disease, or the presence of a general dyscrasia. With either supposition the use of the term cure is inconsistent.

I have lately had a striking illustration of this in a woman seventy-two years old, upon whom I operated in December, 1896. In reply to a letter, she wrote in January that she was well and free from any signs of a return of the disease. In February she entered the City Hospital for the treatment of an ulcer of the leg, and by reason of my inquiries in regard to the results of my operation for cancer of the breast she was examined with especial care. No appearance of disease was noted. Soon after her admission a fusiform enlargement of clavicle was observed, which grew rapidly and was very painful. She failed steadily, and died just one month after her admission. At the autopsy there were found extensive cancerous deposits in pleura, pericardium and peritoneum, and a cancerous growth of the medulla of the clavicle.

Verneuil reports an instance in which the disease recurred *in situ* thirty years after the primary operation. Shields has collected 19 cases in which recurrence took place from the fourth to the eighth year, and 29 cases in which it appeared from the ninth to the twenty-fifth year. The instances of local recurrence are, for the most part, from the histories of incomplete operation, but the visceral recurrences seem to follow complete as well as incomplete. It is therefore, I think, much more exact to speak of prolonged immunity than of cure; and prolonged immunity is certainly an object worthy of our highest endeavor.

Neither the clinical experience of the surgeon nor the laboratory study of the pathologist has as yet given us any clue to the cause of cancer, but it will be generally accepted, I think, that they have pretty conclusively established its local origin. They have shown that it begins almost invariably in one locality; that it extends in certain definite lines, following the course of the lymphatic vessels; and that it is then gradually disseminated throughout the body in the form of multiple metastases. It would seem *a priori*, therefore, that there must be a time when it could be wholly eradicated — a time when it has not yet entered the lymphatics, and a time when it is being carried along in the lymphatics before its general dissemination, and as if during either period its complete removal ought to be followed by a radical cure. We

rarely have an opportunity to witness its earliest beginnings, and careful microscopical examinations of the axillary contents have almost invariably shown some evidences of glandular infection, even when the gross appearances have shown nothing. Heidenheim's observations—since many times confirmed—have also shown that there is very early an infection, not apparent to the naked eye, of the fascia which covers and extends between the fibres of the pectoral muscle. These invisible recurrences are believed to be the foci of the local recurrences, and their number and extent to explain the initial multiplicity of most recurrences as against the primary, solitary outbreak of the disease.

From a theoretical standpoint, then, the most complete operation should offer the largest chance of immunity. From a practical standpoint, the nearer we come to eliminating the probability of a recurrence in or about the seat of the primary growth the stronger should be our belief in the possibility of total eradication, and the nearer should we be approaching our ideal result. The subject of local recurrence has thus become one of the most important in the future development of the operation.

It was the ancient custom to raise the affected breast from the body, and with the red-hot iron to remove the whole of the gland with all of its cutaneous covering. But in the course of the natural revulsion from such a barbarous method, its completeness and thoroughness seems to have been lost sight of, and instead it became the habit to remove the tumor with more or less of the surrounding breast tissue through an elliptical incision. In 1868 Moore, of the Middlesex Hospital, in an exceedingly valuable paper which seems to have excited but little interest or discussion, first called attention to the incompleteness of the method then in vogue, and to the necessity of a more radical extirpation of the disease, and especially of the overlying skin. In speaking of the operation as it was ordinarily performed at that time, he says: "Sometimes the tumor only is removed—sometimes that segment of the breast in which the tumor lies is taken away with it. Sometimes, with the intention of extirpating the entire mamma, a portion of it is unwittingly left behind; sometimes the breast is removed, but the propensity of cancer to extension in the skin is misapprehended, and for symmetry's sake a flap which even includes the nipple is preserved; and yet again, there being no definite plan in the mind of the operator but that of cutting wide of the tumor, portions of the breast itself are left behind. The consequence of this last method of operating may be at once apparent, when, on examining the mass thus dug out of the centre of the breast, hard cancerous cords, continuous with the principal tumor, are found to have been cut across."

In place of this inadequate operation, in language that expresses as well the opinion of today as if it had been written by Halsted or Cheyne, he says that "it is not sufficient to remove the tumor or any portion of the breast in which it is situated—mammary cancer requires the extirpation of the entire organ. In the performance of the operation it is desirable to avoid not only cutting into the tumor but also seeing it. Diseased axillary glands should be taken away by the same dissection as the breast itself without dividing the intervening lymphatics, and the practice of first roughly excising the central mass of the

breast and afterwards recovering successive portions which may be of doubtful soundness should be abandoned."

Of Moore's own practical results we know but little, and the next step in favor of more radical operation did not come until 1880, when Gross published his classical monograph on "Tumors of the Breast," with its carefully prepared statistical evidence upon the natural course of unoperated cancer, and upon the results which ought to be expected from operations. He advocated the removal of the entire breast and its coverings by a circular incision, a search for outlying lobules, the removal of the pectoral fascia, and the prolongation of the outer portion of the incision into the axilla, with a view to its thorough exploration. He was followed in 1882 by Mitchell Banks, who advocated substantially the same procedure. In 1896 Watson Cheyne urged not only the complete removal of the gland, with all its ramifications, and the exploration of the axilla, but also the removal of at least a part of the underlying muscle, and of all the contents of the axilla except the nerves and vessels, whether microscopic evidences of disease were present or not. Still later, Halsted has added to the theoretical reasoning of Moore the value of his practical experience in removing in every case the breast, its overlying skin, the sternal portion of the pectoral muscle, and the contents of the axilla, *en masse*; and in his last series of 53 cases has included an equally thorough dissection of the lymphatics in the inferior cervical triangle. There has been, thus, a steady progression toward a more radical removal of mammary cancer; and Halsted's method, the last step in this progression, has probably given us as nearly perfect a technique as it is possible to reach. Now, what are the results?

The objects to be attained are, as we have seen, two, namely, the prevention of local recurrence, and the securing of a longer immunity from the disease.

First with regard to the prevention of local recurrence. The following table compiled by Halsted is taken from the results of about 1,200 operations performed by the most prominent German surgeons. They include both antiseptic and pre-antiseptic operations: Billroth had 85% of local recurrences; Czerny, 62%; Fischer, 75%; Gussenbauer, 64%; König, 60%; Kuster, 60%; Lucke, 66%; Volkmann, 59%.

To these we may add the results of 35 cases reported by Sir Thomas Smith, operated on by the incomplete method, with 74% of local recurrences. In over 1,200 cases, therefore, operated on by a more or less incomplete method, the growth reappeared in or about the scar of the primary operation in 67%. The percentage of local recurrences in the cases collected by Gross was 68. The number of cases in which a complete operation has been done is not nearly so large—about one-fourth—but the results are very striking: Halsted had 25% of local recurrences; Watson Cheyne, 18%; Rotter, 14%; Dennis, 5%; or an average of 15½% against 67%. So wide a discrepancy can be accounted for only on the theory that the less thorough operation leaves behind infected tissue which subsequently comes to the surface, and that the more complete methods of operating diminish the probability of any such recurrences to a very remarkable degree. So striking is this contrast that it would almost seem to justify the very positive declaration of Watson Cheyne, "that improvement in the results can only take place if we

put the blame of local recurrence on the operator. For just as we must assume at the present day that suppuration after an operation through unbroken skin is entirely the fault of the surgeon, so it must be admitted, though not by any means to such an extreme extent, that a recurrence in the track of an operative wound or in the neighboring glands also implies an imperfect operation."

With regard to the period of immunity which is secured by the operation, we find that Billroth, in 1876, reported that 4.7% of his cases has passed the three year limit without any reappearance of the disease; Gross, in 1880, reported 9%; Kuster, in 1881, 21%; König, 23%; and Bergmann, 39%. Halsted had 40%; Dennis, 45%; and the average of Rotter, Helfferich and Cheyne was 49½%. Of Cheyne's 61 cases, 30 passed the three-year limit free from disease, and thus far in only 1 has recurrence been noted. It is therefore quite apparent that, as the extent and thoroughness of the operation have increased, not only has the tendency to local recurrence very much diminished, but the probability of a complete immunity for at least three years is very much greater, being, in the hands of some of the ablest surgeons, an even chance. Surely such a showing as this is a sufficient answer to the critics whose opinions I quoted at the beginning of my remarks; and it is the more remarkable when it is remembered that in the older statistics benign tumors must occasionally have been included, while the recent cases have all been verified by microscopic examination.

In the light of these results I think we should review carefully our own experiences, and see where we fall short of what is thus demonstrated to be possible. Since my first operation, in 1888, I have endeavored to remove the whole breast with the skin directly over the tumor, and have in every case but one opened endeavored to clear out the axilla. In most of the earlier operations I also removed the pectoral fascia. The one incomplete operation was in a very thin woman, eighty years old, who had a tumor of very slow growth and no evidence of glandular infection. She is still living, free from disease, four years after the operation. Two years ago I began to remove the greater pectoral muscle, and within the last year have endeavored to copy the technique of Halsted as well as I could and remove the breast muscle and axillary contents in one mass, endeavoring not to cut across the infected track anywhere from the lower margin of the breast to the apex of the axilla. My later experience with this method has impressed me very forcibly with the imperfection of my earlier operations. I not only sacrificed too little of its covering, but I often—in fact, usually—left outlying lobules of the breast itself. Until one attempts to remove the breast as a whole, he has little idea how far in all directions—especially inwards and upwards—it extends. I am satisfied, too, that in failing to remove the gland and axillary contents as a whole, I have often left portions of the connecting lymphatics, which are, of course, very apt to be sources of rapid recurrence. Another point with which I have been strongly impressed is that when I have removed the sternal portion of the pectoral muscle my patients have not only recovered the full use of the arm, but have actually recovered it more quickly and more perfectly. This is to be accounted for, I think, by the fact that one of the chief factors in

binding the arm to the side has been the sternal portion of the greater pectoral, which by its involvement in the scar fails to recover its normal elasticity.

My operations, including the incomplete one above referred to, have been 57. There has been no mortality. Ten were done in 1899, and have not recurred; but as so short a time has elapsed they are not included in the following statistics. Of the remaining 47, 46 have been followed up to the present time. Of these, local recurrences took place in 27, or 57½%, a far worse showing than I think it ought to be, and than I think will be made by later cases. Of the remaining 20 cases, 8 died from internal cancerous disease; 2 died over three years after operation, 1 of diabetes and 1 of apoplexy—both without recurrence; and 9 are well and free from recurrence after passing the three-year limit. Thus, in 11 out of 47, or 23½%, there has been immunity from the disease for at least three years. One case was operated on in December, 1897; had a small local recurrence which was removed in December, 1898, and at present shows no return.

Although these results are by no means what they ought to and might be, they are sufficient to convince me that in the thorough, complete removal of the cancerous breast we have a means of offering a long immunity from cancerous infection to a large proportion of these patients, and a considerable hope that the immunity may be permanent, a hope which, in the absence of any alternative, is so strong that it certainly ought not to be smothered by a refusal to interfere. To have reduced the mortality to almost nothing, the local recurrences, that is, the external recurrences, from 67% to less than 20%, and to have increased the number of those who pass the three-year limit free from any recurrence from 10% and 15% to more than 40%, would seem to be a sufficient justification for the operation. But it must be remembered that these results are to be obtained only by a most thorough and extensive operation; and it is, I think, fair to hope that, if such an operation can be performed when the growth is discovered early, while the external manifestations are limited to the breast itself, even better results may be expected.

THE INJURIOUS EFFECTS OF IMPROPERLY CONSTRUCTED SCHOOL CHAIRS.¹

BY J. S. STONE, M.D., BOSTON.

WHILE the theoretical importance of certain principles in regard to school seating may be freely admitted, yet these considerations do not always determine the action of those charged with the purchase of school furniture. It is generally admitted that the height of the seat should equal the knee height, that the width of the seat should be but slightly greater than the width across the buttocks, that the depth of the seat should be about two-thirds the length of the thigh, that the difference between the height of the desk and the height of the seat should correspond to the height of the elbow above the tuberosities when the arm is very slightly raised, as in writing, a difference which also secures the proper distance from the eye in reading.

In regard to the horizontal distance between the

¹ Read before the Boston Society for Medical Improvement, April 2, 1900.

desk and the seat and in regard to the desk slope there has been considerable discussion. The best opinion, however, is that in writing the edge of the desk should considerably overhang the seat, that is, there should be a minus distance in spite of the somewhat greater difficulty in getting in and out of the seats, and that the desk slope should be about one in eight or one in ten, although on theoretical grounds a little greater slope might be better. The Chandler desk top, by a simple mechanism, allows a change both in distance and in slope, and yet, on account of the slightly greater cost, the manufacture of this top has been largely abandoned.

The conditions existing in the Boston Public Schools eight years ago were shown by Dr. Scudder. It is to be hoped that the conditions today are better, and yet there are reasons to fear that the matter has not received here in Boston all the attention it deserves and which it is receiving in Cuba, where 116,000 adjustable desks have just been ordered. The adjustments for height of seat and of desk are so easily arranged that marked misfitting is inexcusable in rooms furnished with adjustable furniture.

Unquestionably, strong children can withstand without permanent injury the bad effects of improperly fitting school seats and desks. But when certain facts with reference to the development of lateral curvature are considered, the importance of placing children under the best possible hygienic conditions when in school cannot be overestimated, especially with the long school terms and the home conditions existing in large cities today. Lateral curvature is a disease originating almost always during school life, the number of cases found increasing regularly with the age of the scholars examined. It is much more frequent among girls than among boys.

It is a well-recognized fact that the ordinary type of lateral curvature is that of the writing position. There is universal agreement that the habit of holding the writing book to the right of the body is bad. There is no dispute as to the necessity of holding the book directly in front of the median line of the body. There is some dispute as to whether vertical or slanting penmanship is preferable. Leaving aside the possibility of any injury to the eyes from oblique penmanship, it is plain that when it is practised the head inevitably turns so that the eyes may follow the line of the writing. From this bending of the head to the left the centre of gravity is altered, the left arm slips from the desk and is lowered, while the right is pushed forward and upward onto the desk. In Nuremberg twice as many incorrect postures were found among those writing the oblique as among those who wrote the vertical script; in Munich two and a half times as many; in Fürth and Würzburg four times as many. Yet in the face of these facts vertical penmanship has been lately abolished in one of our suburbs.

The chair back has always been the great problem. In sitting, the weight of the body is borne by the tuberosities of the ischium and the under surface of the thighs. There are recognized three typical sitting postures, the upright, the forward and the backward. In the upright position when the centre of gravity falls directly on a line connecting the tuberosities the body can be maintained in equilibrium without great muscular exertion, but of course it is not practical to maintain this position for any length of time without support. In the forward position support soon be-

comes necessary and is secured by leaning on the desk. In this position there is great liability to assume faulty attitudes.

So great is the liability to malposition when the child is leaning forward that Schenk and Lorenz advocate writing in the reclining position with the back placed at an angle of about ten degrees. There are, however, certain practical objections to this. In writing a forward position is naturally taken. A reclining position is awkward unless an impracticable desk slope is adopted. But in the forward position there is ordinarily no support for the spine.

In the backward position, although the rolling back of the pelvis is limited by the sacrum, some support higher up is necessary to avoid great fatigue. The great problem of constructing school chairs has been in regard to the back. There are two essentials to a proper back. In the first place, under no circumstances should the shoulders be forced forward. In the second place, the physiological anterior lumbar curve should be maintained. That is to say, there should be a firm support for the sacrum and lumbar region, and at the same time a moderate support for the dorsal region up to the shoulder blades. In this way the liability to round shoulders is decreased, and account is taken of the fact that full extension of the spine tends to prevent lateral curvature, while flexion allows it.

The necessity for a proper support for the lumbar spine has been recognized in the seats made for typewriters. Although the typewriter is able to move about more freely than the scholar, can regulate the distance between her chair and her work, which the scholar cannot do, can regulate the height of her chair at will, which the scholar cannot do, it has still been found a matter of commercial value to supply her with an adjustable automatic spring back constructed on hygienic principles. The introduction of the typewriter chairback has not come about through the agitation of theorists, but has been brought about through a recognition of the fact that the avoidance of fatigue is of financial value. The question is whether the health and well being of the growing children of the community is of as great consequence as the comfort of the typewriters, in whom, because of greater age, deformities are much less likely to arise.

In the past the great defect in the school seats has been the failure to recognize the fact that no attitude, no matter how good in itself, can be long maintained without fatigue. Change in position is necessary, and if a proper change is not possible, a scholar must for the sake of change alone assume an improper attitude. It is to allow a change of distance, to allow an upright and a reclining position, to allow for some changes in the anteroposterior curves of the spine, while at the same time always giving a firm lumbar support, that Professor Miller has devised his chair.

HORSE MORTALITY IN SOUTH AFRICA.—A peculiar and up to this time not understood disease has broken out among American horses sent to South Africa for service in the British Army. The native horses are not affected, but the affection, which appears to be of malarial character, has proved very fatal to imported animals. Veterinarians are making a careful study of the condition.

Clinical Department.

A CASE OF PAROVARIAN CYST WITH TWIST OF THE PEDICLE OCCURRING DURING THE FOURTH MONTH OF PREGNANCY; OPERATION; RECOVERY; NORMAL DELIVERY AT TERM.

BY F. B. LUND, M.D., BOSTON.

HOWEVER much opinions may differ as to the mechanics of twists of the ovarian pedicle, whether they are produced by the peristaltic action of the intestines which impinge on the tumor, by the alternate filling and emptying of the bladder and rectum, or by sudden movements of the body of the patient, there can be no question but that there is one prerequisite for the torsion of the pedicle, and that is that the tumor should have one. The longer and freer the pedicle, other things being equal, the more probable will be the occurrence of a twist. Another characteristic which will be favorable to the twisting of the pedicle of a tumor will be irregularity in its shape, which will favor both rotation under the influence of gravity, which may act unequally upon its different sides, and also that of the movements of neighboring viscera. Storer,¹ out of 248 cases of torsion, found dermoids 43 times, whereas if the normal proportion of dermoids to other ovarian tumors, which is about 5%, had been maintained, we should have only 12 instead of 43. In about 83% of reported cases the tumor was polycystic, solid or dermoid, making a decided preponderance of tumors of irregular shape.

We have, therefore, two reasons which would lead us to expect that torsion of the pedicle in parovarian cysts would be rare, (1) because parovarian cysts commonly have no pedicle, or at least a short and broad one, and (2) because they are regular in shape, being always monocystic, and generally spherical in outline. Arising as these cysts do from the remains of Gartner's duct in the mesosalpinx, they commonly develop between the folds of the broad ligament, are intraligamentous, and it is only in the exceptional cases that they expand toward the superior border and become distinctly pediculated. In a somewhat hasty search through the literature of the subject I was able to find only one article dealing with twist of the pedicle in parovarian cysts. Bouilly² has collected 3 cases from literature, and adds 2 of his own, 1 of which, as in the case reported in this paper, occurred during the fourth month of pregnancy. The case which I am able to add to these previously published occurred in the practice of Dr. E. S. Boland, of South Boston, by whom I was asked at 8 p. m., on July 13, 1899, to see the patient in consultation.

We found a woman of twenty-seven, who had been seized with severe pain in the right inguinal region of the abdomen, accompanied by vomiting, at about four o'clock that afternoon while engaged in cutting pastry, standing by the table and reaching over. She was of excellent general appearance, well developed and nourished, lying in bed and complaining of severe pain in the right inguinal region, recurring every ten or fifteen minutes. She was married and had had two children, both living, and the last born

ten months ago. Her menses had returned seven months ago, and had been regular until three months ago, when they ceased. She had had morning vomiting, vaginal discharge and increased frequency of micturition, and believed herself three months pregnant. Examination of the abdomen revealed a fluctuating tumor larger than a uterus pregnant at three months, extending upward to the umbilicus, occupying the hypogastric region, and extending rather more into the right than the left inguinal region. There was acute tenderness in the right inguinal region. On bimanual examination the cervix was found soft and patulous, and a mass of moderate size and extremely tender was made out in the right lateral cul-de-sac. The epigastric tumor could not, under the condition of muscular spasm present, be distinguished from the uterus. The temperature was 100° and pulse 90.

She was taken to the City Hospital and admitted to the service of Dr. M. F. Gavin, who kindly placed her in my charge. Her pains continued during the night and in the morning a small tender mass was distinctly felt in the right iliac region, suggesting a swollen appendix. Owing to the continuance and severity of the pain, and the presence of the mass, it was deemed wise to open the abdomen. The writer operated under ether at 9.30 A. M. Owing to the presence of the tender mass in the right iliac region the case was thought to be probably one of appendicitis occurring during a pregnancy, the pregnancy having existed longer than the three months alleged by the patient, in order to account for the large size of the supposedly uterine tumor. Ovarian cyst with twisted pedicle and extra-uterine pregnancy were also considered. A short incision was made through the outer part of the right rectus muscle and came down upon the twisted pedicle, which consisted of the broad ligament with veins enormously dilated, and even ruptured, as was shown by extensive subperitoneal ecchymoses. The cyst, with thin, translucent walls, dark from dilatation of the vessels over its surface, was seen behind and above the uterus, which was of the size and appearance of a three months' pregnancy. The rectus incision was sewn up in layers with continuous chromicized catgut sutures, and a longer incision made in the linea alba. The cyst was tapped and about a quart of thin, smoky fluid removed. The cyst was then drawn out, the pedicle, which was twisted on itself three times, untwisted and tied off in sections with silk, and the wound sutured in layers with chromicized catgut.

The patient made an uneventful recovery, was discharged from the hospital August 5, 1899, and in January, 1900, was delivered by Dr. Boland of a boy baby in excellent condition. There was at that time no separation of the transversalis fascia from stretching of the scars, or other evident weakness of the abdominal wall at the seat of the incisions.

The character of the fluid suggested a parovarian cyst, and the examination of the specimen by Dr. R. M. Pearce showed that the cyst belonged to this class. Dr. Pearce's report follows:

"*Gross examination.*—Specimen consists of a large membranous sac attached to mass of solid tissue. The sac has a capacity of 700 cubic centimetres, and is a cyst wall drained of its contents. The thickness of the wall is that of heavy parchment. It is easily separable into two layers and is traversed by many blood vessels. The outer surface is smooth and glis-

¹ A Study of Axis Rotation, with Especial Reference to the Torsion of Ovarian Tumors. Boston Medical and Surgical Journal, November 5, 1896.

² De la Torsion des Kystes Parovariens. La Gynécologie, Paris, 1898, iii, 481.

tening, of pink color, and shows no inflammatory adhesions. The inner wall is traversed by many slightly elevated bands of connective tissue, radiating in all directions. Old hemorrhages into the cyst wall are indicated by slightly raised patches of a deep red color and averaging 5 millimetres in diameter. The tuba uterina runs within the cyst wall. Its distal end is free; its proximal end sectioned near the uterus. The ovary is pendant from the cyst wall but is not incorporated in it. It is intensely congested and measures $2\frac{1}{2} \times 6\frac{1}{2}$ centimetres. Its surface is glistening, smooth, and of a dark reddish-brown color. The cut surface is moist, smooth and fairly firm. The area sectioned shows two follicles and one corpus luteum.

"Anatomical diagnosis.—Parovarian cyst."

The case is of interest from several points of view: First, what is the mechanism by which such a twist is produced? The traumatism which finally produced strangulation of the pedicle must have been one of the slight movements of the body connected with the by no means active exercise of cutting pastry. It is by no means an uncommon history in these cases that the strangulation is produced by slight and comparatively gentle movements of the body. It seems entirely improbable that so slight a movement as brought on the symptoms in this case could have produced the three distinct turns of the pedicle found at operation. A more probable hypothesis is that the tumor, lying in such relation to the pedicle that movements of the abdominal wall, intestines, etc., twist it in a given direction, becomes gradually turned several times on its pedicle and then finally some slight movement gives it the final additional twist which produces strangulation.

A second point of interest is the question of diagnosis, the swollen, turgid pedicle in this case simulating a swollen appendix. If accurate differentiation could have been made between the pregnant uterus and the cyst, the diagnosis would have been established beyond a doubt. As it was, the wisdom of opening the abdomen in the presence of acute abdominal symptoms, even in the absence of an exact diagnosis, is indicated. It is more important to save the patient than to wait for an exact diagnosis.

The fact that an operation on the female genitals during pregnancy did not result in miscarriage is one which is a matter of so frequent occurrence in modern surgery as hardly to excite comment.

Medical Progress.

REPORT ON PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

(Concluded from No. 8, p. 189.)

CONICAL STUMP AFTER AMPUTATION IN CHILDHOOD.

POWERS,⁴¹ in an article on this subject, tells of a young man of eighteen years who in August, 1899, showed him the result of an improperly made amputation of the arm. The amputation had been done for a crush of the arm some ten years before. The young man stated that directly after the amputation was made the stump was in excellent condition, and it

so remained for two or three years, but after that the bone began to press against the soft parts at the end of the stump, and, in time, to come through. The process had been gradual. He held the physician who had done the original amputation responsible for the result. The arm had been amputated near the junction of its upper third with the lower two-thirds. The stump was in a typically conical condition, the pointed end of the fragment of the humerus coming through the soft parts.

The author states that of course the proper management of this would rest on the removal of a suitable amount of bone. But these cases have an important aspect, which is this: After amputation through the upper part of the arm or the upper part of the leg in childhood, a slow development of a conical condition is physiological and is to be expected. This is quite independent of the nature of the stump after the original amputation. It is because the humerus and the leg bones are developed in large part from their upper epiphyses. The growth takes place at these epiphyses and simply pushes the bone through the soft parts.

Some years ago the author presented⁴² a number of these cases before the New York Academy of Medicine, and he states that unless the child's parents are warned by the surgeon at the time of the first amputation of what is likely to occur, they may blame him when the conical condition appears.

MODERN BULLET WOUNDS.

The descriptions which have prevailed hitherto in works on surgery of the lesions inflicted by bullets must be completely rewritten. The remarkable changes of recent years in the diameter and velocity of rifle bullets have been followed by changes equally remarkable in the wounds produced by them. A few weeks ago some very interesting experiments were described which had been performed to determine the comparative effects of modern bullets, and the results were of great value because the experiments were comparative. These experimental results had to be tried on the touchstone of actual experience, and a very interesting letter from Sir William MacCormac⁴³ shows that the practical results fall far short in severity of what might have been expected as a deduction from the experiments referred to. Sir William MacCormac is particularly well qualified to express an opinion on the severity of bullet wounds, for he had excellent opportunities of observing the lesions from bullets during the Franco-Prussian War, and he states that in most cases the damage done by the modern bullet, especially by the Mauser, cannot be compared in severity with that inflicted by the needle gun or the Chassepot. The slight severity of the injury has struck him with amazement. The projectile bores a small, clean hole right through the part and the aperture of exit can hardly, if at all, be distinguished from that of entrance. The wounds are on the whole aseptic and heal readily under a simple antiseptic dressing. So rapid is the healing in most cases that instances have already occurred of men who had recovered from one wound and been discharged being readmitted later for a second bullet wound. When only the soft parts of a limb are perforated and no important vessels have been torn,

⁴³ Annals of Surgery, April, 1900, p. 436.

the shock at the time of infliction of the injury is but slight and recovery is rapid and complete. Sir William MacCormac cites a case where a Mauser bullet traversed both thighs, passing in front of one femur and behind the other. There was very little hemorrhage and the man was able to run another 800 yards after receiving this injury. Even where a bone has been hit the bullet may make a clean hole through it without any splintering, or with very little. This is naturally more common in the case of flat bones, such as the scapula, than in the long bones. It has also occurred in the case of the bones of the skull. In many cases even when important structures have been in the line of the bullet no harm seems to have resulted. In one instance a bullet entered on the right side of the neck immediately behind the sternomastoid and an inch above the clavicle, and its point of exit was in a similar position on the other side. Some difficulty in swallowing and speaking followed, but this passed off almost completely in a very short time. In another case the shot passed through the left ilium just below the crest and emerged a little more than an inch below the ensiform cartilage. From the situation of the apertures of entrance and exit, and remembering that a Mauser bullet passes straight from one to the other, turning neither to the right hand nor to the left, one is justified in thinking that the bullet must have pierced the stomach, but no symptoms of any such injury appeared. The patient took his food from the beginning without any inconvenience and had a rapid and uneventful convalescence. In yet another instance, from the situation of the wounds and from the fact that a most obstinate constipation followed the injury, it is almost certain that the colon was perforated, yet no peritonitis arose. Not the least remarkable of the effects of the Mauser bullet is the very slight hemorrhage resulting from perforation of the lung. There is generally a little hemoptysis which soon ceases and convalescence ensues. Even when a comminuted fracture of a bone of a limb has been produced, complete consolidation of the broken bone may result, though the fracture was necessarily compound. A striking case of perforation of a joint shows that only a slight synovitis may follow. This is in marked contrast to the havoc produced by a large-bore bullet. These results must produce a feeling of hopefulness in the treatment of modern bullet wounds, for they show that in many cases a temporary interference with military service is all that is produced. To Sir William MacCormac the profession owes a deep debt of gratitude for his graphic pictures written from the seat of war. While helping his country he is at the same time making a solid contribution to scientific knowledge.

THE SURGICAL ASPECTS OF THE MODERN SMALL-BORE PROJECTILE.

Schachner⁴⁴ derives the following conclusions from his study of the subject:

(1) All advanced nations have practically the same character of rifle and projectile, and the remarks applying to one apply practically with equal force to all.

(2) The modern small-bore projectile is capable of producing wounds of both a humane and a gruesome nature.

(3) The nature of the wound produced by the small-bore projectile is either dependent upon the intervening distance or the character of the structure wounded, or both.

(4) The precise manner in which the explosive action is developed in structures filled with or rich in fluid is still *sub judice*.

(5) The weight of evidence and the majority of authors favor the hydrodynamic rather than the hydrostatic theory.

(6) The new projectile is propelled with greater energy, velocity and accuracy; it is lighter, has a smaller frontage, and is less liable to deformation on striking an object.

(7) The new projectile has less "disabling capacity," and on the whole produces wounds of a more humane character than the old leaden bullets.

(8) By explosive action is meant the damage created in structures outside of the projectile's path.

(9) The explosive action depends upon the deformation of the projectile, the range, and the character of the tissue.

(10) The shorter the range within the first 400 to 600 yards of the projectile's flight the more pronounced the explosive action.

(11) At 800 or 1,000 yards explosive action is occasionally met with, and then only in the skull or in parts of the body filled with and rich in moisture.

(12) At a distance of 800 or 1,200 yards the new projectile, as a rule, creates wounds with small orifices of entrance and exit, and little or no explosive action.

(13) The rotatory action of the projectile may continue after its penetrative movement ceases, and the character of the wound is partially dependent upon this rotation.

TREATMENT OF FRACTURE OF THE PATELLA BY SUTURING THE CAPSULE.

Vallas⁴⁵ draws attention to the fact that a good functional result is sometimes found when marked separation of the bony fragments persists after patella fracture, and that a bad functional result is sometimes observed when accurate bony union has been obtained. Experimentally, it can be shown that division of the patella alone does not admit of a separation of the fragments greater than a few millimetres even when the knee is fully flexed, but that division of the capsule on either side of the divided patella at once permits the occurrence of wide separation. Fractures of the patella without injury to the capsule should be treated like hemarthrosis — by compression, massage and early mobilization. The difficulty of recognizing absence of capsular injury is great. Slightness of the separation of the fragments is insufficient for diagnosis. In doubtful cases the author treats as for hemarthrosis, until, after the lapse of three or four days, swelling and pain have diminished and thorough examination is possible. Palpation may show capsular rupture. If the injury involves the patella alone, the patient, by the fourth day, ought to be able to voluntarily lift his leg above the plane of the bed. If he cannot do this, sufficient capsular injury is present to call for operation. Any case in which 2 centimetres of separation are demonstrated must be operated upon.

⁴⁴ *Annals of Surgery*, January, 1900; *American Journal of the Medical Sciences*, April, 1900, p. 466.

⁴⁵ *Rev. de Chir.*, October, 1899; *Annals of Surgery*, March, 1900, p. 383.

Operation. — Make a median vertical incision from 1 centimetre above the superior fragment to 1 centimetre below the inferior fragment. Make a transverse incision at right angles to the above and make it follow the line of fracture. This transverse incision must be long enough to expose to view the whole of the capsular rent. Carefully clean the joint cavity, removing all blood clots, etc. Clean and freshen (if necessary) the fractured surfaces of the patella, and pare away any shreds of periosteum which might get between the fragments when they are brought together.

The following layers of tissue are now in evidence: (1) Skin and subcutaneous tissue; (2) the deep fascia; (3) the anterior ligament of the knee or articular capsule, consisting of the patella in the middle line, with the peripatellar fibrous tissue on either side and lined by the synovialis; (4) the condyles of the femur.

Suture is begun at the ends of the wound remote from the patella. The author uses metallic sutures. A suture is passed through the whole thickness of the lower lip of the wound from the skin into the joint, then from within outward through the synovialis and fibrous capsule of the upper lip of the wound. The upper end of the suture is passed in the reversed direction, that is, first from without inward through the fibrous capsule and synovialis of the upper lip of the wound, and then from within outward through all the layers of the lower lip of the wound. The free ends of the sutures are twisted over a pad of gauze. A sufficient number of these sutures are introduced to close the wound. Suture of the patella itself is unnecessary. The external wound is closed with silk-worm gut. A slightly compressing dressing is applied without drainage, and the whole covered with a plaster-of-Paris bandage. The first dressing is made after about eight days, the stitches are removed, and a splint or plaster dressing is applied. One week later splints are removed. Massage is applied to the thigh muscles, and the patient encouraged to voluntarily contract the quadriceps without lifting his leg from the plane of the bed. About eighteen or twenty days after the operation, massage of the knee is practised and passive movements are begun. Active movement of the knee and convalescence soon follow.

FRACTURE OF THE NECK OF THE HUMERUS WITH DISLOCATION OF THE UPPER FRAGMENT, WITH A REPORT OF THREE CASES TREATED BY OPERATION.

Curtis⁴⁶ derives the following conclusions from his study of the subject:

(1) In fracture of the upper end of the humerus with displacement of the upper fragment from the glenoid cavity, when proper attempts at simple reduction under general anesthesia have failed, operative measures should be resorted to unless shock, other injuries, or extensive damage to the soft parts about the shoulder justify delay. A delay of from one to four weeks will not impair the result.

(2) Anterior displacements require an anterior incision; subglenoid or posterior displacements require a posterior incision, preferably by Kocher's method.

(3) The head should be restored to its place, if possible, and resection resorted to only when reduction is impossible or would require such extensive damage to

the parts, or such prolongation of the operation as to increase the dangers of wound infection or of shock.

(4) Resection will probably give a better result in fracture of the anatomical neck than in that of the surgical, but reduction is to be preferred in both cases.

(5) Asepsis is an indispensable requirement for a good functional result, and these operations must not be undertaken except under aseptic conditions.

(6) Motion should be begun in the joint as soon as the wound has healed, in ten to fourteen days after the operation.

A DIRECTOR FOR THE INTRODUCTION OF THE GIGLI SAW IN SKULL RESECTIONS.

H. Gross describes an instrument which he uses satisfactorily for this purpose.⁴⁷ It consists of an instrument 15 centimetres long and 4 to 5 millimetres wide. It is shaped like an ordinary "director." The point beyond the termination of the groove terminates in a bulbous end. At this end of the groove is a small hook (so small that it does not project out of the groove), over which one end of the saw can be hooked. The instrument is used as follows: The skull is trephined. The end of the director is curved up slightly, the eye at one end of the saw fixed over the hook, the instrument inserted through the trephine opening and pushed along between the skull and the dura till the second trephine hole is reached. The saw accompanies the director and lies in its groove. The curved-up end of the director emerges from the second trephine opening exposing the hook and the end of the saw. The saw is freed from the director and now lies under the portion of the skull to be divided, either end projecting from a trephine opening. The skull is now sawn through, the director serving to shield the brain and dura from injury from the saw, the saw cutting through the curve of the skull while the director lies along the chord of the arc. Dr. Gross claims that the bulb-pointed end will push its way between the sinuses and the skull without injuring the former.

THE TECHNIQUE OF CRANIOTOMY: A NEW CONDUCTOR FOR THE WIRE SAW.

Podrez,⁴⁸ realizing the advantages of craniotomy when performed by the osteocutaneous flap method, with the use of the wire saw, has devised an instrument for passing it rapidly from one opening in the skull to another, and afterward protecting the brain and its membranes from injury while the bone is being divided. The instrument is made from a watch spring, 3 to 4 millimetres broad and 13 to 15 millimetres long. At one end is a ring or handle, at the other a rounded tip perforated with an eye, to receive the silk ligature that is connected to the saw and is double the length of the conductor. The ligature is attached to the saw, then threaded to the middle in the eye of the conductor. Two openings are made at the ends of the line of incision, in a slanting direction, in which the saw is to be passed. The director is then passed, armed with its thread, and is made to emerge at the second opening. The thread is removed from the eye and the saw drawn through. The guide, on account of the recoil of the spring, presses the membranes of the brain and the brain itself inward and prevents injury by the saw. Three sides of the square to be removed are cut in this

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting, Monday, April 2, 1900, Dr. E. H. BRADFORD in the chair.

The subject for consideration was

THE PROPER SEATING OF SCHOOL CHILDREN.

DR. JAMES S. STONE read a paper upon

THE INJURIOUS EFFECTS OF IMPROPERLY CONSTRUCTED SCHOOL CHAIRS.¹

PROF. EDW. F. MILLER, of the Massachusetts Institute of Technology, demonstrated

A CHAIR DEvised TO MEET THE ANATOMICAL REQUIREMENTS.

The chair, a model of which was shown, was presented in its earlier form two years ago at the Harvard Medical School. The main feature of the chair then was the two movable links supporting the seat. The idea was to obtain by the chair alone what is accomplished by a movable top on a desk giving the plus and minus distance, and also to change the angle of the seat so as to get greater comfort while reading. The chair has a motion forward and back of two and a half to three inches. At the same time it was felt that the chair as it tipped back should not elevate in front, because if it did it would stop the circulation in the legs. For that reason the front link is made longer and the elevation of the front of the chair when carried from the forward position to the back is but trifling, not over three-fourths of an inch. In writing the person naturally leans forward and the centre of gravity is carried forward. That holds the back link nearly vertical, and the front link is swung over some little distance. As soon as the person gets through writing and leans back, the centre of gravity travels back, the chair moving away from the desk, the long link becomes vertical and the short link swings back, dropping the rear of the chair and giving the same effect as in a rocking chair, avoiding pinching the blood vessels on the under side of the leg. In the earlier chair there was a fixed back. Since then some modifications have been made and the first one was in substituting a movable back. The

back is made so as to swivel about a horizontal axis, the longer arm being at the top. The height of the back support is adjustable and can be regulated by means of slot and screw in the back to suit any height. A second adjustment was put on by making the back have forward and back motion, so that if a person was writing and felt the need of more pressure on the spine by reaching down and turning the screw the back of the chair could be moved forward as desired. There is a motion of five inches allowed by means of the screw. The chair is adjustable in height the same as all of the modern school chairs, and it has been endeavored to make the machine-work as simple as possible, so that it could be put together by cheap labor. All of the mechanism at the bottom is on one casting, held to the chair by four screws, and the machine work is drilling and putting in pins which can be done at small cost. The castings are cored out to make them light, and the surfaces rounded to prevent catching dust. There are rubber stops to prevent noise as much as possible. This is only the second attempt, and I still see some features in the chair which could be improved. The base is thicker than it need be, and there are some slight modifications I would make in the back to give it further adjustment, so that the chair can be used as a sort of reclining chair if desired for office work.

MR. BUTLER: I came this evening to see Mr. Miller's chair, and in relation to ours to give you what little information I can in regard to it. I think the chair is so well known in the city it is hardly necessary to say anything in regard to it. I was one of the first to see Professor Miller's chair in its crude state and have taken a great interest in it, and I think that chair combined with this desk top would make the best article of furniture I ever saw, speaking from the manufacturer's standpoint. This top, while it is very necessary to have that movement of plus and minus which has been shown so necessary by Dr. Hartwell, Dr. Scudder and yourself, in a great many different instances, the plus and minus motion should be momentary, and something which could be adjusted at a moment's notice — the desk top as well as the chair, because in writing, especially with the vertical system, you should regulate the slant of the top of the desk as well as the plus and minus distance from the desk. This top is adjustable to any slant from 1° to 20°; by loosening these screws you can determine the plus and minus motion by bringing it to you this way, so you sit erect all the time; you determine the slant by bringing it that way. If it comes to a question of purchasing this desk, from the manufacturer's standpoint the only question of its universal adoption in my opinion would be the cost. There is a difference in the cost of this desk and an ordinary desk of this style of 35 cents. It would almost seem that any committee would pay that difference and have this desk, but I think in the city of Boston there are none in use. I believe in the city of Syracuse there are 1,300 or 1,400. It was endorsed by the College of Physicians and Surgeons of the State of New York, 250 strong, at Syracuse. This chair was also endorsed as the best back at that time. Professor Miller's would undoubtedly be endorsed today in preference to this. I think that that chair of Professor Miller's could be made for a very little difference in cost between that and ours. We get over the plus and minus with this

¹ See page 206 of the Journal.

model. The cost of this chair is \$1.75. Professor Miller's chair could be made for \$2.25. The question would come up as to the room in the school room. Professor Miller's would necessitate the desks being placed a little farther apart. Otherwise than that I think that is the best chair, Professor Miller, I ever saw.

DR. STANDISH: I have not a great deal to say. I am not much of an expert on school desks and chairs, but the average ophthalmologist fails to see why it is necessary to have all sorts of adjustable things in order to prevent the chair from coming underneath the desk. The schoolmaster has reasons, I suppose, but from the position of the ophthalmologist they are not obvious. A child studying, a young child especially, instinctively will put its eyes too close to what it is trying to learn. If he does not know what a letter is or what a word is he thinks somehow he is going to find out better by putting his head closer to it. If a scheme can be devised whereby children shall not do that thing that is a step in advance. Now, if we pull the chair way back and push the desk way over in the old-fashioned way, it enables the schoolmaster to stand his children up between the desk and the chair in rows, but it also fixes it so that the child usually stoops forward and gets down to his book. Now the scheme which you have here to-night, the minus distance, simply is this, that if you bring the table near enough to the child's chest he cannot stoop over it and be comfortable. That is desirable, and the great advantage of the vertical handwriting comes from practically the same thing, that the child does not want to stoop over. Every line going straight away from the child, he naturally keeps the erect position and can sit at a desk projecting over a seat and write without fatigue. But somehow the schoolmaster never took to that. He must have means of getting his children in and out from the desk. Well-to-do parents often fetch a child to the ophthalmologist at the age of three or four, simply because the child puts his head near his book or other small object. The examination of the eye shows no myopia. The child returns for another examination at seven, eight, ten or twelve years of age, and it is found that the child actually has acquired nearsightedness. There is a distinct period at seven or eight years of age, and another distinct period not sufficiently recognized about puberty when nearsightedness is acquired, was not there before, and is acquired principally by the faulty use of the eyes. Anything that we can have in the way of desks, or in the way of hammering it into the teachers' heads that a child should be made to sit up straight and put the book in the right place, is a desirable thing to do. The one thing from the oculist's point of view is this, that the desk should overlap the seat sufficiently so that it will be uncomfortable to the child if he tries to sprawl over it.

DR. BLAKE: I have not very much to say on this subject, which is not a new one in Boston. Twenty-five years ago we began agitating the subject of school hygiene, which included this among others. We tried to surround the children with healthy conditions, endeavoring to protect them not only from diseases which might be contracted while in the school, but also from the danger of developing spinal deformities. We succeeded after a very long time in getting a sort of modified medical inspection of schools which was

confined largely to precautions against the introduction of contagious diseases. We considered the question of proper school furniture, but were unable to accomplish anything.

Unquestionably, there are in the schools many hundred children who need this sort of chair, which seems admirably adapted for the purpose. I think if teachers were instructed to give special attention to children who showed an inclination to fall forward or lean sideways, it would be an excellent thing. To ask that such children be supplied with this chair would be both reasonable and proper. As a result, probably, would come its gradual introduction, so that all children would be protected. Many do not need it, but it is perfectly evident to me from my familiarity with the subject that a great many do, and that it would be a very great benefit to them if their wants could be supplied. The request would be a moderate one, would not call for any great expenditure of money and the results would show themselves very quickly.

MR. SEAVER: This subject certainly has received a good deal of attention from the school authorities in Boston during the last eight or ten years. Dr. Hartwell himself did a good deal towards securing more reasonable action in the matter of furnishing school rooms with proper desks. It is a fact that some of the older buildings did at one time contain rooms with only one size of desk. The old scale, which was a scale of ages, was supposed to be sufficient in a rough practical way for the purpose; but it was found by the more observant teachers that the edge of the chair was too high from the floor, so that the foot did not rest squarely upon the floor. A very simple remedy was devised by providing small pieces of pine plank two inches thick and placing them on the floor in front of the chair to be used by the children whose legs might be too short to reach the floor. In another way adjustment was made by providing three or four different sizes of desk in the same room. That change, I think, was quite extensively carried out in the newer buildings fifteen or sixteen years ago. Since the introduction of adjustable furniture it has been possible to fit most of the children with chairs admirably well. It is not necessary to furnish the whole room with adjustable furniture. You can put in a row on one side and a row in front or back of adjustable furniture; the rest can be standard furniture of different sizes; then with a little care the children can be well fitted to the school chairs and desks. We have not been able to come down to the fine points of adjustment in each and every case, and I dare say Dr. Hartwell, if he were to go into the schools today, would be able to find some children not well seated; but I also believe he would fail to find anything like the number that he did when he first began his observations; so that in a practical way I hope that we are making some progress towards the better seating of children or a better adaptation of school furniture to the children. There is one old-fashioned practice which ought to be thoroughly broken up. The old practice I refer to is "seating by rank." At the end of the month, after the examinations, the children were placed on a rank list and the one at the top was allowed to choose his place of sitting. That would be the first seat, first row, regardless of the size of the children. The practice is not yet completely broken up. This whole subject of the hygiene of school life is, it seems to me,

a most important one, and one which medical men will do well to study a good deal more than they have heretofore. The production of nearsightedness, lateral curvature of the spine, round shoulders and all those ills which arise from the fact that the growing human animal is kept five hours in a day in unnatural confinement — all these things need the most thorough and scientific study, and for one I am glad to see that they are beginning to receive it.

DR. CALDERWOOD: Mr. Seaver has spoken of the manner of seating the children at the present time. Of course with the stationary furniture and the two rows of adjustable chairs they can be seated better than perhaps ten years ago, but yet, with the present adjustable furniture, there is the difficulty in having the chairs so near the desk that the children cannot get out quickly. That is the objection which the masters have, while this chair or a chair similar to this would prevent that, as it can be moved back from the seat. I think this is a very great subject, a very important one to one who has been in the schools and seen the pupils as they have been seated in years past. Dr. Hartwell spoke of one room where there were only two children who could put their feet on the floor. Of course that is an exception, but it shows what has been and what is now taking place to a certain extent. This is a subject that really cannot be controlled fully by the School Board. I think the physicians of the city should take it up. The influence that might go out in that way would have a great deal to do with carrying it out in the schools, and I am not sure, Mr. President, but that it is a matter for the legislature to provide in some manner inspection of the children in the schools and have proper seating in that way.

DR. DURGIN: I think this question has been well discussed for years and to my satisfaction, and it seems to me the time has arrived when Boston should be ready to put in adjustable furniture for our school children. I think further discussion might be expected down in Cuba, but I am surprised to learn that the Cubans have adopted a good thing while Boston is still discussing it. It seems to me that the discussion might go on in the medical society indefinitely, but until the business men of the School Board are convinced that the time has arrived for making this change we shall not get ahead much. I think it is a question of dollars and cents and votes in the School Board. I have felt an interest in this subject and had something to do years ago in bringing about an expert board upon this subject, and I felt disposed then, as I do tonight, to take their word as to the best furniture for this purpose. I hope that something will be recommended and adopted and done as soon as possible. I have been much interested in Dr. Blake's remark, reinforced by Mr. Seaver's, in regard to having a portion of the pupils thus seated at once in the improved chair. I would like to be the person to pick out the number who should have the adjustable chair and desk. It might be well, however, to begin that way and by contrast it would be seen by the School Committee that the change was desirable, and the amount of such adjustable furniture might be rapidly increased.

MR. BUTLER: I would like to give a few statistics which I think will be of interest. I listened to Superintendent Seaver's statement as to how many chairs were needed in a room, and the question came to my mind as to how he would pick out those pupils and

designate which should have adjustable furniture and which not. I want to say for the benefit of the ladies and gentlemen present that there is not a city that I know of in this State outside of Boston but what buys adjustable furniture only and at the same price as for stationary. The cry of a few adjustable desks in the room is put out by manufacturers who have a poor adjustable desk. In the past they have sold stationary furniture and nothing else. This city has taken a front rank in everything. I think we owe the encouragement we have and the business we have done to the city of Boston. I would like to pay a tribute here and now to Dr. Hartwell, Dr. Scudder and these other gentlemen here who were instrumental in giving support when we started in the line of adjustable furniture. There is not a manufacturer in America but what is making adjustable furniture, and when we started it was considered a fad. You can buy adjustable furniture just as cheap as stationary. There is no reason why all castings should not be adjustable. The only idea in making it stationary is to lock the bolt. If the time comes that you want to adjust it to fit the pupil the bolt must be loosened. I have heard principal after principal in the city of Boston say: "We would like to have adjustable furniture if we could get it." Why can't you get it? It is to be bought at the same cost. We have sold in the city of Boston thousands of sets of adjustable furniture. A great many schools we have fitted out entirely with it. In the last few there have been a few rows of adjustable furniture. When Dr. Hartwell was on the board we put in all adjustable furniture.

MR. SEAVER: Has it always been true that adjustable furniture was furnished in the market for just as little money as paid for the stationary furniture?

MR. BUTLER: No, sir; but it has been within the last four or five years.

MR. SEAVER: That is not in accordance with my own information. Bids come in from the dealers with very substantial difference. I think the reason for using partly adjustable and partly stationary furniture is that there has been a substantial difference in the cost.

MR. BUTLER: You have had bids from me a great many times the same price as stationary.

DR. C. M. GREEN: It seems to me, as Dr. Durgin has said, that the members of the School Board are the ones to be convinced; for a long time the medical profession has appreciated the importance of properly seating the pupils in the public schools. I well remember the effort that was made in 1892 to introduce adjustable desks and chairs. It was then that Dr. Bradford, Dr. Hartwell and Dr. Scudder endeavored to interest the School Committee in the proper seating of pupils, and at this time Dr. Scudder's paper was printed as a public school document. I was then a member of the School Board, and I visited a good many of the schools, with the object of investigating the seating of the pupils. I was shocked at the number of "misfits," particularly in the older school buildings. I remember very well the conditions found in the Brimmer School, in which little boys were found in big boys' seats, and *vice versa*. One boy in a front row, I remember, was so large that he could not flex his legs under his desk, but was obliged to sit with his legs extended. The conditions were as bad in other schools, in which pupils were seated according

to rank. At that time I tried to interest the committee in this subject, and succeeded in having adjustable furniture placed in the new Prince Primary School. I left the School Board soon afterwards, and I never knew how well the adjustable furniture, then introduced for the first time, suited the requirements. But it seemed to me at the time that very little interest was taken in the matter. At that time adjustable furniture cost more than the old standard desks and chairs; but now that we are informed that the cost of approved adjustable furniture is no more than the old furniture, I see no reason why all the school buildings should not be adequately furnished with it. Perhaps if this society would bring the matter once again to the attention of the School Committee, the members of the board might be convinced of the wisdom of heeding the advice of those competent to decide how properly to seat the public school pupils.

DR. BLAKE: From what I know of the revenues of the School Board, we should have to resort to the process of gradual emancipation from undesirable school furniture. If we could prevail upon the board to fit out every new building with this improved form of furniture, and to provide a certain number of these desks and seats for all the schools, and if then Dr. Durgin's corps of school inspectors would select the pupils who need them (which I am glad to hear him say is feasible), I think we should be making a very substantial gain. I know it would be utterly useless to expect that the School Board would undertake to get rid of all the present furniture, but I have no doubt that this discussion will interest them, and perhaps help to arouse them to the necessity of doing something more than is at present being done about the subject.

DR. GEORGE B. SHATTUCK: I had a certain general knowledge of what had been done in regard to this matter eight or ten years ago, and I was interested in coming here tonight to see and to learn what there was new that would be shown and said. Now it does not seem to me that there is very much new from the point of view of the profession. I think that what we have been told tonight is very much what was told us about the year 1892, published in the school documents, and pretty well developed from the scientific and the professional point of view at that time. The one thing in which, as far as I can judge, we have something actually new is the development of Professor Miller's chair. Now I have no doubt that there is great merit in iteration and reiteration and emphasizing things, and especially things of this sort, and I have no doubt that the profession might be called upon to iterate and reiterate and emphasize, and have another committee and report again on this subject, but I should distinctly feel that I should sympathize with what Dr. Green said, that after all the touchstone of the whole thing must be in the School Committee. The medical profession may point out what they believe to be scientifically and practically the best thing, but that is not equivalent to its adoption. I confess that I am a little puzzled when we are told here that the adjustable furniture and the stationary furniture are of the same cost, and are not of the same cost. I should think that is a subject in regard to which it would be possible to have one categorical uniform statement, and, even if there should be a difference in the cost, from the point of view of the pro-

feSSION, it seems strange that Somerville and Malden and Lowell and Cuba should be able to care for their school children in a way that Boston is not able to. Now, moreover, if there is a difficulty about having school teachers who are sufficiently intelligent to adjust adjustable furniture, it seems to me strange that Somerville and Malden and Lowell and Cuba should apparently have school teachers who in this respect are so much more intelligent, at least from the mechanical point of view, than the school teachers in Boston.

DR. KELLER: I don't know that I can add anything to what has been already said, except perhaps to say that while some think that the matter rests with the School Committee, I think it rests with the condition of the treasury. I have always, as Dr. Calderwood will remember, favored the introduction of the adjustable desk and chair, always voted in that way when it was brought to a vote of the board, and I think if the committee whose duty it is to furnish the new buildings were to bring the matter before the full board it would be carried by a large majority. It seems to me that it would be a large expenditure of money which the city could not well afford at this time—perhaps it might at some future time—to take out of the buildings the stationary desks and chairs and introduce the adjustable desks and chairs into all the buildings. I think the committee are in earnest about desiring the very best furnishings for our schools, the most modern and most healthful furnishings in our school buildings, and while we are looked upon as slow and uninterested and unconcerned in regard to the health of the children, I am sure that it is an accusation which should not receive the sympathy and support of at least the educated class of people. I think the idea of furnishing new buildings with the most approved desks and chairs should receive the consideration of our School Board. I must say that as I have gone into the schools in the last two or three years, the seating of the children has been better than it was ten or eleven years ago, when I first came on to the board. There have been faults to be found with the desks and chairs which were put in conscientiously, believing they were an improvement upon the old plan, and I think they were; they still do not conform to the idea of an hygienic seating of children, and from the little I have seen of the chair which has been presented, it seems to me it has all the indications which the others have lacked, and I like it very much, except I have wondered whether that chair would not take up more room than a chair such as that at the desk before me. It seems to me that from the fore part of the seat to the bend of the support it occupied more space, and in our school buildings, where we are expected to seat I am ashamed to tell you how many, it would take up room, making it impossible to put as many seats in a building, but that might be a good thing. I hope something will be done which will bring about the reseating of our children.

DR. SHATTUCK: I don't wish to advocate any injudicious or faulty propositions in the way of expense as a taxpayer. I have no desire to suffer unnecessarily, but I would as lief suffer as a taxpayer in behalf of the little children as in behalf of any other proposition, and I think it would be as good an investment as a taxpayer could make, because it not only serves them, but serves the future generations. One is glad to learn that the School Committee would now

be eager to introduce the most approved furniture into all *new* buildings, and of course in a moderate length of time that would create a revolution, and we should doubtless be in a very satisfactory position, but one cannot help reflecting that if the discussion of this subject which occurred seven or eight years ago had been followed by the same eagerness, and this process had been going on all these years, we should today be in a good deal the condition it is promised we may hope to be in several years hence.

MR. SEAVER: In the last seven or eight years very large quantities of adjustable furniture have been put into school buildings in Boston, and there is a gentleman sitting over there who could probably guess better than I could how much adjustable furniture he has sold to the city of Boston. I think, as a rule, every new school building for the last seven or eight years has received a share of the adjustable furniture. A considerable number of the buildings are furnished with adjustable furniture throughout. There are others where adjustable furniture and stationary furniture both have been used for the reason that at the time there was an important difference in the cost. But suppose every new building built in the last ten years were furnished with adjustable furniture — that is not half of the solution of the problem; it is only one-fourth. The new buildings contain but a small fraction of the total number of the children of the city. The serious part of the problem is how to change the furniture of the old buildings without expending more money than the taxpayers — not as liberal as the one who has spoken tonight — would countenance the committee in expending, in throwing out some 50,000 old seats. We are not exactly in the condition of Cuba. We have a lot of old furniture in pretty good order which has been used, and which the economical taxpayer thinks we ought to use a little longer. I am in favor of adjustable furniture, and have done all I could to have adjustable furniture used.

PROFESSOR MILLER: The point has been raised about the room which this chair takes up. This particular chair was made for an adult. I imagine in the ordinary school chair this seat could be shortened several inches. It will no doubt take up more room than the chairs now in use.

DR. FITZGERALD: There are two things I should like to say: First, as to the matter of fact regarding the comparative cost between adjustable and non-adjustable furniture. I had occasion to ask that question of the purchasing agent of the city within a month, and his reply was that there was a difference in favor of non-adjustable furniture of 35 to 50 cents. If that is true that they are for sale at the same price, it would be well to let the purchasing agent of the city know that fact. He does not know it now. I regret having been called upon, because my investigation by the direction of the Committee on Hygiene and Physical Training has shown me, I am sorry to say, that the seating of children in rooms fitted with adjustable furniture is not as well carried out as it is in rooms fitted with three different sizes of seats. As a believer in adjustable furniture that is not a pleasant thing to say, but it is true. There were more children seated uncomfortably in rooms furnished with adjustable furniture than in rooms fitted with three sizes of seats, and it is largely owing to the difficulty of the present form of adjusta-

ble seat. I am informed that a rule was passed at a meeting of the Boston School Board last year, and as a matter of fact all the new buildings fitted up last year were fitted with adjustable furniture.²

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

(Continued from No. 8, p. 193.)

SECOND GENERAL MEETING.

The second general meeting of the congress took place on Monday, August 6th, in the large amphitheatre of the Sorbonne, which was fairly well filled when PROFESSOR LANNELONGUE took the chair at 2.15 p. m.

The general secretary, M. CHAUFFARD, first read a long list of honorary presidents of the sections. Among the Englishmen so honored were Lord Lister, Sir William MacCormac, Bart., K.C.V.O., Jonathan Hutchinson, Sir John Burdon Sanderson, David Ferrier, Professor Sherrington, Alexander Bruce. Among the other nationalities were Virchow, Waldeyer, von Bergmann, Hitzig, Koch, von Leyden, Politzer, Fraenkel, Metschnikoff, Bacelli, Retzius, Kitasato, etc.

PROFESSOR PAVLOV, whose address was postponed at the first general meeting in the Salle des Fêtes on the opening day of the congress, was absent through illness, so PROFESSOR LIKHATCHEFF read his paper, entitled

EXPERIMENTAL THERAPY AS A NEW AND EXTREMELY FRUITFUL METHOD OF PHYSIOLOGICAL RESEARCH.

In support of his subject the Russian professor described minutely his numerous experiments on section of the pneumogastric nerve, and its consequence, more especially in dogs. The intimate association of medicine with physiology has served more than once a useful purpose. The physician who treats a case of myxedema, for instance, with preparations of thyroid gland acts exactly analogously to the physiologist who makes an injection of thyroid extract in an animal deprived of this organ, in order, by synthetical means, to make clear the mechanical, chemical and nervous functions of those glands. The professor then spoke of his experiments with Professor Mosseu on dogs, in which all the blood of the portal vein was poured into the inferior vena cava. This operation, which is usually fatal, was not so in some of the animals, thanks to a special dietary. The professor touched on the brilliant and important experimental therapy which forms part of contemporary bacteriology. In conclusion, he paid a tribute to Claude Bernard, who in his vast and profound brain united in a harmonious whole physiology, pathology and experimental therapy.

PATHOLOGICAL PROBLEMS OF THE DAY.

PROFESSOR BACELLI (Rome) should have been the next speaker, but owing to the national mourning of Italy, he withdrew.

PROFESSOR LANNELONGUE in the name of the congress expressed his profound sympathy to the Italian professor, and then called on SIR JOHN BURDON SANDERSON, who spoke in French, on

² Since this meeting satisfactory action has been taken by the School Board. See Editorials, June 21 and June 28, 1900.

SOME OF THE PATHOLOGICAL PROBLEMS OF THE
PRESENT DAY,

and as he warmed to his subject was received with many rounds of applause. The professor stated that forty-five years ago, after taking his degree of Doctor in Medicine, he came to Paris to complete his medical education; and now, nearly at the end of his medical and scientific career, he felt it a great honor to speak before the congress. Sir John then called the attention of his audience to the above period. At that time in Paris, without speaking of the great clinicians, Claude Bernard was in the most active period of his career, Brown-Séquard had demonstrated the functions of the vasomotor nerves, and had begun his work on the physiology of the spinal cord. Everybody came to Paris to see the latest progress in experimental medicine. This was also the epoch of "cellular pathology." He then sketched the progress in cellular pathology from 1858, when Virchow published his work, through the work of Cohnheim, Recklinghausen, Leber, and Pfeffer, down to the beginning of the bacteriological period in 1878. But microbiology has not hindered the advance of pathological histology. On the contrary, never has the progress of histology been so rapid, in support of which statement he cited the work of Golgi, of Pavia, and of Ramón y Cajal in Madrid. Every one recognizes the great value of bacteriological diagnosis and of sero-therapeutics, but microbiology has rather produced its greatest influence on the science of medicine by the new and more extended ideas it has given us of the physiological functions of the cell, and consequently of cellular pathology. Pathology is today fundamentally as emphatically "cellular pathology" as it was when Virchow adopted the expression. Leucocytes, which were formerly interesting chiefly as factors in the process of inflammation or as typical examples of contractile and ameboid protoplasm, are now known to possess special chemical functions indispensable to the life of the organism. From the work of recent years one is led to believe that the actions of the cell on its surroundings, and vice versa, are due to ferments, the products of the evolution of the living cell. The professor alluded to the work of Miescher and Drechsel, and the more recent work of Kossel, of Marburg, on this subject.

MEDICINE AND DOCTORS IN THE UNITED STATES.

PROFESSOR JACOBI (Columbia University), before a very scanty audience, then read this paper. In a very interesting manner the professor traced the growth of the medical profession, education and press in the United States from its earliest beginnings in chaos down to the present day. This terminated the proceedings, when everybody went away to dine and prepare for the *fête* in the evening in the Luxembourg Palace described in the *JOURNAL* of August 23d.

MASSAGE AND MOVEMENT IN THE TREATMENT OF
FRACTURES.

On Monday morning, August 6th, at the Hôtel Dieu, before a crowded amphitheatre, M. LUCAS CHAMPIONNIÈRE gave a lecture and demonstration on the varieties of fractures in which the right treatment is massage and mobilization, with suppression of fixed apparatus. In expounding the principles and theory of the new method, the surgeon laid emphasis on the

fact that a methodical moderate movement is favorable to the setting of fractures; it is favorable to the formation of a firm callus. Surgeons of every age have condemned the fractured limb to immobility for the following reasons: It permits the primitive form of the limb to be restored; it ensures the reunion of the bones; it prevents or cures the inflammation of the region; and it is therefore the indispensable condition for the restoration of the functions of the limb. M. Lucas Championnière has introduced the following new and contradictory principles in the treatment of fractures: Movement is as necessary for the repair of all living parts as for their regular vitality, and this fact should be stated as soon as possible after the traumatism. The good influence of movement is incontestable for all soft parts, but it is not the less evident for solid structures also, in spite of their being solid bony levers. Not only do the muscles and soft parts more quickly and more completely regain their vigor with movement, but the bony callus also is formed more quickly, it is more solid and resistant, the reunion takes place more quickly and more firmly. The movement necessary for this bony reunion must be methodical, and, so to speak, "dosed" in a certain measure. An excessive range of movements has drawbacks. This "dose" of useful movement can be obtained by massage immediately after the traumatism. This is the best method of anesthetizing the limb, of removing the pain. Immobility only suppresses the pain for it to reappear each time that movement occurs, and by stiffening the limb to prepare the way for a new kind of pain. Whenever massage is painful, you can be certain that it has not been performed according to the rules laid down by the professor. This new method does away with muscular contraction, which is the cause of a considerable extent of the deformity and against which fixed apparatus is often powerless. It follows, therefore, that massage avoids deformity, which is especially noticeable in the clavicle, at the elbow, at the olecranon process. The disappearance of ecchymoses and inflammatory products takes place, and more rapidly in a massaged limb. The vitality of the skin is preserved, but more especially is the vitality of the limb restored. Muscular atrophies are reduced to a minimum, and have often disappeared from the time of the first attempts at normal function. The fractures which can always be treated by massage and movement are: Fractures of the humerus in its upper portion as far as the deltoid insertion; fractures of the lower end of the humerus up to a hand's width above the elbow; fractures of the elbow and especially fractures of the olecranon (M. Lucas Championnière has never sutured an olecranon); fractures of the radius at the wrist in the great majority of cases, fractures of the clavicle ditto; fracture of the fibula, except in cases where deviation of the axis of the foot threatens. The same holds in perimalleolar fractures without deviation. These cases are among the most satisfactory, and in which, on the other hand, rigidity is most to be feared. At the knee fractures of the femur without tilting of the fragment, and fractures of the head of the tibia (*plateau du tibia*) give marvellous results. In all the above cases this treatment is the regular and common practice, the apparatus being reduced to a minimum, and is replaced by the least support after the first few days. To give an idea of the generalization of this treatment, the professor terminated in giving the sta-

tistics of cases treated during the last five years at the Beaujon Hospital and at the Hôtel Dieu.

OPERATION FOR HERNIA.

On Tuesday morning, August 7th, M. LUCAS CHAMPIONNIÈRE gave a demonstration on his method of treating hernia, and operated before the numerous members of the congress who were present.

VISIT OF ENGLISH SURGEONS TO A SURGICAL CLINIC.

Several English surgeons having expressed a wish to see a French surgical clinic, a very successful visit was arranged through the energy of the secretaries of the British committee, Mr. D'Arcy Power and Dr. Garrod. Under the guidance of Dr. Mercier, from Montreal, who acted as interpreter, about twenty-five English surgeons met on Tuesday, August 7th, at 9.30 A. M., at the gates of the Laennec Hospital. M. Faure, surgeon to the hospital, performed two operations for the benefit of the visiting surgeons.

SECTION OF INTERNAL MEDICINE.

The first question on the programme of this section was the

PATHOGENY OF GOUT.

The discussion was introduced by DR. LE GENDRE, physician to the Tenon Hospital, Paris: SIR DYCE DUCKWORTH, and PROF. WILHELM EBSTEIN, of Göttingen. The following are abstracts of their reports:

DR. P. LE GENDRE said that since the uratic nature of tophi and uricemia in gouty subjects had been determined the efforts of theorists had almost always had as their object an explanation of the pathogeny of gout by accumulation of uric acid in the economy and the precipitation of urate of soda in the tissues. The author replied by the principal theories, namely, the introduction in excess of uric acid by the food or of nitrogenous substances generating uric acid; the formation in excess of uric acid by destruction of the nucleins or nucleo-albumins proceeding from the leucocytes or from the nuclei of all the cells in the body; the accumulation of uric acid by insufficiency of transformation into urea whether through torpidity of the liver or default of a ferment permitting it to fulfil its uropoietic function, or by inadequate oxidization throughout the organism; the retention of uric acid in the blood by insufficiency of the eliminatory function of the kidney; the resorption of uric acid in the kidney, which, being supposed normally to have the function of effecting by certain of its cells the formation of uric acid by combination of the urea and glyocol proceeding from the liver, would become incapable of eliminating the acid formed. This being reabsorbed would in the blood become quadriurate of soda, which being present in superabundance precipitates itself under certain influences in the tissues in the state of biurate of soda. Some hold that the presence of urate of soda in the articular tissues sets up therein only a paroxysmic inflammatory reaction as a foreign body. Others maintain that the uric acid acts as a chemical poison causing necrosis, and that the preliminary mortification of the tissues is necessary to the formation of the crystallized uratic deposits. Some explain the gouty localizations by the smaller vascularization or the

less resistance of predisposed tissues and the onset of attacks by the hindrance of the renal functions. Others attribute the localizations, paroxysms and metastases to a nervous influence. It has also been believed that uric acid was hurtful only after having undergone certain physical or chemical modifications, and that a pathogenic rôle should be attributed equally to substances other than uric acid, such as alloxuric bodies. Each of these theories is open to valid objections, chemical, physiological or pathological; the most plausible, moreover, can explain only the mechanism of the gouty paroxysm, not the permanent and hereditarily transmissible disturbance of cellular transmission, which is the necessary link between the intermittent morbid phenomena in the individual as between the disease of the father and that of the son. Clinical statistics, however, have placed it beyond question that gout is observed with a special frequency in individuals whose ancestors or descendants suffer from diseases of the so-called arthritic group or from trophic inadequacy. First, diabetes and obesity and then gout are often associated with some of these diseases in the same person. The numerical relations established between diseases of the arthritic group warrant us in attributing to each of them the pathogenic process which has been shown to be true as regards one of them by Bouehard, after whose investigations it is no longer permissible to doubt that diabetes consists in a diminution of the aptitude of the tissues to burn up sugar, to carry to the extreme the transformations of carbohydrates. If clinically gout is of the same nature as diabetes, there is a great probability that there exists in the gouty subject a defective elaboration of nitrogenous material, an inaptitude of the tissues to destroy albumin thoroughly. Among the consequences of the incomplete destruction of refuse must be included the incumbrance of the organism both by certain acids (oxalic, acetic, lactic, etc.), which can diminish the conditions of solubility of uric acid without that substance being necessarily in excess in the blood, and by certain organic bodies the toxicity of which may contribute to the production of the manifold accidents of gout. Clinical statistics further place in evidence the morbid affinities of gout with simple albuminuria and interstitial nephritis as the frequency and intensity of the disturbances in gouty subjects. It may be inferred from these co-existencies that the functional disturbances of the kidney, as those of the nervous system, play a part in the preparation of gout and in the outbreak of its paroxysms, either by hindering the eliminations of the toxic waste products of the denutrition of the tissues, or through neurotrophic inhibition of the intracellular metabolism. When gout is acquired, the nutritive disturbance of the cells is brought about by a defective hygiene (abuse of food stuffs, nitrogenous or rich in oxalic acid, and of certain fermented drinks, insufficient physical activity, and overstrain of the nervous system), or by the action of a poison (lead). When gout is hereditary it is that the nutritive disorder of the cells of the first begetter has been continued through the ovum or the spermatozoon in the descendants of these cells.

SIR DYCE DUCKWORTH read a paper, of which the following is a summary:

(1) That gout as a morbid condition depends on an inherent vice of nutrition, which is manifested by an imperfect metabolism in various organs or parts of

the body, presumably in the kidneys, and probably in the liver.

(2) That this trophic disorder or inadequacy (*calentissement de nutrition*) leads to the formation of uric acid, probably in excess, and to the periodic retention of it in the blood (gouty uricemia).

(3) That histology throws no light upon the intimate nature of this defect, which thus relates to cellular potentiality, possibly under neurotrophic influence, and not, as far as we know, to structural alteration.

(4) That this textural disability, or a tendency to it, may be primarily acquired, and also transmitted as a fault, thereby inducing from time to time uricemia with gouty manifestations in the descendants.

(5) That in most instances, under conditions which provoke it, and in some cases independently of these, attacks of gout may grow up and come to a crisis. Such crises are attended by an alteration in the solubility of the uratic salt in the blood, whereby irritating crystals of biurate of sodium are produced and precipitated in various parts of the body.

(6) That a paroxysm of gout, the sites of its occurrence, and its metastases are determined by nervous influences, probably dominated from the bulbar centre, and that the local attacks alight either in the joints or in textures which have been weakened or rendered vulnerable by impaired nutrition, owing to past injury or overuse.

(7) That this central neurosis is an essential and transmissible feature in the pathogeny of gout, and pertains to the arthritic diathesis generally.

(8) That the uricemia of gout is peculiar and unlike that which is induced by other morbid conditions, but that the occurrence of uricemia in the gouty is by itself inadequate to induce attacks of gout.

(9) That uratic deposits in any part of the body may be removed in course of time, but are apt to be permanent in the least vascular tissues.

(10) That uratic deposits may occur to an enormous extent in gouty persons without the occurrence of any pain or paroxysms.

(11) That the clinical features of gout indicate that both hemic changes (due to inherent morbid tissue metabolism) and a neurotrophic disturbance act as pathogenic factors, and that, consequently, gout is to be regarded as a neurohumeral malady.

DR. EBSTEIN summed up his conclusions as follows:

(1) Gout is a more or less chronic disease of which the fundamental substratum is a hereditary morbid proclivity, which is almost always congenital. To this proclivity is given the name "uric-acid diathesis."

(2) As regards ultimate cause of the uric-acid diathesis, nothing more than hypothesis can be advanced. The intimate relations existing between the nucleins and uric acid make it probable that we have to do in the uric-acid diathesis with an abnormal state of the cell nuclei or of the protoplasm of the individual proclivity, which can be followed throughout whole generations and races of men, and is in any case of the greatest importance in the uric-acid diathesis.

(3) It appears that there are various circumstances which may contribute to the development of the diathesis and its transformation into positive gout. Among these circumstances must be mentioned the following:

(a) Gout develops, all the circumstances being alike,

the earlier and more intensely the diathesis is more pronounced; (b) there are habits — laziness, luxurious living, often a combination of both these causes, in the highest degree the abuse of alcohol — which favor the development of gout; the temporary fluctuations that have been observed may generally be attributed to those circumstances; (c) there are acute and chronic intoxications, which, given the existence of the diathesis, favor the development of gout; bacillary poisons are in that case of great importance; relations of gout with rheumatism, syphilis and lead poisoning should in the first place be borne in mind; influenza, too, seems to favor the appearance of gout; (d) contagion, which was considered a factor of the first importance by Boerhaave, appears to be of no importance; (e) climate seems to have no influence.

(1) Uric acid seems to be poison (the *materia peccans*) of gout. The question of knowing whether or not, besides uric acid, other products of the organism belonging to the family of the alloxans or nuclein bases play a part or not is still unsettled. It is probable that it is only the uric acid formed at the expense of the nucleinic substances of the human body and not that formed at the expense of the nucleins of the elements which has an influence on the pathogeny of gout. It has not yet been proved that in gout uric acid is formed in excess, and Ebstein does not think that this is indispensable. Nevertheless he thinks that an excess of uric acid is very probable. The history of leukemia teaches that gout is not the result of increased production of uric acid (estimated according to the quantity of uric acid separated in the urine), for there is in some cases of leukemia a secretion of uric acid such as is never seen to such a degree in gout.

(5) Uric acid is a chemical but not a septic poison. The influence of the poison is not equal either on different animal species or on animals of the same species differing in age. Inflammatory and necrosing changes of the tissues in question are the necessary consequence of the presence of uric acid, which finally causes a complete necrosis. When the tissues are utterly dead, but not before, the acid is deposited in them in the form of crystallized acid urate of soda (monosodium urate, Tollens), (sodium biurate, Roberts). Tollens thinks that the uric acid circulates in the blood and the alkaline juices of the human body in that same form and not, as Roberts has supposed, as sodium quadriurate (called more rationally hemisodium urate by Tollens). It may be admitted without hesitation that the monosodium urate (Tollens), sodium biurate (Roberts) may be deposited in a crystalline form in the tissues necrosed either by uric acid or another poison.

(6) To understand the pathogeny of the different symptoms of gout one must assume (a) a primary articular gout; (b) a primary renal gout. The former is the most widespread form of gout which does not prevent its subjects from reaching an advanced age. Primary articular gout develops itself first under the influence of a retention of uric acid; this retention is localized because it affects only one or more parts of the human body. In primary renal gout we have to do from the first with a generalized retention of uric acid, which consequently affects all parts of the body; it is always caused by a primary and material change in the kidneys.

(To be continued.)

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 30, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DR. ELLISTON'S ADDRESS BEFORE THE BRITISH MEDICAL ASSOCIATION.

As this year's president of the British Medical Association, Dr. William Alfred Elliston addressed the association on the topic, "Some Incidents in the Evolution of the Modern Physician." We are perhaps too apt to forget in our realization of what we as a profession are, what we have been and how crude the conceptions of our forefathers were, in the light of our present knowledge. It will take very few generations more to place the days of painful and septic surgery, still fresh in the minds of some men yet living, in the same category with indiscriminate blood letting and the generally empirical therapeutics of a century ago. It is particularly true of medicine that we are inclined to live almost exclusively in the present, with frequent forecasting of the future, but with little respect for the past. The historical instinct is often painfully lacking even in well-educated physicians of the present day, a consequence no doubt quite inevitable where so much yet remains to be done. The neglect of the teaching of the history of medicine, even in our best medical schools, bears out this proposition, a neglect which we sincerely hope the near future may see rectified. Retrospective addresses are on the whole looked upon with disfavor at great medical gatherings, an attitude of mind often justified by the lack of critical analysis which such addresses too frequently represent. This generation is, it must be admitted, wholly weary of the history of anesthesia and surgical cleanliness, so often has it been reiterated by the uninspired medical orator, but there are other matters, less familiar and no doubt less important in a practical sense, but still of vital interest to us as representatives of a liberal profession. It is, therefore, altogether appropriate that we should hear from time to time a description of the events which have brought medicine to its present position of universal respect. This Dr. Elliston has done in his elaborate address and in a highly entertaining fashion. His remarks are confined rather exclusively to British medicine, a limitation no doubt

necessitated by the time at his disposal, but out of this history we are led to see the steps which have produced the present-day physician.

The event which really marked the beginning of medicine in England was the granting of a charter to a small body of medical graduates, who thereafter were known as the Royal College of Physicians. This charter, largely through the influence of Thomas Linaere, was granted in 1518. Later, in 1540, the barbers and surgeons were united, and incorporated as the "Masters or Governors of the Mysterie and Commonalitie of Barbers and Surgeons of London." During this century also the Royal College of Surgeons of Edinburgh and the Faculty of Physicians and Surgeons of Glasgow were founded. At about this period a stimulus was given to medical science by the introduction of the study of human anatomy in addition to the dissection of the lower animals. In 1597 Mr. George Bacon was master of the Barber Surgeons' Company. He was a bookmaker apparently of a dignified sort. "I would not have," he says, "every ignorant asse to be made a chirurgeon by my booke, for they would do more harm with it than good." "In the sixteenth century," Elliston writes, "there were already established physicians, surgeons and apothecaries. The surgeons were associated in their guild with the barbers and the apothecaries with the grocers. While the physicians were men of education, cultured according to the education of the time, the surgeons and apothecaries were not a very highly educated class and they remained so, with few exceptions, until the rise of the nineteenth century."

The advent of Gilbert and Harvey brought a new energy into the progress of medicine not only in England, but throughout the civilized world, and, in fact, Harvey's work on the blood was a discovery without which advance must have been checked for many years thereafter. It is an interesting fact that the rate of the pulse was not taken by a watch until nearly a century after Harvey's time. Importance was apparently attached to the character of the pulse rather than to its exact rate, something we, in our day of precision, are often too apt to forget.

The Royal Society was founded in 1662 by a body of students at Oxford, and is therefore the oldest scientific society in Great Britain. It was made up not wholly of medical men, but in general of those who were interested in the development of mathematical and physical science. This gathering together of men interested in scientific subjects, no doubt, did much to stimulate medical practice and to raise it to a higher level. From this time on, at least, progress was continuous, and the physicians gradually established themselves in a firmer scientific and social position.

Dr. Elliston in his address discusses Boerhaave and Hales, the birth of chemistry, the progress of medicine in the eighteenth century, the unfortunate relation of the apothecaries to the physicians, medical societies and notable practitioners. The raising of the

standard of medical education was one of the most important advances of the early part of the nineteenth century, by legislation known as the Apothecaries Act of 1815: "The use of wise legislative enactments in the social influence and status of the profession soon became apparent, but, of course, its full effects were not evident until many years had elapsed. It is quite within my memory that the only qualification recorded in many instances in the annual *Medical Directory* was 'in practice prior to 1815.' It is not a little singular that the Apothecaries Act has gradually extinguished the apothecary, as then understood. I can remember an apothecary's shop in this town (Ipswich). That has now become a thing of the past, as will soon, I trust, what is called the open surgery of today. With the better education required and the institution of examinations, a different class of students were attracted to medicine, and they were rarely satisfied with the apothecary's license, but sought further a surgeon's diploma."

The progress of this century is covered more briefly and we are glad to note that but one paragraph is given to the time-worn subject of antiseptics and anesthetics. The following description of the first operation under ether in England, as given by Mr. William Cadge, who was present, is, however, not without interest: "Robert Liston was the first surgeon in this country to use ether, and those who were present at University College Hospital on December 21, 1846, and witnessed the complete and perfect success of that first venture will not easily forget the dramatic character of that scene. I was present and assisted at the operation—amputation of the thigh by the double-flap method. Some one present timed the operation; it took thirty seconds; the few arteries were tied, and all signs of blood cleared away. A towel was then thrown over the stump, and we watched anxiously for the patient to show that he was not dead; he presently woke up, and when asked once or twice if he could stand the pain of the operation, he accused us of cruelly trifling with his feelings, and when the towel was removed and he saw the naked stump, he burst into tears, and I thought Liston would do the same."

Dr. Elliston concludes his address with a very practical matter, namely, the expense of modern medical education. We quote in part his remarks, which surely apply elsewhere as well as in England:

"In conclusion, may I briefly refer to the growing expense of medical education? It is certainly the most costly of all the learned professions. This is due to the long period of time required for the medical curriculum, and to the multiplication of qualifications which I regard as a fashionable absurdity. I am not unmindful of the up-to-date requirements of general culture; of an accurate knowledge of anatomy, chemistry, physiology, biology, bacteriology, pathology, physics, optics, mechanics, electricity, and photography, which are all essential to the well-educated physician; they are daily called into requisition

in order to diagnose and to direct the eye and hand in the treatment of disease. The necessity for the highest education for this mental training is obvious, and it rests with the General Medical Council to see that this can be obtained without undue restrictions. What I venture to think is wanted is early qualifications, and if the elements of science were more generally taught in school life that would be easily possible."

Altogether this address is a welcome and fitting one on the occasion of the opening of a great medical congress, and we beg to call those of our readers' attention to it who feel an interest not only in the future but also in the past of their profession.

HYSTERIA AN ORGANIC DISEASE.

To one who testifies in court regarding the effects of trauma upon the nervous system, the difficulty has no doubt often come of explaining to a jury the nature of hysterical manifestations. The average juryman looks for something tangible; a broken leg or a bruise appeals to him, but a disturbance of sensation or a contracture without a cause which he can see is not likely to impress him deeply. His judicial faculty is quite in abeyance and he is too likely to depend upon the judge's charge or precedent in the formation of his opinion as to a just verdict. To explain these subtle matters to wholly untrained and often ignorant men from the disadvantageous position of the witness stand is no easy task, and men of great intelligence often leave the stand conscious of the fact that their elucidations have fallen on deaf ears, rather from the difficulty of the subject than from any fault of their own. The *Philadelphia Medical Journal*, under the heading "Organic Hysteria," suggests a possible way out of the difficulty, which appeals to us as logical and legitimate. We quote in part:

Of all the purely functional disorders which result from trauma it must be conceded that hysterical affections are probably the commonest and the most puzzling. That they are frequently disguised under assumed names in our courts is a matter of common observation. The prejudice against the term "hysteria" is not confined to the medical profession, but is entertained widely by all persons, and especially by the ignorant classes, from whom largely our juries are recruited. . . . Recently, in a Camden court, a man secured a verdict for \$5,000 for a typical hysterical paralysis of an arm caused by a shock of electricity from a low-hanging arc lamp, but the lawyer in the case had evidently succeeded in convincing the jury that the muscles and nerves had been destroyed by the mysterious current. Soon after, in a Philadelphia court, a woman with an almost identical paralysis caused by a blow from a falling sign failed to receive damages because apparently it was successfully demonstrated to the jury that the affection was merely hysteria. These two cases illustrate the subject perfectly. They prove that there is something in a name when damages are concerned. They also show that the attitude of both the medical profession and the courts toward such cases is illogical and unscientific. . . . Why

not abandon the misleading phraseology which assumes a paradox, that is, that a function can be disturbed without a change in its organic basis, and boldly state, as a sound pathological doctrine, that a neurosis is an organic fact. We have long thought that the more permanent stigmata of the grand neuroses should be grouped under some such designation as "organic hysteria." A muscle that is paralyzed for many weeks, or contracted, or the seat of tremor, is a disabled muscle; and all it needs to dignify it in the sight of men and courts is an acknowledgment of the fact that its disability is not dependent on a caprice, or whim, or volition of the patient, but on some minute change in the cytoplasm of nerve cells that is as real, though perhaps not as permanent, as the changes wrought by a poison or a process of degeneration. Surely pathology, of all the sciences, should no longer acknowledge the trammels of mere scholastic distinctions.

We are somewhat doubtful whether such a statement of the case would relieve the expert witness of all his embarrassment. At the same time the suggestion is a good one and should be put into practice far more often than it is in spite of the searching cross examination it would probably receive at the hands of a shrewd lawyer.

MEDICAL NOTES.

DEATH FROM PLAGUE IN GLASGOW. — It is reported that a member of a family certified to be suffering from bubonic plague having died, ten families living in their neighborhood have been placed under medical observation. This death was the second which has occurred from plague. Forty families are now isolated.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 29, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 76, scarlatina 10, measles 22, typhoid fever 27.

BOSTON DEATH STATISTICS. — The total number of deaths reported to the Board of Health for the week ending August 25th was 226, against 219 the corresponding week last year, showing an increase of 7 deaths, and making the death rate for the week 21.24. Of this number 114 were males and 112 were females; 156 were born in the United States, 67 in foreign countries and 3 unknown; 47 were of American parentage, 153 of foreign parentage and 26 unknown. The deaths from consumption were 25; pneumonia, 14; whooping cough, 4; heart disease, 20; bronchitis, 2, and marasmus, 6. There were 12 deaths from violent causes. The number of children who died under one year was 69, the number under five years, 87. The number of persons who died over sixty years of age was 42. The deaths in public institutions were 65.

DIPHTHERIA IN ROXBURY AND DORCHESTER DISTRICTS. — There are a number of cases of diphtheria in the Roxbury and Dorchester districts. Since Au-

gust 25th the Board of Health has reported 12 cases. Of these latest cases 8 are reported from Roxbury and Dorchester. The North End is said to be practically free of the disease. The disease is of a mild form and it is probable that, owing to the increased care in making bacteriological examinations, many cases have been reported which in previous years would have escaped unnoticed.

NEW BUILDING FOR WEST END NURSERY, BOSTON. — It is hoped that the buildings of the West End Nursery may soon be enlarged, to meet the added demands which are constantly being made upon it. To this end the land behind the present building will be bought when sufficient funds are raised, which will give space for needed enlargement of the out-patient department and added lecture rooms.

NEW YORK.

WATER SUPPLY OF NEW YORK. — The "Inquiry into the Conditions Relating to the Water Supply of the City of New York," which has just been published by the public-spirited Merchants' Association, is a most admirable document, supplementing, as it does, the comprehensive report made some months ago to Controller Coler by Mr. John R. Freeman, and being even more exhaustive than this. For the additional supplies of water which the growth of New York will shortly demand, two sources are stated to be available. One of these is the great watershed of the Catskills, which is capable of furnishing at least 400,000,000 gallons per day. The other is the much larger area of the Adirondack watershed, draining into the upper Hudson, which, it is computed, can be counted upon to furnish 1,500,000,000 gallons per day. The plan favored by the committee of the Merchants' Association, and one which would entirely free the city from having to depend on the grasping Ramapo Company for its future water supply, is to establish an ample filtering plant above Poughkeepsie and thence conduct the water of the upper Hudson by an aqueduct discharging into a storage reservoir near New York. An early addition of 250,000,000 gallons per day from this source would, it is stated, meet all the expected requirements of the city for twenty years to come, and such extensions of the system are practicable as, in the judgment of the committee, would supply a population of 18,000,000. This plan contemplates the construction of reservoirs in the Adirondack district to be filled by heavy rains and freshets, and to be discharged during dry seasons into the streams leading to the Hudson, thus maintaining the delivery of the river fairly constant through the twelve months. This, it is believed, would settle the water question for considerably more than a century to come. The financial aspects of this great undertaking have been carefully worked out, and appear to present no difficulties. On the contrary, it could add 250,000,000 gallons per day to the water supply, pay for the plant by 1937, and earn large revenues from water rates; whereas it is shown

that a twenty-year contract with the Ramapo Company would entail to the city a net loss of not less than \$195,000,000. To supply New York with 250,000,000 gallons additional water per day from the upper Hudson would require an investment in plant of \$36,880,000, which, in the judgment of the committee, can be easily met out of the revenue from the additional supply, without any increase in the present water rates. This will also hold true, it is believed, of additional supplies up to 1,500,000,000 gallons per day.

DEATH OF FRANKLIN BOOTH, M.D. — Dr. Franklin Booth, one of the leading physicians and surgeons of Long Island City, died at St. John's Hospital, in that place, on August 19th. His death was a peculiarly sad and heroic one. He was run over by a trolley car at Elmhurst, Borough of Queens, New York City, and had both his lower extremities terribly mangled; with great coolness he instructed the bystanders how to apply temporary tourniquets to the injured members. One of his legs was amputated on the sidewalk by the ambulance surgeon who was summoned to his relief. After being taken to St. John's Hospital, he consulted with the surgeons in attendance as to the best treatment of his case. It was decided to amputate the other leg, and a few hours after the operation he died. Dr. Booth was a native of Windsorville, Conn., and was graduated from Bellevue Hospital Medical College in 1868. He was one of the attending surgeons to the hospital in which he died.

DEATH OF WILLIAM B. WATERMAN, M.D. — Dr. William B. Waterman, of Brooklyn, N. Y., died after an illness of several months, on August 21st. He was born in Brooklyn thirty-eight years ago, and was graduated with honor in 1885 from the Medical Department of the University of the City of New York, where he was awarded the Mott prize and medal. For a number of years he was a member of the surgical staff of the Eastern District Hospital of Brooklyn.

Miscellany.

THE HYGIENE OF HIGH ALTITUDES.

It is well known that the chemical composition of the atmosphere differs but little, if at all, wherever the sample be taken; whether it be on the high Alps or at the surface of the sea, the relation of oxygen to nitrogen and other constituents is the same. The favorable effects, therefore, of a change of air are not to be explained by any difference in the proportion of its gaseous constituents. One important difference, however, is the bacteriological one. The air of high altitudes contains no microbes and is, in fact, sterile, whilst near the ground and some one hundred feet above it microbes are abundant. In the air of towns and crowded places not only does the microbial impurity increase, but other impurities, such as the products of combustion of coal, accrue also. Several investigators have found traces of hydrogen and certain

hydrocarbons in the air, and especially in the air of pine, oak and birch forests. It is to these bodies, doubtless consisting of traces of essential oils, to which the curative effects of certain health resorts are ascribed. Thus the locality of a fir forest is said to give relief in diseases of the respiratory tract. But all the same these traces of essential oils and aromatic products must be counted, strictly speaking, as impurities since they are not apparently necessary constituents of the air. As recent analyses have shown, these bodies tend to disappear in the air as a higher altitude is reached until they disappear altogether. It would seem, therefore, that microbes, hydrocarbons, and entities other than oxygen and nitrogen, and perhaps we should add argon, are only incidental to the neighborhood of human industry, animal life, damp and vegetation. — *Lancet*.

BACTERIOLOGY OF ACUTE TROPICAL DYSENTERY.

At the recent meeting of the British Medical Association Professor Simon Flexner, of Philadelphia, spoke on the "Bacteriology of Acute Tropical Dysentery." He is reported in the *Journal of Tropical Medicine* to have said that it was erroneous to suppose that tropical dysentery was of a single kind. The disease had been attributed to different groups of organisms. The bacillus coli communis was still believed by many to be the cause; the pyogenic cocci were regarded to be so by others, and the ameba coli ranked as a potent pathological factor. Whilst investigating the diseases of the American soldiers in the Philippines he had succeeded in isolating a group of organisms (allied to the coli) not normally present in the intestines and showing peculiar reaction. When the acute form set up by these organisms became chronic the ulcers were superficial and were not undermined. Experiments showed that certain animals could be rendered immune with the products of these microorganisms. Flexner believes the organisms he found are identical with those described by Japanese investigators as occurring in dysentery in that country. There seems some justification for the adoption of the term "infectious dysentery" as distinct from tropical dysentery.

METEOROLOGICAL RECORD.

For the week ending August 11th. in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Date.	Barometer	Thermometer.		Relative humidity.			Direction of wind.		Velocity of wind.		Wet'b'r.		Rainfall in inches.

Address.

THE SCOPE AND AIM OF THE SECTION'S WORK.¹

BY COLONEL KENNETH MACLEOD, M.D. (RET. I.M.S.),
President of the Section of Tropical Diseases of the British Medical Association.

SINCE the last meeting of this section events have occurred which have emphasized the significance and enhanced the importance of its work. The war in South Africa has stimulated into vivid reality the unity and solidarity of the British Empire. The imperial idea implies not only a community of interests—social, commercial and political—between the mother country and her colonies and dependencies, but also a community of suffering; and as tropical conditions and tropical diseases prevail in Greater Britain to such a large extent, the study of these as they affect both the governing and the governed has come to be recognized as a matter of vital and cardinal necessity. This has been fully acknowledged by the able minister who presides over the Colonies, and who has realized more clearly than any of his predecessors the immense importance of inquiry and education as regards tropical pathology and hygiene. The Government of India has also awakened from its torpor, and taken thought and action in the same direction by encouraging research, training men in bacteriological methods, establishing laboratories, appointing commissions and promoting special investigations.

A knowledge of the pathology and pathogenesis of disease must obviously precede and guide preventive and curative effort; and it cannot be too loudly proclaimed that this knowledge can only be obtained by systematic scientific research. The days of casual and statistical observations and dissertations have gone, and it is now universally understood that nothing will avail for the solution of pathological problems except the undistracted work of trained agents provided with ample opportunities, facilities and appliances. The recent history of malariology, to employ a new and expressive term, is a signal illustration of the dependence of sanitary and therapeutical endeavor on pathological discovery. Laveran in 1880 furnished the key to the morbid processes which in malarious disease take place within the body by the discovery of the plasmodium malariae. Manson and Ross pioneered the brilliant investigations which have revealed one, if not the one, means by which this organism leaves the infected subject, lives and breeds in outer nature, thus compassing the communication of what must now be admitted to be an infective disease. It is interesting to observe how this knowledge is being at the present time turned to practical account, and how it explains and gives precision to methods of prevention and cure which had previously been resorted to empirically. Koch, in the Dutch Indies and German New Guinea, has been attacking the plasmodium within the human host, and claims, by destroying it in that phase or stage of its existence, not only to cure the individual, but to reduce greatly, or altogether abolish, the prevalence of malarious disease in the community. Sambon and Low, in Italy, are addressing themselves to the extrinsic life of the parasite, and endeavoring by special contrivances and precautions to cut the mor-

bific circuit outside the body. Koch's labors have an intimate bearing upon the subject which has been selected for discussion at this meeting, and will, no doubt, be noticed and criticised by those who take part in it. The results of the proceedings of Drs. Sambon and Low will be eagerly watched, as they will contribute an important aid to the solution of the question whether the "anopheles" is the only medium of malarious infection, and, if so, whether this occurs invariably by inoculation.

The South African war has forced into prominent and painful attention two diseases which, although they cannot be called tropical diseases, manifest themselves with special severity as regards incidence and fatality under tropical conditions—namely, enteric fever and dysentery. The theatre of the war—the uplands of South Africa—cannot be classed, either as regards position or physical characters, as tropical. Malarious disease, the special and predominant product and index of tropical countries, is conspicuous by its absence among the causes of disability and death occurring in the British army of South Africa. But the meteorological conditions which obtained during the early months of the campaign were most aptly described by the term "tropical." Sunstroke and sun fever were very common. I have endeavored to ascertain whether these cases were all or mostly cases of heat shock, and whether any considerable number of them presented the phenomena of heat fever—so called "siriasis"—and, if so, whether these occurred in epidemics or appeared to be communicable. I regret to say that I have not succeeded in obtaining any information on these points. The cases which I have met with at Netley have presented a similar history and similar sequelae to those received from India. Perhaps, when the medical history of the campaign comes to be compiled, some facts bearing on these questions may be forthcoming. I allude to the matter here and now in the hope of eliciting information.

That enteric fever existed in South Africa and was apt to prevail in South African towns and cantonments during the summer months was well known, and its appearance among the troops engaged in this war was fully anticipated; but the excessive prevalence of the disease in a country and climate with a reputation for exceptional healthiness has come as an unpleasant surprise. No doubt the circumstances and exigencies of warfare are mainly responsible for the heavy tribute of sickness and death which enteric fever has levied. War shares with famine the malignant power of enhancing the susceptibility to whatever infection is present at the place and time.

Enteric fever has been in grim evidence during recent wars on the Indian frontier and in the Egyptian Soudan; but malaria, cholera, yellow fever and dysentery have on other occasions been stimulated into disastrous activity by war. So with famine: malarious disease, smallpox, diarrhoea, dysentery and relapsing fever have attended or followed it, and at the present time cholera and plague are raging among the famine-stricken in India. The infection of enteric fever seems to be ubiquitous, portable, and peculiarly facile and subtle; and perhaps the most urgent question of the hour is how to mitigate its prevalence in the British army, in which in times of peace it causes one-third of the total mortality.

It is important to note that a very marked contrast exists between the ordinary incidence and mortality of

¹ An address delivered at the opening of the Section of Tropical Diseases, at the Annual Meeting of the British Medical Association at Ipswich, July-August, 1900.

the disease in temperate and tropical or subtropical countries — in England and Canada on the one hand, and in India and Egypt on the other. A similar contrast appears in the French army stationed in France and in Northern Africa. How much of this great excess is due to tropical conditions, tropical and climatic, and how much to remediable sanitary defects it is not easy to say.

But side by side with the excessive suffering of the army in India we are confronted with the remarkable fact of the immunity of the native population. Whether a similar immunity exists among indigenous races and habitual residents in South Africa is an interesting question. Evidence seems to indicate that it is so. The native immunity in India, though not absolute, is undoubted; its cause has not been satisfactorily ascertained. It has been attributed to habituation to minute dosage of the contagium, to protection conferred by attack during infancy and childhood, and to racial resistance acquired in the course of generations through both of these influences. Some experiments by Freyer and others indicate that natives give positive reactions to Widal's test; but more extended and exact investigations on this point are desirable. It is quite certain that the immunity of natives is not due to superior sanitary conditions. Whether a similar immunity — temporary or permanent — can be engendered in European subjects by a process of inoculation such as has been devised by Professor Wright, of Netley, and practised on a large scale among soldiers proceeding to the seat of war, is a question the reply to which is awaited with eager anxiety. Some figures obtained from Ladysmith have been published by Professor Wright, which seem to show that some immunity is conferred by these inoculations, but though encouraging, they are by no means demonstrative. Similar procedures for creating an immunity against cholera and plague initiated by Professor Haffkine have in India been attended with satisfactory results. But although a certain measure of preventive success has been obtained by these inoculations, the employment of them appears at present to be practicable and useful only as an emergent expedient in the presence of a serious outbreak; and the prevention of cholera, plague and enteric fever on a large scale must apparently be essayed on other lines and by other methods.

Dysentery has been very rife in the South African army, but the disease has exhibited mostly a mild type and been amenable to treatment. In some camps it has presented the aspect of an epidemic or infectious disease; but whether the infectiousness is apparent or real — due to common exposure to certain noxious conditions or to communication from man to man of some specific contagium — it is impossible in the absence of knowledge regarding the nature of the contagium or contagia of dysentery to say. The dysentery of war and famine is believed to be infectious, but notwithstanding much able and laborious research we have yet much to learn concerning the pathology and causation of dysentery. Imperfect conservancy, foul water, alternations of temperature, exposure, fatigue and bad food, which are undoubtedly adjuvants if not factors of dysentery, have been in baneful operation in this war, and a new disease resembling dysentery has been described under the name of "dust colic." This seems to be a muco-enteritis caused by the swallowing with water and food of irritating particles of grit

blown about by dust storms. The presence of the grit in the evacuations does not seem to have been sought for or found.

The persistence of plague in India and the appearance of the disease for the first time south of the equator — in Mauritius, South Africa, South America and Australia — are events deserving of special notice. The disease has during its present prevalence confined itself mostly to warm and hot countries, and, though not exclusively a tropical disease, nor apt in the tropics to be at its worst when conditions are most typically tropical, it appears to find in tropical countries and circumstances the most favoring environment. It is curious to remark that, while in India natives appear to be readily susceptible to the infection of plague, Europeans, though not absolutely insusceptible, exhibit a comparative immunity — the reverse of what happens as regards enteric fever. This immunity is doubtless what I venture to call a sanitary immunity, due to a purer personal domestic and social life, and perhaps to circumstances and habits rendering admission of infection less easy. This kind of immunity is also observable in some places — in Calcutta, for example — as regards cholera. How far an immunity of this sort is capable of being achieved as regards the infection of enteric fever, it is not easy to say. Certainly it has not been accomplished as yet in India or Egypt. The Bermudas used to render the highest ratios of enteric prevalence and mortality, but within recent years considerable reduction of these rates has occurred through sanitary reforms in the matter specially of water conservancy and sewage disposal. Similar causes have reduced the burden of enteric suffering in the French army of Algeria, and the power of sanitation has also obtained signal illustration in the banishment of beriberi from the Japanese navy. Great Britain appears also to have acquired an immunity against cholera through sanitary reform and effort. These experiences are full of encouragement and hope.

I trust that I have succeeded by these discursive observations in showing that recent events have expanded the scope and aim of our work in this section; and it seems to me fitting that we should at the commencement of our sectional labors remind ourselves of what these are. Our concern is not only with exclusively tropical diseases, many of them strangely named and imperfectly investigated and understood, which may be encountered and contracted in hot places where Europeans are compelled to reside for purposes of protection, administration or commerce, and are not as a rule met with outside of the tropics. More important are those diseases, originally or essentially tropical, which may be disseminated by intercourse with the tropics, and may prevail for a time in extra-tropical localities in which they are not habitually present. And, finally, there are the diseases which are not specially tropical, but which are liable to be aggravated in prevalence or severity by tropical conditions. These three classes represent a wide field of research, and, in addition, interesting questions arise as regards diseases which, common elsewhere, are rare or unknown in tropical countries.

The field of study thus presented has its scientific and humanitarian aspects, and its cultivation has become an essential part of the business of imperial administration. It embraces not only acute infections and the sequelæ or constitutional incapacities resulting

therefrom, but includes also those conditions affecting health and life which are vaguely designated as climatic, remediable only by adaptation, or which arise from sanitary defects or neglects capable of more easy amelioration. Hygienic improvements, personal, domestic and social, have undoubtedly raised the standard of health and the value of life in the tropics, and residence and service in hot countries offer fewer and less formidable risks than they did in times past. But behind the question of individual impunity looms the question of colonization or the continued vigor and vitality of the race when transplanted from temperate to torrid zones. The solution of these weighty problems constitutes the reason and purpose of our distinct sectional existence.

Original Articles.

NOTES ON DERMATITIS VENENATA.¹

BY GEORGE F. HARDING, M.D., BOSTON,

Physician to the Skin Department, Boston City Hospital and Curney Hospital.

THE term "dermatitis venenata" is used to indicate forms of inflammation, or irritation, of the skin produced by the action of substances applied externally. The number of substances which can produce such conditions is very large, and although the symptoms produced by them are often transitory and cause but little annoyance, still they may be very severe. Therefore, for the sake of preventing recurrences, I consider their recognition of much importance. Many of these substances are among our familiar garden plants and wild flowers; many are among the drugs which we apply to the skin therapeutically; some are used in various trades and show their effects upon those working with them; others may be found in articles of clothing, household articles, paper boxes, playing cards, cosmetics and nostrums of various kinds. There is also a class of animal irritants which it is necessary to bear in mind, and which in my experience is often overlooked in making a diagnosis. The effect of these substances varies greatly in different individuals and even at times in the same individual. It seems in the majority of cases to be a matter of idiosyncrasy, or of individual susceptibility, but this is not always the case. I have seen, for example, persons who were able to handle poison ivy at times with impunity, but who on other occasions experienced a severe dermatitis from it. The same fact applies to local therapeutic applications. A person may be able to get benefit from an ointment of a certain strength and containing a certain drug at one time, when at another it would cause considerable irritation.

The form of dermatitis produced is as a rule of the erythematous, or eczematous, type, but occasionally much deeper grades of inflammation are seen. Itching, burning and pricking are the usual subjective symptoms, and sometimes there is numbness. The site of the inflammation is as a rule limited to the area to which the substance has been applied, but in some cases, possibly through absorption, it becomes more widespread, or even general. The diagnosis is not always easy, and often much questioning and search is necessary in order to find the irritative factor; but

such considerations as the site of the eruption, its limited area, its intensity, its acute onset, the habits or trade of the individual, or the history of some application having been applied, will be of much aid in clearing it up.

I propose to take up only a few of the many substances which may cause a dermatitis venenata—a consideration of them all being sufficient to fill a volume—and shall give the histories of some cases which illustrate their effects. The form of dermatitis venenata which is most commonly seen about here is that due to members of the rhus group. This group consists of three species: rhus toxicodendron, poison ivy; rhus venenata, dogwood or poison sumach; rhus diversiloba, poison oak. The first two varieties and the results they produce are so well known here that I need do little more than mention them. They may produce dermatitis of varying grade, from an erythema with a few vesicles and papules to an inflammatory condition of erysipelatous type accompanied by marked edema and serous exudation. The activity of the poison does not seem to be limited to fresh growths, for cases have occurred in which a dermatitis was produced by the dried specimen. The poison oak does not occur in this part of the country, but is seen frequently in California, where it takes the place of our poison ivy. Its effects are the same as the poison ivy, but it is generally more virulent, and it sometimes happens that persons who are not affected by the ivy may be by the oak. This is also true of dogwood. I have seen persons who could with impunity rub their hands with poison ivy be almost immediately affected by dogwood. The Japanese lacquer, which we now see more commonly than formerly, may be responsible for some cases of dermatitis venenata. It is made from the sap of a tree which closely resembles our rhus. I have seen 1 case which seemed to me undoubtedly due to that. It occurred in a person who was confined to the house by illness. He had handled no plants, but had recently had a picture painted in lacquer. The eruption was vesicular, localized on two fingers with which he had touched the painting, and much resembled ivy poisoning. I have been told by persons who had lived in Japan for some time that lacquer poisoning was not infrequent there, even occurring from contact with old lacquered articles. Among the wild flowers which I have known to produce dermatitis of mild grade are the buttercup, field daisy, golden rod and wood anemone. These flowers are so frequently picked without injurious effect that one would never suspect them of causing any trouble, and the occurrence of a dermatitis from handling them is unusual, but that it may occur is, I think, without question. The cases which I have seen were all of a mild grade of vesicular inflammation, and the eruption had recurred every time that the person affected had been brought in contact with the plants. I was particularly surprised with this effect of the anemone, which is one of our earliest and most common wild flowers, but on looking the subject up, I find that several authorities have reported its irritant effect. There is also an early tradition to the effect that the wind which had passed over a field of anemone was poisoned and that disease followed in its wake. I have seen 2 cases of vesicular dermatitis which I thought I could attribute to the action of the clematis, which occurs in the woods abundantly and is also seen in gardens. I was unable, however, positively to ex-

¹ Read before the Brookline Medical Club, February 14, 1900.

clude contact with other plants in these cases. The plant has the reputation of being an irritant, and cases showing this effect have been reported. The garden nasturtium is capable of causing a dermatitis which is of the type of a papulo-vesicular eczema, and which might be considered that were the cause not recognized. The following case will illustrate this fact.

A. B. came to me with an apparent acute eczema of both hands. She stated that it had been recurrent for a number of years, but only came on in the summer, when she was at her summer residence at the seashore. I gave her a lotion, and an ointment to be applied constantly on cloths. In a few days the acute condition had subsided, and I ordered the ointment to be used at night only. Within two days she came back with a fresh attack. This disappeared under treatment, but was followed by a third outbreak which led me to think of some external cause. On inquiring I found that at her summer home she had been in the habit of training and picking nasturtiums. While she had the applications on her hands she refrained from handling the plants, but as soon as her hands were free, and only night applications made, she returned to them. The nasturtium gardening was given up after this, and the dermatitis did not recur.

There are a number of substances which are used locally as household remedies, and which are capable at times of producing much irritation. Among the most popular of these is tincture of arnica. It is used for sprains, bruises, etc., in the form of fomentations, mixed with other substances in liniments, or painted directly on the part. The following cases show well its irritating character.

CASE I. A. D., suffering from a severe attack of lumbago, applied, on the advice of a friend, hot fomentations of tincture of arnica and water to his lumbar region. After an hour he experienced so much burning from the application that he threw it away. I saw him the next day, and his back was largely covered with a papulovesicular eruption on an erythematous base, which itched intensely.

CASE II. P. D., a professional athlete, while exercising with the punch bag, slipped and wrenched his knee. His trainer gave him a mixture of tincture of arnica and laudanum to rub on the part every hour. The following day he came to the hospital, having made some six or eight applications with considerable friction. His knee was badly swollen, and the leg as well up to the thigh; there was an intense hyperemia of the whole surface, and numerous small vesicles, some of which were crusted, others exuding. There was much itching.

CASE III. M. C. came to the hospital with the following condition: The forearm and hand were covered with a fine papulovesicular eruption on an erythematous base, there was some edema and numerous excoriations from scratching. Having sprained his arm by a fall, he had painted it several times the day before with tincture of arnica. The skin had not been broken before the application, and he had noticed no burning or sign of irritation until the night before I saw him, that is, about twelve hours after the application had first been made.

The eruption in all the cases which I have seen was of about the same character as that described in the foregoing cases. More exaggerated types of inflammation have been described, however, as a result of this application.

Another household preparation which was formerly very popular as a remedy for cuts, bruises and wounds is the so-called balm of Gilead. This is a tincture made from the buds of the *populus canadensis*. It is, I think, not much used at present; but when it is, it is capable of causing an intense grade of dermatitis, as the following case will show.

T. W., a boy ten years of age, was brought to my office by his father, and showed several areas of dermatitis of varying grades on different parts of the body. His right knee was inflamed and edematous and covered with bullae, some of which had broken and exuded freely. The left ankle and foot were of a bright red color, so much swollen that he was unable to wear his shoe, and dispersed with bullae and vesicles. On the hands, particularly between the fingers and on the flexor surface of the right wrist, were small vesicopustules, producing a condition closely resembling that seen in scabies. It was an evident case of dermatitis venenata, but although I questioned closely, I could find nothing to lay it to. Finally, the following week, the father told me that they had had some balm of Gilead buds sent down from the country, and made a liniment of them and applied it to some cuts and bruises which the boy had; but as they had never used them before, they had not the least idea of connecting them with the boy's trouble, nor did they suspect that they were capable of causing such a condition. The affection of the face was probably caused by touching that part with the hands, after the liniment had been applied to them, as it had not been applied to the face directly.

Kerosene oil is frequently used by the laity for the relief of pain, as a parasiticide, and sometimes for shampooing. It is capable of causing a dermatitis, generally of the erythematous type. The most exaggerated type of dermatitis from this substance which I have ever seen was in a man whose wife had saturated his underclothing with it to prevent him from going out. He put them on, however, in spite of the oil, and when I saw him the following day he had a general scarlatiniform eruption. This was followed by an exfoliative dermatitis which lasted several months. Crude petroleum, on the other hand, from which kerosene is derived, has never shown the least irritant effect in my hands, and I have used it extensively as a parasiticide on scalps which had large areas of excoriations, and in some cases, in order to test its effect, every night for a week without the slightest sign of irritation. Hamamelis, in the form of fluid extract or tincture, or what is known as Pond's Extract, is used frequently in barber shops as an application after shaving. It is also used as an antipruritic, and popularly for lameness, bruises, etc. I have seen a number of cases in which a papular, or erythematous, dermatitis had been produced by its use, particularly when applied after shaving. The cheaper grades of so-called bay rum will produce the same effect, but as a rule to a greater degree. The "Seven Sutherland Sisters' Hair Grower" is said, in the book, "Secret Nostrums," to contain bay rum, extract of witch hazel, common salt, hydrochloric acid and magnesia. I have not tried to determine the ingredients myself, but I think the following case shows that it may prove an irritant. A. B., a man somewhat over forty years of age, came into my room at the City Hospital with an intense dermatitis of the face and scalp, erythematous in type, and accompanied by considerable edema

about the eyes, and some scaling and crust formation. On being questioned, he stated that he had rubbed the above-named preparation into his scalp on two consecutive nights. On the morning after the first application there was a slight redness of the scalp, and some burning and itching, but as he thought that was a sign of activity in the application he tried it again the following night. The next morning the eruption showed on his face, and he could hardly open his eyes.

What ingredients in this nostrum caused the dermatitis I am unable to say. One of the stated ingredients is common salt, but the quantity is small. Common salt in saturated or strong solutions may cause a hyperemia and desquamation. I have seen a number of cases of extreme irritation from its use by hair dressers, who applied it with friction in order to get a stimulant effect. In the form of strong brine baths it may produce a general papular eruption of the skin.

There are always a certain number of cases appearing at the hospital with dermatitis following the application of liniments. In some cases the applications have been made by means of cloths wet with the preparation, in others they have been rubbed in with considerable friction. The eruptions in these cases are nearly always of the same character, being erythematous or papular, occasionally accompanied by edema, and sometimes showing vesicles and bullæ; the intensity depending somewhat on the part to which the application had been applied. These preparations, for the most part proprietary, are largely made up of the essential oils, especially oil of thyme and turpentine, and some contain caustic soda. They may show their irritative action on the face, or some sensitive part, by accidental contact with the hands which have been moistened with the application. Certain plasters, particularly belladonna plaster, applied as counterirritants may cause a scarlatiniform eruption, not only in the neighborhood of the application but over the general surface. There are quite a large number of cases of dermatitis, many of the *eczema* type, which are due to irritating substances brought in contact with persons on account of their occupation. The most common among these are seen in domestics who have been using strong alkalis, strong soaps or soap powders, such as pearline and soapine, for household purposes. The various brass and metal polishes, and shoe polish, particularly that used in cleaning tan leather shoes, may cause dermatitis of varying grades. Printers are liable to a dermatitis of the hands from handling type wet with caustic potash solution, that substance being used to clean the type. Painters may get an inflammatory condition of the skin from the use of turpentine, and they may also have a dermatitis from some of the pigments which they use. Arsenic is largely used in the arts, more so formerly than at present. It is employed in making such articles as wall paper, playing cards and artificial flowers, also in curing hides. It is a favorite ingredient in cosmetics, proprietary face lotions and powders, and depilatory pastes. It may produce erythematous, papular, vesicular and pustular eruptions, and the grinders of the arsenious acid coming in direct contact with it may get ulcers. Its effects are more commonly seen on the hands, about the nails, in the *alæ* nose, on the lips, behind the ears, or anywhere where folds of skin come together. Longshoremen may show its

effects from handling hides, also taxidermists and furriers, who employ it constantly. Chromium, or bichromate of potash, is used perhaps more extensively than arsenic in dyeing, calico printing, and to produce pigments. It may be found in various articles of wearing apparel, and may produce a dermatitis on persons wearing such articles. Mercury is responsible for a certain number of cases of inflammation of the skin from occupations. It is used in the form of the acid nitrate by makers of felt hats, also by furriers, taxidermists and those making thermometers and barometers. The surgeon and nurse, as you well know, come in for their share of its irritant action. It is also employed in many of the cosmetic nostrums and may cause much trouble thereby. The pathologist may suffer from an eruption of *eczematous* type from having his hands in tissue soaked with solutions of formalin or various fixation fluids, as Zenker's fluid, for example, which contains corrosive sublimate, bichromate of potash, sodium sulphate and glacial acetic acid. I have seen 2 cases of dermatitis in girls who worked in a chocolate factory. Both were on the arm and hand, took the form of a papulopustular dermatitis, disappeared under treatment when they changed their work, and reappeared when they returned to it. One occurred in a girl who stirred the hot chocolate, the other in the one who made it into moulds. I am not prepared to state positively, from the observance of these 2 cases, that the chocolate only was responsible for the dermatitis, as these are the first cases of the kind that I have seen mentioned. The appearances favor such an opinion, however. A mild papular dermatitis may be seen at times among those working in candy factories, but I have never seen among them anything of the type shown in the above cases. A dermatitis termed "impetigo glycosique" has been described by Nivet, as occurring in sugar refineries. In using certain drugs externally with therapeutic intent, one must be on the lookout for signs of irritation, which may at times arise even from a weak application. Many times the trouble arises from too free use of the drug, or a too vigorous application on the part of the patient; but more often from a too strong preparation being used on an unknown skin. The condition of the skin must also be considered, for an ointment which could be applied without any irritation to a sound skin might cause much irritation if the skin were broken. The quality or age of the drug may make much difference in its irritant qualities. For example, an ointment of chrysarobin from one druggist may have no injurious effect on a skin, while a neighboring shop with the same prescription will produce an ointment which causes much irritation. The ointment base may be a source of irritation, either from the fact of individual susceptibility to a certain base, or because it has become more or less rancid. Glycerin, for example, seems to act as a decided irritant to some skins even when much diluted, and occasionally one meets with a case when any form of fat seems to be contraindicated. Almond oil appears most frequently to have an irritant effect, possibly because it becomes so easily rancid. It is used pretty generally by the so-called facial massagists to make what they term skin food. I have had two of these people come to my office with an active *eczematous* inflammation produced by their own applications. This may have been, as I have said, due to a slight rancidity of the oil, or there may

have been some cheap grade of oil used, and such grades are very apt to be adulterated. Preparations containing mercury, either in the form of an ointment or lotion, are among the most active of therapeutic agents in producing dermatitis. The degree and extent of irritation depend on the strength of the application, and the length of time which it is applied, also largely on the susceptibility of the individual. I have frequently seen under a surgical dressing of corrosive sublimate a mild papular eruption limited to the site of the application; but occasionally one sees a general erythema from such an application, and in some cases the eruption beneath the dressing is papulovesicular and the part edematous. The most frequent application against pediculi pubis is probably unguentum hydrargyrum; so much so in fact that it has become a popular remedy for that trouble. Personally I never prescribe it for that purpose, for I believe that the average person will use it much more extensively than ordered, and that in consequence disagreeable results may follow.

The most exaggerated case of local inflammation from this preparation that I have ever seen was in a man who came to the City Hospital clinic some time ago after using it. His penis and scrotum were enormously enlarged, hyperemic and edematous, the former being nearly as large as a quart bottle. There was also an extensive papulo-erythematous dermatitis over the pubic region and abdomen. He stated that he had been given for relief from pediculi pubis an ounce of "blue ointment," and told to rub it in the affected parts for three consecutive nights. In order to save time he rubbed it all in the first night, and not only over the pubic region but up on to the abdomen as well. The result was the condition which I have described.

Another case was that of a woman who had been given unguentum hydrargyrum for the same cause by the surgeon on one of the ocean steamers, and had applied it for four days and nights. When I saw her, about a week after the applications, she had a general eczematous dermatitis which included the face as well as the body. I have seen the same general eruption with symptoms of salivation produced in a person who used inunction of unguentum hydrargyrum for one application only, the abdomen being the site of the application, and 2 drachms of the ointment being used. This of course was a case of extreme susceptibility to the drug. Mild grades of localized dermatitis of the erythematous type after inunctions with unguentum hydrargyrum are, in my experience, not uncommon. In a hairy individual I have often noticed an inflamed condition about the hair follicles after inunction, and this was undoubtedly due largely to friction. I have also seen cases of papulovesicular eruptions in infants who had been swathed in flannel smeared with unguentum hydrargyrum.

Dermatitis from the application of iodoform to ulcers and wounded surfaces is not at all uncommon, and many cases of varying intensity have been reported. The dermatitis may be caused by the drug in powder form, in ointments, in an ether solution, or in gauze. The eruption is usually erythematous, but may be papular, vesicular, or even bullous, and accompanied by edema. As a rule it is localized, but, as the report of cases shows, it may be general. Even the powder flying about the room is sufficient to affect some susceptible individuals. Its irritant action is undoubtedly

due to the iodine which it contains. A few years ago I tested several persons in whom I had seen iodoform dermatitis with iodide of potash given internally and found them all extremely sensitive to that drug. Carbolic acid may cause varying degrees of inflammation, from erythema to destruction of tissue. As with other substances used as antiseptics, individual susceptibility often shows itself to a marked degree. I have known a physician who was obliged to give up surgery entirely owing to such a susceptibility. It is an extremely valuable drug in dermatotherapy, especially as an antipruritic, but it must be used carefully and its action watched, as it may in an unsuitable case cause much irritation. It is a favorite ingredient of proprietary ointments, in some of which it is introduced in considerable quantities. I have seen a decided vesicating effect produced by the application of some such nostrums. The much advertised Cuticura ointment is said to contain nothing outside of coloring matter and perfume but 2% of carbolic acid and a vaseline base. Salicylic acid is a drug much used in treating skin diseases. It has also been used in surgery as a substitute for carbolic acid, and its use in this connection has given rise to frequent cases of dermatitis. It may be used in treating some skin diseases as strong as 12% in ointment form, but I have seen much irritation from the application of an ointment which contained only 1% of the drug. Applied to the scalp in an alcoholic solution, or a 6-per-cent. ointment, I have seen it produce a diffuse, fine, papular eruption over the forehead, ears and neck. Quinine is used in so-called hair tonics, particularly those of a proprietary character, to a considerable extent. It is also recommended in alcoholic solution as a local application in hyperidrosis and for the relief of night sweats. Any of these applications may produce irritation, particularly on the scalp, varying in character from a pruritus to a scarlatiniform eruption. Persons who are sensitive to the local action of this drug are generally susceptible to its internal action as well. So before using it locally it is well to inquire if the person has ever had an eruption after taking it internally. Sulphur is a drug which is constantly used by the laity for skin eruptions and advised by druggists, their choice lying between that and oxide of zinc. It is certainly a valuable drug in many cases if properly used, but it must be used carefully and its action watched, for it is capable of causing much irritation in some cases. It may cause a dermatitis of varying grades — erythematous, vesicular, or papular, whether applied as an ointment or lotion, in powder form, in a bath, or by fumigation. The following case, which was a surprise to me, illustrates well its action in a susceptible individual.

A. B., a girl seventeen years of age, being troubled with dandruff, applied to her scalp on going to bed an ointment containing 10 grains of sulphur and 15 grains of zinc oxide to an ounce of vaseline, which had been prescribed for another member of the family. About four or five hours after, she was awakened by a sensation of burning on the scalp and about the face. This increased in intensity and she was finally obliged to get up and wash the head. In the morning, when I saw her, the face was covered with a patchy erythema, the skin about the eyes was much swollen, and the scalp very tender and much reddened. Such a case is of course remarkably unusual, but from a stronger ointment, and especially if there is an in-

inflammatory condition of the skin, as an eczema, such results are not uncommon.

Tar in its several forms is extremely useful in some forms of skin disease, but, if injudiciously used, it is capable of producing much irritation. Like some other drugs it cannot be used on certain skins even in very dilute applications, and in acute inflammatory conditions it must be used with the greatest care. It may produce erythematous and papular eruptions, and at times those of an erysipelatous character. The dermatitis may extend some distance beyond the point of application. Another condition which may be produced by it is the so-called tar acne. This is composed of small, hard, red papules, in the centre of each of which is a dark point. This condition is most abundant in the hairy portions and is very rebellious to treatment. It persists for a long time after the applications have ceased, and may take several weeks to completely resolve. Chrysarobin is a drug much used in the treatment of psoriasis and some other chronic conditions of the skin. It probably causes local irritation more frequently than any other drug commonly used. It stains the sound skin a purplish-red color but not the diseased patches. It also stains the nails and gives the hair a purple tinge. The dermatitis produced by it is usually erythematous, or finely papular, but it may be more intense. I had under my charge at the Carney Hospital a girl with a general exfoliative dermatitis which was brought about by a few applications of an ointment containing 6% of chrysarobin. Applied to the face or scalp it is very apt to produce a violent dermatitis of erysipelatous type and maybe a conjunctivitis. I saw such a case at the City Hospital a few weeks ago. It may irritate the sebaceous glands and produce an acne like the so-called tar acne, with a black point in the centre of each papule. In applying the drug a very weak strength should be tried at first. In susceptible individuals and those with delicate skins, I have seen a 1-per-cent. ointment cause much irritation. In using an ointment, only a small amount should be applied at a time, and that well rubbed in with a swab. Otherwise the ointment is apt to get rubbed on to the neighboring sound skin, which being more sensitive than the diseased portions may become inflamed. Solutions of the drug in collodion or traumaticin dry where they are applied, and so do not spread in this way; but they are not always suited to the condition of the skin. Of the animal irritants, the mosquito, flea, bed-bug, black fly, wasp, bee and hornet are apt to make their presence appreciated, and as a rule the person afflicted makes his own diagnosis. Sometimes, however, especially in emigrants, the dermatitis produced is so extensive that it makes one suspect one of the exanthemata. I have seen an emigrant so poisoned by mosquitoes that the eruption on the exposed parts closely resembled variola. Spiders may drop from the ceiling during the night and cause an inflammatory condition of the face which at first sight might be mistaken for erysipelas. Caterpillars may cause a line of erythema, wheals or vesicles where they have passed over the skin, or even deeper forms of inflammation. The jelly fishes which are abundant in the salt water about here may cause much redness of the skin, and even large wheals. I have seen a boy who got into a school of these fishes and whose body was so covered with large wheals as to suggest a giant urticaria.

NOTES ON THE TREATMENT OF ATAXIC PATIENTS BY CO-ORDINATION EXERCISES, WITH THE DEMONSTRATION OF TWO PATIENTS.¹

BY JAMES J. PUTNAM, M.D., BOSTON.

THE power to see the hopeful aspects of hopeless diseases is one of the best gifts of modern medicine. The number of maladies whose very name make the physician think only how he may gracefully bow the patient from his door grows daily less; yet it is at once a warrant of the blindness in which we tread our accustomed paths and also of the hopefulness of the future that now and then the pointing out of obvious principles can claim the merit of substantial discovery. Why should the idea of training the ataxic patient to control his disorderly movements have waited for its practical development and almost for its conception until 1890, when the progress of the ataxic baby and that of the relatively ataxic school boy had been forever before us? Obviously, the reason is that we saw only too clearly the final outcome of the disease and, like fatalists, let our energies be paralyzed by the prospect.

It is to Dr. Fraenkel, a Swiss physician, that the credit of bringing the true value of this method before the profession is justly given, though Granville,² and perhaps others, had long before recognized the theoretical possibility of success in this direction. Fraenkel's first communication, in 1890, was followed in 1897 by a second, made before the Medical Congress of Moscow, at which the method was elaborated, various apparatus described and cases reported. Since then a host of physicians have brought their confirmations and criticisms, and, as is usual, the methods and the apparatus have been shown more and more to be susceptible of simplification, so that in fact the treatment in its essentials is at the command of any physician or gymnast, or even of any intelligent person who will master the principles at stake. In saying this, I would not be understood as meaning that skill and labor are not required for the best results, and in fact one of the medical gymnasts who has trained several of my patients has told me that the lesson is peculiarly exhausting for the teacher.

The following points should be strictly borne in mind:

(1) It is skill, not strength, that it is sought to develop. It is indeed important that the muscles should be in a state of good vigor and healthy nutrition, and special treatment, as by massage and exercises, may be directed if necessary to that end, but so far as the inco-ordination is concerned the need is to teach the brain and through it the lower reflex centres, to feel, and gauge, and respond to the feeble and distorted impulses that come from skin and joint and muscle.

(2) The movements, such as walking and stooping, or writing and simple piano exercises, etc., which one would freely prescribe to a healthy person, are often far too complex for the ataxic, and it is therefore necessary to begin with relatively elementary motions, such as drawing the leg up and down in bed, or moving the finger from one spot to another. On the other hand, however simple the movement, the patient should be called upon to perform it with promptness

¹ Read before the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, April 18, 1900.

² See Collins's Treatment of Nervous Diseases. Wm. Wood & Co., New York, 1900.

and accuracy and at the word of command. To inculcate these habits from the outset, and to reduce the difficulties at each step so that attention and effort will make success possible, and will ensure skill and confidence, are the prime requisites for a good result.

(3) Dulness, monotony and fatigue, on the one hand, and superficiality on the other, are the rocks to be avoided, both by the introduction of sufficient variety into the exercises and by giving them something of the entertainment of games of skill. For these reasons the exercises of putting the finger on to spots on a card or into holes on a board, as suggested by Fraenkel, are well modified by using marbles of various sorts or colored pegs, for the same purpose (as also suggested), or by giving these tasks an amusing turn, taking care, however, that the amusement occupies a subsidiary place. Simple tunes, played on a glass-chord, or on bells or glasses, by calling, at varying rates of speed, the numbers indicating the notes which the patient should strike, would be in this line.

As regards the leg co-ordinations, the infinitely variable movements of walking, at the command of a prompt instructor, so many steps forward, backward, to the right and to the left, with the eyes open, with the eyes closed (as should indeed be the eventual aim with most of the exercises); stepping over obstacles, halting, balancing and the like, furnish ample opportunity for the exercise of skill and for the training of persistence, attention and habit.

(4) The temptation is often strong to let the patient try to get on without any instructor, by following a set of prescribed exercises, and in the first case I treated I attempted this, using a good set of movements which had already been suggested by a colleague in another city. The result was not encouraging, however, and I should not again waste time in the effort if it was possible to get even moderately skilled assistance. The necessity for obedience to the word of command, which calls for close attention and for movements which come to have something of the character of involuntary reflexes, is certainly a great help in stimulating both the conscious and the sub-conscious attention and the power of instinctive control.

(5) Finally, there are certain classes of cases which the experience of various physicians has shown to be ill adapted for this sort of treatment. These are summarized as follows by Collins in his excellent book on the "Treatment of Diseases of the Nervous System," page 243. "The employment of this method of treatment is contraindicated in weak, anemic patients and in those who suffer more or less constantly with pains or crises; in cases of acute or subacute tabes, that is, in cases of sudden onset and in which the habitual manifestations of the pre-ataxic period succeed each other rapidly; in patients with tabic optic atrophy, fragile bones and those who have had what is generally called spontaneous fracture or rupture of tendons. When any cardiopathy or aneurism exists the method must be tried very tentatively, if at all. It is not applicable to very obese or arthritic patients, and, finally, it is absolutely contraindicated when there are great laxity of the ligaments and severe arthropathy."

My experience is not sufficient to justify me in supporting or in contradicting these statements, but, in fact, they are not borne out by the history of the two patients whom I bring before the society tonight. The first of these has improved considerably in spite

of a tendency to pretty severe pains in the legs, and the second, whose improvement has been truly remarkable, is one in whom the ataxia developed with great rapidity.

The first patient had been suffering from characteristic pains for many years and from disorder of co-ordination for about two years. This had increased during the six months before he presented himself at the Massachusetts General Hospital to such a degree that he was then almost confined to his chair, though able with the aid of the furniture to get about his room and shop a little. The treatment by training in co-ordination was begun in June, 1899, but was continued for only a few months, and in a somewhat desultory manner, owing to the necessities of the case. This year it has again been resumed. The aim was first to teach him to walk with crutches, then with canes, and this has been accomplished to such a degree that he now goes about with the aid of the former in the neighborhood of his house quite freely, and in the way of exercises he can walk across the room alone. He is still improving. The treatment has been carried out faithfully in the face of considerable difficulty by Mr. Harding, the superintendent of the gymnasium of the Boston Young Men's Christian Union.

The other patient is a much younger man, of excellent general health. The rapidity with which the ataxic symptoms came on is well indicated by the fact that only two weeks before he came to me, supported by a friend on one side and with a cane in the other hand, he had been to several dances, and had walked, in the night, during a snowstorm, four or five miles to his home. He had, in fact, considered himself perfectly well up to that time, though in reality some unmistakable signs of tabes had been already present. Under the guidance of Mr. Wiberg, teacher of medical gymnastics, he devoted himself assiduously to the treatment here indicated, day by day and almost hour by hour, with the result that at the end of three months he was able to walk several miles alone or with the partial aid of a cane. His gait is still ataxic, but he has recently been able to resume his work, which without this method of treatment would have been impossible. I may say, further, that the latter patient and one other have thought that the paresthesias from which they had suffered diminished under the co-ordinatory improvement.

Clinical Department.

TWO CASES OF ABNORMAL SEXUAL DEVELOPMENT.¹

BY GEORGE G. SEARS, M.D., BOSTON.

THE following cases are interesting illustrations of a condition described by recent writers under the head of infantilism, in which more or less complete arrest of development of the genital organs is associated with changes in the economy of a most diverse kind and manifested by gigantism, dwarfism, feminism, muscular dystrophies, or affections of the special senses, but about which our knowledge is still too incomplete for definite classification. In the first, im-

¹ Read before the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, April 18, 1900.

perfect development of the genital organs in a boy is accompanied by dwarfism and feminism, while in the second (a girl) the failure of the genitals to develop is associated with a tendency to gigantism and the assumption of male characteristics. The thyroid gland was not felt in either case.

CASE I. A male, twenty-five years old, but who appeared no more than sixteen or eighteen, was admitted to my wards in the City Hospital a few weeks ago, after an altercation with the police, in which a difference of opinion arose as to whether he had had a fit or was simply drunk. Physical examination revealed an individual not more than five feet two inches in height, but of good muscular development.

The first glance failed to discover the sex. The hair on the scalp was luxuriant in its growth, but the cheeks and chin were devoid of beard. On the upper lip there was a little soft down, but no more than is often seen in women with dark skins. The deep-set eyes, surrounded by dark shadows, and the rather thick lips gave the impression of great sensuality. The voice was somewhat high pitched, but was more becoming to a man than a woman. The hips were broad, well padded with fat, and moulded with well-rounded curves. The penis was small, though not diminutive. It might be described as too large for a boy and too small for a man. The testicles were

nearly spherical in form and about half the normal size. The pubic hair was thick, but grey like that of a woman, with a sharply defined horizontal upper limit. The most striking feature, however, was the breasts, which were of remarkable development, pendulous and of a size more than sufficient to perform the functions for which such organs are presumably adapted. The nipples and areolae were also well developed and the latter were deeply pigmented. His sexual appetite, according to his statement, was normal. He claims that he should have been married some time ago were it not for his diminutive size. He says that he has a brother who has developed on the same lines as himself. In the photograph the deep shadows have given a harder appearance to his face than was really present. The curves of the hips, on the other hand, appear less pronounced, while the very redundant prepuce gives, in the picture, the appearance of greater size to the penis than is really possessed. Examination of the heart showed the presence of a well compensated mitral lesion.

CASE II. A female, twenty-six years old, was admitted June 18, 1898. Her family history was negative. When twelve years old she began to grow mentally dull, and from that time until she was sixteen was troubled with frequent severe headaches often lasting a week. During the succeeding week she slept most of the time. When sixteen years old she states that there was a sudden swelling of the feet which lasted for a short time and then subsided, but the feet and hands then grew very rapidly. She has never menstruated, but has regular monthly attacks of vertigo and weakness. Physical examination showed an individual five feet eight and a half inches tall, weighing 145 pounds. Her face was distinctly Mongolian in type. The cheek bones were high and prominent, the lips rather large, the lower jaw heavy but not prognathous, the nose was normal, the hands and feet were much beyond the average size. The latter required a number nine shoe, while the former would probably need a number nine or nine and a half glove. The bones of the forearm and ankles seemed rather heavy, but the hands and feet themselves were not ill shaped. An x-ray photograph of the hands showed no abnormality except the size. The muscular development appeared normal, but she became easily tired. There was no axillary or pubic hair. The external genitals were those of a girl of ten. The vagina scarcely admitted the little finger, which reached with difficulty a very rudimentary cervix. The ovaries could not be felt. There was absolutely no development of the breasts, and her hips and general contour were those of a man rather than a woman. Her mental development had apparently been arrested with her sexual, for she was very childish and easily led. She was depressed, and frequently expressed a wish to die.

A NEW JOURNAL FOR NURSES.—The first issue of a new journal edited and owned by nurses will appear October 1st. It is to be the official organ of the Associated Alumnae of Trained Nurses of the United States. The editorial staff contains the names of many women who have long been intimately associated with the development of nursing in this country. The general scope of the journal will be to disseminate knowledge of new methods which may be of interest to nurses and mothers.

Medical Progress.

REPORT UPON PHYSIOLOGICAL CHEMISTRY.

BY HENRY F. HEWES, M.D., BOSTON.

Physician to Out Patients at the Massachusetts General Hospital, Boston; Assistant in Chemistry, Harvard Medical School.

THE PHYSIOLOGICAL CHEMISTRY OF ALCOHOL.

THE question of the influence of alcohol upon the metabolism of the human body has been the subject of a considerable amount of investigation during recent years.

To ascertain definitely this action of alcohol in and upon the metabolism of the human body three facts must be determined:

(1) The method of the disposal of alcohol in the body.

(2) The effect of alcohol upon the respiratory metabolism, the metabolism of the non-nitrogenous organic tissue substances.

(3) The effect of alcohol upon the metabolism of the proteids or nitrogenous tissue elements.

The first fact is today definitely and finally determined for us. Alcohol is oxidized in the body. Upon this point the results of all the investigations of recent years are in agreement.¹ The most complete observations prove that of a quantity of alcohol, not exceeding 72 grammes ethyl hydroxide, introduced into the body during twenty-four hours at least 95% to 96% is consumed, the remaining 4% to 5% being eliminated as alcohol.²

In regard to our second fact our knowledge is less settled. The results of earlier investigations were in practical unanimity that alcohol in moderate doses caused a loss of body substance as measured by the effect upon respiratory metabolism.³ More recent results show a lack of uniformity upon this matter. Thus the experiments of Futh,⁴ Vogelius⁵ and Bödlander⁶ indicate that alcohol causes a lessened respiratory exchange, those of Zuntz⁷ and Bjene⁸ that it causes an increased change, while those of Geppert⁹ indicate that the variations observed under alcohol are within the normal limits of variation. Atwater's published observations show in one case (Experiment 7) a loss of carbon under alcohol as compared with a companion non-alcohol experiment (Experiment 8), in the other no variation between the alcohol and non-alcohol experiments (Experiments 9 and 10).¹⁰ A careful critical study of all these researches leads us to conclude that the effects of moderate quantities of alcohol upon respiratory metabolism vary much according to the conditions present. In most conditions it appears to cause a loss of substance.

In regard to our third fact also, our knowledge cannot be said to be absolutely settled. Here, however, our lack of uniformity is much less in evidence

than in regard to our second point. Some discrepancy is found in the results of the several researches of certain observers, but the majority of cases under each observer and the great total majority of cases investigated indicate that alcohol in moderate doses (40 to 72 grammes ethyl hydroxide in twenty-four hours) causes a loss of nitrogen to the body. And the study of the several researches conducted upon men during the last ten years, seven in number, leads us to conclude that the alcohol, though its effect in moderate doses upon proteid metabolism is obviously slight, fails to spare the proteid tissues. Large doses are distinctly prejudicial to proteid metabolism.

This work upon the effect of alcohol upon proteid metabolism in the human body published during this present decade consists of, a research of von Noorden in 1891,¹¹ one by Miura under the direction of von Noorden in 1892,¹² one of Schmidt under Rosemann's direction,¹³ one by Schönesseifer,¹⁴ one by Neumann,¹⁵ one by Stromm,¹⁶ and one by Atwater.¹⁷ Rosemann¹⁸ has shown that all the work upon this subject done previous to 1890 is valueless, owing to the fact that the observers worked with insufficient data.

In von Noorden's investigation upon 3 individuals, a loss of nitrogen under alcohol was observed in 2 cases, a maintenance of nitrogenous equilibrium in 1. The case without loss received a rich proteid diet.

Stromm, in his researches, found that a loss of nitrogen was the rule under alcohol. Exceptions were present in some observations.

Miura made three similar researches upon the following plan: In the first period the subject (himself) was brought into a condition of nitrogenous equilibrium upon a regular diet. In the second period a certain portion of the carbohydrate of the diet was replaced by isodynamic quantities of alcohol (65 grammes alcohol daily). In the third period the regular diet was restored, the sugar again replacing the alcohol. In the fourth period a diet minus both the sugar and alcohol (a reduced diet) was given. Miura's results showed that under alcohol the nitrogenous equilibrium was not maintained, the loss of nitrogen under alcohol equalling that lost upon reduced diet (Period 4). When the sugar was replaced in the diet nitrogenous equilibrium was restored. This research of Miura appears to be the most complete and adequate upon the subject published up to date.

The researches of Schmidt and of Schönesseifer gave results similar to those of Miura.

Neumann claimed that the results of his observations indicated that alcohol spared the proteid tissues of the body. Rosemann,¹⁹ however, has made a careful review of this research of Neumann, in which he proves conclusively that the experiment is inadequate and the conclusion drawn from it by the author unwarranted by the results. We cannot, therefore, accept the testimony of this research in regard to our question in hand.

Atwater has published two researches. In both the

subject received 72.59 grammes ethyl hydroxide daily in place of isodynamic quantities of carbohydrates or of fats. In both researches there was loss of nitrogen under the alcohol as compared with the results under the regular diet. Professor Atwater tells me that further experiments have given conflicting results, in some cases a maintenance of nitrogenous equilibrium under alcohol, in some a failure in this maintenance.

THE NUTRITIVE VALUE OF ALCOHOL.

The question of the nutritive value of alcohol has long been a subject of controversy among physiologists. Liebig, arguing from the similar chemical composition of alcohol to that of the fats and carbohydrate food substances, classed it among the fuel-food substances, and many physiologists have accepted this classification. An equal number of scientists, on the other hand, deny that alcohol has any nutritive value whatsoever in conditions of health.

It is interesting to consider this question in the light of our modern scientific knowledge. According to Voit, a nutriment is a substance which replaces or spares any necessary material of the body. The ordinarily recognized nutriments of the body are the organic foods, the proteids, carbohydrates and fats, and the inorganic foods, as water, sodium chloride, oxygen. These substances all replace similar materials in the body. Some of them, as the fats and carbohydrates, also possess the property of sparing the proteid tissues. Alcohol cannot replace a similar material in the tissues, since alcohol is not a fixed constituent of the body. Its nutritive action — if it possess any — must therefore consist in sparing by its action in metabolism some native tissue material. The review, given above, of the investigations up to the present time upon the action of alcohol in and upon the body metabolism reveals the following facts in this regard: Alcohol is oxidized in the body with the consequent liberation of energy therein. Its effect upon proteid metabolism appears to vary somewhat with the conditions of the organism. As a rule, in the normal individual its use is accompanied by a loss of nitrogenous tissue. In small doses this effect upon proteid metabolism is slight. In large doses it is marked. The effect of alcohol upon the metabolism of the non-nitrogenous organic tissue elements appears to be variable even in normal conditions. In most cases it fails to spare the fats of the body. Its effects in small doses in either direction are very slight.

As compared with the fuel foods which it resembles in its chemical composition we find that if in normal conditions 500 calories' worth of fat or carbohydrate in a diet, under which a man maintains himself in tissue equilibrium, be replaced by an equal calories' worth of alcohol, a loss of nitrogenous tissue will as a rule result. If this alcohol be in turn replaced by the fat the body will as a rule return to its state of nitrogenous equilibrium. That is, alcohol has not, in the general rule, the sparing property upon the tissues of the body possessed by the ordinary organic foods.

Summing up our results we find, then, that alcohol resembles the organic foods in the fact that it is oxidized in the body. It differs from them in that, while these can as a rule in normal conditions be depended upon to replace a given amount of body material, or to spare such material, it cannot be so depended upon.

The results of our scientific researches in regard to the nutritive value of alcohol at present, therefore, permit of our drawing only the restricted conclusion that in the average case it has no such value. The variations present forbid an absolute denial of this property in all cases.²⁹ Since, however, these results show clearly that alcohol either lacks the tissue-sparing property of the regular fuel foods or possesses this property in a much less degree than these, they justify the full and unreserved conclusion that its nutritive value, if it possess any at all, is clearly less than that of any of these substances, and, calorie for calorie, sugar or fat should always be preferred to alcohol. Why the alcohol, producing an equal amount of energy in the body to the fat or sugar, should not be of equal value there cannot be absolutely determined. It is probable, however, that through its well-recognized poisonous action upon the nervous system, some disturbance of metabolism or of the oxidation of the tissues is effected, as a result of which the proteids or other tissue elements fail to get the benefit of the nutritive aid of the alcohol as they do that of the ordinary foods. This fact is in a manner an evidence that this poisonous action of alcohol is present even when small quantities are taken. Else why should not the same results upon tissue metabolism be obtained with alcohol which are obtained with the same quantities of sugars and fats?

Of the existence of this poisonous action of alcohol, even in small doses, upon the nervous system, or upon the body through its effects upon this system, we possess a mass of experimental evidence. Kraepelin, Lombard, Aschaffenburg and others have reported experiments which show that even small amounts of alcohol (doses of 20 to 30 grammes hydroxide) cause diminution in the total capacity of the individual for mental or muscular effort. The work on this subject reviewed by Kraepelin in a recent article includes over 2,000 researches. It is a well proven fact that, though the combustion of alcohol must provide heat to the body, still the action of the alcohol upon the nervous system is such that by the resultant dilatation of the peripheral vessels the body is made less rather than more able to maintain its heat supply under alcohol.

Whether this poisonous action is, as is generally believed, a paralysis of the nerve centres or not, it certainly is present to a greater or less degree in all cases in health, and it is natural to suppose that it is this result which offsets any beneficial nutritive influence which the energy derived from the alcohol might tend to lend to the body.

The variation in the results of the experiments with alcohol quoted may be in part explained by the possession of a greater or less immunity in the subject of experiment to this poisonous action. The sum total of all the results of alcohol upon the body metabolism certainly inclines the unprejudiced student to agree with Horsley that total abstinence has a scientific basis.

THE INFLUENCE OF THE INORGANIC COMPOUNDS UPON THE VITAL PHENOMENA OF THE ORGANISM.

Physiological chemistry has been up to the present time for the most part the study of organic chemistry

²⁹ The property of sparing tissue is possessed by several narcotic substances, as morphia. It would be as reasonable to class this substance among the foods as alcohol, if this property were taken as the distinctive quality of a food.

and of the organic compounds. In the absorption in this branch the study of the inorganic chemistry of the body has been, to a great extent, neglected, and its importance overlooked.

A priori evidence of the importance of the inorganic compounds and of this branch of chemistry in the life phenomena of the body has never been lacking. The large ash obtained from the cells, especially from the cell nucleus, is evidence of the importance of the inorganic compounds in the constitution of living matter. The evidence is clear in botany. We know that iron is necessary for the formation of chlorophyll in plants, although it does not enter into the chlorophyll molecule. Bacteria and moulds form organic compounds by synthesis of the inorganic, thus forming compounds in which the phenomena of life is possible.

The same salts used by the moulds are found in the ash of the nucleus of the cells. And it is a reasonable hypothesis that the nucleus, like these, builds up inorganic substances into organic synthesis, and that in these inorganic substances thus synthesized we have the basis of living matter. And thus in the study of these compounds and their relations to the body processes, we have an important part of the chemistry of life phenomena.

The truth of this hypothesis and the importance of the inorganic salts or their bases in the animal economy has been forcibly brought out by some recent experimental work of Loeb, which shows that slight variations in the inorganic content of a tissue have a decided influence upon its properties, producing changes in these properties having far-reaching effects upon such vital functions as muscular contraction or even development of the ovum.

CHANGES IN THE PROPERTIES OF TISSUES RESULTING FROM VARIATIONS IN THEIR CONTENT OF INORGANIC SALTS.

Loeb²¹ has found that if a tissue, as muscle, be placed in turn in equimolecular solutions of certain substances capable of ionization, as sodium chloride, calcium chloride, potassium chloride, its property of holding or absorbing water is greatly varied according to the metal ion present in the solution used. A muscle placed in a .7 NaCl solution absorbs about 7% of its own weight of water in eighteen hours. One placed in an equimolecular KCl solution absorbs 40% to 50% of water. One placed in CaCl₂ loses 20% of water. The same phenomena are presented if the bromide or iodides of these same metal ions are used. A parallel of this influence of the ions upon absorption of water is found in the case of the Na, K, and Ca soaps. With these soaps it is found that the K soaps bind most water, the Na less and the Ca least. If K ions be substituted for Na ions the soap gains in water. If Ca ions be substituted for Na a loss of water occurs.

Ion proteids.—It thus appears that these metal ions exist in combinations with the elements of the muscle tissue, the proteid elements, as ion proteids in which one ion can be easily substituted for another, as in the soap compounds. That it is the ions which are changed in these alterations and not the whole salt, or electrolyte, is proven by the fact demonstrated in this and further experiments, that the

only alteration in the constitution of the substances as the muscle or soaps involved in this change of property is the variation in its content of particular kind of metal ions, Na or K or Ca.

In the same way, the property of contractility of muscle may be varied.²² Skeletal muscle in ordinary conditions lacking the property of rhythmic contraction at once takes up this property when introduced into a solution of NaCl. It does this, however, only when a certain amount of calcium or potassium salts is present in its tissue. These changes in tissue are observed only under treatment by solutions of substances capable of ionization, not in solutions of non-conductors, as sugar, urea, etc. They occur only in the presence of certain ionizable substances, as sodium, potassium, calcium and magnesium salts, not with all electrolytes.

From these experiments the author concludes that the presence of certain ions, as Na, K, Ca, in certain proportions in the constitution of a tissue, is an important determining factor in regard to the properties of this tissue. These ion salts, or electrolytes, do not exist in living tissue entirely as such, but partly as compounds of proteids, ion proteids, entering into combination not as a whole, but through their ions. These ion proteids are capable of disassociation under simple conditions, the Na ions being replaced by Ca ions, the Ca by K, and so on, with consequent alteration of the properties of the tissue.

The relation of the ion proteids to the normal conditions of the tissues and functions of the body.—In regard to these ion proteids and the effects upon the properties of tissue, Loeb observed further that a skeletal muscle which takes up rhythmic contraction in a NaCl solution, if immersed in a solution of the chlorides of Na, Ca and K in the same proportion as in the blood, fails to take up this property. A muscle, however, which after a period in NaCl solution has finally ceased its rhythmic contraction, is started up again by the addition of calcium or potassium chlorides to the solution. The same fact is true of a living organism (*fundulus*) which, having lost its natural activity under subjection to NaCl, retakes it again if subjected to small amounts of CaCl₂ or KCl.²³ That is, the properties of tissue, as irritability or contractility of muscle, are dependent to some extent upon the association of ion proteids present in or accessible to the tissue. These ion proteids of Na, Ca, K, Cl, etc., exist in certain proportion in a given body tissue or the blood. While this condition is maintained the tissue shows its normal properties. Change this condition by placing in a foreign medium (as an NaCl solution, in which the ions can be freely dissociated and thus an excess of the Ca or K ions of the tissue be replaced by Na) and the property of the tissue is changed, a skeletal muscle, for example, developing the property of rhythmic contraction. These muscles do not take on this property in the body, since the blood contains the ion salts NaCl, CaCl₂, KCl, etc., in proper proportions to keep each other balanced in the muscle. By artificial substitution of ions, however, this balance may be broken and a new balance or property set up. The author confirms these conclusions by a large number of experiments.

If it is true that life and normal properties of tissue

²¹ Loeb: Arch. f. d. ges. Physiol., 1899, Bd. lxxv, S. 303; American Journal of Physiology, vol. iii, No. viii, p. 327.

²² Loeb: American Journal of Physiology, vol. iii, No. 7, p. 327.

²³ Loeb: Loc. cit.

depend upon the presence of a number of various metal proteids, Na, Ca, Mg, in definite proportions, it must follow that pure solutions of one class of ion salts, as, for example, pure solutions of NaCl, are poisonous, for the Na would finally replace all the Ca in the tissues and thus the normal properties disappear. And this proves to be the case. A fundulus which can maintain life in even distilled water soon ceases to act in a pure NaCl solution.²⁴ If, however, Ca and K are added to the solution the vitality returns. That it is the anion, the Na or Ca, which is the essential factor in the changes, and not the cation, the Cl, is proven by the fact that in this experiment chlorides, NaCl, KCl, CaCl₂ are used in all cases. If the Cl were the poisonous agent, and not the Na, then the KCl would not relieve the poisoning.

*Experiments upon the medusa.*²⁵—The regular contractile action of the medusa is maintained by a set of nerve ganglia situated in the margin of the bell. The central portion contains no ganglion system and if separated from the bell will not contract in sea water, though the separated outer portion or bell continues to do so. In a solution of NaCl, however, the central portion at once takes up the process of rhythmic contraction just as the skeletal muscle in the first experiment described. That is, the tissue of the central portion of the medusa does not possess the property of irritability in its natural condition and environment. When, however, its content of ion salts is affected by a change in this environment it takes on this property. The presence of the Ca and K in the sea water prevents this contraction, for the property is at once lost upon the addition of Ca and K ions to the NaCl solution. These phenomena of the medusa are similar to those of the heart. Here the rhythmic contraction under the influence of the ganglia is normal in the environment of the body fluids with their proportions of Na, K, Ca and Mg ions. An isolated heart will continue its action for a much longer period in a solution containing Na, Ca and K than in a pure NaCl solution, for the latter gradually replacing the Ca in the tissue by Na ions soon upsets the proportion of the ion proteids necessary for the maintenance of this property. Hence the value of Ringer's solution over normal salt solution. The value of such mixed solutions is not, however, as generally supposed, due to the stimulating action of the calcium upon the heart, but to the presence of the several salts necessary for the proper interaction of the ions. The sodium is the agent which initiates the irritability, the calcium checks this effect, causing the cessation of the beat, and thus by alternate starts and checks the rhythm is maintained. Remove either entirely and the property is lost.

These observations have led the author to advance the hypothesis that rhythmic contraction of any tissue is a phenomenon of the constant alternate association and disassociation of the ions Na, Ca, K in their proteid combinations and is thus primarily a chemical process, the Na and Ca and K ions replacing each other in turn and thus causing the constant action. In the heart and medusa bell the process is under ganglion control and it is the ganglia rather than the tissue itself which are influenced. In the medusa centre, the skeletal muscle, the embryonic heart

before the appearance of the ganglia, perhaps the chemical process in the tissue itself, may account for the phenomenon. It is not the reception of these ion salts from the surrounding media which is essential to the maintenance of life or a special property, but the possession of them in proper proportions in the constitution of the tissue. For the fundulus lives perfectly in distilled water.

Development of the unfertilized egg of the sea urchin.—Some very striking evidences of influence of inorganic salts upon the vital processes are found in Loeb's experiments upon the development of the unfertilized ovum.²⁶ This author noted (1) that changes in the state of liquefaction or solidification of a tissue might play an important part in the life phenomena of the tissue; (2) that certain ion salts, as Ca or Na, favor coagulation or solidification in tissues, while others, as Mg or K, favor liquefaction.

The latter condition is also influenced by simple concentration of surrounding fluids. Applying these discoveries to the study of the important life phenomena of development of the ovum, Loeb found that simple concentration of sea water effected some division of the sea urchin ovum to twenty, thirty, or even sixty cells. The development never reached the blastula stage, however, the resultant growth being therefore similar to tumors or galls. The same result was obtained by the addition of certain quantities of Mg or K to the water.

From this experiment and by analogy with those upon the fundulus and medusa already mentioned, the author concluded that the constitution of sea water prevented the parthenogenetic development of the eggs of the sea urchin and other animals in whom the eggs require fertilization.

Since acceleration of this development followed influences which promoted liquefaction, it seemed possible that by reducing the agents favoring solidification (the Ca or Na ion salts) or increasing those favoring liquefaction (the Mg or K ion salts) in the surrounding media for a period a parthenogenetic development of the egg of the sea urchin might be accomplished. After various experiments Loeb found that if unfertilized eggs of the sea urchin were exposed for two hours to a solution of 5,000 cubic centimetres of 1% MgCl₂ plus 5,000 cubic centimetres of sea water, and then placed in ordinary sea water, a development of blastulae, gastrulae and plutei occurred as after impregnation by the spermatozoon. Thus it seems proven that the unfertilized egg has all the possibilities for parthenogenesis, the constitution of the sea water alone preventing this phenomenon. The Mg probably acts by liquefying the nuclear membrane and thus starting division. Any salt extracting water from the egg would probably do the same. The spermatozoon probably possesses a double action, (1) a liquefying action similar to the above, and (2) the transmission of the inherited characteristics. The properties are apparently separate; and the Mg ions are apparently able to perform the first property as well as the spermatozoon.

The influence of the electrolyte constituents of the sea water upon the development of the ovum are shown by some experiments of Loeb upon the fertilized egg of the sea urchin. This egg fails to develop an embryo in a solution of a single chloride (NaCl

²⁴ Loeb: American Journal of Physiology, vol. iii, No. 7, p. 227.

²⁵ Loeb: Loc. cit., No. 8, p. 333.

²⁶ Loeb: American Journal of Physiology, vol. iii, No. 3, p. 135, and vol. iii, No. 9, p. 434.

or $MgCl_2$, etc.) or in a solution of two chlorides. In a solution of the three chlorides which the experiments upon the fundulus and muscels had suggested to be the salts most essential to life phenomena (the chlorides of Na, Ca and K) the development of the embryo occurs, though without a skeleton. By the addition of $MgCl_2$ and Na_2CO_3 to this solution the complete embryo with skeleton is developed.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

J. BERGEN OGDEN, M.D., SECRETARY.

REGULAR meeting, Wednesday, April 18, 1900.
DR. H. F. VICKERY in the chair.

DR. G. G. SEARS reported

TWO CASES OF ABNORMAL SEXUAL DEVELOPMENT.¹

DR. J. J. PUTNAM: I have been much interested some years past in studying the subject of infantilism, which I think is too much neglected amongst us. A number of very interesting communications have been made by French physicians, and it is perhaps more common than has been supposed. Infantilism, with tendency to feminism, which generally go together, would express the condition of the first case Dr. Sears reported. One curious speculation it seems to me is with regard to the causes of these states. To a certain extent they can be reproduced artificially or by accident through mutilation or disease of the reproductive organs. I have seen myself one interesting case of that sort following injury of the testicle. A good many are on record and the more common results which follow are classed under the head of eunuchism. Then the very curious phenomena presented by birds are well known. The female birds of certain species, when they pass the reproductive age, assume the plumage of males. The question arises how to classify this change of structure, whether to consider that it is simply due to the withdrawal of some chemical substance such as may be supposed to be passed into the blood from the testicles or ovaries—a sort of internal secretion—or to suppose that the change is one dominated by the nervous system. If the former is true then we have something more or less analogous to what occurs in myxedema, where the removal of a gland is followed by a large number of curious and widespread changes, some of which seem to be to a considerable extent morphological in their character. The comparison between the true cretinism of Switzerland and northern Italy and the sporadic cretinism produced by disease of the thyroid would seem to be something like the relation between the artificial eunuchism and the infantilism and feminism. In the case of the sporadic cretinism the condition can be largely counteracted and made to change back again in spite of its complexity, by the introduction of the thyroid secretion. In the case of the cretinism of Switzerland that is impossible. Similarly one might suppose that the results of castration could be prevented by the introduction of testicular products,

whereas one could hardly expect results of that sort to follow from a similar influence in pronounced feminism or infantilism. It cannot yet be positively asserted that the results of castration can be relieved in that way, but it always seemed to me a very proper subject for experimentation and to a certain extent it has been experimented on in the Harvard Medical School in the past two years.

DR. J. J. PUTNAM presented

NOTES ON THE TREATMENT OF ATAXIC PATIENTS BY CO-ORDINATION EXERCISES, WITH THE DEMONSTRATION OF TWO PATIENTS.²

DR. TAYLOR: I should like to ask what the object of the trunk movements is, as demonstrated in one of the cases?

DR. PUTNAM: I suppose that although it is true that co-ordination is the thing chiefly aimed at, still if one must call a great deal on certain groups of muscles, of which the trunk muscles are pre-eminently important, it is necessary that their nutrition should be in first-rate condition, and it is simply with the idea of developing the nutrition of the muscles most used that these exercises for strength are put in. I think the particular object is that when one is going to call for co-ordination, you want the nervous system and the muscles to be in healthy condition before you start.

DR. GRAHAM: With regard to movements, the larger movements I think should be begun first and later the finer movements come into play. All this is exceedingly interesting and I am sorry so few gentlemen are here this evening to have witnessed it. I notice that Mr. Harding began with the foot movements, and these have done very well, and perhaps his plan was to begin with the movements that were easiest. It is a very good plan indeed, but it seems to me it would be more natural to begin with the larger movements and graduate down to the finer movements; for in the natural evolution of the human being from childhood up, the large and easy motions come first, the more delicate and difficult ones later.

DR. PUTNAM: When any movement of an extremity is made, the first thing that is done is to fix the muscles of the trunk, so that it would seem essential that a patient should be assured of the condition of his trunk muscles as regards strength and capacity for, at least, sustaining balance moderately well.

DR. VICKERY: I should like to ask Dr. Putnam what nerve channels convey the co-ordination in these cases. I suppose the reason this had not been tried before was that people thought the circuit was broken by an irreparable destruction of nerve tissue.

DR. PUTNAM: It seems to me that is just where the error lies. I remember reading many years ago, without getting the moral which the case should have carried with it, the report of a patient who had been treated in several of the German clinics, and was found eventually to have a pronounced and typical condition of sclerosis of the spinal cord, but nevertheless recovered his power of walking to a very considerable extent, so that he was considered one of the cured patients. Again, it has been noted many times that patients who have general paresis at the same time that they have these tabetic changes in the cord do not have, as a rule, as much ataxia as when they had better command of their mental faculties, and the notion has been that they threw themselves more on

¹ See page 232 of the Journal.

² See page 231 of the Journal.

their instincts and without trying to do so much actually succeed in doing more. I have also in mind a young woman with advanced sclerosis, whose legs were in a spastic condition, and she was confined to her chair entirely. Her mother heard a noise in her room one night and found that while still asleep she had walked to the door. On waking her up she had difficulty in getting her back. This case seems to show that we do not need for locomotion anything like the amount of information that we ordinarily get through our nerves, but when wideawake and trying to do the right thing all the time we interfere with our own success because we recognize the defects in our mechanism too much and do not rely in a simple and confident way on what we have left.

DR. GRAHAM: I suppose all the paths of conduction in the spinal cord are not destroyed and the patient has the power to throw his will down through the channels capable of conveying the impulse when a suggestion is made to him that he can do so and so. There must be certain tracts open to convey the influences down, otherwise they would not go. The men who work suggestion often do so to good effect. It is worth the effort and if you do not succeed it does not do any harm.

DR. PUTNAM, in answer to a question as to whether this treatment effected any improvement in the pathological condition, or whether it tended to retard the processes in the cord, said it was his belief that it tended to retard the progress of the disease, inasmuch as the spinal cord and the rest of the nervous system are stimulated to more healthy and normal functions. He supposed one could hardly expect to make a regression in conditions that had already taken place. Sclerosis would remain.

DR. GRAHAM: Dr. Putnam said acute cases do well. I remember a chronic case that was doing well and finally had an acute attack which took him off his legs and then he resumed massage and exercises pretty vigorously. After a while I told him one day he was going to walk without crutches, and he said, "Never." Some weeks later I noticed that he was doing his resistive movements while lying down so well that I told him I thought he could now go without his crutches. He replied that he had been going without them for a fortnight. Evidently he wished me to find out for myself that my prophecy had come true. In chronic cases with an acute attack perhaps we can do more than we expect sometimes.

It is certain that massage and movements often restore lost power of motion, and if in disturbances of central and peripheral origin they do this not only by their local effect, but also, as has been claimed for them, by arousing psychomotor impulses in the function of new associations and combinations, then they are certainly worthy of more consideration than they have yet received.

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

(Continued from No. 9, p. 219.)

SECTION OF INTERNAL MEDICINE.

THE DIAGNOSIS OF RENAL INSUFFICIENCY.

DR. C. ACHARD said that the diagnosis of renal insufficiency formerly rested entirely on a complex of general and functional disturbances, such as uremic

phenomena—dropsies, slight signs of "Brightism," *bruit de galop*, and a summary examination of the urine consisting in the estimate of its volume and density, and the discovery of albumin and casts. Thanks to the simplicity of the investigation, and the long experience acquired with regard to them, these signs still remain the primary condition of every renal affection. But they are better fitted to establish the existence and the nature of the lesions of the kidney than to make known functional disturbances of these organs. The anatomical change and physiological disorder do not always proceed *pari passu*, and on the other hand the functions of the kidneys may be seriously compromised even when the preceding symptoms remain unpronounced. A deceptive appearance of general health is maintained, and a more or less precarious compensation masks the danger—which is nevertheless very real—that threatens the organism. Therefore some complement of the investigation into the state of the function becomes necessary. To this end a whole series of researches has been devised, having for their object the exploration of the urinary secretion, especially through comparing the urine and the blood, by various procedures, clinical (dosage), physical (cystoscopy) and physiological (toxicity). Moreover, instead of studying the product of the spontaneous secretion of the kidney it has been proposed to inquire how that organ accomplishes a work set it to do, consisting in the induced elimination of a foreign substance introduced in a known dose into the organism. Of the methods referred to, only two are sufficiently practical—cystoscopy and induced elimination. The comparative cystoscopy of the urine and the serum which affords knowledge of the number of the molecules without distinction of nature contained in the two fluids indicates the permeability of the kidney combined with the dosage of certain ingredients of the urine, the measurement of its amount, and the estimation of the weight of the body; it appears capable of also furnishing very instructive information as to the state of the renal circulation and the nutrition as a whole. Achard, however, thinks it possible that the ingenious calculations which allow us to draw all those deductions are somewhat wanting in the simplicity necessary for everyday practice. As regards the test of induced elimination which is generally carried out with methylene blue, it enables us to judge within what limits of time, and in what proportion the kidney accomplishes the disencumberment of the organism from the substances for which it serves as the emunctory. Differing in their mechanism, those explorations may furnish somewhat dissimilar indications. It is advantageous, therefore, to combine them. They are interesting in a double respect. First, they constitute a method of study applicable to pathogenic researches, and are suitable for the elucidation of certain obscure points in the domain of theory. Next they have a practical utility, for they confirm by making more precise the data acquired by simple clinical examination, as it is carried out cursorily at the bedside. Sometimes even they suffice for the detection of disorders of the renal function which would have remained uncertain or unknown; this is especially the case in certain cases of interstitial nephritis running an insidious course.

DR. S. LAACHE in his report treated the question

from the clinical and the therapeutic point of view. He took for his starting point the function by virtue of which the kidney is the most important secretory apparatus of the organism for waste matters, liquid and solid, the last being represented chiefly by urea. He referred to renal edemas, *edema fugax*, universal anasarca and the decisive part played by the heart. As regards diagnosis, in connection with which he alluded to the milder form of Bright's disease, he said the researches of Aehard and Castaigne had opened up a new way. Treatment should be by preference prophylactic; but if this was impossible, the well-known principles already followed in the treatment of renal affections should be applied. Special attention should be given to the state of the heart.

TREATMENT OF MUCOMEMBRANOUS COLITIS.

DR. ALBERT MATHIEU, physician to the Hôpital Andral, Paris, said he would confine himself to a summary review of the principal pathogenic and symptomatic indications and the broad lines of treatment corresponding thereto.

(1) Constipation is the rule in mucomembranous colitis; it is often spasmodic. The diarrhea, which is always transient, is the result of a *debâcle* or an attack of catarrhal colitis.

(2) There always exists in mucomembranous colitis a secretory irritation of the mucous membrane.

(3) The syndrome mucomembranous colitis does not occur in its full intensity except in individuals predisposed by a pre-existing neuropathic condition. The colitis tends to aggravate this neurosis and localize it in the abdomen. The same holds good with regard to visceral ptoses. Locally, the neurosis induces hyperesthesia of the walls of the large intestine and disorder of its motility; it is especially a cause of spasmodic contractions.

(4) The general and local conditions very often react on each other in mucomembranous colitis and reciprocally aggravate each other. In treatment both these elements must be kept in view. Disorders of alimentation, attacks of pain, doubtless also auto-intoxication, are a cause of anemia, wasting, sometimes even true cachexia.

(5) Lastly, certain complications, acute dysenteriform or febrile attacks, hemorrhage, etc., furnish special indications for treatment. The constipation is at once a cause and an effect; before everything the removal of this condition must be aimed at; its disappearance is the sign and guarantee of the cure of mucomembranous colitis. In dealing with it measures must be employed that do not increase either the secretory irritation, the pains, or the tendency to spasm. Castor oil, large enemata and belladonna are especially useful. The castor oil should be given in the morning in small doses with the early breakfast; its employment should alternate with that of the large enemata; these should be given at a low pressure, slowly and at a temperature near 104° F., in doses of 1½ to 2½ litres. These enemata soothe the painful and spasmodic irritation of the intestine, bring about the evacuation of material accumulated within it and act as a mechanical antiseptic. Boiled water may be used with a weak solution of biborate or salicylate of soda to reinforce the antiseptic action and a very dilute solution of neutral ichthyolate of ammonia to exert a modifying action on the intestinal catarrh. Care must be taken to avoid everything likely to cause irri-

tation of the bowel; for instance, drastic purgatives, astringent injections, massage in the cases where there is marked hyperesthesia of the intestine or painful spasm of the colon. It has sometimes been recommended that food rich in vegetable detritus—green vegetables, cooked fruits, wholemeal bread, etc.—should be given; in many cases, however, this is not tolerated, and one is obliged to prescribe a regimen that favors constipation but lessens the irritation of the digestive mucous membrane. Enemata of oil are often very useful, especially combined with large enemata at low pressure. Belladonna is often prescribed with success; it soothes pain and antagonizes the tendency to spasm. More rarely one may have recourse to opium and its derivatives. Hot local applications and hot baths have a useful sedative effect; prolonged baths and large hot enemata form the basis of the treatment at Plombières and similar stations. Sometimes in these places ascending douches given at too high a pressure have been abused. It is often also of advantage to act on the general neurosis by the employment of nerve sedatives and hydrotherapy; often the patients are weakened and emaciated and it is necessary to raise the standard of their nutrition and at the same time to prescribe a regimen more appropriate to the state of their digestive canal. The dysenteriform attacks should be treated with enemata of a weak solution of nitrate of silver; the hemorrhages by preparations of hamamelis and large enemata at a temperature of 113° F.

Dr. F. BOAS (Berlin) next dealt with the symptomatology, diagnosis and clinical course of mucomembranous colitis:

(1) By mucomembranous colitis we understand a special catarrhal disease tending to plastic mucous formations of the colon.

(2) In addition to this form, which is the most frequent, there is another much more rare, in which the process manifests itself in paroxysms, whilst in the intervals there is no noticeable malady except constipation; this form is denoted by the term mucous colic.

(3) Lastly, there is a third form which may be designated by the name of artificial mucomembranous colitis; by astringent injections, especially tannin, this form may be induced in persons who are the subjects of colitis, but not in healthy individuals.

(4) The symptomatology of mucomembranous colitis includes constipation, colic, spasmodic atony of the intestines, glairy or membranous masses in the stools, and a general neurotic state; nevertheless, several of the symptoms may be wanting; the only one of them that is almost constant is constipation.

(5) That which alone determines the diagnosis is the existence of characteristic mucous masses; the other symptoms—sensitiveness of the colon, coloptosis, movable kidney and atony of the intestine—at the most can only help to confirm the diagnosis.

(6) It is indispensable that it should be ascertained whether the mucomembranous colitis is an idiopathic condition or a complication; it is equally of great importance to ascertain whether the membranous colitis is of artificial origin.

(7) In regard to the differential diagnosis the only alternative that need be considered is mucous colic; by frequent observations and methodical intestinal injections in the intervals it will almost always be possible to come to a decision.

(8) The clinical course of mucomembranous colitis is absolutely parallel to that of habitual constipation; influences which correct the latter will cause the former to disappear, and vice versa.

DR. JULIUS MANNBERG, physician to the General Polyclinic, Vienna, dealt with the pathogeny and pathological anatomy of enteritis membranacea and colica mucosa.

(1) A distinction must be made between membranous enteritis and mucous colic.

(2) By membranous enteritis is understood a sub-acute or chronic catarrhal affection of the large intestine, accompanied by evacuations particularly rich in mucus.

(3) By mucous colic is denoted a morbid state, of which the special clinical symptoms are paroxysmal crises of colic followed by evacuation of masses of mucus.

(4) It is a question whether the two processes may occasionally be combined.

(5) Each of the two morbid forms of which the only common element is the existence of mucous evacuations has a pathogeny peculiar to itself.

(6) The first form is nothing more than a catarrh of the large intestine characterized by an abundant evacuation of mucus; it has the same pathogeny on the whole as ordinary catarrh of the large intestine.

(7) Mucous colic, on the contrary, has a special pathogeny. In the great majority of cases it rests on a basis of general neurosis (hysteria, neurasthenia), and there is a tendency to consider the disease as an expression of the neurosis. In the exceptional cases where there is no underlying general neurosis the morbid state must be regarded as a monosymptomatic neurosis of the intestine. In addition to this fundamental etiological factor certain occasional factors capable of producing paroxysms must be taken into account. The principal among them are diseases of the genital apparatus (in man as well as in woman), mental disorders, constipation, irritating rectal irrigations, organic diseases of the intestine.

(8) Mucous colic is frequently accompanied by other pathological manifestations to which its production cannot be attributed, but which may be regarded as equivalents of the fundamental nervous element — gastric achylia, nervous dyspepsia, spasmodic constipation, enteroptosis.

(9) The pathological anatomy of membranous enteritis is the same as that of enteritis in general.

(10) As regards mucous colic in the very rare cases in which it has been possible to make an examination either on the living or the dead body no appreciable lesion of the mucous membrane has been found.

PULMONARY EDEMA.

PROFESSOR BASCH, of Vienna, proposed to deal with this question under the following heads: (1) Under what conditions is pulmonary edema produced? What is the nature of the process producing it? (2) What are the secondary consecutive processes? (3) What relation is there between the doctrine of pulmonary edema and that of dyspnea and cardiac asthma? (4) What relation is there between pulmonary edema and muscular insufficiency of the left heart?

(1) The first pathogenic condition of edema is that the capillary circulation of the alveoli should be arrested owing to the elevation of the blood pressure in the left auricle. The second is that the afflux of

blood coming from the right heart, that is to say, from the side of the pulmonary arteries, should be unimpeded. The mechanical consequences of these two conditions are the enlargement of the pulmonary alveoli and increase of resistance in their walls. The enlargement is produced by elongation of the capillary vessels and the increase of resistance by the high tension of the blood in the capillary network. To these two consecutive processes may be added transudation into the alveoli — a natural consequence of the circulatory stasis in the lungs.

(2) The enlargement of the alveoli and the increased resistance of their walls create a mechanical obstacle to respiration, and as a consequence a disturbance in the ventilation of the blood. From this arises a morbid sensation, dyspnea, which is only the expression of the disproportion between the work of respiration and its effect. This morbid sensation becomes intensified proportionately to the increase of carbonic acid which accumulates in the blood as a result of the disturbance of its aëration. It causes an increase of the excitement of the respiratory centres and forced labor of the respiratory muscles. The obstacle increases still more when intra-alveolar transudation is added to the preceding conditions — enlargement of the alveoli and increased resistance of the lungs. There is need to insist on the fact that the transudation alone without concomitant enlargement of the lungs does not hinder respiration so much as is believed. An abundant transudation, if it is associated with a slight pulmonary enlargement and moderate resistance of the lungs, produces much less dyspnea than a slight transudation combined with a considerable enlargement of the lungs and a strong resistance of the alveoli. The persistence of the dyspnea causes an increase of carbonic acid in the blood. The result is death of the heart in consequence of general asphyxia.

(3) The dyspnea and cardiac asthma develop in the prodromal stage of pulmonary edema, that is to say, before the production of the alveolar exudate; but a slight transudation is very difficult to discover by clinical examination, and it is probable that it accompanies both these diseases equally.

(4) Cardiac dyspnea, cardiac asthma, and pulmonary edema have their starting point in muscular insufficiency of the left ventricle, and not merely in primary insufficiency, which is characterized by a low arterial pressure, but also in secondary insufficiency, which is characterized by increase of arterial pressure.

PROFESSOR MASTU'S, of Liège, dealt with the pathogeny of acute pulmonary edema. Edema, he said, is an abnormal accumulation of lymph in the plasmatic spaces. Acute pulmonary edema is only a particular form of it, presenting two peculiar characters, both depending on the acuteness and activity of the pathogenic process and its particular localization. These are, first, the accumulation of the liquid not only in the lymphatic tissue, but also and particularly in the alveolar cavities by transudation through the walls or by rupture of these. Next, the suddenness with which the phenomena show themselves, on which depends the almost uniform clinical symptomatology. The theories of the pathogeny of edema regarded generally are three:

(1) The purely mechanical theory which attributes edema to a notable increase of lateral pressure in the capillary vessels — this should be rejected.

(2) The view of Hamburger and Heidenheim, which considers the formation of lymph as a secretory act of the endothelial cells of the capillary wall and edema as an exaggeration of this function.

(3) The theory of Starling, Winter and Théaulon, which attributes the genesis of the edema to modifications of the osmotic relations between the liquids situated on either side of the vessel wall and to variations in the permeability of this wall.

In regard to the question to be considered two facts are of predominant importance: (a) An active simple non-inflammatory hyperemia of the vessels without hindrance to the flow of the liquid is by itself incapable of producing edema; (b) lesions of the capillary walls entailing an increase of permeability are an important factor of edema. For this reason Masius is unable to admit that acute pulmonary edema has only one pathogeny; clinically it assumes three forms:

(1) Inflammatory edema; here in all probabilities we have to deal with a reflex vasodilatation, circumscribed or widespread, developed under the influence of some casual factor and followed by a direct lesion of the walls by microbes dwelling in the substance of a normal pulmonary parenchyma, a fact demonstrated by one of Masius's pupils.

(2) Stasic edema, which is by far the most frequent. This is the form met with in affections of the heart, especially initial stenosis, in affections of the vessels, — aortitis or arteriosclerosis, — in diseases of the kidney, such as primary sclerosis. The experimental studies on the subject have been numerous, but their conclusions are often contradictory and seldom applicable to human pathology. The fact which appears best established is the production of edema under the influence of an increased pressure in the pulmonary artery dependent on the normal or increased activity of the right ventricle coincidentally with stasis dependent on a parietic or spasmodic inactivity of the left heart. The pathogeny of the edemas included in this group therefore comprises a great variety of factors. One only among these seems to adapt itself to all cases, and so to constitute the basis of the affection; it is the deterioration of the wall of the capillaries of the lung. Thus in chronic aortitis, in the small red kidney there is often an extensive arteriosclerosis and disorders of nutrition which are echoed in the osmotic tension of the plasma as well as on the molecular constitution of the vessel walls. Modifications in the permeability of the walls are in Masius's opinion one of the principal causes favoring edema. On the other hand, many of the affections referred to, especially arteriosclerosis and sclerous nephritis, react on the left heart and singularly diminish its resistance. To explain the suddenness of the accidents, one must invoke occasional factors, such as sometimes irritation of the cardiopulmonary plexus causing reflexly vasodilatation of the pulmonary vessels; sometimes, on the contrary, sudden paresis or spasm of the left heart co-existing with normal or greater contraction of the right ventricle.

(3) Toxic edema, which is known only in the experimental domain. Thus there is an edema caused by the muscarin, cause of which is a cramp of the left heart, combined with a direct action of the poison on the vessels. Again, there is iodine edema, in the pathogeny of which the last named factor is probably of predominant importance.

DR. TEISSIER dealt with acute edema of the lung. He holds that there is a definite clinical entity to

which the name acute edema, or serous apoplexy, of the lung may justly be given. The symptoms are premonitory sensations of tickling in the throat or painful intrathoracic tension, violent dyspnea accompanied by spasmodic and continued cough, soon followed by foamy and pinkish expectoration, a true bronchial froth caused by transudation of blood serum with a rain of fine râles heard over all the edematous region. Teissier has come to the conclusion that primary acute edema of the lung requires for its production a special soil — previous infection (acute articular rheumatism, influenza, the puerperal state, typhoid fever, pneumonia), or intoxication (Bright's disease, and a long way after, alcoholism). Changes in the heart affecting the zones of distribution of the nervous plexuses or ganglions — base of heart, coronary region, left ventricle — must also be given an important place among predisposing causes. The immediate cause of the onset is generally a rapid chill, fatigue or emotion. Under an influence of this kind, a sudden rise of pressure having been produced in the territory of the pulmonary veins, previous changes in the blood facilitating serous transudation and concomitant vasomotor disturbances favoring stasis, edematous fluctuation will be brought about. As interstitial nephritis presents these various pathogenic conditions in the highest degree, it is not surprising that this form of Bright's disease so often presents as an epiphenomenon the syndrome of acute pulmonary edema. Teissier has been able to confirm this view of the etiology by experiments. Acute edema of the lung is more serious from a prognostic point of view than passive and chronic edema, sometimes causing death in a few hours. There are cases, however, in which it may subside spontaneously or metastatically owing to pericarditis or some other visceral inflammation. In general terms the gravity of acute pulmonary edema depends on the degree of renal permeability. When the crisis tends to a fatal issue the disorders of the peripheral circulation become accentuated. Arterial pressure falls more and more, the pulse becomes small, quick and irregular, cyanosis appears and the heart stops in systole, the left ventricle appearing as if tetanised. In regard to treatment, experience has shown the unquestionable utility of bleeding, which, besides relieving the circulation, withdraws a certain amount of toxic substances. Derivatives applied over the nerve trunks and the cardiac plexus are also found beneficial. Atropin, which seemed to be indicated, as it antagonizes the effect of muscarine, has not proved of service. Oxycarbonated nitrite of amyl may perhaps be found useful owing to its vasodilator properties and its marked influence on the contractile energy of the heart. Teissier has in serious cases obtained good results from the administration per rectum of carbonic acid combined with the use of derivatives and wet cupping. Morphine is a dangerous agent, the use of which should be abandoned. In desperate cases puncture of the right auricle and tracheotomy with aspiration of the liquid blocking the larger bronchi have been recommended. But Teissier has had no experience of these measures.

(To be continued)

It is reported in the *Philadelphia Medical Journal* that a certain Almon W. Sargent of Watertown, N. Y., died after taking 440 grains of sulphonal.

Recent Literature.

A Manual of Surgical Treatment. By W. WATSON CHEYNE, M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London; Surgeon to King's College Hospital, and the Children's Hospital, Paddington Green, etc., and F. F. BERGHARD, M.D. and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College, London; Surgeon to King's College Hospital, and the Children's Hospital, Paddington Green, etc. In six volumes. Philadelphia and New York: Lea Brothers & Co. 1899.

The authors' preface well expresses the purpose of this book. "We have ourselves frequently experienced the want of detailed information, especially as regards the after treatment of our cases, and have had to learn the best methods of procedure from experience. Nothing can of course replace experience, but it is often of the greatest advantage to have a detailed record of that of others upon which to base one's work. It is this want that the present work is intended to supply. We have tried to put ourselves in the place of those who have to treat a given case for the first time, and we have endeavored to supply them with details as to treatment from the commencement to the termination of the illness. We have assumed that the reader is familiar with the nature and diagnosis of the disease, and we only refer to the pathology and symptoms in so far as it is necessary to render intelligible the principles on which the treatment is based, and the various stages of the disease to which each particular method is applicable.

"We have purposely avoided attempting to give anything like a complete summary of the various methods of treatment that have from time to time been proposed; to do so would merely confuse the reader. Only those plans are described which our experience has led us to believe are the best, but with regard to these we have endeavored to state exactly and in detail what we ourselves should do under given circumstances. In some cases no doubt several methods of treatment are of equal value, and while we have only discussed at length that which we have ourselves been led to adopt, we have referred shortly to the others."

Volume I consists of the treatment of general surgical disease, including inflammation, suppuration, ulceration, gangrene, wounds and their complications, infective diseases and tumors, and the administration of anesthetics, by Dr. Silk. This volume is filled with many elaborate methods of treatment, some of which are obsolete. There is an uncertainty in the minds of the authors as to the value of asepsis, and some of the clumsy methods which are advocated are not reliable. The surgical pathology is not in accordance with modern knowledge. To many surgeons and practitioners the book will be of real value; it enters into the details of treatment in a satisfactory way.

Volume II consists of the treatment of the surgical affections of the tissues, including the skin and subcutaneous tissues, the nails, the lymphatic vessels and glands, the fasciæ, bursæ, muscles, tendons and tendon sheaths, nerves, veins, arteries and deformities. This volume is of more value than the first. The subject of surgery of the nerves and of the vascular system is very well presented, although many of the illustra-

tions are of no great value. The deformities are not treated according to modern methods. As a whole the volume is very satisfactory.

Volume III consists of the treatment of the surgical affections of the bones and amputations. Fractures are well presented, although many of the splints are antiquated.

The three volumes which have appeared of this "Manual of Surgical Treatment" can be turned to for sound, conservative advice, but not for the modern treatment of today. The work is an ambitious effort and is well done, and while it is possible that the authors do not entirely appreciate the definite advance that has been made in modern surgery, yet the volumes are a real contribution to the art of surgery.

We shall look with the greatest interest for the appearance of the remaining volumes, and hope that the subjects treated will be considered not alone in detail, but more in the light of modern research work.

Surgical Pathology and Therapeutics. By JOHN COLLINS WARREN, M.D., LL.D., Professor of Surgery in Harvard University; Surgeon to the Massachusetts General Hospital. Illustrated. Second edition, with an Appendix containing an enumeration of the Scientific Aids to Surgical Diagnosis, together with a series of sections on Regional Bacteriology. Philadelphia: W. B. Saunders & Co. 1900.

Dr. Warren's "Surgical Pathology and Therapeutics" was published in 1894, and it was generally recognized that it filled a position formerly occupied by Billroth's "Surgical Pathology." It is a very readable book, and the scholarly attainments of the author are shown on every page. It is not sufficiently dogmatic to serve as a textbook.

We are glad that the second edition of the book has been called for, but it is to be regretted that some portions of it could not have been rewritten in the light of recent advances in surgical knowledge. However, it has an appendix "containing an enumeration of the scientific aids to surgical diagnosis, together with a series of sections on regional bacteriology." It is one of the best books on surgical pathology which can be placed in the hands of students.

Atlas and Epitome of Gynecology. By DR. OSCAR SCHAEFFER, Privatdozent of Obstetrics and Gynecology in the University of Heidelberg. Authorized translation from the second revised and enlarged German edition. Edited by RICHARD C. NORRIS, A.M., M.D., Surgeon in Charge Preston Retreat, Philadelphia; Gynecologist to the Methodist Episcopal Hospital and to the Philadelphia Hospital; Consulting Gynecologist to the Southeastern Dispensary and Hospital for Women and Children; Lecturer on Clinical and Operative Obstetrics, Medical Department, University of Pennsylvania. With 207 colored illustrations on 90 plates and 62 illustrations in the text. Philadelphia: W. B. Saunders & Co. 1900.

The work consists practically of a series of plates interspersed with brief text. The latter, though condensed, is good. The plates are the best that we have seen published, more especially the colored ones, which are extraordinarily like the subjects which they represent. The subjects illustrated are well selected and the book is throughout a credit to author and publisher.

PENALTIES OF PROGRESS.

PROGRESS appears to be a matter over which we, as individuals, have small control, in spite of the very palpable fact that we must be ultimately responsible for it. In the mechanical arts the introduction of machinery and labor-saving devices has progressed steadily, although protests from the makers and even the consumers of the final product have at times been loud and vehement. The hand-made article is by degrees, but inevitably, being forced out of existence, and whether we wish or not, we are more and more the victims of mechanical devices. On the whole this is no doubt a benefit rather than an evil, but the matter of interest is that in individual instances, however much we may disapprove, we are quite powerless to resist the tendency.

There is much evidence to show that medicine, even, is not exempt from the tyranny of progress. The last few years have shown a most remarkable increase in scientific devices, which are calculated to substitute machine-made products, as it were, for personal intelligence. No doubt, intelligence is thereby given a broader field for development, and the world at large is the gainer, but the individual unquestionably suffers, in the same sense that laborers in other branches suffer when a new machine is introduced which renders their personal skill superfluous. Not many years ago it would have been thought that medicine would forever be free from this curious phase of progress, and yet if we look about us today we find a state of affairs quite analogous to what has gone on in the various industrial arts. We are gradually substituting mechanical for intellectual means of arriving at conclusions. This perhaps applies particularly to surgery, which in great measure owes its phenomenal development to the fact that it is becoming more and more mechanical, and hence more and more exact. Where fifty years ago skillful and successful surgeons could be counted by tens they are now counted by hundreds. This is as it should be, and shows an advance of which we, as a profession, may well be proud. The causes

are, no doubt, manifold; many of them are too familiar to bear repetition and the others we have no present desire to analyze. What we do wish to emphasize, however, are the possible dangers and drawbacks in such progress. We should possibly have hesitated to present this side of the picture had we not the support of so noteworthy a surgeon as Mr. Treves. In his recent address before the British Medical Association, published in our issue of August 30th, Mr. Treves took occasion to sound a warning note to his professional brethren. In his remarks on the "Surgeon of the Future," he says, after speaking of the tendency toward too radical operation:

One other matter which looms out of the future will suffice to bring this subject to a close. So many have been the artificial aids to clinical investigation which recent science has introduced that it comes to be a question whether the natural acumen of the surgeon will not deteriorate in proportion as he fails to encourage that particular learning which clings to the finger tips of all great diagnosticians. That there will be such a decadence is beyond doubt. The loss is to be deplored, for if there be one point of excellence which stands before all in the qualification of the perfect surgeon, it is bound up in that refined sensibility, that critical perception, that inestimable cunning, which lies in the surgeon's touch.

There is accumulating evidence to prove the justification of this fear. Not long since it was our fortune to hear a surgeon of much eminence say that, after all, diagnosis of certain obscure conditions was becoming unnecessary now that an exploratory operation is so easily and so safely performed. In other words, the mechanical side has been perfected to such a degree that the intellect of the operator may stand in abeyance until the revelations made by the knife inform him of the condition with which he is dealing. It is not our purpose to argue whether or not this is practical surgery, but we are convinced that such an attitude of mind is inimical to the best development of the individual surgeon. The principle is one absolutely fatal to progress in the best sense, even though we admit the paradox that progress alone has made it possible. It is this tendency that Mr. Treves so strongly deprecates. He gives a number of concrete examples. First he mentions the x-rays. The period of irresponsible enthusiasm regarding this means of diagnosis has wholly subsided. The whole subject is now being looked at dispassionately; articles are appearing which point out the possible sources of error in this "exact" means of diagnosis; we are no longer hearing the extravagant claims for the method which the ardor excited by a great discovery at first provoked. Of this Mr. Treves remarks:

A considerable amount of skill is demanded in the examination of complex fractures, of lesions of deep-seated bones, and of injuries about joints. What was to be learned of these troubles once had to be acquired by a tedious manipulation demanding considerable refinement. The surgeon who has now to deal with such conditions can afford to dispense with a prolix examination, and can submit the inquiry to a demonstrator of the Röntgen rays. The skiagraph, although its value is much exaggerated,

embodies a substantial gain, but it is to be discounted by the loss of the great element in education which it is slowly replacing.

We quote, in part, further dangers to which our modern methods are leading :

An obscure tumor — to take another instance — presents itself, and no longer is the surgeon compelled to trust to the acuteness of his inquiry and his patient review of all the physical details of the mass. For what his ready fingers may have learned can be substituted the findings of the exploratory incision, the trochar and the aspirator. Here once more an advantage is minimized by a loss. Or, again, an abdominal swelling is brought under notice. Its features are obscure, but much of the uncertainty of outline can be dissipated by a cultured hand which, with infinite patience and repetition, has learned to construct a reality out of a shadow. It may be said that it is needless to persist in bringing this much elaborated means of inquiry to further perfection since the problem is at once to be solved by an exploratory laparotomy. By such little operation a great advantage is gained, but an opportunity to add to one of the most refined forms of learning is lost. The value of the exploratory incision is beyond question, but among the signs of the times it is impossible not to notice a tendency to resort too readily to this means of solution. The Gordian knot, according to the legend, was ultimately cut, and it is a question whether the sum of human ingenuity would not have been substantially increased if attempts to untie the noose had been more diligently persisted in. In another example, let it be supposed that a suspicious ulcer presents itself for diagnosis. In such case is it well to devote time to a precise and tedious inspection of its edges and to a careful tactile examination of its base, and to check what is discovered by results laboriously gained from like inquiries? Is it not simpler to take a scraping of the affected surface and to submit it to a microscopist, and to thus be spared a method of examination which, although it may not give final results, yet represents an opportunity of furthering a priceless accomplishment? Finally, there are cases which present symptoms hard to interpret at any superficial inquiry. Is it worth while in such to undertake an exhaustive critical research and to submit the whole to a trained judgment? The quest would no doubt develop habits of observation and powers of weighing evidence; but the process is slow, and an inquiry carried out in a bacteriological laboratory will clear up all doubts, and at the same time dispense with the efforts of a cultured sense. Those, therefore, who are concerned with the education of the surgeon of the future would do well to still cherish this ancient power, and to foster a memory of the fact that surgery is, in its very essence, a handicraft, and that in all that he does the surgeon's great endeavor should be to make his own hands self-sufficing.

All this is most certainly true, and worthy of the deepest consideration. As individuals we are undoubtedly losing much that our predecessors possessed, and yet, as a learned profession, we are progressing year by year, and winning a place of universal respect, which our forefathers were far from attaining. Much as we may deplore the tendencies which Mr. Treves so well points out in the passages we have quoted, events will not be turned thereby. The surgeon has been the first to suffer, but there are already indica-

tions that the physician will not be long in following. It is certainly desirable that teachers should do what they can to stem the tide, by inculcating in their students the necessity of dependence upon their own intellects, rather than upon extraneous aids in their art. When this is done, however, we may welcome whatever tends toward greater accuracy, in the belief that such accuracy will not be attained at too great a sacrifice. The range of possible knowledge is, after all, far too great to make us solicitous lest we become merely mechanical. To certain men Mr. Treves's remarks will always apply; to others, and, we trust, the larger proportion, the solution of the simple problems means only the diversion of attention to more difficult questions, which permit of no other than an intellectual solution.

MEDICAL NOTES.

PLAGUE IN GLASGOW. — On September 1st it was reported that over 80 persons were under observation, suspected of having plague. Precautions are being taken to protect outward bound vessels, and quarantine regulations are being enforced against vessels from Glasgow. There is small probability that the disease will gain a permanent foothold.

A NEW ANTITUBERCULOSIS SOCIETY IN FRANCE. — There has recently been founded in France, according to the *British Medical Journal*, a society for the protection of the people against tuberculosis by popular education. It proposes to diffuse a knowledge of the means of preventing the disease by pamphlets, circulars, leaflets, placards, pictures, articles in the newspapers and popular lectures. The president is Dr. J. J. Peyrot, and the committee includes the names of Drs. Armaingaud, of Bordeaux, founder of the Ligue contre la Tuberculose, and other well-known men.

CHOLERA IN SIMLA. — It is reported that the present outbreak of cholera in Simla, India, is one of the most severe on record. The number of deaths has been estimated at 3,000 a week. The epidemic is probably due to the pollution of the scanty water supply during the famine.

THE RUSSIAN MEDICAL SERVICE IN CHINA. — According to the *Medical Record*, the Russian Medical Service is reported to be better than that of the other European nations. The number and good organization of the Russian ambulances should afford, it is said, an object lesson for the other powers. At Moscow twelve new military medical corps have just been organized, and they will shortly start for the East. Each of these corps consists of four physicians, four Sisters of Charity, and eighty-two nurses.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, September 5, 1900, there were

reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 87, scarlatina 18, measles 20, typhoid fever 15.

BOSTON DEATH STATISTICS. — The total number of deaths reported to the Board of Health for the week ending September 1st was 223, as against 189 the corresponding week last year, showing an increase of 34 deaths, and making the death rate for the week 20.7. Of this number 116 were males and 107 were females; 165 were born in the United States, 54 in foreign countries, and 4 unknown; 56 were of American parentage, 143 of foreign parentage, and 24 unknown. The deaths from consumption were 24, pneumonia 12, whooping cough 4, heart disease 18, bronchitis 3 and marasmus 8. There were 9 deaths from violent causes. The number of children who died under one year was 75, the number under five years 101. The number of persons who died over sixty years of age was 37. The deaths in public institutions were 68.

NEW BUILDING FOR CONTAGIOUS DISEASES AT THE NEWTON, MASS., HOSPITAL. — Plans have been accepted for this new and much needed department of the Newton Hospital. The structure will be divided into three separate buildings, 30 feet apart, and connected by roofed passage ways. Beds will be provided for 52 patients, with the possibility of increasing the number should necessity demand. The most modern aseptic methods of building will be used. The pavilions are 118 feet long and 37 feet wide, running east and west. The length of the three buildings together, from north to south, is 172 feet.

UNITED STATES HAY FEVER ASSOCIATION. — The twenty-seventh annual meeting of the United States Hay Fever Association has recently been held at Bethlehem, N. H., where the sufferers from this disorder are accustomed to congregate. Many new members were admitted, and a relation of experiences followed. Whether or not this is good treatment for a disease which certainly has in it a large nervous element would seem to be open to question.

SCHOOL BUILDING REPAIRS. — Considerable improvements have been made in many of the Boston schools, preparatory to the opening of the fall term. A number of the school buildings have been provided with new sanitary arrangements. This work has entailed an expense of \$35,000.

A WOMAN APPOINTED ON THE LYNN, MASS., BOARD OF HEALTH. — Miss Marion Cowan has recently been appointed by the Board of Health of Lynn to be one of its members in the capacity of city chemist.

AGED ONE HUNDRED AND THREE YEARS. — Mrs. Phebe W. Crabbe, reported to be one hundred and three years old, died on August 28th in Boston. She was a native of North Stamford, Conn.

NEW YORK.

DEATH FROM HYDROPHOBIA. — An apparently well authenticated death from hydrophobia occurred at the Harlem Hospital on August 27th. The patient was a lad thirteen years of age, who was admitted August 23d. The remarkable feature about the case was the extremely short period of incubation, which lasted only seventeen days. The bite causing the disease, which was on the nose, was a severe one, and the boy was taken to the Harlem Hospital for treatment at the time, but it was not then supposed that the dog which bit him was rabid, and inoculative treatment was not recommended.

WORK OF THE AMERICAN RED CROSS ASSOCIATION. — The American Red Cross Association began active work in New York on behalf of India famine sufferers on August 27th. Rooms have been taken in the Presbyterian Building on Fifth Avenue, and William Willard Howard is at the head of the special committee having charge of the relief work. Later it is expected to send agents to India to put into practical execution the plans of the association.

PROVISION FOR TUBERCULAR PATIENTS AT BELLEVUE. — The completion of a new ward for the insane at Bellevue Hospital will render possible a much more adequate isolation of patients suffering from tuberculosis than has heretofore been possible. They will have a separate ward

Miscellany.

THE SO-CALLED "POISONED BULLET."

G. H. MAKINS, consulting surgeon with the Field Force in South Africa, writes to the *British Medical Journal* as follows regarding the so-called poisoned bullet:

"For some months past the wax-coated bullets employed by the Boers and discovered amongst captured ammunition have been a source of both interest and anxiety, particularly to the lay mind, in South Africa. To the evil action of these suspected missiles many a case of suppuration and cellulitis has been ascribed. By this time the appearance of the cartridges may be familiar to many of your readers, but to such as are not a short description may be of interest. It has apparently been the custom both by the Boers and some ammunition manufacturers to coat the bullet with a layer of wax, I believe on the theory that the missile in consequence takes the rifling more readily, while at the same time the lubrication preserves the grooving of the barrel from wear by friction.

"The wax coating of the various bullets I have seen differs in tint. In the older large leaden bullets a white wax has been employed, and the wax remains uncolored except where fouled by contact with dust. Many cartridges I have seen have had a coating of white wax applied which apparently from age, and perhaps the conditions under which they have been stored in hiding, has acquired a brownish tinge.

"Of the green-colored bullets I have seen two varieties; in the first and less common, white wax of some

kind has been applied both to the bullet and brass case of the cartridges, and probably from exposure to damp the latter has acquired an incomplete coating of verdigris, which has become irregularly diffused into the wax coating; in the second and more common variety a green-tinted wax is employed in the original coating; cases of cartridges treated in this way are numerous. As to the composition of this wax, I am unable to furnish any information, but in support of the innocuousness of the process I may only first repeat the opinion I expressed on a former occasion, that the surface of the bullet clearing its passage through the grooves of the rifle is almost completely renewed, only the extreme tip and base being untouched, while the velocity with which the missile is started is such as to make it probable that the tip itself would be cleansed by the flight through the atmosphere. This view as to the cleanliness of the surface of the bullet has been most thoroughly confirmed in the case of the coated ones by an experiment performed by Captain Mitchell Wood, at Capetown, as long ago as last March. A green-coated bullet fired by the Manser rifle was made to traverse a book of white paper, and then bury itself in a bank of sand. As a result, when the book was examined no trace of the green wax was found on the margins of the perforation in the paper, and the casing of the bullet itself, although somewhat split, was perfectly clean and white. The complete disappearance of the wax is no doubt partly to be explained by the heat generated during the passage of the bullet through the rifle, which, although insufficient to cauterize the tissues, is yet great enough to fuse the wax, and in part to the actual scraping of the surface by the rifling of the barrel."

THE INTERNATIONAL MEDICAL CONGRESS.

A VALUED correspondent writes us from Paris, under date of August 15th:

"The Medical Congress has seemed to me a success in every way, comparing it to the Berlin Congress, the only other I ever went to. With the Sorbonne and École de Médecine as the places for the meetings and the exposition for a side show, a few thousand doctors more or less are easily handled. The number of papers was large, and, judging from my section, they were of good quality. The entertainments by the President and Minister of Instruction were free from what was so unmedical in Berlin, and were out-of-door *fêtes*: of course there were a number of dinners.

"Paris is crowded with provincials and I should judge fewer strangers than were expected. The city is dirtier than I ever saw it and it is absolutely *bourgeois* everywhere, but otherwise the same, only larger. The exposition is one big *foire* and the temporary buildings are extraordinary stucco *affiches*, crowded without taste or proportion, but full of assertion. The permanent buildings, Palais des Beaux Arts and Petit Palais, are better, but absolutely without reserve.

"The exposition itself is a wonderful collection of merchandise, for the pictures and statues are chiefly France's annual output in art, with those of foreign nations trying to compete. The pictures are of course fine. Coquelin in 'Cyrano' is excellent, but they say the divine Sara in 'l'Aiglon' is for the provincials.

"I saw Dr. J. C. Warren the other day, when he was presented to the French President as a delegate of the congress. He wore in order of the Cincinnati. Dr. Weir, of New York, wore a splendid decoration—the order of Venezuela, won by operating on the 'Boss' of Venezuela."

THE DUST PROBLEM AND ASPHALT PAVING.

JUDGING from the following remarks in the *Medical Press* regarding pavements, the problem is a vital one in Great Britain as well as in America: "Although in this country we are accustomed to hear much of the drawbacks attending the employment of asphalt for paving our roadways it cannot be seriously contested that it offers many and serious advantages. First and foremost there is a comparative freedom from dust, and dust we know is one of the most potent agents in the dissemination of certain diseases. Then, again, it can be readily cleansed by the aid of water without giving rise to dust, and without the substitution of foul mud, which once again became reconverted into dust after a brief period. Lastly, there is a reduction in the noise, asphalt-paved streets being quiet compared with the growl of vehicles passing over macadam and the roar over granite blocks. We are assured too—though this is hardly within the scope of our remarks—that it is more economical and effects a great saving in the wear and tear of vehicles. From a medical point of view its great and incontestable advantages lie in its freedom from dust and ease of cleansing. Wood paving, if even more noiseless, is more costly, wears out more quickly, and hardly admits of local repair, it generates a highly irritating and dangerous dust, and in hot weather gives out a very disagreeable odor, recalling that of an ill-kept stable. With the advent of the motor car the objection raised to asphalt on the ground of the insecure foothold for horses which it affords under special atmospheric conditions will cease to have much weight."

HOSPITAL STATISTICS.

At the recent meeting of the Association of Hospital Superintendents, as reported in the *New York Medical Journal*, T. Sutton, of Detroit, read an interesting statistical paper on the growth and development of hospitals in the United States during the past three years. He stated that during the past three years about \$245,000,000 has been spent in the United States in the erection and equipment of new hospitals, in enlarging and improving old hospitals and in general expenses. Over 1,000 new hospitals were built during that time, a gain of 65%. The approximate cost of these buildings was \$50,000,000. There are now about 2,500 hospitals and asylums proper in the United States, which employ about 65,000 persons in various capacities. The hospitals pay yearly in salaries about \$23,332,000. Over 1,600,000 patients are annually treated and 37,500 physicians attend them. Probably the most interesting part of hospital management is the purchasing of supplies. The amounts of various staple articles

used in all the hospitals are appalling. The author gave the following figures: "There are, during the year, 112,000,000 dozen eggs used, 165,000,000 pounds of butter, 68,000,000 pounds of coffee, 8,000,000 pounds of tea, 332,000,000 gallons of milk, 285,000 barrels of flour, 550,000 barrels of sugar, 1,148,000,000 pounds of fresh meat and 2,000,000 pounds of oatmeal. In all of the hospitals there are 300,000 beds."

Obituary.

JAMES HENRY ROBBINS, M.D.

THE Fellows of the Norfolk South District Medical Society, wishing to express their love and esteem for their deceased colleague James Henry Robbins, M.D., have adopted the following memorial:

"Dr. Robbins has been in active practice of his profession in Hingham and its vicinity for the past twenty years. He has been an active and valued member of this society from its organization and has successfully filled the offices of censor, councillor and president. The interests of this society were very dear to him, and nothing but the most urgent professional engagements prevented his constant attendance at its meetings. Nor was he simply a listener and observer. A man of broad and deep culture, thoroughly informed on the lines of his profession, and also an authority in the broad fields of literature and art, gifted by nature with a wonderfully retentive memory, his words were fraught with the wisdom which comes from long study, accurate observation and deep thought.

"His comrades will miss his warm word of greeting and the cordial handshake, emblematic of the heart which always beat warmly for his professional brethren. There still remains the blessed memory of old friendship and the example of a life conscientiously devoted to the profession which he loved and honored.

"The members of this society offer to his bereaved family their heartfelt sympathy in their deep affliction. To that larger circle who have lost a skilful physician and a warm and sympathetic friend, condolences are extended at this time.

"Resolved, That this memorial be entered upon the records of the society, that a copy of the same be forwarded to the family of Dr. Robbins, and that a copy also be furnished for publication to the *Hingham Journal* and to the *Boston Medical and Surgical Journal*."

METEOROLOGICAL RECORD.

For the week ending August 25th. in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Melrose . . .	14,721	3	1	33.33	—	33.33	—	—

Deaths reported 2,182; under five years of age 988; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 769, diarrheal diseases 420, consumption 215, acute lung diseases 131, diphtheria and croup 42, typhoid fever 38, whooping cough 22, cerebrospinal meningitis 14, measles 9, scarlet fever 6, erysipelas 2, smallpox 1.

From whooping cough New York 8, Boston 4, Baltimore 3, Washington, Providence and Worcester 1 each. From cerebrospinal meningitis New York 7, Boston and Somerville 2 each, Baltimore, Washington and Worcester 1 each. From measles New York 5, Boston 3, Holyoke 1. From scarlet fever New York 3, Worcester 2. From erysipelas New York 2. From smallpox New York 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending August 11th, the death rate was 20.3. Deaths reported 4,520; diarrhea 1,006, whooping cough 84, diphtheria 65, measles 64, scarlet fever 23, fever 21.

The death rates ranged from 11.2 in Burnley to 26.8 in Preston; Birmingham 23.7, Bradford 12.2, Bristol 14.3, Croydon 13.5, Gateshead 15.7, Hull 20.7, Leeds 24.4, Liverpool 26.3, London 20.5, Manchester 22.6, Newcastle-on-Tyne 19.6, Nottingham 22.8, Sheffield 26.1, Swansea 15.8.

APPOINTMENT.

HOWARD T. SWAIN, M.D., has been appointed physician to out patients at the Boston Lying-in Hospital.

RECENT DEATHS.

JOHN FRANCIS RYAN, M.D., M.M.S.S., died in Roxbury, September 1, 1900, aged twenty-nine years.

FRANCIS STEPHEN MILBURY, M.D., of Brooklyn, N. Y., died on August 29th. He was a native of the Province of New Brunswick, and was in the forty-fourth year of his age.

Original Articles.

THE RADICAL CURE OF HERNIA.¹

BY J. COLLINS WARREN, M.D., BOSTON.

At a period when the leading practitioners of medicine of the present day were just beginning their career, any operation for the radical cure of hernia was regarded with suspicion. Attempts had indeed been made by surgeons in good standing to remedy this affection by an operation, notably Wood, of London, but all methods were crude and based upon incorrect theories, and the dangers of sepsis were correspondingly great. Even as late as the eighties the operation was still in the hands of the pioneers and it was not until the beginning of the present decade that the subject may be said to have been placed upon the basis of a routine surgical procedure.

During this later period it has become an integral part of the hospital surgeon's work, and the laboring classes are beginning to appreciate the fact that the operation for a radical cure is pretty sure to be successful and a blessed relief from the discomforts and uncertainties of the truss. Old traditions, however, still prevail amongst the laity and even amongst a large proportion of medical practitioners. The patient who can afford to pay for it is still very generally advised by his physician to buy a truss. After an irksome apprenticeship he finally becomes broken to harness and accepts the discomforts of his new life as a matter of course. It is true that such advice is often followed by excellent results and in rare instances (the truss makers say in about 2% of the cases) a radical cure is effected. But in a very large number of cases the patient feels he has discharged his duty by buying a truss and putting it on—somehow—and there his responsibility ceases. The contents of the hernia are kept within the abdominal cavity part of the time, but at the end of a day's work are not infrequently found held securely in the sac below by the pad. In this way the hernia continues to grow until some complication brings both patient and doctor face to face with the situation.

It is for the purpose of endeavoring to impress upon the profession that the time has come when even the most conservative practitioner should revise his opinions as to the treatment of this disease, and should recognize the advantages of the operation for a radical cure, that this paper has been written.

The following series of 98 cases comprises both those operated upon in the Massachusetts General Hospital and in private practice between the years 1888 and 1900. It includes 74 cases of inguinal hernia, 7 cases of femoral hernia, 12 cases of umbilical hernia and 5 cases of ventral hernia. This includes all cases operated upon up to February 1, 1900.

Great pains have been taken to obtain the subsequent history of all cases operated upon over one year previous to the above date and answers have been received from 62 cases. In 4 of these reports death is stated to have occurred from other causes, the subsequent history of the hernial cicatrix being unknown. This leaves 58 cases from which to obtain definite information as to the question of recurrence.

A careful analysis of all the 98 cases has also been

made to determine the relative merits of the animal tendon, catgut and silk sutures and their probable bearing upon the permanent healing of the wound.

A separation of the cases into two groups—those in which the operation was performed between the years 1888-1894 and those between the years 1895-1900—shows in a striking way the marked change which the improvement in aseptic technique has brought about in the prognosis of the healing of the wound.

	1888-1894	1895-1900	Total
Clean	14	53	67
Septic	16	9	25
Clot evacuated	1	3	4
Drained	1	0	1
Doubtful	1	0	1
Total	33	65	98

It will be seen that prior to 1895 there were 33 cases operated upon, of which 16, or 48%, were septic; whereas, after 1895, of 65 cases operated upon, 9, or 16%, only were septic. The term "septic" includes all cases that did not heal by first intention throughout the wound, with the exceptions mentioned below. The slightest infection of a stitch wound would place it under the above heading. As a matter of fact there were but one or two cases in the whole series in which sepsis became a formidable complication, as is shown by the fact that in none of the 98 cases was there a fatal result.

The term "clot evacuated" includes those cases in which first intention was not obtained, not because of sepsis, but owing to the formation of a blood clot which prevented close approximation of the surfaces of the wound.

The healing of a wound by first intention depends, of course, largely upon the perfection of the aseptic technique, but in hernia especially the sutures become an important factor in the solution of this question. There is more or less tension in the wound at the time of application of the sutures, and this is increased when the patient is in the upright position. The tendinous character of the tissues bounding the lines of suture is not so well adapted to healing as softer and more succulent structures. For this reason surgeons usually have strong preferences for different kinds of suture material.

The following table is therefore submitted with a view to comparing the results obtained in groups of cases in which different kinds of materials were used for this purpose. The sutures were made of silk, catgut, animal tendon (kangaroo) and silkworm gut. In a few cases silk and catgut were used simultaneously and silk was also combined with animal tendon. Wire was also once used with animal tendon.

	Clean.	Septic.	Clot evacuated.	Doubtful.	Drained.	Total.
Silk	49	10	1	0	0	60
Catgut	15	12	1	1	1	30
Silk and catgut	1	3	0	0	0	4
Silk and animal tendon	1	0	0	0	0	1
Wire and animal tendon	1	0	0	0	0	1
Silkworm gut	0	0	2	0	0	2
Total	67	25	4	1	1	98

It will be seen from these figures that in the case of silk but 17% of the wounds were septic, but that in the case of catgut septic conditions were found in 40%.

Inasmuch as the great majority of ruptures were cases of inguinal hernia, it is, perhaps, more instructive to make a study of these in a class by themselves.

¹ Read before the Surgical Section of the Suffolk District Medical Society, April 4, 1900.

The operation employed in the majority of cases was that of Bassini, although Macewen's method was given a test in the earlier cases. The latter proved complicated and the life of the sac was endangered or destroyed by the quilted suture. After having the entire sac slough out in a case which bid fair at first to heal without sepsis I decided to abandon it. Bassini's method I arrived at by a gradual process of evolution, and found, when I reached a method which corresponded as nearly as possible with Nature's arrangement of the parts, that my operation was identical with that known as "the Bassini."

Studying now the causes of sepsis in these operations we find, first, that the period at which they were performed has materially affected the result. As one might naturally expect, the more favorable results were obtained subsequent to 1895. From 1888 to 1894 there were 10 clean and 11 septic cases, 1 of which was drained and healed by second intention, and 1 in which the clot was evacuated, making in all 23 cases. In the 51 cases which were done after 1895 there were 41 clean cases and only 8 septic cases. In the other 2 cases clot was evacuated. The suture also seems to show important differences in its influence upon the healing of these wounds. In 25 cases in which catgut was used there were 12 clean cases and 11 septic cases, whereas in 42 cases in which silk was used 37 were clean and only 5 were septic. Going back now to the series of 23 cases previous to 1895, we find that of the 11 septic cases catgut was used in 9. The 8 septic cases found in the group operated upon after 1895 are thus made up: 4 catgut, 3 silk, and 1 silk and catgut. Here the results are more nearly even and show the obvious better preparation of catgut than was done in the earlier period.

The above analyses seem to show pretty clearly that better results were obtained with silk than with catgut as suture material. The ease with which silk can be sterilized, its superior strength, and the greater facility in handling it are qualities which make it, in my opinion, far preferable to catgut. The disadvantages claimed for it by Bull and Coley are the slow absorption of the material and the danger of the suture working out through sinus formation long after operation. This complication was, undoubtedly, a common one in the early days of the operation, but a careful search into the records of those of my hospital cases in which the wound had healed by first intention, and their subsequent history, has failed to reveal such, and I have had no experience of this kind in private practice. It seems probable, therefore, that the improved methods of sterilization and the improved aseptic technique of the operation have reduced this danger to a minimum. It is also highly probable that the finest grades of silk are as easily absorbed as chromicized catgut.

Coming now to the question of recurrence, we find 58 cases in which an answer was obtained one year or over after the operation. Forty-five of these were cases of inguinal hernia, and in 7 relapse was reported. This gives 84% of cures. There were 3 cases of femoral hernia with no recurrence; 2 cases of ventral hernia with no recurrence, and 8 cases of umbilical hernia with 3 recurrences.

Comparing the inguinal hernias operated upon prior to 1895 with those since that date we find in the former case there was 69% of cures, and in the latter

92% of cures, showing that improved technique had an important influence upon the result. This is shown by an analysis of the causes of failure.

In septic wounds there was 35% of recurrences; in clean wounds, on the other hand, there was recurrence in 7.6% only of the cases. In cases sewed with silk the recurrence amounted to 9%, but in cases sewed with catgut it was as high as 30%. This difference between silk and catgut is shown still more strikingly if we compare the inguinal cases alone with one another. In 18 catgut operations there were 6 recurrences, or 33%, whereas in 23 operations in which silk alone was used there was no recurrence.

If we take now as a standard the operations for inguinal hernia performed since 1895, we find that the percentage of perfect results (92%) is nearly as good as that laid down by Bull and Coley in their last article in the "International Textbook of Surgery." These authors give 95% as a fair estimate of the cures in Bassini's operation.

The age which is most suitable for operative treatment is a point about which many surgeons differ. In children there is always the chance of cure by the truss. The percentage of cases cured in this way is vastly greater than in adults. After the age of twenty-one years the chances of cure fall to the very small percentage already mentioned.

The station in life is a factor of considerable importance. Children who have parents capable of exercising constant and intelligent care can be treated mechanically, but when the chances of such care are uncertain, or there are any complications, the operation had better be advised.

Bull and Coley state in a general way that fifty years is the age limit for operation in the adult, but hospital experience will hardly bear out this view. It is in hospital practice that we see a larger number of hernias, usually of large size, in individuals above this age. They are as a rule patients who are unable to afford a proper truss, or do not understand how to apply it intelligently. It is precisely in this class that an operation seems to hold out hope of great relief. The table here submitted shows that many are operated upon who had passed that limit, and the recurrences reported were all under fifty years of age.

Age.	Inguinal.	Other hernias.	Total.
0-10	4	3	7
10-20	13	3	16
20-30	15	0	15
30-40	13	5	18
40-50	8	8	16
50-60	11	1	12
60-70	2	3	5
?	2	1	3
Total	68	24	92

In 6 cases there were double hernias.

The following figures give the ages of the 7 cases of relapse reported: 43, 42, 38, 33, 27, 16 and 15.

Bull and Coley say: "If a rupture is sound at the end of one year after operation, there is a reasonable prospect of permanent cure, while if it remains well for two years, the chances of relapse are exceedingly small." An analysis of 38 "perfect" cases shows: 1 case was reported cured eleven years after operation; 1, nine years; 2, eight years; 2, seven years; 4, six years; 2, five years; 7, four years; 5, three years; 11, two years, and 3, one year after operation. In all the cases of inguinal hernia in which relapse was

reported recurrence took place within one year after the operation. It seems, therefore, reasonable to assume that if a patient continues well for one year he may regard himself as cured.

There are some points in the technique of the operation which experience shows worthy of mention. The sac, after being dissected from the cord, should be carefully emptied of its contents, and a continuous suture should be passed through the neck before the sac is excised. A ligature may slip and give rise to hemorrhage from some of the numerous vessels adherent to the outer surface of the peritoneum. The wound should be treated precisely like any other wound in the peritoneum. In some cases the sac is hard to find, but it should always be carefully sought for and removed, as this is one of the most important features of the operation.

When the omentum is small in amount it can be returned into the abdominal cavity, but when there is a large quantity of omentum it is more or less matted together and elongated at the point involved, and may become a source of danger when returned, being liable to form a band capable of producing intestinal obstruction or of facilitating a return of the hernia. There is little danger of hemorrhage if the various clusters of vessels which supply the part to be removed are tied separately. In very large hernia the amount of omentum removed is sometimes enormous; but such hernia, although they seem formidable to attack, present in reality no greater technical difficulties than the smaller hernia.

The sutures with which the skin was brought in apposition were silkworm gut in the majority of cases. This material can be used as an interrupted suture or as a continuous buried suture. The latter gives a somewhat more esthetic result, and theoretically is less liable to produce stitch abscess; but I cannot say that I have seen any special advantage in its use.

Great pains should be taken in the preparation of the skin before operation, as this is a region unusually hard to sterilize. I am in the habit of using the permanganate-oxalic-peroxide of hydrogen process, and of repeating the washings after the dressing has been removed at the time of operation.

Cases of large umbilical hernia are usually observed in stout, elderly women who have borne several children. There is then considerable danger of strangulation. At first these hernia contain only a small nodule of omentum, which acts as a sort of plug to the opening in the sac to which it is usually adherent. As the hernia grows, a knuckle of intestine is liable to be pushed into the sac behind the omentum after some unusual exertion, and this gives rise to an attack of colic for which the patient seeks relief. This pinching of the bowel occurs often, but in very large hernia strangulation is rare. Inflammation and suppuration may, however, be one of the complications of umbilical hernia. Permanent relief from colic is usually obtained by the intelligent adjustment of a truss, and in very fat or elderly patients it is better to try this form of treatment, as recurrence after operation is much more common in this than in other forms of hernia. I believe, however, that increased experience will bring with it a decision to resort to the operation more frequently. In 1 case I have succeeded in curing an enormously large hernia after the second operation. The time of election is in early adult life while these hernia are still small.

Umbilical hernia in children are almost invariably cured by the truss.

I have had 2 cases of congenital umbilical hernia into the cord.¹ In one case the contents of the sac was the liver, in the other a large loop of intestine. Both cases recovered from the operation and one was permanently cured. The other infant had a very small umbilical hernia when last seen, which will doubtless in time disappear.

Congenital inguinal hernia is not always healed by the truss. When a young man, in the neighborhood of twenty years of age, applies for treatment of this affection, the operation should be advised.

In non-descended testicle we find the organ usually in the inguinal canal, and the question arises as to whether or not it should be removed. The patient usually objects strenuously to the removal of the organ, and there is no particular harm in leaving it, but after operation it usually atrophies and slowly disappears. These hernia should not be operated upon in youth, as the testis may eventually descend into the scrotum, and the hernia disappear.

I wish to express my indebtedness to Dr. R. B. Greenough for the preparation of the statistics of these cases.

ACTINOMYCOSIS.¹

BY CHARLES ALLEN PORTER, M.D., BOSTON.

At this session last year several cases of actinomycosis were reported by different surgeons. Increased interest has been aroused on the subject by a very thorough analysis of all the American cases by Dr. John Ruhrah, of Baltimore, in the second volume of the *Annals of Surgery*. In that article 62 cases are reported, and 5 more added in a subsequent appendix.

Since the last meeting here, 11 cases have been found at the Massachusetts General Hospital, 1 of primary rib or lung disease, with general actinomycotic pyemia—in this instance the diagnosis was only made at autopsy—and 10 of the maxillary form of the disease. Drs. Homans, Mixter and Balch, 1 each, and 6 of mine were all discovered in the Out-Patient Department. The fact that these 6 cases occurred within three months, and 4 within a week, is, I think, sufficient evidence that the affection cannot be a rare one among us, and that many cases are overlooked.

I will limit myself to the maxillary form, and briefly speak of the histories of these cases.

Though actinomycosis has been considered a relatively rare disease, it seems more probable that it is one which is very commonly overlooked. In its clinical aspects there is little that is characteristic. Though the course of the infection may make the surgeon suspicious, examination by microscope and culture is essential for a positive diagnosis.

The object of this paper is to attract your attention to the possibility that a proportion of the cases ranking as alveolar abscesses may be due to this specific organism, and by a few briefly reported cases to give you an idea of the disease as it affects the mouth, jaws and neighboring regions in man. Statistics of the relative frequency of this disease are really of little

¹ Read before the Surgical Section of the Suffolk District Medical Society, April 4, 1900.

¹ Transactions American Surgical Association, 1893.

value. In 1892 Illich, of Vienna, gathered only 42 cases in man from all that were at that time reported. Dr. Ruhrah, of Baltimore, has published an article in the *Annals of Surgery*, 1899, in which he has collected all the American cases, 72 in number, occurring in all parts of the body. In the past two years I have been especially interested in this subject, and during eighteen months' work in the Out-Patient Department at the Massachusetts General Hospital I have found 8 cases of actinomycosis in about 60 so-called alveolar abscesses examined, and 4 cases have been found by other surgeons. Six cases of mine have occurred within three months, and 4 within one week; so we may conclude, I think, that the disease cannot be one of great rarity.

I will pass about some photographs of these cases, as well as a painting of the pus from the abscesses, which shows very well the gray or grayish-yellow granules which may be found in typical cases.

CASE I. J. C., age thirty-two, coachman, entered Out-Patient Department, November 7, 1899. Five weeks ago noticed a small lump on inner side of right lower lip; this grew larger, without marked pain, until two weeks ago, when an inflamed area was evident on the outside of the lip. There was a red inflamed nodule, size of a five-cent piece, on right lower lip; the surrounding tissue was indurated to the size of a quarter; fluctuation was evident in the centre; no communication with mouth. Under cocaine a small incision was made on the inside of the lip; about one-half a teaspoonful of seropus escaped, with numerous granules, which showed the typical appearance of actinomycosis under the microscope. Simple excision was advised, but the patient would consent only to a thorough curetting through an external opening; the surface was disinfected with peroxide and painted with iodine and packed with iodoform gauze. In two weeks the small wound had almost closed, with considerable induration at the base. No colonies could be found in the discharge.

December 15th, five weeks after operation, only a soft red scar remained; no induration. Whether this infection started from the inside of the mouth cannot be determined; there were no carious teeth, nor any history of a wound. Many sections of the tissue were examined but no colonies could be found.

CASE II. W. C., age forty-five, entered Out-Patient Department, August 29, 1899. Two months ago stuck a toothpick under his tongue, and could not remove the whole of it. One week after this the submaxillary region began to swell. The swelling varied at different times; no pain; tenderness slight; no interference with talking, eating or swallowing. There was an indefinite swelling about the size of a lemon in the submaxillary region on the left side. The skin was somewhat edematous. At the bottom of the swelling was a small area where fluctuation could be made out; over this the skin was slightly reddened. There were no glands in the neck. Under cocaine a small incision was made. Seropus escaped, with a few grayish granules, which proved to be actinomyces.

On the following day a more extensive operation was done under ether. Incisions were made about the involved skin, and the whole submaxillary region thoroughly cleaned from below upward. The submaxillary and a few lymphatic glands were removed with the mass. Just under the jaw a dense fibrous

cord was found, extending upward to the floor of the mouth. Within this connective-tissue tube lay the remains of the toothpick lost two months before. This was removed, the flaps loosely sutured, and an iodoform wick placed to the top of the wound. Under daily packings and iodine the wound healed solidly in five weeks, without evidence of recurrence. This case shows well the common connection of actinomycosis with some foreign body.

CASE III. F. L., age sixteen, schoolboy, entered Out-Patient Department, November 9, 1899. Teeth have always been bad; has had five removed from upper jaw. Second left molar decayed for some time; two months ago a small lump appeared inside mouth about root of this tooth; this gradually grew in size, without pain, and appeared on the outside of the jaw ten days ago as a reddened semifluctuant swelling the size of a quarter, surrounded by a hard and firm border. Inside the mouth a distinct induration could be detected, as of a connective-tissue sinus leading from the tooth to the external swelling. There was moderate trismus; no pain; tenderness slight; no glandular enlargement. A small incision revealed several granules of actinomycosis. Under ether the edges of this wound were excised and the walls of the cavity cut away with scissors; the base thoroughly curetted and painted with iodine. No sinus could be found connecting with the tooth. The wound granulated slowly, but was healed by December 7th, when there appeared on the outer side of the ear a small fluctuating area. This was opened and curetted. In the pus no colonies could be found after very careful search.

December 20th. The induration within the mouth still persisted, but by January 2d this too had disappeared, and there was then no sign of recurrence.

At operation many granules were obtained, which varied in size from a pin head to three times that size. There was considerable soft, cheesy-looking material in the wall of the cavity. Pure cultures from this case were finally obtained by Dr. Wright.

CASE IV. W. W., age thirty, entered Out-Patient Department, November 13, 1899. Five months ago noticed lump inside mouth opposite last molar teeth on right. This grew larger, and becoming very painful he went to Emergency Hospital, where it was lanced, with immediate relief. In another month abscess reformed and face swelled to the eye. After lancing no further trouble until three weeks ago, when he noticed a "pimple" on outside of jaw about the middle of horizontal ramus; this grew larger, with much swelling and pain. On entrance, the whole right side of the face and eye were much swollen; trismus was well marked; over the centre of the jaw was a reddened, fluctuating lump, the size of an English walnut. The surrounding tissues were very hard and brawny. This induration ended very abruptly and gave place to general edema; within the mouth was well-marked induration from first molar to wisdom tooth.

Under cocaine the external abscess was opened and very numerous granules, a hundred or more, poured out in thin seropus. Some of these were unusually large, almost the size of a very small split pea. Under ether the infected skin was freely removed, with the base of the cavity down to sound muscular tissue. Again no sinus connecting with the teeth could be found. Closer to the jaw a small cavity was found containing thick, yellow, stinking pus. The

wound was dressed as before. Within three days the swelling had much diminished and the trismus was much less.

December 10th, almost a month after the operation, the face suddenly began to swell again. Under ether an abscess to the outer side of the upper jaw was evacuated within the mouth. The pus was foul and contained many soft, yellow granules, appearing somewhat like actinomycosis, but under the microscope proved to be masses of mouth bacteria and *leptothrix buccalis*. Just back of the scar of the first operation a "crater" was found, which when opened allowed the little finger to enter nearly to the lower jaw outside of the last molar; the sinus was lined with very dense connective tissue and contained foul pus. Here one or two disorganized colonies of actinomyces were found.

January 5th. In three weeks the swelling and most of the induration had gone; the sinus was healed and the patient in much better condition.

March 20th. Patient reported; no signs of recurrence; no induration; mouth opens normally; about the wisdom tooth there was some exuberant gum.

In this case the focus of the disease was probably not reached until the last operation, and mixed infection undoubtedly played an important rôle. Pure cultures were finally obtained by Dr. Wright from the granules in spite of the contamination.

CASE V. H. G., age twenty-two. On October 10, 1899, five weeks ago, without toothache or external wound, a small swelling formed below the middle of the right lower jaw; there was little pain. It had grown considerably in size within the past few days. The skin was hardly reddened over it, but fluctuation was evident. From the upper part of the tumor a firm cord runs upward for half an inch; the whole mass was movable and seems rather superficial. Temperature 101° ; pulse not elevated; teeth not carious. Incision showed the streptothrix colonies. Under ether the diseased skin was excised and the whole mass removed, with a small portion of the submaxillary gland, which was adherent to it. No trace of sinus leading to mouth could be made out. The excised mass showed a central cavity surrounded by dense tissue, here and there infiltrated by small areas of grayish-red granulating tissue, containing the pearly granules; some of these show slightly darker centres. In the contents of the cavity were several black bodies, which under the microscope were seen to belong to some beetle. Whether this entered through the floor of the mouth and gradually worked down, or came from the tonsil or esophagus, is not clear. A man could hardly get the body of a beetle into a wound of the face without knowing it. No history of any external wound could be obtained. Evidently the fungus entered with the beetle. The wound was soundly healed in two weeks.

CASE VI. M. C., age twenty, laborer, entered Out-Patient Department, November 14, 1899. Three years ago patient had similar lump in the same place, which broke and went away. This swelling began a week ago as a little round, painless lump. Below horizontal ramus of right jaw was an oblong red swelling, size of a peanut, which fluctuated in the centre. From this to the level of the lip the tissue was firm, swollen and boggy. There was also some swelling over and about the submaxillary gland. Trismus was well marked; could barely open mouth one-fourth

inch. On opening the small superficial abscess, a thin, seropurulent discharge appeared with several colonies; at a deeper level 3 drachms of foul pus was found, without actinomyces colonies. Apparently diseased tissue; everted thoroughly and cavity drained after painting with iodine. In a week the edema had disappeared and the trismus was much less. Examination of the mouth showed that the three right molars were all carious. In three weeks wound soundly healed; normal motion of jaw.

March 18th. Two months afterwards another abscess rapidly formed, which Dr. Balch opened and Dr. Wright found to contain two typical granules.

March 25th. Dr. Balch kindly asked me to see the case again. Trismus was well marked. At the site of the old scar was a small sinus from which a little bloody serum came. The scar was dense and firmly adherent to the anterior edge of the masseter. Under the jaw were two enlarged glands. Under ether I excised the mouth of the fistula with the surrounding skin. The wall of this sinus was surrounded by very dense connective tissue, which ended abruptly at the cavity, which was lined with soft, flabby granulations. Following along this sinus an inner cavity was found, the inner wall of which was formed by the periosteum of the jaw. From this another small sinus could be traced backward for an inch and a half to the base of the second molar tooth. The whole sinus and cavity was excised and the three carious teeth removed; iodine and gauze drainage; few stitches. In the centre of the second molar tooth a fairly characteristic granule was found, but on microscopic examination this proved to be a mass of mouth bacteria. The sections have not yet been examined. The case is now entirely healed.

CASE VII. J. S. six months ago broke left lower jaw just anterior to masseter muscle. The bone healed, but whenever he got drunk he had soreness and swelling at the point of fracture. Once a little pus was discharged into his mouth. He came to hospital with a small fluctuating abscess just under the skin. On opening this the typical granules were found. The abscess cavity was thoroughly excised; no bare bone was found. In two weeks the wound was healed. There has been no recurrence. The natural diagnosis was necrosis after fracture: yet no dead bone was found, and thorough excision stopped the spread of the disease.

CASE VIII. P. S., age forty (Dr. G. W. W. Brewster's case). For two years has had trouble with left molar teeth, which are carious. Had had several small abscesses opened inside the mouth. In January left side of face swelled and large abscess was evacuated. Since then there had been intermittent purulent discharge into the month, and jaw had been sore. Patient entered on April 15th. The left side of the face was much swollen; he could hardly open the mouth; in front of the masseter muscle, over the horizontal ramus of the jaw, was a reddened fluctuating abscess, the size of a walnut. This was opened and found to contain the granules.

Under ether the abscess cavity was dissected out and a sinus found leading back to the second molar tooth; here a small piece of dead bone was found. The sinus passed between the jaw and the masseter muscle, which was also involved in the disease. The whole cavity was thoroughly everted and cauterized, and the bad tooth extracted. In ten days the patient had

only a small sinus left, which was granulating in a healthy manner.

This case is a good example of the recurrent abscesses which occur until the disease has been thoroughly removed.

The infection seems to enter most frequently near a carious tooth, or is carried in by a foreign body through the mucous membrane of the mouth or pharynx. The process is essentially subacute or chronic, and the disease tends to advance by a sinus towards the skin. Infection is rarely pure, but is usually mixed with ordinary pyogenic organisms or mouth bacteria. It is rarely painful and the accompanying pain, when it occurs, is due, I think, to the mixed infection. Clinically and under the microscope the disease is characterized by the formation of an unusual amount of dense connective tissue, which ends more or less abruptly at the periphery and infiltrates the adjacent muscle or fat. In the jaw the bone itself is rarely involved in human actinomycosis, though it may be thickened from periostitis.

It would seem that this surrounding connective tissue could later become infiltrated by the growth of the streptothrix and break down. In all the cases I have examined the inner wall of the cavity shows a clearly cut line of demarcation between the connective-tissue wall and the lining—flabby, soft, grayish-red granulating tissue. Glandular enlargement was conspicuous by its absence, and when present seemed to be due to mixed infection. Metastasis seemed to occur through the blood current and not by way of the lymphatics. In serious cases the disease may progress down the neck, into the antrum or through the base of the skull. Though a definite connection cannot be always demonstrated, it would seem that a sinus at one time leads from the original site to the superficial abscess. In M. C.'s case, for example, at the last operation such a sinus was found leading directly to the carious tooth.

Trismus, though often present, is no more characteristic of this disease than of other inflammatory affections, though if the masseter were involved in the dense connective tissue, the jaw would probably remain stiff for a long time.

It is rarely possible, I think, to make a clinical diagnosis of actinomycosis; recurrent abscesses, without necrosis, chronic, painless, subcutaneous abscesses, about the jaw, evidently not connected with tubercular glands, would lead to a suspicion of this disease. If these fluctuating areas were surrounded by especially firm and hard connective tissue, and a sinus could be felt under the skin, if there was little edema and swelling, perhaps a probable diagnosis could be made.

Examination of the discharge is of great assistance, but the mere presence of the so-called "sulphur granules" is not by any means conclusive, and no case should be considered as one of actinomycosis without competent microscopic examination. Small, round masses of fibrin or tubercular debris sometimes simulate a colony, in the mouth or adjacent regions. Round masses of mouth bacteria, or leptothrix buccalis, occasionally appear very like a true colony. Even under low powers the resemblance is very similar. Dr. Wright has kindly photographed for me one of these masses, removed from M. C.'s tooth. It presents a radiating arrangement, but under a higher

power is seen to consist of vast masses of bacilli and the large, thick, non-branching filaments of the leptothrix buccalis.

In examining for actinomycosis, gauze sponges which absorb the discharge should not be used. All bleeding, when possible, should be stopped before opening the abscess wall. Unless badly contaminated, actinomycosis pus appears usually as a clear, perhaps blood-tinged, slightly syrupy seropus. Placed on a cover glass, the granules vary in size from a millet seed to the head of a large pin. They are usually round with a clear-cut periphery; the color is gray or grayish yellow, often suggesting a small pearl; the centre is not rarely somewhat darker. The surrounding pus is non-adherent and the granules can be readily removed alone. Fluid should be examined *at once*, for these granules are found with great difficulty when the blood has clotted.

With reference to treatment, two facts speak strongly, I think, for the self limitation of the disease in the majority of cases:

(1) Though it cannot be a rare affection, few cases enter the hospital with advanced actinomycosis of the jaw, and it seems therefore certain that many recover after simple incision of the abscess, and even through a natural rupture of it.

(2) It is surprising to find, on microscopic examination of sections, how infrequently the colonies are found in the walls of the abscesses, though the pus contained many granules. The surrounding connective tissue probably proves an effective barrier to the spread of the disease.

Simple opening, curetting and drainage have proved sufficient in many cases; though recurrences may be frequent, healing eventually takes place. Where possible, excision of the inner half of the abscess wall or sinus is the best treatment. The danger from swallowing the granules, where the discharge empties into the mouth, is hard to estimate. Certain cases of generalized disease in the lungs, intestinal tract, liver, etc., occur in which the organism gained entrance through the food, or was swallowed, and therefore the surgeon should aim at making *external* drainage. This question is often a difficult one to decide. On the one hand, he wishes to avoid a scar on the face, especially in women; on the other, he wishes thoroughly to eradicate the disease; for with recurrence the scars would probably be worse than from a single, thorough and clean operation. The individual case and the severity of the infection must determine the choice between curetting and cauterizing the cavity with tincture of iodine or carbolic acid and a more radical excision. Iodide of potash, in doses of 20 grains three or four times a day, has distinctly influenced some cases for good, and should be used in connection with the local treatment.

Finally, I trust that when your attention has once been called to actinomycosis of the jaw, you will be enabled, through this brief paper, to make an early diagnosis of the disease, and I feel sure that a careful examination of chronic alveolar abscesses will show that the streptothrix actinomycotica is the cause of perhaps one-eighth or one-tenth of them.

PLAGUE IN GLASGOW.—On September 10th an additional case of bubonic plague had been reported in Glasgow. The total showed 16 cases and 112 persons under observation.

FOUR CASES OF ACTINOMYCOSIS.¹

BY JOHN C. MUNRO, M.D., BOSTON.

CASE I. Hyman G., clothing dealer, forty-five years old, was seen in consultation with Dr. A. L. Flanders and Dr. Henry Jackson, to whom I am indebted for notes on the history of the case. In March, 1899, the patient had had a cough with expectoration for several months, and for two weeks an irregular fever, pain in the back, and increasing shortness of breath. Coarse râles were heard over both backs and in the left lower back, about the region of the eighth to tenth ribs, an area of dullness was found with diminished respiratory murmur and absence of fremitus. A diagnosis of bronchitis with limited encapsulated pleurisy was made. No tubercle bacilli were found in the sputum. A week later the patient was reported to have been cyanotic for a short time; the expectoration continued, but no change in the physical signs was found. The fever continued for a fortnight longer, up to the first week in April, when bulging of the chest wall in the area of the dullness appeared, with marked pain. The chest was aspirated several times, but only blood was obtained. Examination at my first visit on April 5th showed a smooth, hard, slightly tender tumor below the angle of the scapula, flat on percussion and solid in feel. A diagnosis of sarcoma or local empyema was made.

Under ether on the following day the tumor was incised, and beneath the outer layer of muscles a small abscess containing thick pus was opened. The upper edge of the ninth rib was found denuded, and leading thence was a small sinus from an encysted empyema about an inch and a half in diameter. A section of the rib was removed, the cavity, whose walls were rough, thick and sarcomatous in feel, with much granulation tissue, was curetted out and packed with gauze. The operation caused no shock, but the general condition did not improve, the cough continued, the temperature often ranged as high as 105° or 106°, and in the course of a few weeks the patient died. The actinomycetes were found in both the curettings and the sputum.

CASE II. Allen G., a carpenter living in Prince Edward's Island, was referred to me by Dr. Muttart, of East Boston, in February, 1900. There was no clue to the original source of infection. In July, 1899, he fell, striking his right cheek against a board, but thought nothing of it at the time. In August he noticed that he could not open his jaw, and a month later a swelling appeared either in the parotid region or at the angle of the jaw. This swelling grew slowly until December, when it increased rapidly. Examination showed a hard, projecting tumor of the right side of the face, softened in the centre, where the skin was reddened. No connection with the bone of either jaw could be found. The induration extended from the ear to the lower edge of the ramus, and nearly to the angle of the mouth, and upwards nearly to the lower edge of the orbit. No enlarged glands were to be felt. Diagnosis lay between a malignant tumor of the parotid, for which he was referred to me, or actinomycosis. The soft area was opened and examination of the pus revealed the actinomycetes. Under ether, Dr. Bottomley curetted and dissected out all suspicious tissue, the cavity being

treated with tincture of iodine, peroxide and iodoform packing. Two weeks later there was a suspicious local recurrence, and again under ether I curetted thoroughly and dissected off some of the masseter, and probably part of the parotid gland. This wound healed slowly, and by the end of March there was a small granulating area from which saliva escaped irregularly and in decreasing amounts, and the patient returned home to his physician.²

CASE III. Robert W., a carpenter thirty-five years old, entered Dr. Bolles's service at the City Hospital on February 19, 1900, with a fracture of the lower jaw at the symphysis and in the molar region on the left side. Two years and eight months ago his jaw was broken in a fight, at the symphysis and on the left side; it healed in seven weeks under treatment at the Massachusetts General Hospital. Five months ago he worked about horses with the "scruffles" (circular ulcers of the legs and nasal discharge). Ten days ago, while drunk, he fell 10 feet, striking on the left side of his face and jaw.

On the following day he was referred from the Massachusetts General Hospital to the Dental School, where a splint was fitted which he did not wear. The day before entrance to the City Hospital he began to have marked pain and swelling of the face, and at entrance there was a swelling from the ear to the symphysis, and 4 inches down the neck, red, tender and indurated. Two days after admission the abscess was opened under ether inside the mouth, and a few suspicious granules were seen. Six days later a diagnosis of actinomycosis having been returned from the pathologist, and the abscess not draining well, he was given ether again and the abscess thoroughly curetted from the outside. No characteristic granules were seen at this operation, though the fungus was found in the scrapings. Ten days later he was discharged to the Out-Patient Department with a sinus, considerable discharge, moderate induration, diminishing in area, and ability to open the jaw half an inch. Up to present time there has been no recurrence.

CASE IV. Emma L., a healthy college girl from the middle of the State, came to Drs. E. C. Briggs and Hardy for an alveolar abscess of the left lower jaw. Two weeks before she came to Boston, a local dentist had extracted a carious molar tooth for tooth-ache, but without relief, the swelling increasing, so that when I saw her with Dr. Briggs in February last there was a soft, fluctuating abscess along the lower edge of the jaw with moderate induration of the surrounding tissues. In order to avoid a sear if possible, under ether I opened and curetted the abscess through the mouth, evacuating an ounce or two of pus that was not at all suspicious of anything beyond a simple alveolar abscess. Dr. Hardy carefully drained and cleaned out the cavity daily, but the bluish induration of the tissues did not soften down satisfactorily. Tuberculosis and actinomycosis were considered, but the former seemed much more probable from the family history and the failure to obtain any clue to the inoculation of the ray fungus. On March 8th, under cocaine, I opened the pocket from the outside and curetted out considerable granulation tissue. In the scrapings one granule was seen that looked suspicious, and that led us to have a pathologi-

¹ Read before the Surgical Section of the Suffolk District Medical Society, April 4, 1900.

² After complete immunity until August following, the disease reappeared in the neck.

cal examination by Dr. Mallory, who reported the actinomyces. The patient then entered the City Hospital, and under ether all suspected tissue was curetted and dissected and preserved *in toto* for examination, one colony being found. Ten days later a small area at one edge of the wound that looked suspicious was curetted out, and three colonies were found. Five days later another similar looking spot was thoroughly cleaned out, but no colonies were found. The patient is still under treatment, but without any evidence of further relapse.

The pathological examination was made in each case by Dr. Mallory.

All the face cases showed invasion of the soft tissues only, the bone being free. In none of them could any definite trace of the original infection be found.

All the cases were given iodide of potash, and the wounds treated with peroxide, tincture of iodine in full strength or solution, and packed in iodoform gauze until all evidence of presence of the fungus had disappeared.

TENDON SUTURE.¹

BY EDWARD S. HATCH, M.D., BRIGHTON, MASS.

D. J. A. entered the Carney Hospital, as an accident case, on August 28, 1899. This afternoon he plunged his right hand through a window and cut the anterior part of his wrist on the ulnar side. When he entered the hospital he had a cord tied around his arm which was not arresting the hemorrhage.

I applied a rubber tourniquet, and after having the patient etherized I cleaned up the cut and parts surrounding it with a solution of chlorinated soda, then soap and water, and finally with corrosive. The cut was about two inches long. This cut I enlarged, both vertically and horizontally, and found the following structures divided: The tendons of the palmaris longus, flexor carpi ulnaris, and flexor sublimis digitorum. The ulnar artery and the median nerve were also found cut. The ulnar nerve was cut about halfway through its structure. The tendons of the flexor profunda digitorum were slightly nicked. The tendons and nerves were united with fine silk sutures. The ulnar artery was tied, both the proximal and distal ends. No attempt was made to unite the tendon sheaths. The skin wound was united with interrupted silkworm-gut sutures. Sterile gauze was put over the wound, and the arm was put up in anterior and posterior splints, with fingers semiflexed. The operation took two hours and fifteen minutes, and the patient was put to bed in good condition.

August 29th. Patient feeling well today, has little pain. Says he begins to have feeling in fingers.

September 2d. Dressing and splints removed, wound healed by first intention. Sense of feeling not so good over the distribution of median nerve.

September 8th. Dressing removed. Sensation slowly returning. Fingers can be moved a little. Stitches removed.

September 12th. Patient is able to move all fingers slightly. Sensations better than on previous days. Hand put up in anterior posterior splints. Anterior splint shortened.

September 16th. Movements of fingers improved. Hand dressed as before. Patient left the hospital. Is to be treated as an out patient.

September 25th. Movements of fingers improving. Hand put up in more extended position.

October 2d. Sensations and motions gaining. Hand put up still more extended.

October 18th. Motions improved. Anterior splint left off today.

October 28th. Splints all removed. Not any pain. Motions better. Massage started today to be continued three times a week.

November 13th. Fingers gaining in extension all the time. Only a very light dressing put on.

February 15, 1900. Patient has had massage three times a week up to this time. Extremely good flexion and extension; good sensations. Massage discontinued.

April 4th. At the present time the patient has normal flexion and extension, with normal sensation over the distribution of the ulna and nearly normal sensation over the distribution of the median nerve. It is interesting to note in this connection that the nails of the thumb, first and second fingers, died and then grew again, so that now on these fingers he has half of the dead nail, which is being thrown off, and also half of the new nail. He can separate the fingers and draw them together again with perfect ease.

A METHOD OF TEACHING PRACTICAL MEDICINE.

BY THOMAS F. HARRINGTON, M.D., LOWELL, MASS.

SINCE the publication of an article presented to the American Medical Convention at Columbus, Ohio, in June, 1899,¹ entitled the "Philosophy of Sickness," several articles have appeared in the medical journals, either elaborating my ideas or suggesting similar methods of reaching the same end, therefore I thought it best to explain in detail what I had merely given in outline, in order that the profession could judge rightly of the value or uselessness of my method of giving medical instruction to classes at the medical schools. It is not my intention to criticize existing methods as practised in the best medical schools today, nor to attempt to offer a different plan for doing the work, but simply to give the views of one who has felt the shortcomings of the modern schools, and who has given considerable thought to the correction of the same.

I believe the courses offered in the best schools in this country are capable of giving the greatest amount of good to the largest number. It is not the addition of new courses, but rather the appreciation of the value and possibilities of the present courses that I would like to emphasize. Much of the criticism of today on the method of teaching medicine is due to a misunderstanding, both on the part of the teacher as to the needs of the student, and on the part of the student as to his duty in the work. It will be my object first to try to clear, to a degree at least, some of the causes leading to this state. That there is a science of medicine as well as an art seems to have been overlooked by those who are protesting against existing methods, and it is to the neglect of this funda-

¹ Read before the Surgical Section of the Suffolk District Medical Society, April 4, 1900.

¹ Boston Medical and Surgical Journal, August 17, 1899.

mental principle that many errors and much confusion are due.

It is an inherent quality of the human mind to form some idea of what is brought to it by the senses. If the mind has been stored with the right knowledge, the ideas formed will be true ones, but the absence of such knowledge, or of any knowledge at all, will not prevent the mind from forming some view; hence arise new theories or hypotheses founded on what is called "experience," all of which tends to overthrow the science of medicine and substitute in its place the art of healing. The science of medicine is not productive; it cannot change; it has its fixed laws, dealing with the conditions of health and disease, the best means of preserving the same, the action of certain agents, etc. When we begin to put these fixed principles into practice, with the view of producing certain definite results, we go from the science to the art of medicine. Now it is evident that the first can be learned only through study, while the proficiency of the art is founded on practice, having of course a good intellectual basis. The science of medicine fixes established principles in the mind of the student about which he can group other facts. It shows him that there is a fixed relationship between certain things, and that it is to the learning of this relationship that he should bend his mind, rather than to the creating of new relationships. The student should know that mere acquaintance with many theories, discoveries, etc., is worse than no knowledge at all, for it is not real knowledge, and is more apt to be dangerous to him, for it gives him false and misleading views of things. The science of medicine disciplines the mind to a certain end; it forms the habit of order and method, of grouping and comparing new facts learned, and adding them in their proper place to the fixed principles; it teaches the student to think, reason, and express himself logically; it stimulates in him the desire for obtaining information for himself, and gives him the means to do it; it forms the habit of judgment, a most necessary quality in the medical profession. The science of medicine teaches caution, exactness, analysis and discrimination, teaching the student to distinguish what he knows from what he does not know. It is evident therefore that no bedside teaching, however extensive, no library, however useful in itself, no laboratory work, however conclusive, can take the place of methodical and laborious teaching.

While I claim all these advantages for the necessity of teaching the science of medicine, I recognize that in these progressive days it is impossible for the medical student to keep pace with the advances made, and give the necessary time to other studies. Dr. George B. Shattuck put the condition aptly at a recent Medical Alumni dinner thus: "Medical science is expanding by geometrical progression, and the possibilities of the individual who seeks to follow it by an arithmetical progression." By the method of instruction which I am to suggest, it is possible, I believe, to give the student the basis of medical science, supply him with sufficient advanced ideas to keep him up to date, and at the same time give him a greater amount of *practical* knowledge than he now receives, leaving the more advanced part of the science for his study, if he is to be other than a general practitioner. To criticise lectures and recitations, with the argument that the time taken up in their behalf might be better

spent, is a misunderstanding of what a lecture should be. In the first place, a lecture is not intended as an oratorical display nor the rehearsing of funny anecdotes; the business at hand is of a more serious nature, and has for its object the understanding of the patient and his condition, with the end in view of bettering the same. This demands on the part of the student more than mere *passive* attention; he must be actively and actually a party in the work; he must not only be taught but he must learn; he must grasp the material offered, and use it as his own, even going more than half way for the same. There should be the freest and closest communion between the teacher and the student, both remembering that it is the slow, patient, persevering, routine method, making good each step taken, which is of the greatest benefit. While there are exceptions, which should not be overlooked, the primary object of medical education is to produce *practitioners* of medicine, and with this end in view most of the schools have provided courses capable of accomplishing that result.

I believe there should be a sharp line of distinction between the courses of the first two years and those of the last two years spent in a medical school. During the former I would have medical science taught in all its entirety, while the last two years should be the practice of medicine rather than the preparation for that practice. The student should get in his last two years, and not before then, just that work which he gets in private practice. It is to the production of this class of men that I would offer the method of giving clinical instruction herein described, as follows:

Cases are assigned to students in regular order, and a record kept of each case, with the name of the student in attendance; these cases can be either ambulatory cases (out patients) or hospital cases (in the wards); the student sees his patient as often as he thinks necessary, learns the history of the patient from birth, family history, past illnesses, nervous temperament, worry, occupation, environment, etc.; learns thoroughly the subjective symptoms just as the patient describes them; observes all objective signs of health and disease, — pulse, temperature, respirations, bodily weight, etc., — after which the student makes his own diagnosis, prognosis and treatment of the case, making use of lectures, demonstrations and textbooks, as needed, to assist him. Now the student is prepared to come before the professor and the class: here the *teacher* receiving the *student* in the same way and asking him the same questions that he would a patient in his private office, learns from the student (acting as patient) all that which he might learn from the patient himself, were he present; then the teacher gives his diagnosis and treatment to the student in the same way as he does to patients in his private office. The student at this point ceases to be the patient. Then would follow a discussion by the students on the question of diagnosis, pathology, therapeutics, the teacher correcting false conclusions expressed by the students, and referring them to the latest literature on the diseases under discussion. And then follows the professor's advice as to diet, clothing, climate and mode of living, the exercise ending with the student (patient) making known to the class the diagnosis and treatment of the teacher as given to him at the end of his consultation with the teacher. By a systematic grouping of the cases by

the teacher, a lecture could be given on the various groups by the pathologist, therapist or specialist. Each student would in this way come in personal contact with the teacher, who should always be a practitioner himself, and who, by his method of cross examination and mode of procedure would teach the student just what every young physician finds himself deficient in, namely, how to learn his *patient*.

Now let us see what the advantages of this method would be. In the first place, the student would be growing up, as it were, among sick people; he would have the same opportunity to study his patients which the physician has in actual practice; he could use the science of medicine, as learned in his previous courses, to guide him in reaching proper conclusions; his textbooks and lectures would be of great benefit to him; he would get his facts direct from the living patient, which is always a surer teacher than the best authorities. This method would develop a spirit among the students, from their close intermingling and common interests, of a sort of self reliance and self esteem, marking each student as an individual, and in time generating a *genius loci* which leaves its stamp on all who come within its pale; it will bring the teacher and student in closer contact, and form a bond of mutual advantage, which can never be reached under existing methods; it would avoid much of the repetition on the various subjects, as well as the tendency of teachers in special lines to make their specialty the prominent one; it would show the student the daily variations even in the so-called "type," a view hard to get from any written record; it would do away with the ward visits in large sections, yet permit the whole class to study the case through the student. Each clinic would be a lecture, demonstration and recitation combined, with the advantages of all; it would raise the student from the plane of a school boy to the dignity of a physician; while it does not destroy the opportunity for those who intend to pursue a special line, yet it would insist on a solid ground work, without which no one should be permitted to proceed. In a word, it would be combining the old method of preceptor and student, which produced such men as Willard Parker, Austin Flint, Calvin Ellis, Jackson, Storer and Bowditch, as well as our own Elisha Bartlett. Neither is it an untried method, for it is founded on the principles laid down by Hippocrates himself, of each student pushing each case to its scientific cause, a plan which made the schools of Holland, Vienna, Paris and Berlin the recognized medical centres of the world.

It is impossible to turn out completed physicians by any one method, but I believe the method described will give the greatest freedom to the individual student, rather than the binding influence of a fixed curriculum fitted to the average student. It is not so much the number of cases seen as it is the opportunity and necessity of not only studying but learning each case seen—it being as fatal to crowd the mind with so great a mass of knowledge that it is repelled as it is to force upon it a quantity of undigested knowledge.

As to the practicability of the method there is no question; it is merely using the present unwieldy amount of material to a better advantage. True, there may be some patients who would object to the method, but might it not serve as a remedy for the abuses now so prevalent in the clinics, driving out un-

deserving cases in a way that no system has yet accomplished? Then again the experience of the obstetrical department at Harvard shows that no fear need be entertained as to its effect on the quantity of material available.

There is another result of this method which would make it most valuable, that is, the feeling it would engender among the alumni of a school and the great benefit such allies in private practice would be to the carrying on of the work.

Medical Progress.

RECENT PROGRESS IN GYNECOLOGY.

BY EDWARD REYNOLDS, M.D., BOSTON.

ON THE USE OF THE UTERINE SOUND.

JOHN BENJAMIN HELLER¹ discusses the passage of the uterine sound to a distance far exceeding the depth of the uterus, and that without the exercise of force and usually without ill results. Either the womb must stretch, or the oviduct admit the sound, or the uterine wall be perforated. In many cases the evidence is inconclusive, but in some it has been possible to demonstrate what occurred.

As evidence that the sound may enter the oviduct, the most important case is Floeckinger's. In curetting a patient for incomplete abortion, who had also had a subserous myoma, he found that the sound would pass to the handle; some time later it was decided to perform abdominal section for the myoma, and during the preliminary sounding the instrument passed once up to the handle. On opening the abdomen, it was found lying in the left tube, the tube and uterine wall being considerably stretched; it was also found possible to pass it into the right tube. Ahlfeld records a similar case, apparently verified by bimanual examination; others have been verified post mortem.

In most cases actual perforation has occurred, judging by such cases as have been investigated by laparotomy. Courant reports such a case in curetting a myomatous uterus, Odebrecht in introducing Orthmann's instrument to raise the uterus for a ventrofixation, Glaeser in curetting three months after delivery, Rosenfeld in curetting preliminarily to vesicofixation, Donald in curetting for hemorrhage three months after abortion, Brothers in curetting for chronic endometritis, Donald in curetting for post-puerperal endometritis. In some of these cases the perforating instrument was the sound, in others the curette. Kelly has perforated six times without bad results, but one of his assistants had a death in such a case from septic peritonitis. The writer had a case of incomplete abortion two months after miscarriage, that had been flooding persistently; curettement was apparently simple, when suddenly the instrument passed 5 inches towards the right side of the uterus, though the distance to the fundus was but $2\frac{3}{4}$ inches; in the former position it could be felt through the abdominal wall. The cervix was lightly plugged with gauze and the patient manifested no untoward symptoms. This personal experience impressed the writer with what

¹ Quarterly Medical Journal, July, 1899.

others have reported, of the extreme ease with which in these cases the instrument penetrates, seeming to pass without the exercise of the slightest force; in fact, in one case, on examining the uterus after its removal, it was found that the sound's own weight was enough to carry it through the uterine wall. The conclusions are that the most needful precautions are asepsis, careful estimation of the size and position of the uterus, extreme gentleness, avoidance of powerful ovum forceps in abortion cases, and rest in bed and careful surveillance after curetting. It seems that the accident may occur even with the greatest gentleness. Gauze packing and rest is usually followed by recovery; in very serious cases exposure of the uterus and suture of the rent have been followed by excellent results.

PALLIATIVE TREATMENT OF INOPERATIVE CARCINOMA.

Gessner² summarizes this subject as follows: The three symptoms to be relieved are hemorrhage, offensive discharge, and pain; the two former may be checked by judicious operative interference. Narcosis is advisable, for the moral effect as well as for the purpose of doing thorough work. The technique is, briefly, disinfection of the field of operation, thorough curettement with a sharp spoon, deep cauterization, and tamponade with iodoform gauze after the application of borotannin. The tampon is removed in five or six days, and after separation of the slough strong tincture of iodine is applied. Chloride of zinc is more or less dangerous, since its action cannot be controlled. Chloride of iron, pure carbolic acid, and other similar caustics produce no permanent effect, and must be used repeatedly. Injections of alcohol, pyoktanin, etc., are painful and uncertain. The flap operations of Martin, Chrobak and others are of limited application. If no operation is possible the best local treatment is the application of dry disinfectant and astringent powders. Permanganate of potash (1-1,000) is the best solution for vaginal injection, peroxide of hydrogen and thymol being also recommended. Narcotics should be used sparingly at first, the coal-tar derivatives being tried before opium.

THE CAUSE AND PREVENTION OF UTERINE CANCER.

W. W. Grant³ says that statistics show that the mortality from cancer has doubled in the last twenty-five years, while Dührssen states that a woman during the climacteric is in as great danger of dying from cancer as a soldier is of being killed while engaged in active warfare. Seventy-five per cent. of the cases of cancer in women are of the breast and uterus, while the proportion of cases of cancer of the cervix to cases of primary cancer of the fundus uteri is as 16 to 2. Embryological cellular degeneration has been accepted as a theory of the causation of cancer, but more recent researches point to a distinct cancer bacterium, though its exact nature has not been fully determined. But traumatism, as an established predisposing cause, at least, must be recognized. Cancer of the cervix is rare in women who have never borne children, nor have suffered lesions of the cervix from the use of instruments in the hands of gynecologists. The disease usually begins in the

squamous epithelium, but may begin in the cylindrical or epithelial cells of the cervix and invade the body of the uterus by direct extension. It usually occurs in the latter part of, or soon after the close of, the child-bearing period, and is more common in the well-to-do than in the hard-worked classes.

Matthews Duncan, a most acute observer, aid of the diagnosis of cervical cancer: "We have no way of making sure of the beginning, even if we were constantly examining. The earliest and best grounds attainable are indications of disease already considerably advanced." The earliest possible diagnosis is of the greatest importance, as upon it rests the chief hope of curing the disease by the one reliable remedy—complete extirpation. A watery, irritating discharge and hemorrhage are generally the first outward manifestations of the disease. Histological examination of the blood may be of aid in the matter of diagnosis, but the disease, being local at the beginning, will have made some advance before blood changes occur.

Cervical cancer is a common sequel to laceration and contusion of the cervix; but it must be borne in mind that not all cervical injuries are apparent at the external os. Hard cicatricial tissue often exists in the cervix and at the internal os, while the external os seems normal. If there is as a result imnutrition, interstitial infiltration, hardness, interruption of the circulation and innervation, these are favorable environments for degenerate cell development and for parasitic infection. Prevention of injuries to the cervix during labor or during operative procedure is of first importance, but if they do occur, prompt repair is demanded. Trachelorrhaphy, by restoring the integrity of the cervix and its normal vascular, nerve and nutritive supply places it in the best possible condition to resist disease of any kind.

Dührssen, when suspicious symptoms present, removes the entire uterine mucosa, as some pathologists believe that cancer can only develop in epithelial tissue; but vaginal hysterectomy is preferable, being safer and more certain in results. Others advise high amputation of the cervix in the beginning of disease. The present mortality in operations for cancer of the uterus is about 40%. But with earlier diagnosis and more prompt and more radical operative treatment, this percentage should be greatly lowered.

ON THE SURGICAL TREATMENT OF UTERINE CANCER AND ITS RECURRENCES.

Theodor Landau⁴ says that of all methods of treatment for carcinoma the surgical still yields the best results; therefore it should be our aim to make as early a diagnosis as possible in order to render this treatment efficient. Each organ has, so to speak, its cancer characteristic, both in histological structure and tendency to metastasis; in carcinoma of the body of the uterus the disease is at first confined to the womb, then involves the pelvic connective tissue and the lymph vessels, then spreads to the neighboring organs, but affects the lymphatic glands and distant organs only very late; these facts are shown by post-mortem findings, and also clinically, most inoperable cases being such, not on account of metastasis in distant organs, but on account of the danger of injury to the bladder, uterus or intestine. The same thing is demonstrated by the tendency of recurrence

² Veit's Handb. d. Gynäk. [Abstract in the Centrbl. f. Gynäk.], 1899, No. 29.

³ Denver Medical Times, August, 1899.

⁴ British Medical Journal, May 27, 1899.

(whether due to foci left behind or to a new formation like the first) to be local in or around the scar. Especially is the essentially local character of uterine carcinoma shown by the fact that operations in which the entire broad ligament is excised or necrotised, even in far advanced cases, yield results relatively splendid, compared with those operations in which the uterus alone is attacked. Uterine carcinoma is, therefore, especially adapted to surgical treatment, and the indication for such treatment depends solely on the possibility of its complete removal. The writer prefers the vaginal operation in all cases except a few where the carcinomatous enlargement of the uterus or its complication with myoma is so great that not even with the aid of vaginoperineal incisions can the parts be brought out *in toto* through the vagina; he prefers clamps to ligatures on account of the wide crushing and necrotising effects of the former. Of 123 cases operated on under the above indications, 8 died from the operation; of 48 of these operated on more than five years ago, 13 have remained well; that is, we may consider 1 in 4 permanently cured.

A case is reported, first operated on at the age of thirty-seven years for cauliflower carcinoma, who three years later presented at the site of the scar in the vault of the vagina hard, knob-like prominences; anteriorly a cone-shaped body, of the length of an almond, projected into the vagina, while behind and to the left there were wart-like, friable, easily bleeding masses. A free vaginoperineal incision going around the rectum to the tip of the coccyx was made, and the left ischio-rectal fossa was separated up to the level of the vaginal vault, giving free access to the entire field of operation. An incision was made around the carcinomatous excrescence $1\frac{1}{2}$ centimetres from the edge of the diseased parts. No difficulty was encountered except to the left and anteriorly on account of the close proximity of the bladder. The excised mass was about the size of a hen's egg. The slit in the peritoneum was drawn together, a piece of gauze introduced for drainage; this was removed on the fifth day, and on the fifteenth day the wound was completely healed. It will be seen that this case was not one of metastasis, but a local recurrence in and around the scar. Attempts to remove these local recurrences are almost unknown in the literature, the writer having been able to find but 1 case.

DISAPPEARANCE OF RECURRENT MAMMARY CANCER AFTER OÖPHORECTOMY AND TREATMENT BY THYROID EXTRACT.

G. Ernest Herman, in the *Lancet* for June 11, 1898, reported a case of the above nature, and can now add to that report the fact that the patient has continued in good health since.⁵ A second case has since been similarly treated, of which a history is appended. In 1894, the patient then being forty-five years old, a lump was noticed in her right breast, and in June, 1895, the right breast, with the fascia covering the pectoral muscle, and four enlarged axillary glands, were removed. The growth proved to be carcinoma. In October of the same year three nodules situated just beneath the scar, together with some lumps in the axilla, were removed. In November, 1897, a lump was noticed in the left breast. On admission to the London Hospital the following July

there was an ulcerating surface over the third and fourth ribs on the left side, depressed at its centre with thickened margins. In the right axilla was a depressed cicatrix, separate from the ulceration and without sign of recurrence of cancer. In the left breast was a lump of stony hardness, measuring $3\frac{1}{2}$ by 2 inches. The left nipple was drawn in, and there were hard, enlarged glands in the axilla.

The day following her admission to the hospital both ovaries were removed, and as soon as vomiting ceased after the anesthetic, the patient was put upon thyroid extract, 5 grains three times daily. In September the ulcer had completely healed, and the left breast was much softer, and the patient had gained twelve pounds in weight. One month later there was no distinct lump in the left breast, and no enlarged glands in the axilla. When seen March 28, 1899, the left breast was apparently healthy, although the nipple was retracted. The patient's health was good, and she had gained much in weight. She has continued the use of the thyroid extract.

The relative importance of the two parts of the treatment, oöphorectomy and thyroid extract, must be alluded to. Stanley Boyd has collected 15 cases treated by oöphorectomy alone, but in only 4 was there "relief worth obtaining." He also publishes reports of 5 cases in which thyroid extract was given. In 1 case it was only given for a month; in another, where recurrence of the growth had occurred *after* oöphorectomy, and in 2 out of the other 3 cases some benefit seemed to follow. Four cases have now been published where the combined treatment was used, and in 3 of these the cancer disappeared. Of course, it is impossible to say that these patients are "cured" until they have been watched throughout the remainder of their lives. But if that condition of the organism can be maintained which led to the disappearance of the cancer, it is reasonable to expect that this condition will be incompatible with return of cancerous growths. They cannot develop new ovaries, and are instructed to continue the use of the thyroid extract as long as they live.

ON THE EXPERIMENTAL PRODUCTION OF HYDROSALPINX AND HYDROMETRA IN ANIMALS AND ITS RELATION TO HYDROSALPINX IN THE HUMAN SUBJECT.

C. J. Bond⁶ recalls that in a previous article he established the fact that in rabbits, guinea pigs and other animals a typical hydrosalpinx could be induced by antiseptically ligaturing the Fallopian tube close to the cornu of the uterus and also at its beginning; the fluid thus produced closely resembles the fluid of a human hydrosalpinx. If the ligature be placed instead about the uterine cornu, the cornu distends above the ligature and a hydrometra results, the fluid resembling that derived from the tube. The fact that in the lower animals the secretion of the uterus and of the tubes is so much alike corresponds with the slight degree of differentiation between these two portions of the oviduct; whereas in the human subject, differentiation having advanced further, the uterine secretion is a mixture of blood, mucus and epithelial debris, at least during the menstrual period; whether in the intermenstrual period a saline watery fluid be produced and reabsorbed we do not know.

In animals there is an important difference between ligature of the uterine cornu and ligature of the tube.

⁵ The *Lancet*, April 22, 1899.

⁶ *Lancet*, July 22, 1899.

If the tube be ligatured only at the uterine end no distention takes place, the secretion probably occurring, but escaping into the abdominal cavity, where it is absorbed. If, however, the cornu be ligatured at any point, the cornu distends above the ligature with resulting hydrometra, any backward current being prevented, even though the tube remains unobstructed and the passage seems to be clear in the other direction. This throws light upon the fact that distention of the human uterus with blood or fluids does not cause backward distention of the tubes, except in cases of mechanical displacement or bacterial infection; it does not oppose the view that spermatozoa may enter the tube. A number of points are illustrated by the following case: In a young girl, whose vagina was absent, an attempt to restore the canal by dissection resulted in a septic endometritis followed by a right pyosalpinx; on abdominal section the left tube was found normal, except that it ended in a cul-de-sac close to the uterus. Not only did this case illustrate the direct extension of the infective process in the case of the right tube, but also in the left tube that occlusion at the uterine end does not produce hydrosalpinx.

This absence of regurgitation from uterus to tubes, even under pressure, in animals, led the writer to think that the menstrual fluid occasionally found during menstruation in human tubes originated therein. Conditions in the human subject are different, however, and it appears that in cases of retroversion of the uterus regurgitation of the uterine menstrual fluid does actually take place into the tubes; it is suggestive that in these cases there was great congestion of the fundus due to mechanical displacement. This regurgitation has been proved in some cases by means of particles of carmine.

It seems to be demonstrated that in animals, and in the human subject as far as the Fallopian tube is concerned, the mucous membrane of the oviduct has a characteristic secretion. This secretion seems to be absent during pregnancy: A rabbit in which one cornu was ligatured became pregnant in the patent cornu; on killing the animal at term, it was found that no hydrometra had occurred in the ligatured tube, although it was somewhat larger than formerly from hypertrophy of the mucous membrane similar to, but less marked, than that in the pregnant cornu. An analogous condition is present when pregnancy takes place in one horn of a human uterus bicornis; and a case is cited of extra-uterine pregnancy in the subject of a uterus bicornis in which both uteri presented a well-marked decidua. It appears, therefore, that the uterine secretion is associated with the ordinary destructive processes of the generative canal and not with the constructive processes and increased tissue growth of pregnancy. We must not regard human hydrosalpinx as a final condition in infective inflammation of the tube, but only as a mechanical distention by normal secretion, due to closure of both ends of the tube by inflammation; while pyosalpinx occurs when the infection has invaded the whole tubal mucosa, destroying its secreting powers and changing it into an abscess cavity.

Another interesting fact — that the fluid in a simple parovarian cyst closely resembles that in distended Fallopian tubes — points to the origin of these cysts in a hyperdistention by a physiological fluid of a portion of the efferent ducts of the paroöphoron.

RELATIONSHIP BETWEEN UTERUS AND THYROID GLAND.

Dickson's observations are based on some 200 cases, and from them he concludes that diseases of the thyroid are much more common among women than men — 6.55 to 1. A direct sympathetic relationship, if nothing more, exists between the thyroid and the uterus and manifests itself in many ways. Thus, before the establishment of the function of menstruation the thyroid is often enlarged. This enlargement frequently is reduced on the establishment of the menses, and in those cases in which the gland is not reduced it is observed that some thyroid engorgement is present before each menstrual period, diminishing as the flow is established. Goitre occurring after puberty is frequently associated with amenorrhœa. When a woman with an enlarged thyroid becomes pregnant, the gland increases in size with each pregnancy, receding shortly after parturition. At other times pregnancy is directly responsible for goitre, it making its first appearance early after impregnation. The three periods in life during which the thyroid has been found most refractory to treatment are before puberty, during pregnancy and after the menopause.

MENSURATION AND CAPACITY OF THE FEMALE BLADDER.

Guy L. Hunner and I. P. Lyon state that in 25 women examined, the average bladder capacity by atmospheric distention was found to be 303 cubic centimetres, individual cases ranging from a minimum of 160 to a maximum of 545 cubic centimetres. The average fluid capacity was found to be 429.7 cubic centimetres, varying in individual cases from 210 to 840 cubic centimetres. The fluid capacity was thus found to be one-third greater than the air capacity.

The influence of child bearing on the capacity of the bladder is shown in the following table:

	Atmospheric capacity.	Fluid capacity.
Nulliparous . . .	313.8 c. c. (average 13 cases)	464.5 c. c. (average 11 cases)
Parous	291.2 c. c. (average 12 cases)	395.0 c. c. (average 11 cases)
	303.2 c. c. (average 25 cases)	429.7 c. c. (average 22 cases)

The average measurements obtained under atmospheric dilatation in the knee-chest posture were: To summit, 7.14 centimetres; to posterior wall, 5.77 centimetres; to left lateral wall, 6.70 centimetres; to right lateral wall, 6.92 centimetres. Taking the measurements separately for nulliparous and for parous women, the averages were found to be:

	Summit.	Posterior wall.	Left lateral wall.	Right lateral wall.
Nulliparous (average 13 cases)	7.43 cm.	5.75 cm.	7.03 cm.	6.12 cm.
Parous (average 12 cases)	6.83 cm.	5.79 cm.	6.35 cm.	5.72 cm.

The explanation of these figures, showing the greater capacity of the bladder of nulliparæ, is doubtful; it may be that it is purely accidental, due to the limited number of cases. They suggest, however, that it may be due to the greater elasticity of the

bladder in the nullipara, influenced both by her average younger age and the fact that her surrounding tissues have not been injured. In the above table of measurements it will be seen that the dilated bladder is asymmetrical. In 16 cases the left lateral measurement is greater than the right. This fact may be explained by the fact that the rectum in women is found much more commonly on the right side than on the left within the pelvis. The uterus is usually displaced somewhat to the left of the median line, thus lowering the point of greatest outward bulging on the left side. The bladder, when dilated with air and observed during operations within the pelvic cavity, was found to be ellipsoidal in form, flattened somewhat in the anteroposterior diameter. The average length of the urethra in 17 cases was 3.3 centimetres.

A NEW OPERATION FOR PERSISTENT INVERSION OF THE UTERUS.

Barton Cooke Hirst,⁷ after reviewing the history of this accident and enumerating the operations which have been proposed and practised for its relief, describes the operation which he used in a recent case. It consisted simply of splitting the vaginal portion of the cervix as high as possible in the median line posteriorly. This trifling procedure at once unlocked the difficulty, and the inverted uterus, which had previously resisted prolonged taxis, was immediately replaced by very trifling pressure. The little cervical incision was then stitched up, and the whole procedure occupied about fifteen minutes.

BACKWARD DISPLACEMENTS OF UTERUS.

Arthur E. Giles's⁸ conclusions, arrived at in this paper, may be summed up in the following propositions:

- (1) Retroversion of the uterus requires no treatment when it causes no symptoms.
- (2) A simple retroversion may cause symptoms of disturbances of circulation, by pressure, or reflexly.
- (3) Pressure symptoms are uncommon in the absence of enlargement of the uterus.
- (4) Reflex disturbances are most frequently gastric, vesical or nervous.
- (5) A simple retroversion can usually be cured by the temporary use of the pessary.
- (6) Retroversion with endometritis is frequently complicated with prolapsed ovaries.
- (7) In the treatment of this condition, the inflammatory condition must be cured before the introduction of the pessary.
- (8) Pronounced endometritis requires curetting, with trachelorrhaphy in some cases, before the displacement can be dealt with.
- (9) When retroversion is associated with fixation by adhesions, the first step must be to restore the mobility of the uterus.
- (10) To introduce a pessary in a case of retroversion with fixation is to add risk to inefficiency.
- (11) When milder measures fail, the abdomen should be opened, the adhesions separated and the uterus fixed in its proper position.
- (12) In the absence of adhesions, hysteroplexy is sometimes required to cure an intractable retroversion.
- (13) Retroversion of the gravid uterus is usually reducible with the help, in some cases, of an anesthetic.

(14) In cases of irreducible retroversion it is usually better to free the uterus by abdominal section than to terminate the pregnancy; but in some cases the induction of abortion will be necessary.

VAGINAL LAPAROTOMY.

Dührssen⁹ concludes his latest monograph on this subject by saying no one can reproach him with allowing an operation rich in blessings to be discredited by his silence in respect to its advantages. He has performed vaginal laparotomy 400 times in the last eight years, on account of retroflexio uteri. Vagino-fixation is superior to ventrofixation, he states, as it is less dangerous; there is no chance for ventral hernia, nor adhesions of omentum to the abdominal cicatrix, nor of ileus; less dread of the operation on the part of the patient; and much less subjective post-operative discomfort. Intra-peritoneal vagino-fixation ensures normal anteversion. It requires skill on the part of the operator, and possible failures due to the operator's technic should not be ascribed to the method. He has also performed anterior colpoceliotomy for vagino-fixation of the round ligaments, for vesicofixation of the retroflexed uterus, tubal pregnancy, extirpation of benign uterine growths and ligating the tube for the purpose of ensuring sterility. Fifteen died out of 503 thus operated on; 6 out of 358 cases of retroflexio uteri treated by vagino-fixation. Since 1895, when he slightly modified his technique, pregnancy has not been interfered with in any case.

NEW METHOD OF TREATMENT AND DRAINAGE IN GENERALIZED PERITONITIS.

F. Bode¹⁰ describes, in his preliminary communication, the particularly favorable results obtained at the City Hospital at Frankfort-on-Main, by taking out the entire contents of the peritoneal cavity after a median incision, pelvis elevated, without regard to slight fibrinous adhesions, but under constant sprinkling of warm physiologic salt solution, poured from a china pitcher holding one or two litres. The intestines are wrapped in compresses moistened with the salt solution, and the warm solution is poured over them from time to time to prevent their chilling. Strange to say, instead of this procedure inducing collapse, on the contrary, the weak, rapid pulse becomes fuller, probably from diminished intraperitoneal pressure and removal of toxic substances. The perforation causing the trouble is easily found and sutured. The empty peritoneal cavity is thoroughly washed out with 30 to 40 litres of the salt solution, with especial attention to the liver and spleen regions and the small pelvis. The fluid accumulating in the depressions is very gently mopped up with compresses, and when the cavity and the serosa of the intestinal loops have thus been cleansed of their suppurating secretions, the loops are replaced under continuous sprinkling with the salt solution. This is easily accomplished. The red and meteoric loops frequently contract with peristaltic movements under the influence of the salt solution. A loop about the centre is then lifted, the mesentery stretched taut, and a slit made in it at a point free from vessels near the radix mesenterii. A long drainage tube is passed through the slit, forming an arch as the loop is replaced, the ends of equal lengths passing through

⁷ American Journal of Obstetrics, January, 1900.

⁹ Berlin. Klin. Woch., November 27, 1899.

¹⁰ Centrbl. f. Chir. (Leipzig), January 6th and 13th.

the peritoneal cavity and emerging through two new incisions to the left and right, just above the colon. The tube has a number of openings along the centre. Besides this main tube, another is inserted in each side incision, a third in the lowest point of the median incision and a fourth in the liver, stomach and spleen region. The abdomen is then closed; the air left in the peritoneal cavity is expelled by pouring in more salt solution as the suture is progressing, leaving a considerable quantity of salt solution in the abdomen. The permeability of the main drainage tube is also assured by sending a little salt solution through it, under slight pressure. The patient is put to bed with the head and shoulders raised, to send the fluid down near the drain tubes, and the abdomen is rinsed out two or three times a day with 1,000 to 1,500 cubic centimetres of the saline. "By this combination of rinsing and drainage it was possible to evacuate quite considerable quantities of pus from the abdominal cavity in seventy-two hours, without material discomfort to the patient. We frequently observed that the rinsing was followed immediately by increased peristaltic movements and passage of flatus, much to the relief of the patient, and amounting in some cases to slight diarrhea under the influence of the salt. There is nothing to prevent permanent irrigation through the main tube. Serious symptoms usually disappear by the third or fourth day, when the rinsing tube is removed and the drain tube replaced, at first with smaller drains and then with loose tampons, and the openings finally closed. Generally speaking, the course of peritonitis treated according to this method was remarkably smooth and mild, convalescence extremely short, and the patient usually completely recovered by the end of three weeks. Similar irrigations, practised on the cadaver with colored solutions, showed that the fluid penetrated to the remotest portions of the abdominal cavity, even under very adverse circumstances."

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

F. G. BALCH, M.D., SECRETARY.

REGULAR meeting, April 4, 1900, DR. J. W. ELLIOT in the chair.

DR. C. A. PORTER and DR. JOHN C. MUNRO read papers on

ACTINOMYCOSIS.¹

DR. ELLIOT: This very interesting subject is open for discussion. I feel as if Dr. Porter had made a true discovery in finding that the Out-Patient Department is full of these cases. Only a year ago we had a meeting on this subject, and several far advanced cases were reported and one or two others that were said to be cured. We then wondered if such cases could be cured. Now we have a view of the beginning of this disease by observations made in these cases. I think there is much interest in this subject.

DR. PAUL THORNDIKE: I should like to add 2 cases to the list. The first case I wish to speak of be-

cause it is one of the older and farther advanced cases and I wish to bring out one or two points in connection with the clinical history. A woman of fifty-four for several months had recurrent abscesses which broke and discharged periodically. At the time she entered the hospital she had an enormous brawny swelling of the right cheek, extending from the zygoma down to the clavicle, involving the whole side of the face. It was a dense, hard, purplish swelling with a number of sinuses in it. The mouth was foul and teeth carious. She was etherized and the sinuses dissected out as carefully as possible. No communication with the bone could be found anywhere, in spite of the fact that the case had been going on a number of months and was very much more extensive than any of the cases reported tonight. One of the points I want to emphasize is that even in a case as far advanced as this there were no glandular enlargements. The granules were found in the scrapings and smears, and the pathologist confirmed the diagnosis of actinomycosis. Since she left the hospital I have been unable to follow her up, so that I do not know whether the disease recurred.

The second case was in a woman, forty-eight years old, who had up to three weeks before entrance to the hospital no history except that of a pleurisy nine years previous, with a history of tappings. Three weeks before entrance a small lump appeared to the outside of the left nipple, and it was supposed by her physician that she had an empyema. If I remember rightly she was tapped before entering the hospital, but nothing found. Examination of the chest revealed nothing except that the respiratory sounds were not so easily heard on that side as on the other. The abscess was opened and a large amount of foul pus with characteristic granules was evacuated. Absolutely no connection could be found either with a rib or with the pleural cavity on this side. She died in two weeks from exhaustion and at the autopsy an actinomycotic area in the left lung and involving the pleural cavity was found. I am sorry I was not able to bring the autopsy record with me.

DR. CODMAN: I have a case of actinomycosis which I have followed five years, and reported to this society two years ago. I thought it was worth mentioning to the society that the man was still well, although he has a small abscess open on the chest wall every three or four weeks that heals in a few days. He is able to do ten hours' work a day. The disease is in the chest wall and was probably primary in the lungs. The first symptoms were cough and high fever and shortly afterwards an abscess appeared in the cardiac area. Since then several sinuses have been opened there. I have tried twice to dissect them out, but as they run under the ribs and directly over the heart it seemed to me unwise to go very deeply, particularly as the patient is getting along so well. He takes very large doses of potassium iodide, and, as I say, is perfectly well otherwise than these little abscesses that break now and then. The diagnosis was confirmed by Dr. Mallory several times.

DR. BALCH: I should like to add one more to the list of cases which have been seen in the Out-Patient Department of the Massachusetts General Hospital. I saw P. G. last December. He had been operated upon once for what appeared to be a typical alveolar abscess; then came to the hospital and was opened again, and Dr. Wright found the actinomyces in the

¹ See pages 251 and 255 of the Journal.

pus. He was curetted out two or three times, twice under ether and I think once under cocaine. The granules were found at least twice, I think perhaps three times, either in the curettings or in the pus. The thing which struck me most in the case was the way it would heal up and apparently be all well, and break out in another area a short distance from the first. He has finally healed up entirely, I am told. This case lasted a little over a month. He was treated by curetting and painting the inside of the abscess cavity with strong carbolic acid. Internally he was given iodide of potash in large doses.

DR. ELLIOT: A remark made by Dr. Wright, that we are in danger of forgetting that this may be a serious and general disease, is in great contrast with the last year's meeting, where in the cases reported the lungs or liver or whole abdomen were invaded, and it was quite refreshing to see another phase of the disease where it is getting well. We shall now be suspicious of certain localities, the neck, jaw, lung and liver. I have had cases where the disease had invaded the lung, liver and abdomen.

DR. EDWARD S. HATCH read a paper on

TENDON SUTURE.²

DR. GOLDTHWAIT: I think it would be hard to find more brilliant illustrations of what can be done in the way of tendon suture than is represented by these 2 cases, and it strengthens my feeling that much more can be accomplished in the way of tendon surgery than has commonly been supposed.

In regard to the adhesion of the skin, mentioned by Dr. Lund, it has been my custom in performing such operations to dissect up a layer of subcutaneous tissue and to use this for the first covering of the tendons, so that they cannot adhere directly to the skin.

DR. LUND: Dr. Richardson, in his article in the "International Textbook of Surgery," on suture of nerves, recommends suture of the nerve sheaths and the use of silk. I believe before function of the motor nerve can return, the peripheral portion has to degenerate, and from the central portion the axis cylinders have to grow down through and reproduce themselves. Leaving a material like silk in the substance of the nerve would, it seems to me, be more apt to interfere with the growth of the new fibres than the use of catgut, as catgut will be absorbed and out of the way more quickly. I have therefore used catgut for the nerve and silk for the tendons.

DR. GOLDTHWAIT: In connection with the question of nerve suture it might be interesting to speak of 2 cases recently operated upon and reported by Dr. Peckham, of Providence, in which for the relief of infantile paralysis he has transplanted a section of the peroneal nerve. In this, after a long period of complete paralysis, a distinct contraction is produced in the paralyzed muscles. Just what the permanent result or how perfect the use of the muscles will be it is, of course, too soon to tell.

DR. MUNRO: I have sutured tendons with catgut and begun passive motion in ten days. I do not believe it is always necessary to put in silk.

DR. ELLIOT: A remark of Dr. Lund's reminded me of a case I had in the hospital. Dr. Lund remarked that the extensor tendons were much less important; that therefore it is much more important to suture the flexors with care. I had a patient who was

a laundress, and whose hand was caught in a mangle. The hot cylinder came against the back of the hand and destroyed all the extensor tendons; the entire back of the hand was burned to the bone. That patient recovered with a solid scar on the back of the hand, and that hand is an entirely useful hand. She works in the laundry as before. Her flexor tendons pull down against this scar tissue, and when she lets go the scar pulls the fingers back. She can brush her hair and button her collar, and in fact is working at the same mangle that mangled her.

DR. J. COLLINS WARREN read a paper entitled

THE RADICAL CURE OF HERNIA.³

DR. LUND: In the Out-Patient Department you see a great many cases of hernia done with silk which after healing develop a sinus, which keeps the patient an invalid a very long time, until the silk is taken out.

DR. ELLIOT: I took out some catgut ligatures from a hernia about four years after the operation, and in another case I took out catgut from an umbilical hernia a year after. In the first case chromicized catgut had been used. I think chromicized catgut does not dissolve at all, and that it is one of the best materials for hernias, if there is any virtue in a suture which is not absorbed.

DR. MUNRO: I saw a hernia today operated on a year ago with absolutely no trace of the chromic catgut used. I am charitable on the animal tendon in hernias. I did a lot of hernias at the City Hospital several years ago with animal tendon. The cases went on all right for three or four weeks, and then suddenly broke down, and I lost faith in kangaroo tendon, until later we discovered that we had contaminated the wounds at the time of operation, through a defect in the autoclave, by which the sponges were not sterile. I am pretty sure that in cases where there is infection it may come from the operator, either from sponges or hands, or in some other way, and the catgut or tendon be blamed unjustly for the trouble.

DR. ELLIOT: I think there is no question that silk comes out because it is not antiseptic. Silk soaked in corrosive sublimate never comes out if it is put in clean. I have used silk for a year in the abdomen and never had any come out in a clean case.

AMERICAN NEUROLOGICAL ASSOCIATION.

TWENTY-SIXTH ANNUAL MEETING, HELD IN WASHINGTON, MAY 1, 2 AND 3, 1900.

FIRST DAY.

THE president, DR. EDWARD D. FISHER, of New York, in his address to the association, said that the position of neurology among the divisions of medicine and surgery has changed very much during the past twenty-five years. Among other things to be considered is that neurologists must not separate themselves from general medicine, and while specialists may remain narrow and limited, this should not be the case with neurologists. The tendency should be towards the study of general medicine. Neurologists must recognize and fully understand general diseases. They should be able to examine the heart, the lungs and the other internal organs in order to make out any

² See page 256 of the Journal.

³ See page 256 of the Journal.

disease of special nervous character. Therapeutics is also important. Neurologists are accused of being more interested in diagnosis and localization of disease. The fact is that physicians and patients not only look for diagnosis, but also suggestions in reference to treatment. The importance of the necessity of the continued study of the histology and pathology of the nervous diseases is not underrated. The note of warning Dr. Fisher would sound and especially to those about to enter this field of medicine, is to keep up as broad a knowledge of general medicine as possible. No one should enter neurology as a specialist without first having had an experience in general practice. If the signs of the times are read aright, that is the tendency of the neurology of the future.

CHRISTIAN PSEUDOSCIENCE AND PSYCHIATRY.

DR. SMITH BAKER, referring to the January number of the *Christian Science Journal*, in which an article appeared by Judge Joseph R. Clarkson, of Omaha, to the effect that "Christian Science makes stronger, healthier, more unselfish, more honest, holier, purer poor people," and that "through Christian Science there have been, as well as can be estimated, more than a million cases of healing every sickness," and that "in the opinion of the best qualified judges there is no disease Christian Science cannot meet, arrest and destroy"; he further quotes Mrs. Eddy as saying that "Christian Science aims to destroy the patient's unfortunate belief by both silent and audible argument." Dr. Baker notes that if a disease is really an acute one, it easily falls within one of two classes: Either it is natural, self-limited or readily cured by any means, or else it has been wrongly diagnosed. No intelligent person, he said, can suppose that a real fracture or dislocation or a case of crushed bone can be healed by Christian Science. No one can suppose a real case of typhoid fever or of smallpox or of pneumonia to be under the dominance of the healer. But that many cases of those, as well as almost every acute ailment, or, at any rate, of such as have been given some sort of technical name, are healed, there seems to be a question as to evidence. It is altogether more certain that every such includes a very large proportion of long-standing functional troubles like neurasthenia, hysteria, asthenopia, diffuse or shifting pains, joint aches or limitations, vicious digestion, faulty excretion, etc.

DR. EDWARD B. ANGELL read a paper entitled

IMPERATIVE IDEAS IN THE SANE AND THEIR MANAGEMENT,

and said that even in the normal mind constantly are recurring words, phrases, emotions or ideas which force themselves into prominence against the will. In the morbid state of mind these demands of imperative ideas become a disease against which the most strenuous efforts of the will seem impossible. Dr. Angell said his object was to determine how far our present knowledge through proper classification and analysis of these imperative ideas will enable us to recognize their significance. It is necessary in the investigation of these morbid ideas to study the mind in its automatic activity, a condition which, to a very large extent, prevails in states of sleep, hypnosis, somnambulism, hysteria and insanity, during which normal evolution is largely or wholly suspended. Dr. Angell thought hypnotism certainly formed a promising means

of relief. In a general way much may be done to lessen emotional influences by training the patient to withstand painful stimulation of the skin.

DR. SMITH BAKER thought that antecedent to all parental conception are certain conditions of the mind in the form of a stress brought about by deprivation, for instance in sexual obsession, this has been found when one of the patients or both of them have lived a life of absolute sexual stress of the order of deprivation. Take parents during the child-bearing period, who are eager for property and yet are deprived of obtaining it. That stress of mind or body seemed to be the ground field in which the child will bear a weak spot, where the imperative obsession will be developed later on. Dr. Baker was rather skeptical about hypnosis, and preferred rather to endorse the straightforward method of educating the mind by some such work as Emerson's "Essays," or some new science, or a new field of work.

DR. KNAPP did not think the claim Dr. Angell made of imperative conception and fixed idea is one that can be strictly maintained in practice. Removing a fixed idea in hypnosis seems like putting on a spinal brace to cure a weak back.

DR. S. WEIR MITCHELL related a case of a lady who possessed a condition of repetition; that is, when she moved a book, for instance, she would feel impelled to move it a certain number of times, associating therewith some one of her relatives. For instance, if she turned the book on the table when thinking of her cousin, she would do it three times. When her mind dwelt on her husband, she did it seven times. She referred this peculiarity to a similar desire in childhood to move her shoulders. She was practically cured by being pinched, associating the discomfort with the pinch.

DR. SACHS thought that the subject of imperative concepts is a psychical phenomenon which is closely allied to a physical condition, and does occur in persons otherwise normal. He expressed himself as of the opinion that to hypnosis was attributable the origin rather than the cure of imperative concepts.

DR. PUTNAM expressed the opinion that where there are severe sexual perversions and drug habit cases, the use of hypnotism proves helpful.

DR. BROWNING, in relation to imperative ideas, said that if a woman who comes from a good family and grows up with little to do, who has no opportunity for mental culture, could have a wider field of mental and physical application, she would be cured.

DR. ANGELL, in closing, said that he did not think the American men or women are as susceptible to hypnosis as are the French or German or other Continental races.

DR. HOWELL T. PERSHING, of Denver, read a paper on

A CASE OF WERNICKE'S CONDUCTION APHASIA, WITH AUTOPSY.

He reported a case of a man of robust appearance, aged forty-five years, who was brought into the hospital in an unconscious condition, November 19, 1897. The history, which was meagre, indicated that the man had fallen from his wagon into the bed of a small stream, where he lay for about thirty-six hours before being found. He was removed to the hospital, and on examination the right arm and leg were found rigid and tremulous, the head and eye showing

slightly marked direction to the right. There was no sign of an injury to the head; the pulse and heart were normal; respiration 20, somewhat stertorous; temperature $99\frac{1}{2}^{\circ}$; urine normal. A diagnosis was made of a vascular lesion with syphilitic thrombosis in the left hemisphere, and inunctions and potassium iodide were ordered. Consciousness returned in the course of a week, but the man's talk was a mere jargon. He generally failed to do all that he was told to do, but responded readily when shown by a gesture. No paralysis could be detected. During the second week in the hospital the word deafness disappeared, and no sign of the cerebral lesion then remained except jargon paraphasia and certain associated defects. His reading was markedly paralexia; acuity of vision was good. There was no hemianopia. He had a keen eye for all that went on about him. The patient's condition remained substantially the same until January 23d, when he suddenly began to vomit and was found to be unconscious. There was conjugate deviation of the eyes, and the left pupil was larger than the right. Pulse 64, weak and soft; heart sounds normal. Temperature in right axilla 97.7° , the left 97.2° . Respiration of the Cheyne-Stokes type. Unable to swallow. Death occurred from intercurrent anemia January 29th.

DR. JOSEPH SAILER read a paper entitled

A CASE OF BULLET WOUND OF THE SPINAL CORD.

This was a man of thirty-one years of age, formerly a major in the Cuban army, who was wounded November 2, 1896, by a ball that entered 1 centimetre to the left of the right nipple and just below it, and which passed out about 2.5 centimetres to the left of the spinous process on the twelfth dorsal vertebra, having penetrated the lung, the liver and the spinal column.

DR. S. WEIR MITCHELL thought that the most remarkable thing in this case was the disappearance of the buttock muscles.

DR. PUTNAM referred to a woman who came to him about a month ago suffering from a fall in 1897. She developed complete paraplegia and complete loss of sensation of the lower extremities and of the trunk, and blunted sensation of the arms, but no loss of power of the muscles of the upper extremities. Upon operation it was found that the cervical spine of the sixth vertebra had been broken and was freely movable. After operation the bladder resumed its normal function.

DR. SAILER said that Dr. Mitchell has instituted massage and electricity with the result of considerable improvement of nutrition of the muscles, particularly of the thigh.

DR. G. L. WALTON read a paper entitled

CONTRIBUTION TO THE STUDY OF THE PLANTAR REFLEX, BASED UPON SEVEN HUNDRED AND FIFTY TESTS, MADE WITH SPECIAL REFERENCE TO THE BABINSKI PHENOMENON.

DRS. CHARLES K. MILLS and W. W. KEEN reported a case of

TUMOR OF THE SUPERIOR PARIETAL CONVOLUTION ACCURATELY LOCALIZED AND REMOVED BY OPERATION.

This case was of unusual interest from the clinical, physiological and surgical points of view. The medi-

cal history of the case was presented by Mr. Mills, the surgical history by Dr. Keen, and a pathological report on the nature of the growth by Dr. William G. Spiller.

The patient was a man fifty-six years old, who had had some neurasthenic and other symptoms since 1884, but who first began to have paresthetic attacks affecting his right upper extremity in 1894. These attacks were of irregular and infrequent occurrence, and were variously described as ant-like feelings, of crawling, tingling or battery sensations. After the attacks the arm usually felt somewhat heavy. He frequently complained of a feeling of pressure or discomfort in the head and especially in the left frontoparietal region. Sometimes this feeling was described as a headache, but he never had the typical headache of a case of brain tumor. Optic neuritis was absent from first to last, and vertigo and vomiting were so infrequent as not to call for special consideration. The patient was frequently hysterical and despondent. About five months previous to the operation the patient began to show some ataxia in the right arm and later in the right leg, and when investigation of his condition was first made by the writer all forms of cutaneous sensibility were impaired, muscular sense was lost, and astereognosis was a marked symptom. As the case progressed paresis and eventually paralysis of the arm and leg supervened, this when complete of course masking the ataxia. The patient developed a disorder of speech chiefly showing itself as a verbal amnesia and fatigue on reading. At one examination the patient showed a temporary partial right hemianopsia. Reversals of the color fields and contractions of the fields for form similar to those supposed to be typical of hysteria were present at several of the examinations. The reflexes on the ataxic and paralyzed side were somewhat exaggerated, ankle clonus being present. The patient was emotional and markedly hysterical.

An operation which was successfully performed by Dr. W. W. Keen, November 24th, exposed a tumor in the exact region which had been assigned as the seat of the growth, namely, the superior parietal convolution. The patient made a complete surgical recovery, and improved in all his symptoms with comparative rapidity. His speech completely returned, the paralysis of the leg and arm largely disappeared, cutaneous sensibility was in time restored, and he was so far recovered that he was able in March to start for a short trip to Egypt. He reached this country again April 19th, and was seen last by Dr. Mills, April 24th, just one week before the meeting of the congress. He has regained all the movements of the extremities on the affected side, although he has not full strength in the affected limbs. The muscular sense, especially in the lower extremity, is still somewhat impaired, as would be expected from the tissue lost by the encroachment of the growth.

Operation, November 24, 1899. As the flap was not to be in the thin squamous portion of the temple, but in the parietal, which might cause great embarrassment from a very thick skull, not only by the time required to chisel through the bone, but the difficulty of fracturing the base of the osteoplastic flap, Dr. Keen first made two trephine openings .5 centimetre in diameter at the two points between which he wished to fracture the flap. The skull was found, as had been feared, unusually thick, a full centimetre. This

being the case a Gigli wire saw was passed between the two points and the bone sawn half through in order to weaken the base of the flap. A large flap, each side of which measured 10 centimetres long, was then made, the anterior border of it being a little in front of the fissure of Rolando, the upper border within 1 centimetre of the median line.

As soon as the dura was exposed at the lower portion fluid was suspected beneath it. A dural flap was then cut, with the base upward. The tumor suddenly came into view at the anterior superior angle. It measured 3.5 by 4.5 centimetres and it weighed 1 ounce and 3 drachms after removal. It was made up of small granular masses like those of an ordinary raspberry and was of a deep red or purple color. In order to remove the entire tumor a portion of bone was removed by the rongeur forceps anteriorly. The tumor had begun as a subcortical mass and recently burst through the cortex. The tumor, being separated from the brain tissue, was removed and with it a long finger-like cyst which extended, by measurement, 10 centimetres (4 inches) into the substance of the brain and contained $1\frac{1}{2}$ to 2 ounces of fluid. The patient made a complete and very smooth recovery, the wound being entirely well by the sixth day.

DR. WM. G. SPILLER made a careful microscopical investigation of the growth. He classes it as an endothelioma and believes that it probably originated in the walls of the blood vessels. He said that from a pathological standpoint, while the tumor first looked like a sarcoma, it was finally proved to be epithelioma. The tumor was dark in color, not adherent to the dura, and the wall of the cyst was intact. It resembled very closely the finger of a kid glove in appearance.

DR. DERCUM said that he had seen the patient himself and that he thought too much credit could not be given to Dr. Mills for the brilliant and successful outcome of the case.

DR. WALTON said it was of interest to place on record all such cases of established tumor. In the absence of headache, vomiting and optic neuritis, though this possibility is recognized, it requires courage to make the diagnosis. He reported a case of an elderly man commencing with tremors in the wrist and gradually replaced by paralysis, finally complete in the arm and practically so in the leg, the latter of the spastic variety.

(To be continued.)

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

(Continued from No. 10, p. 242.)

SECTION OF SURGERY.

PROF. ANDREA CECCHERELLI, of Parma, opened the discussion on

SURGERY OF THE PANCREAS.

He summarized his conclusions as follows:

(1) Surgical operation on the pancreas stands in direct relation with all questions affecting the function of the organ.

(2) Wasting, the presence of fat in the feces, sugar in the urine, bronzing of the skin, jaundice and pain, are the symptoms accompanying the majority of pancreatic affections.

(3) Considerable difficulties are met with in complete extirpation owing to the pancreas being deeply situated in intimate relation with other viscera, and being very rich in vessels and nerves.

(4) The surgery of the pancreas has not hitherto advanced as it appeared legitimate to hope from the progress of visceral surgery, because very often the diagnosis is difficult, and on that account it is seldom possible to attack the morbid process at its beginning. At present everything tends to show that the surgeon is warranted in operating on the tail of the pancreas rather than its head.

(5) It has been proved experimentally that extirpation of the pancreas is possible and compatible with the life of an animal. It has not been proved that the same thing holds good in the sphere of clinical surgery, notwithstanding a few positive cases. This is all the more true that the morbid processes which call for the operation are generally not limited to the pancreas. As a matter of fact one has to do with malignant tumors infiltrating the neighboring parts, or with adenomata which can be diagnosed only with difficulty. Extirpation is not justified in tuberculous or syphilitic disease. Partial extirpation should be performed in such a manner as to leave one of the two ducts, provided the duct of Santorini does not end in a blind sac.

(6) The tumors that most frequently develop in the pancreas are cysts. These may be blood cysts, the result of injury or apoplexy; retention cysts, or hydatid cysts. In these intervention is legitimate and useful, but extirpation of the whole organ is not necessary; extirpation of the cyst, if it be possible, or incision being sufficient. In regard to extirpation, one has to consider the question of opening Wirsung's duct, and of the probable escape of the pancreatic juice into the abdominal cavity. In incision of the sac it is prudent, if possible, to stitch the walls of the cyst to the abdominal parietes.

(7) In the case of pancreatic calculi the surgeon may usefully intervene for their extraction.

(8) An affection which has lately been studied with great care is necrosis of the pancreas. This may call for intervention for the elimination of the fragments of the necrosed organ.

(9) In cases of suppurating or gangrenous pancreatitis the rule is not to operate in the acute stage. Later, if there is an abscess, or if the organ is gangrenous, intervention may be useful. Three routes may be chosen: Lumbar, extraperitoneal, transplenal, or median subumbilical. Suppuration must be avoided, but sometimes it is necessary that a portion of infiltrated or necrosed pancreas should be eliminated.

(10) In cases of chronic pancreatitis complication may be produced by compression of the bile duct or the pylorus, but in that case the surgeon may usefully operate not on the pancreas, but on the liver or the stomach, in order to prevent the interference with function caused by compression.

(11) In hernia of the pancreas following wounds reduction and even fixation may be suitable. The thoracic route is preferable if the hernia is diaphragmatic.

(12) Intervention may be necessary in contusions and wounds of the pancreas, especially if bleeding occurs. In that case hemorrhage should be stopped either by suture or by ligation of the bleeding vessel.

sels; the clots found in the abdominal cavity should also be removed.

(13) Cases of movable pancreas may be observed. Experimental pathology justifies fixation of the organ.

(14) In invagination of the pancreas Ceccherelli thinks the surgeon should intervene if complications occur and if elimination is not regularly performed.

(15) If as the result of any process the opening of the duct between the pancreas and the duodenum is blocked, a new channel for the pancreatic juice may be made, or if that is not possible a pancreatic fistula may be established.

(16) Pancreatic hemorrhages may occur even without wounds. They depend upon disease of the pancreas, most frequently gangrenous. In this case the surgeon should intervene as if the hemorrhage were traumatic.

(17) In constricted pancreas surgeons have hitherto abstained from operating, but it might be necessary to cut the band or to intervene to remedy the results caused by it on the stomach or intestine.

(18) Sutures through the pancreatic parenchyma cause no disorder or change, and are tolerated just as they are in the kidneys, the liver and the spleen.

(19) Wounds of the pancreatic duct may be sutured, but as far as possible in such a fashion that the thread be not in the middle of the duct, in order to avoid the probable formation of concretions.

(20) Union of wounds of the pancreas takes place by proliferation of the cells, especially of the connective tissue.

(21) It is certain that regeneration of the pancreas takes place.

(22) After complete extirpation there is seen a great development of the glands of Galeati, and especially a karyokinetic increase in the epithelium, so that it may be supposed, in accordance with the experiments of Martinotti, that these are capable of adequately replacing the extirpated viscus.

(23) The escape of the pancreatic juice into the abdominal cavity does not always cause peritonitis because absorption is rapid. There is reason to believe that, like bile, pancreatic juice is harmless if it is healthy, and hurtful if it is altered.

(24) In extirpation of the pancreas care must always be taken to place ligatures before, so as to avoid hemorrhages and the escape of pancreatic juice. Neither thermocautery nor galvanocautery should be used. They are unsafe, and in such cases the separation of eschars is to be feared; moreover, by radiation they may produce dangerous effects in the neighboring parts.

PROF. MAYO ROBSON presented a

REPORT ON PANCREATIC SURGERY.

He began by stating that he is convinced that pancreatic affections are much more common than is usually thought. He bases his remarks on his personal experience, he having operated on 40 cases of pancreatic disease and having seen a considerably larger number of cases in which operation was either not consented to or not thought advisable. He dwelt on the importance of posterior drainage where practicable in acute and in suppurative pancreatitis. For reaching the main pancreatic duct he has found it practicable to incise the second part of the duodenum and lay open the termination duct from the papilla. Cancer, of which he has seen over 50 cases, he has

found usually to occur after forty, and he believes that the cases occurring earlier in life are, in many cases, chronic interstitial pancreatitis, which may resemble cancer not only in the symptoms but in the naked-eye appearance after death. After describing the symptoms he remarked on the importance of distinguishing between cancer of the head and that of the body and tail of the pancreas. He then discussed the diagnosis, advising that especially in young subjects, but also at times in older patients, a hopeless prognosis should not hastily be given before surgical treatment has been tried, as if the case turns out to be chronic interstitial pancreatitis a cure may result from treatment. He expressed the opinion that excision of the pancreas for cancer can seldom be feasible or justifiable except in those cases where the disease is limited to the body or tail of the organ, and then only when it is caught in an early stage. Of the 15 cases on which he had operated for the relief of symptoms by cholecystotomy or cholecystenterostomy, 9 recovered and lived for some time in greater comfort. The important fact, however, that some of the cases operated on and thought at the time to be cancer of the head of the pancreas, but which recovered and are now in perfect health — showing the tumors to have been chronic interstitial pancreatitis and not cancer — has led him to advocate operation in all cases not too far advanced, especially in young or middle-aged patients, not because much good will be done if the case be truly cancer, but under the hope that the tumor may be inflammatory and not malignant.

Pancreatic cysts. — He has operated on 5 cases of pancreatic cyst, for which as a routine treatment he advocates incision and drainage, which he has performed in 4 cases with 3 recoveries. In 1 case the cyst was so easily enucleated that it was removed in that way, and the patient made an uninterrupted recovery, but his experience, not only in his own cases, but in others seen under the care of his colleagues, would lead him to believe that excision can only rarely be justifiable. In none of his cases were any pathognomonic symptoms present, and the author thinks that the diagnosis must usually be made from the physical signs.

Pancreatitis. — He draws a parallel between the inflammatory diseases of the liver, such as infective and suppurative cholangitis and chronic interstitial hepatitis, and similar diseases of the pancreas and its duct. He believes he has seen functional ailments of the pancreas ending in recovery that would come under the heading of infective catarrh of the pancreatic ducts, and he adduces positive evidence of suppurative catarrh of the ducts, as well as of chronic interstitial inflammation of the gland. He believes that as diagnosis becomes more perfected these diseases will be more frequently recognized and awarded their proper place in medicine. The author assents to the pathological classification proposed by Fitz, of dividing acute pancreatitis into suppurative, hemorrhagic and gangrenous pancreatitis; for clinical purposes he considers the subject under acute, subacute and chronic pancreatitis. In discussing the etiology, he laid stress on bacterial infection as being the essential and immediate cause, but enumerated a number of extrinsic causes, such as gastroduodenal catarrh, injury, and pancreatic and biliary lithiasis. The mode of infection he believes is nearly always through

the ducts. Although pancreatitis is a disease without exact pathognomonic signs, the diagnosis can usually be arrived at by a careful study of the history, mode of onset, and the combination of symptoms and signs. A case of acute and infective pancreatitis coming under the author's observation is related, also 4 cases of the suppurative form which were operated on after abscess had formed; of 2 in which the pus was evacuated by an incision in the loin, recovery followed; of 2 opened from the front, both died. In both cases leakage of pus had previously occurred into the stomach and had been vomited. In 1 case of suppurative pancreatitis in which rupture of the abscess occurred in the bowel, the patient was too ill when seen to bear operation, and gradual recovery occurred without surgical treatment. The treatment of acute infective and frequently that of suppurative pancreatitis practically resolves itself into that of peritonitis, commencing in the superior abdominal region, and Professor Robson lays stress on getting rid of inflammatory products by lumbar drainage if practicable, although it may be necessary to make the diagnosis by an interior incision. In the acute form he draws a comparison between gangrenous appendicitis and acute infective pancreatitis and considers surgical treatment just as necessary in one as the other, as soon as a probable diagnosis can be arrived at. If there be great distention in the epigastrium it will be easier and safer to make the exploratory incision in the left costovertebral angle. Treatment other than operative in order to get rid of the distention, relieve pain, fever and other symptoms until a definite diagnosis can be made was also considered. The details of reaching the abscess when found were also discussed, whether the collection be lumbar, subdiaphragmatic, epigastric or pelvic.

Chronic interstitial pancreatitis.—He lays great stress on the importance of this disease, which he believes is often mistaken for cancer of the head of the pancreas and which he believes has not received much attention either from clinical observers or from pathologists, certainly not as much as it deserves. His experience in this class of cases has resulted from his having operated on a considerable number of cases of jaundice depending on obstruction in the common duct, the obstructive jaundice, wasting paroxysmal attacks of pain and ague-like seizures having given rise to the suspicion of gall stones, and the absence of relief by medical treatment having rendered surgical treatment necessary. He argues that its recognition is of vital importance, since it is a disease not only capable of relief but of absolute cure by surgical treatment. The author illustrates his assertion by a brief report of 15 cases on which he has operated, with recovery in 14.

JULES BOECKEL (Strassburg) said: Operations on the pancreas are indicated in cases of injury, inflammation and its consequences (suppurating, gangrenous or hemorrhagic pancreatitis, pancreatic necrosis with fatty necrosis), tumors, solid and liquid (cysts). In recent injuries the scope of intervention is very limited, wounds of the pancreas generally proving fatal very quickly from hemorrhage or concomitant lesions of the neighboring organs. Of 10 recorded cases death occurred in 8. The only rational treatment is to plug the wound after asepticizing it. The search for and ligation of injured vessels, though right in theory, are practically impossible in the

great majority of cases on account of the dangerous condition of the wounded person. In inflammation and tumors the surgical procedure is sometimes on the gland itself, sometimes in its more or less immediate neighborhood. The latter condition is realized when a collection of blood, pus, or other material developed primarily in the pancreas ruptures and becomes encysted between one or other of the numerous peritoneal folds near that organ, or when a solid tumor insinuates itself among the same folds. Under these conditions the operation is extremely simple. The tumor causes a more or less considerable projection, and the serous folds covering it are intimately bound together. One need generally only incise the most projecting part of the tumor to lay it bare and then act according to circumstances. On the other hand, when only the gland itself is involved, intervention is more delicate, more laborious, and necessarily limited. It is delicate because the pancreas lies deep, surrounded by numerous and important vessels, the wound or ligation of which may cause fatal accidents. It is limited because only small portions of the pancreas can be extirpated, complete removal inevitably inducing a rapidly fatal form of diabetes. These intrapancreatic operations are indicated in localized tumors and inflammation of the gland. When the affection has been diagnosed—and this is a difficult point, since diseases of the pancreas have no really pathognomonic symptoms—the first thing to be done is to lay bare the organ. According to the case it may be reached by three different routes:

(1) Subgastric, when, as is seldom the case, the tumor projects above the lesser curvature of the stomach.

(2) Gastrocolic; this is the procedure of choice.

(3) Transmesocolic, when the tumor has insinuated itself between the folds of the mesocolic omentum.

In exceptional cases recourse may be had to incision through the flank (tumors of the tail of the pancreas), the operation then being continued outside the peritoneum. The pancreas having been cleared, search must be made for the focus or the tumor, and then curetting or enucleation should be carried out. Intraglandular operations are of course more dangerous than extraglandular, but even as regards the latter, unless when one has to do with cysts, the prognosis is sufficiently gloomy. The limited statistics at present available prove nevertheless that pancreatic affections, which a short time ago were looked upon as incurable, may now be dealt with successfully by surgical intervention made at the right time. Thus among 20 cases of suppurating and gangrenous pancreatitis there have been 11 cures and 9 deaths; in 23 cases of hemorrhagic pancreatitis there have been 5 cures and 18 deaths; in 11 of solid tumors there have been 3 deaths and 8 cures, 4 of which were permanent. Cysts have been operated in 144 cases, which may be subdivided as follows: Operation in one sitting, 99 cases, 92 cures, 7 deaths, of which 2 occurred during the operation; operation in two sittings, 16 cases, all cured; total or partial extirpation, 25 cases, 21 cures, 4 deaths; cases of which no details are forthcoming, 4, 3 cures, 1 death. Extirpation, which is more rarely applicable, is more serious, more troublesome, and often incomplete. It should be attempted only exceptionally when the cyst is movable and a pedicle can easily be formed. In addition to these radical operations, palliative procedures may be practised

when phenomena of compression of the bile duct or of the duodenum place the life of the patient in danger, as in tumors and chronic inflammations of the head. The serious risks of these operations, and the very slender advantages obtainable from them, make it impossible to recommend them. In the case of solid tumors, cholecystenterostomy has given in 15 cases 7 speedy deaths and 8 recoveries, with a maximum survival of only fourteen months. As regards cholecystogastrostomy (4 cases with very transient improvement), pancreatico-enterostomy (1 case which ended fatally), gastro-enterostomy (2 cases of which 1 died speedily and 1 survived four months), they need only be mentioned by way of record. Jejunostomy, recommended recently by Maydl, seems to give better results. The same operations may be performed with success in chronic pancreatitis of the head, which is so often taken for cancer of the organ. They may even be curative rather than palliative when regression of the inflammatory process takes place, which may happen when the lesions are not too old. Cure is then definite.

RADIOGRAPHY IN THE STUDY OF FRACTURES AND OF LUXATIONS.

G. MAUNOURY, of Chartres, in opening a discussion on this subject, said that the errors that might be committed in the study of the results of radiography were attributable not to the method itself but to defective interpretation. To avoid such errors it was desirable to secure greater precision in the examinations, and to indicate on the prints certain data, notably the point where the vertical line let fall from the focus on to the plate meets the plate.

Fractures.—Dealing first with simple fractures, the author said that in diagnosis radiography rendered invaluable services by indicating the number, form and position of the fragments, their overriding—which, when the proof was clear, corresponded with sufficient exactness to the shortening of the limb—their displacement in different directions and the situation of splinters. To obtain precise information as to the disposition of a fracture it was necessary to radiograph it at two different angles; generally it was taken from the front (frontal plane) and in profile (sagittal plane). There was no absolute rule about this, and each fracture might require a special position of the tube. Very exceptionally a fracture might escape detection even when the bone was examined in different directions. Stereoscopy also gave valuable information as to the position of fragments. The clinical diagnosis of fractures was as valuable as ever, but radiography complemented it very successfully by making it more definite. It might even give it a character of certitude in cases where the complexity of the lesions or considerable swelling of the soft parts left it doubtful. Lastly, it made it less painful by reducing to a minimum the exploratory manoeuvres directed to the seat of fracture. Radiography is useful in all fractures, but especially in fractures of the upper end of the humerus, which are often at the bottom of stiffness and ankylosis attributed to peri-arthritis; of the lower end of the radius, which are often accompanied by lesions of the carpus; of the leg and especially those involving the tibiotarsal articulation—in these last radiography alone can give exact information as to the relations of the astragalus, with the tibio-peroneal mortise, a vital point in the prognosis and treat-

ment of these fractures; of the astragalus, which a few years ago were wrongly looked upon as being very rare; lastly, of the metatarsal bones, which are the anatomical lesion of an affection well known to military surgeons, as to the pathogeny of which there had long been much discussion without its true nature being suspected. The formation of the callus is very interesting if studied with the help of radiography. The first stage cannot be observed, but after some twelve days at the end of the fragments there becomes visible a light clouding which becomes gradually darker. If coaptation of the fragments is perfect the callus forms at the line of the fracture a diffuse globular mass, which by degrees becomes transformed into a distinctly limited fusiform sheath incorporated with the compact tissue. If there is slight overriding the cloudy deposit on each fragment forms the medullary canal and constitutes a thick layer where the fragments touch each other at the side. If the overriding is very extensive this lateral interfragmentary callus does not extend the whole depth of the line of contact, but is produced only at the level of one of the fractured ends, which seems to take a prominent part in the work of the bony union. The time taken in the formation of the definitive callus varies, seeming to be larger in proportion to the size of the bone. In certain cases, notably in oblique fractures of the tibia, the callus may remain a long time invisible even when consolidation appears to be complete. Radiography makes visible in the living body all the varieties of callus known to pathological anatomy, and shows how certain kinds of callus may simulate a perfect coaptation of two fragments which are nevertheless very badly reduced. It shows that in the child the work of bony consolidation, instead of, as is the case in the adult, being limited to the immediate neighborhood of the line of fracture, spreads far along the line of fragments. In treatment radiography enables us better to reduce fractures and to see to what degree such reduction is possible; it is easy to watch the position of the fragments and to rectify it as far as may be necessary during the work of consolidation. When the patient may be regarded as cured, radiography furnishes precise information as to the result. By its means the action of different splints and apparatus—immovable, for continuous extension, etc., can be studied. It has shown that if they are often very effective, they are far from always giving perfect anatomical results; fortunately, perfection of form is not indispensable for the satisfactory restoration of function. Radiography indicates in what cases wiring of the bones may be practised; it is especially in fractures communicating with a joint that this procedure is valuable, for example, in fractures of the elbow and the ankle. In such cases radiography enables one to see if the relations of the articular surfaces have been sufficiently re-established by reduction. If instead of a recent articular fracture one has to do with an old one, radiography alone can define the position of the bones and their deformities, and indicate what operation may be necessary, in what direction the bones should be divided, what should be removed, etc. It will also guide us in the treatment of faulty and irregular callus. In compound fractures radiography greatly simplifies the operative intervention so frequently indicated, obviating the necessity of groping about for splinters, and in cases where wiring is needed showing how the fragments are to be sawn. In fracture of the joint it

shows whether conservative surgery or resection is preferable. In fracture by gunshot it shows the presence of foreign bodies.

Luxations.—Radiography is much less useful in the case of luxations, although in some cases where a luxation has been overlooked it has shown its existence. But it has so far given no information as to the most frequent causes of irreducibility, which lie especially in the soft parts. In old luxations it shows the new-formed bone productions which oppose reduction and reveals the production of false joints. Radiography has enabled us to study and to treat better congenital dislocations of the hip, and it also gives interesting information as to luxations which supervene in coxalgia.

PROF. E. VON BERGMANN, of Berlin, presented a communication on the

PROGRESS IN THE TREATMENT OF FRACTURES SINCE THE INTRODUCTION OF THE RÖNTGEN RAYS.

During the last ten years our knowledge of fractures had made important progress in two particulars: (1) In regard to the operative treatment of certain simple fractures, with the object of effecting exact coaptation of the fragments, and (2) the diagnosis of the seat of fracture and the pathological anatomy of the bone lesions by means of radioscapy and radiography. There are obvious local causes that hinder the union of fractured surfaces: it is known, for instance, that in a broken femur the interposition of muscular fibres prevents the formation of the callus. Unfortunately, it is not possible, with the help of the Röntgen rays, to define this with sufficient exactness to warrant an incision. We can only suppose that the case is so if in the image given by the fluorescent screen we see a gap between the bone surfaces separated from each other in the sense of a *dislocatio ad longitudoem*, and this gap always remains equal in the most various positions in which we may place the broken limb. There are, however, other local causes of want of union, which are shown clearly by radiography; this is particularly the case in fractures of joints and of small bones. It is sufficient to quote an example, namely, fracture of the patella. Malgaigne had deplored the frequency with which cases of fracture of this bone remained unhealed, and recommended long before the antiseptic era an operative intervention by the application of the hooks known by his name. These hooks, however, are much more dangerous than incision and suture of the fragments with silver or bronze aluminium wire. Examination of fractures of the patella by means of radiography reveals three principal obstacles to union:

(1) The inequality in the size of the fragments, the upper being much larger than the lower; they therefore require wiring to keep them in place.

(2) The number of the fragments. In addition to the two principal fragments there are small accessory fragments, or small splinters which slip into the line of fracture, and thus prevent accurate coaptation.

(3) One of the fragments may be displaced by a movement of rotation in such a manner that the fractured surface of the other fragment meets it at its outer surface, so that contact of the fractured surfaces cannot take place. These various displacements being made visible by radiography, the surgeon is able to make up his mind as to the necessity of an operation, and to search for the seat of fracture, so as

to remove the obstacles which have been mentioned, and wire the broken fragments together.

Bergmann, in his clinic, has obtained complete bony union in more than 25 cases of this kind. The operations proved that the union was bony, and not fibrous, and that the metallic suture cured speedily and permanently. Therefore the operation is the general mode of treatment of fracture of the patella. The question of operation presents itself in a different aspect in the case of other fractures; for instance, when one had to do with a fracture of the lower end of the radius, a subject which has been thoroughly studied by E. Gallois. Whilst the treatment of fractures of the patella is almost uniform, the case is otherwise in respect of fracture of the lower end of the radius, the treatment of which varies according to the seat of the fracture and the displacement of the fragments. Professor Bergmann showed a series of photographs taken in his clinic demonstrating the different types of those fractures. Fractures of the tarsal and metatarsal bones were almost entirely unknown before the invention of radioscapy. The symptoms of those fractures were taken for inflammatory swelling or contusion of the foot, and were often treated by massage, with the result that the displacement of the fragments was increased. When the fracture is recognized, it must be treated by complete immobilization. Illustrations of these fractures were also shown.

(To be continued.)

Recent Literature.

Anesthetics: Their Uses and Administration. By DUDLEY WILMOT BUNTON, M.D., B.S., Member of the Royal College of Physicians; ex-President of the Society of Anesthetists; Member of University College; Administrator of Anesthetics and Lecturer in University College Hospital, etc. Third edition. London: H. K. Lewis; Philadelphia: P. Blakiston's Son & Co. 1900.

The third edition of this useful little manual has been carefully revised and brought up to date. Important procedures which have been developed since the previous editions were published, such as Schleich's solutions for general anesthesia, Bier's method of intrathecal cocainization, etc., have rendered this necessary, and are adequately treated in the present edition.

The manual will be found a reliable guide in the various methods of anesthesia, and will be especially valuable to those who wish to become acquainted with the complicated apparatus employed for anesthesia with ether, ether with nitrous oxide, etc., which are generally employed in England. Whether or not we consider that more complication than comfort results from the intricate methods and machinery of our English brethren, we ought, at least, to follow their practice of employing for all serious surgical work a skilled anesthetizer, rather than to entrust our patients to the chances which must be taken in the hands of an etherizer without special training. Our medical schools also ought to see to it that adequate practical instruction in anesthesia be a prerequisite for a degree.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 13, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS

THEORY AND PRACTICE.

WE have frequently found occasion to comment on the popular idea that medicine is divided into two more or less sharply separated groups of men, one of which is devoted to the theoretical side of medical problems, and the other to the treatment of the sick. We have grown wholly weary of the expressions, now so frequently heard, of "the scientific man," and "the practical man," as if they represented two diametrically opposite tendencies. Surely nothing could be more practical than the discovery that cleanliness is prerequisite to surgical success, and nothing could be more scientific than the knowledge underlying the ability to bring a difficult obstetrical case to a successful conclusion. What we must have in the future is not a widening of the breach which separates the theoretical man from the practical man, but a clearer recognition of the fact that theory demands a constantly growing knowledge of practical application, and practice a no less increasing knowledge of theory. There is evidence on every hand to show that this state of things is coming. The routinist, whom Dr. Osler so sharply stigmatized in his recent address in London on "Post-Graduate Study," must, before long, be forced out of existence, and his place taken by Osler's rationalist, who finds time and opportunity to use his microscope and his instruments of precision. These comments, trite as they may be, are not out of place so long as we hear men criticised for being theorists, and hence unreliable in the practical conduct of their professional work. Within a few weeks this has been our lot. A man suggested as a consultant was declined by a physician of many years' practice and experience, because he was claimed to be a theorist, an opinion based upon the fact that he worked in a laboratory. This particular man may have been quite unfit to give an opinion in the case in question, but it was most certainly not because he worked in a laboratory, and tried thereby to get at his subject from all points of view. He may have been a theorist from natural inclination or previous training, but it appears to us extraordinary that in these enlightened days he should have been excluded on the ground

that he was a laboratory, as well as a clinical, student of disease. We claim no special gift of prophecy when we say that the next thirty years will see a readjustment of feeling on this matter, which will render such discriminations impossible.

AS TO PROFESSIONAL VISITS.

FROM time to time physicians are forced to appeal to the courts to obtain their just deserts in the matter of fees. The necessity is always an unpleasant one and one, no doubt, to which the large majority of medical men are slow, and we sometimes think too slow, in resorting. This is a matter of regret since it encourages a certain carelessness on the part of the laity in the payment of their debts and increases the laxity in business methods of which physicians are proverbially guilty. We are therefore always glad to see and to note opinions expressed by the legal fraternity on matters which will tend toward the establishment of generally recognized precedents. A case of this sort has recently been determined in the Supreme Court of Illinois, the question at issue being whether a physician should determine the number of professional calls he should make or should call only when expressly summoned by the patient. A physician sought to obtain payment for a certain number of calls, objection being raised by the defendant that the calls were made without the express request of the patient, and for which he therefore was not financially responsible. The court held that a physician was not called upon to prove the necessity of making the number of visits for which he charged. Citing a previous case, the court ruled as follows:

"Where a physician is called by a person to treat him or his wife, and he takes charge of the case and attends from day to day, evidently, in view of his responsibility for skilful and proper treatment, he must, in the first instance, determine how often he ought to visit the patient, and so long as the person employing him accepts his services, and does not discharge him or require him to come less frequently, or fix the times when he wishes him to attend, he cannot afterward be heard to say that the physician came oftener than was necessary. There was no proof that the claimant came when he was forbidden to come, or that he was discharged and continued to attend thereafter."

Such a ruling would appear to us to be the only one at all consistent with reason and justice. The physician must alone be competent to determine the necessary frequency of his visits and it is altogether unlikely that the confidence reposed in him is often abused. At the same time it is desirable that legal opinion should support the dictates of common sense in this as in other more or less self-evident matters. If such things were to be left wholly to the caprice of the laity it is evident that in the hands of designing persons a very considerable degree of injustice might be done, from which redress would often be impossible.

THE GALVESTON DISASTER.

It is difficult to imagine a more distressing situation than that resulting from the recent storm at Galveston, Texas. The general devastation and destruction of property and life are appalling to contemplate, and particularly when this includes the loss of various hospitals and the patients which they harbored. So complete appears to have been the work of the storm that ordinary means of relief of a medical and surgical sort were for a time quite impossible, owing to the cutting off of outside communication. Incomplete as the reports still are, it appears that the bodies of the dead are being taken out to sea for burial, to prevent the subsequent development of disease among the survivors. The one bright spot in the picture is the hope that future suffering may in great measure be obviated by timely precautions of this sort. Impossible to avert as such catastrophes are, their consequences are at least greatly mitigated by modern sanitary knowledge. Not many years ago we would have anxiously awaited the inevitable reports of suffering through epidemic disease brought on by ignorance of hygienic laws and inadequate means of meeting so unexpected an emergency. In these days of greater knowledge and more perfect equipment we are practically sure that disease will gain no foothold to add to the sufferings already endured. Tents and provisions have already been ordered from Washington, and extreme as the immediate loss of life may prove to be, we may rest assured that the added misery induced by deprivation and want, with their accompanying physical ills, will be wholly averted. Small as this consolation may be, it is at least something, when we pause to think of the effects of a similar disaster fifty or more years ago.

MEDICAL NOTES.

WORK OF CHICAGO MUNICIPAL LABORATORY. — The following details of the work of the Chicago Municipal Laboratory, as given in the July report of vital statistics, are of interest: Total bacteriological examinations, 328; city water, 112; other water, 37; ice, 42; suspected disease (diphtheria 20, typhoid 43, other 13), 76; glycerinated vaccine, 26; food, 35. Distributed: Glycerinated vaccine, 2,450 tubes; diphtheria antitoxin, 310 vials; outfits for bacteriologic diagnosis of diphtheria, typhoid fever, tuberculosis and influenza, 334. Total chemical analyses, 2,222: Milk and cream, 2,052; city water, 100; ice, 41; miscellaneous, 29. Of the 2,052 samples of milk and cream analyzed, 445 were brought to the laboratory by private individuals; the remaining 1,607 were collected by the milk inspectors. Of the 1,607 inspectors' samples 191 were tagged "skimmed milk" and 948 were not tagged, therefore sold for whole milk; of these 90 were found below grade. Out of 468 samples of cream 14 were found below grade. Per cent. of inspectors' samples of milk and cream below grade, 6.47. Of the 445 samples brought to the of-

fice by private individuals, 277 were milk, of which 20 were below grade, and 168 were cream, of which 1 was below grade. Per cent. of samples of milk and cream brought to office found below grade, 4.71. Per cent. below grade, all sources, 6.09. The mortality rate of bacteriologically verified diphtheria treated by antitoxin is reported as 0 in 46 cases treated.

APPOINTMENTS. — Dr. John B. Murphy has accepted a professorship in surgery and clinical surgery in the Northwestern University Medical School and Chicago Medical College. Dr. Murphy has also been appointed surgeon in chief of Mercy Hospital, with the direction of the surgical teaching in that hospital. Dr. Archibald Church has been recently appointed professor of nervous and mental diseases in Northwestern University Medical School and Chicago Medical College, and head of the Neurological Department. Dr. George P. Dreyer, associate professor of physiology in the Johns Hopkins Medical School, has been appointed professor in charge of the Physiological Department of the College of Physicians and Surgeons (Chicago), the medical department of the University of Illinois.

YELLOW FEVER IN HAVANA. — Governor-General Wood has appointed a board of immigration consisting of four physicians, who will draw up regulations concerning immigrants. Since July, 1899, 26,000 immigrants have arrived in Havana, and 10,000 are expected during the next two months. Fifty deaths from yellow fever were reported in Havana during August. While the general health of the city is better than ever before, there is a comparatively large number of cases of yellow fever, owing to the large number of immigrants. Seventy-five per cent. of the total number of cases were among immigrants who had been in Havana less than a year.

A BABY-REARING EXHIBITION IN VIENNA. — According to the *British Medical Journal*, a hygienic exhibition intended for the training of mothers was recently held in Vienna. The chief feature of the exhibition was the display of all that is necessary to the care and nursing of little children. It was intended that the exhibition of new-born babies in incubators should form part of the show, but the authorities forbade this on the ground that there are objections to a public exhibition of children requiring the extreme quiet.

ASSOCIATION OF WAR NURSES. — It is proposed to organize a society to be known as the Spanish-American War Nurses' Association, membership to be given only to those who were in active service at least one month during the war. Of these there are about 500. The president of the association is to be Dr. Anita Newcomb McGee, of Washington, Acting Assistant Surgeon, U. S. Army.

A CUBAN MEDICAL JOURNAL. — According to the *Journal of the American Medical Association*, Dr. John Guitéras, formerly professor of pathology in the University of Pennsylvania, who now holds a posi-

tion in the teaching faculty of the University of Havana, has established a medical journal there entitled *Revista de Medicina Tropical*.

CHOLERA IN INDIA.—Lord Curzon, Viceroy of India, reports that the deaths from cholera for the week ending September 1st were: Native states, 1,930; British districts, 4,021.

APPOINTMENT OF DR. TH. ZIEHEN.—Dr. Th. Ziehen, of Jena, has been appointed professor of psychiatry in the University of Utrecht.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, September 12, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 89, scarlatina 12, measles 11, typhoid fever 16.

BOSTON DEATH STATISTICS.—The total number of deaths reported to the Board of Health for the week ending September 8th is 214, against 168 the corresponding week last year, showing an increase of 46 deaths, and making the death rate for the week 19.9. Of this number 108 were males and 106 were females. The deaths from consumption were 24, pneumonia 18, heart disease 13. There were 10 deaths from violent causes. The number of children who died under one year was 55.

YALE MEDICAL SCHOOL.—The oldest professor in Yale University to leave its service this year is Dr. Moses C. White, for more than a quarter of a century at the head of the work in pathology in the Medical School. He will be continued as professor emeritus. The chair in pathology will be filled by Dr. Charles J. Bartlett, who has been assistant professor in the Medical School for five years. The chair of obstetrics and gynecology, which was made vacant by the death of Prof. George Campbell a year ago, has been filled by the appointment of Dr. Otto G. Ramsay, of the Johns Hopkins University.

CLOSING OF THE FLOATING HOSPITAL.—The season of the Floating Hospital closed Saturday, August 8th. Since the first trip of the summer was made, July 5th, there have been but two days when it was necessary to give up the trip on account of the weather. The summer has been a particularly trying one because of the excessive heat, and more patients have been cared for than ever before. It is hoped another year to extend the season from the middle of June to the middle of September.

DEATHS DURING AUGUST IN NEWTON, MASS.—There were 46 deaths in Newton during August, the rate per 1,000 being 20. Three of the deaths were from accidental drowning, 1 from diphtheria and 3 from typhoid fever.

NEW YORK.

CLOSING OF CITY BATHS.—At the request of the president of the Board of Health, Commissioner Kearney, of the Department of Public Buildings, has

closed two of the free city baths, one located on the Hudson and the other on the East River. With the request was enclosed a report from Dr. F. H. Dillingham, assistant sanitary superintendent, showing that sewers opened near these baths, and pointing out that this was a condition detrimental to those using them. The Health Department was not consulted by Commissioner Kearney when selecting the sites for the baths in question, and they will probably be reopened in more salubrious locations.

RESTRICTIVE LEGISLATION.—Several important changes in the laws which were adopted by the last legislature went into effect on September 1st. Among them was the total suppression of prize fighting in the State by the abrogation of the provision which permitted so-called glove contests (sparring exhibitions with gloves of not less than five ounces each in weight) under certain conditions. Another amendment to the penal code provides that no spring or air gun may be sold to a child under twelve years of age, nor any toy pistol shooting loaded or blank cartridges to a child under sixteen years, without the consent of a magistrate.

NEW HOSPITAL FOR TUBERCULOSIS.—At its annual meeting, held at Albany on September 6th, the Board of State Pensions passed a resolution adopting the report of Commissioner Mantanye, which recommends Dannemora (the location of one of the State prisons) as the site for the erection of the State Hospital for Consumptives, and urging the Hospital Commission to act in favor of the recommendation. Dannemora is situated in the northern part of Clinton County, in the Adirondack region.

PRECAUTIONS AGAINST PLAGUE.—Special precautions were adopted by the health officer in the case of the steamship *City of Rome*, which arrived at New York on September 3d, and was the first vessel to reach the port from Glasgow since the appearance of bubonic plague in that city. One of these was the taking of the temperatures of the passengers and crew and the retention under observation of two or three individuals in whom the temperature was found to be slightly abnormal.

BEQUEST TO A HOSPITAL.—By the will of the late Judge Francis O. Mason, of Geneva, N. Y., the residue of his estate, estimated at \$50,000, is left to the Geneva City Hospital. Judge Mason was president of the institution at the time of his death.

Miscellany.

OBSERVATIONS ON AN OUTBREAK OF DIPHThERIA.

We quote from the *Bulletin* of the New York State Board of Health the following summary of observations made by Dr. W. A. Macy on an epidemic of diphtheria occurring at the Willard State Hospital:

“Early in 1897 diphtheria was brought into the institution through employees who had been in con-

tact with a case near by. There followed an epidemic, a moderate number of cases developing from time to time for six months, when it ceased without recurrence then or during the following year. In June, 1899, diphtheria broke out again, probably likewise imported, spread rapidly, 75 cases occurring, of mild type. It has continued, with intermissions of a month or two, till now, there being at present no actual diphtheria, but a number of germ cases in isolation.

"The condition is of a long lasting epidemic, in an institution, mainly adults, of 2,700 population, under resident medical supervision, with a well-appointed laboratory used on so extensive a scale that every member of the community had cultures taken over and over again, all of which are recorded. It was observed:

"(1) That the type of the disease varies in different epidemics; in the first, 1898, nearly every one exposed, even slightly, took diphtheria, but the course of the disease was mild; in the present epidemic it was much less infectious, but much more virulent in character.

"(2) The germs of diphtheria can maintain activity with much persistence outside the body and resist the action of ordinary disinfectants. Recurrence of the epidemic after all the people were found germ free was found to occur in rooms which after occupation by the sick had been subjected freely to formaldehyde, sulphur fumigation, washing with bichloride, hot soap suds or soda solution, both walls and wood work. Twenty-five cultures were often taken before a building was found free.

"(3) It was found that cases discharged from quarantine after three negative cultures communicated diphtheria, and new cultures showed Klebs-Löffler germs present; the sick were discharged only after three negative cultures taken on alternate days. None of these thus tested were found afterwards to show the disease germs, but nothing short of this was found trustworthy.

"(4) Presence of the germs in healthy throats was found; they persisted there for weeks; cultures were almost or quite as pure as from membranous cases; virulence tests in the laboratory showed them to be as dangerous as those from cultures taken from clinical cases. Membranous diphtheria followed exposure to such, and even at second hand, for in one clear instance a person associating with a germ case without sore throat carried in his clothing the disease in virulent form into a family living several miles distant, bearing germs taken from that case. It would appear then that bacteriological diphtheria is as potentially dangerous as clinical.

"(5) Change in the shape of germs attended convalescence; when these 'degenerate' forms occurred the disease generally soon yielded. There was reason to think that these attenuated forms may under conditions favorable to rapid development increase in strength, but that they have not sufficient virulence to be actually dangerous. While in membrane cases the bacilli followed a definite life history, those from a normal throat may differ daily, a fact important to bear in mind.

"(6) Immunization by antitoxin of all employees, through whom almost solely it spread, and of all exposed patients gave reason for satisfaction, and this experience commends its use for all much exposed.

A lessened dose on repetition is commended, and to give it in fleshy parts of the body not protected on by clothing, not in the extremities. It was used with great confidence in treating the sick, and of 75 membrane cases there were no deaths."

A NEEDLE IN THE HEART.

A most curious case of suicide, as given in the *Medical Press*, has been reported from Ipswich, England. At a first sitting of the coroner's jury the inquest was adjourned, as the medical witness professed his inability to state the cause of death. A post-mortem examination was then made with results of an extraordinary nature. The pericardium was found to contain about two ounces of fluid blood. A darned needle some two inches in length was sticking in the muscular wall of the heart, but had not penetrated its cavity. On further examination a puncture was found in the left breast. The immediate cause of death, however, was not the foreign body in the heart, but poisoning by oxalic acid. The opinion of the medical witness who gave that evidence was that deceased may have taken the poison on account of the pain caused by the needle, which may have reached the position as the result of an accident. It was stated that an uncle of deceased shot himself. This case is of considerable clinical interest, as it shows that a heart can withstand for some time a good deal of traumatic irritation. Indeed, with the aid of a Röntgen ray localization and an operation the patient would possibly have had a chance of recovery.

Correspondence.

CALCIUM HYDROSULPHATE PASTE AS A SURGICAL EPILATORY.

BOSTON, September 5, 1900.

MR. EDITOR:—One of the most important points in surgical technique is the complete removal of hair from the field of operation. The razor is often badly tolerated, and shaving is difficult, especially of the scrotum, the vulva and anus. For some time I have employed with great advantage a paste of calcium hydrosulphate, as recommended by Raybaud, of Marseilles.

The preparation of this paste is as follows: Two parts of freshly slaked lime, from which all grit has been removed, are mixed with three parts of water. The resulting milk of lime is traversed by a current of sulphuretted hydrogen. The milk of lime becomes pasty, and from milky white the mass becomes a bluish green. The odor of sulphuretted hydrogen is not very pronounced.

This product is not caustic in the slightest degree, and may be manipulated without any fear. It will not soil the hands unless they are moistened with a solution of some mercurial salt whose metal is precipitated by sulphuretted hydrogen. The paste must be put up in brown glass bottles and well corked, because calcium hydrosulphate is decomposed by both light and air, more especially the latter. The carbonic acid in the air liberates the sulphuretted hydrogen and transforms the paste into an inert carbonic compound.

The way of employing this paste is very simple. With a spatula or spoon-handle a thin layer is spread on the parts from which the hair is to be removed. If the hair is very long it may be clipped off with the scissors first, but this precaution is not necessary if one is careful to see that the paste is applied down to the skin. The paste is left on

for five minutes and then with tepid water and a towel it is removed by gentle friction. The skin will then be found to be completely free from any trace of hair and better shaven than by the cleverest barber.

The paste is absolutely devoid of any irritating properties to the skin, is painless and leaves no trace behind. The hair grows again perfectly, just as when it has been removed with the razor. In scalp wounds, in genito-urinary, rectal and gynecic surgery it is much better than the razor, as a perfectly smooth skin results.

Truly yours,
CHARLES GREENE CUMSTON, M.D.

AN IMPOSTER.

BOSTON, September 5, 1900.

MR. EDITOR:—Please notify your readers that a man about forty-five years of age, a doctor from Ireland (such is his story), who has had all kinds of hard luck, etc., is looting (to use a military phrase) the medical offices of the city. He gave me his name as Dr. W. J. Campbell. I have excellent reason for believing he is an accomplished "crook."

Truly yours,
J. J. HANLEY, M.D.

SOCIETY NOTICE.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. — The meeting of the association will be held at Atlanta, November 13th, 14th and 15th, under the presidency of Dr. A. M. Cartledge, of Louisville. Members of the medical profession are invited to attend.

RECENT DEATHS.

JOHN LANGDON SULLIVAN, M.D., M.M.S.S., of Malden, died September 5, 1900, aged seventy-three years.

BENJAMIN WEBBER BARTLETT, M.D., M.M.S.S., died in Rowley, August 6, 1900, aged fifty years.

WILLIAM S. WARD, M.D., one of the oldest and most prominent physicians of Newark, N. J., died on September 1st. He had been ill for more than two years in consequence of injuries received by being thrown to the ground from a trolley car. He was born on July 12, 1821, at Bloomfield, N. J., where his father practised medicine for nearly fifty years. He was graduated from Princeton College in 1841, and from the College of Physicians and Surgeons, New York, in 1849, and had passed his entire professional life in Newark.

TREATMENT OF POTTS'S DISEASE AFTER THE DEVELOPMENT OF THE DEFORMITY.¹

BY EDWARD H. BRADFORD, M.D., AND F. J. COTTON, M.D., BOSTON.

The treatment of Pott's disease after the deformity has been developed presents itself to the examiner in two aspects: (1) Treatment of the disease itself for the arrest and cure of a pathological process, and (2) the treatment of the deformity, that is, its correction or the prevention of its increase.

The first of these, the treatment of the disease itself, is a topic which has hitherto been much discussed, but upon which the surgical world is at present in accord. It is agreed that the spinal column should be fixed in such a position as to diminish or abolish intervertebral pressure at the point of disease until complete cicatrization has been established. This fixation should be as complete as is compatible

FIG. 1. SPECIMENS FROM THE WARREN MUSEUM.

with the exercise and fresh air so beneficial in promoting healthy metabolic changes and so counteracting the invasion of the tubercular process. This exercise, however, should be limited according to the urgency of the surgical indication of protection from injurious trauma of the diseased portion of the spinal column. In short, treatment consists in the proper fixation of the spinal column, either in a recumbent position in the acute stage, or with thorough fixation and ambulatory treatment in the subacute and convalescent stage, that is, as soon as the slight jar

¹ Presented by Dr. Bradford at the Thirteenth International Medical Congress, Paris, 1900.

unavoidable in locomotion is permissible without ill effect.

CORRECTION OF THE DEFORMITY.

In the examination of a number of spinal columns affected with Pott's disease it will be seen that there is considerable variation in the condition and in the

FIG. 2. METHODS OF CORRECTION.

(1) Metzger-Goldthwait apparatus; (2) simpler apparatus for producing hyperextension.

curves. In some instances the bodies are but slightly affected; in others the destruction is extensive. The curvature may in some instances not be great, owing to the resistance of unaffected bone tissue sufficiently strong to support the superimposed weight. If, however, the process continues unarrested, complete destruction of the vertebra, with falling forward of the column and an increased projection of the spines, results. If, on the other hand, a condensing osteitis is developed, a cure follows, with deformity. The deformity, as Ménard has shown, depends not only on the extent of the destruction of bony tissue, but also upon the portion of the spinal column affected, it being from static reasons greatest in the dorsal region.

Although attempts at correction of the deformity are as old as surgery, yet at no time have these been more actively considered than at present, thanks to the efforts of French surgeons. Formerly curvature was regarded as a condition not only not to be corrected, but a necessary result, indicating the establishment of a cure; at present, however, the kyphosis is looked upon more properly as an evil to be prevented or corrected if possible.

Since the publication of the recent French surgical writings on the subject, forcible correction has been attempted all over the surgical world, and the results

FIG. 3. DR. R. T. TAYLOR'S APPARATUS FOR CORRECTION.

obtained are worth careful consideration. The accompanying statement presents the statistics of for-

eible correction found in the literature on the subject:

Six hundred and thirty-nine cases were performed by thirty-four operators.² Time elapsed varied from a few days up to three years and more. Of the separate detailed cases in 7 more than one year had elapsed; in 35 more than six months.

Deaths reported from all causes, 25; various diseases, 5; general tuberculosis, 4; trauma of the operation and chloroform, 5; intercurrent disease, 7.

FIG. 4. DIAGRAMS ILLUSTRATING METHODS OF APPLYING FORCE.

I. With kyphos upward, traction in the long axis of the spine, support beneath the two ends, downward pressure on the knuckle. II. With the kyphos downward, resting on a point of support, traction in the long axis assisting the correcting influence of the weight of the two segments either side the supporting fulcrum. III. With the kyphos similarly placed, downward pressure at the opposite ends of the spine. IV. The apparatus used for experiment.

Immediate results: Respiratory embarrassment, 7; pain, 6; severe shock, 3.

Abscess present before operation, 19; ruptured, 4; benefited or absorbed, 6; appeared after operation, 2.

Paralysis present before operation, 23; relieved, 17; not relieved, 2; made worse, 1. Paralysis appeared after correction in 4.

Direct effect on deformity in 240 cases: Complete correction, 130; incomplete, 94.

Result in 77 cases: No relapse, 20; some relapse, 50; total relapse, 7.

Although it is irrational to place too much stress on statistics, yet from the figures here presented it appears that more force can be used with safety in the attempt at the correction of a kyphosis than was formerly considered possible (639 cases with but 5 deaths from the procedure itself). The amount of force to be employed with safety may be said to depend upon the amount of resistance and solidification of the affected bone. It is of course unsurgical to produce a severe trauma in tubercular bone in the process of a conservative cicatrization, but the rectification of a curve with the employment of comparatively slightly injurious force, as it diminishes the intervertebral pressure, is of benefit. The less force required in correction the more readily is the rectification to be undertaken. If force is needed to produce correction involving fracture of solidified tissue, the method is inapplicable. Osteotomy is also unadvisable. If a large gap is to be left, demanding too

great reparative power in the diseased tissue for the development of an ossifying osteitis, complete rectification is undesirable. If a considerable amount of caseous detritus lies in the concavity of the kyphosis, or if rectification would increase dangerously the pressure of the tubercular mass retained under a pleural or peritoneal wall, a correcting force should either not be applied or applied with great care and judgment. Existing paralysis of Pott's disease is sometimes relieved by correction. On the other hand, paralysis at times may be caused by forcible correction.

The accompanying drawings (Fig. 1) from specimens in the Warren Museum illustrate three stages in the development of the curve: (1) When the process is active and the curve flexible, permitting rectification; (2) when fusion of the posterior column has occurred with an unhealed gap; (3) where complete solidification and fusion and cure with deformity results.

Correction treatment is admissible in the first of the stages only.

When correction by force is undertaken several methods have been employed: (1) Vertical suspension from the head; (2) vertical suspension by the head and arms; (3) horizontal traction of the recumbent patient with the pull upon the head, arms and legs; (4) the same with downward pressure upon the projection and support at the neck and hips, the patient lying upon the face; (5) traction with the patient lying upon the back; (6) downward pressure upon the pelvis and upper portion of the trunk, with upward resistance at the back at the point of maximum projection, the patient lying upon the back, with or without traction to the head and feet; (7) the patient lying upon the back, with upward pressure by means of a strap passed under the patient at the point of greatest projection connected with a cord and pulley; (8) correction with the patient seated, the upper portion of the trunk being stretched backward while the point of projection is pressed forward at the knuckle and the pelvis secured by a strap.

These different modes involve the employment of two methods of application of force: one that of press-

ure, the other that of a pulling force. Experiments upon the cadaver show that the correcting force to be

² These figures are based on the statistics collected by Dr. R. H. Vose for the article by Drs. Bradford and Vose in the *Annals of Surgery*, vol. xvii, p. 223, 1899, the data from more recent reports being added.

preferred is that of pressure rather than traction, as the former is more precise in its effect upon the diseased tissue than a pulling force, which is partly expended upon the secondary curves. A pulling force involves an unnecessary strain upon the neck and on the lumbar region which, where an anesthetic is not used, causes pain not essential to correction. A pressure force may be made to act more directly and with less waste.

It can be said that the mode of application of a correcting force which is desirable varies necessarily according to circumstances, but that method is to be regarded the best by which the force applied can

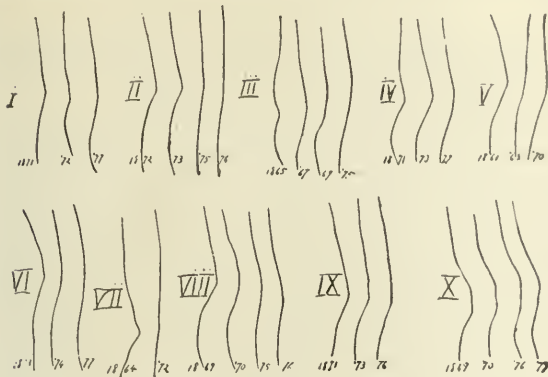

FIG. 6. TRACINGS SHOWING RESULTS OF BRACE TREATMENT AS CARRIED OUT BY DR. C. F. TAYLOR.

I. Two and three-quarters years, first and second lumbar disease, five years' treatment. II. Eight years, eleventh and twelfth dorsal, four years' treatment. III. Four years, first lumbar, ten years' treatment. IV. Three and one-half years, six years' treatment. V. Five years, twelfth dorsal, first and second lumbar, nine years' treatment. VI. Five and one-half years, sixth and eighth dorsal, four years' treatment. VII. About eighteen, dorsolumbar, eight years' treatment. VIII. Nine years, seventh to ninth dorsal, seven years' treatment. IX. Twenty years, five years' treatment. X. Ten years, eight years' treatment. (Dates are given with tracings, the age given is that at which treatment was begun.)

be more easily controlled by the surgeon and which can be employed with the least discomfort to the patient. That also is to be preferred in which the retaining jacket can be applied to a spine held in a corrected position with the least discomfort to the patient and the greatest facility to the surgeon. If no force is needed on the secondary curves or upon the neck, an anesthetic is often not needed to enable the surgeon to use as much correcting force as is desirable.

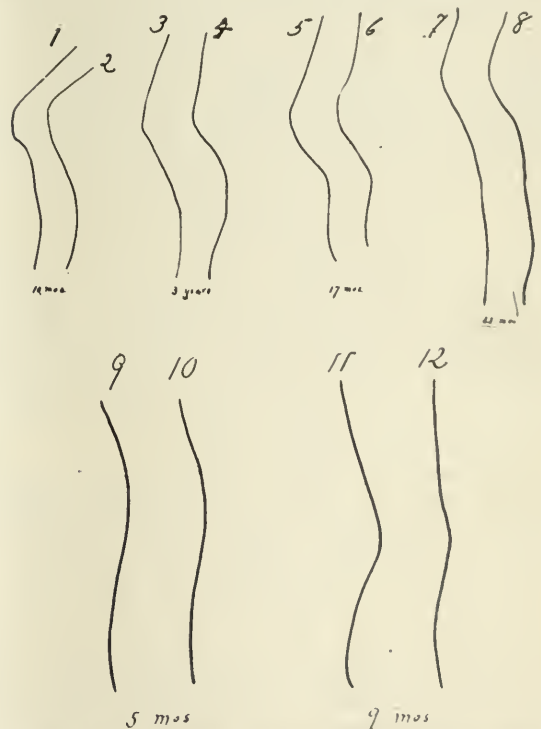

The difference in the effect of a pulling force from that of a correcting pressure force upon a distorted spine is demonstrated by the accompanying experiments:

EXPERIMENT I. The cadaver was of a five-year-old child, in whom death had occurred after Pott's disease of several years' duration, with abscess and amyloid. There was a marked lower mid-dorsal curve, involving two vertebrae, and an accumulation of pus under the quadratus lumborum of both sides, but more marked on the left. The curve was flexed and rounded. The abdomen was opened, all organs removed, and traction applied to the head and thighs. Pins were inserted into the bodies of the vertebrae adjacent to the point of disease at right angles to their long axis. During traction, the distance between the heads of these pins was measured. Under trac-

tion of great force, separation of half an inch was possible, the trunk being recumbent and the traction being in the same plane with the table on which the trunk was placed, with the face upward. If a support was placed underneath the projection, raising it, and a slight downward pressure applied (without traction) at the shoulders and hips, a separation of an inch was easily obtained.

EXPERIMENT II. Specimen at the Harvard Medical School: An adult spine with destructive disease of the third lumbar vertebra; moderate sized knuckle, but not much deviation in the axis of the vertebral bodies (see Tracing 1, Fig. 5). With the dorsum upward, a pull in the axis of the spine of about 150 pounds failed to correct the deformity or to do more than stretch some of the adhesions. On laying the spine with the dorsum down, however, and fixing the portion below the knuckle on the table, downward pressure applied at the upper end of the spine began to be effective with a force of 30 pounds, and an entire abolition of the kyphosis was possible with but little more force. After the adhesions had thus been ruptured, a direct pull in the axis of the spine was again tried; even with much force the best attainable correction was that shown in Tracing 2, while a few pounds of downward pressure at the upper end (the spine being supported with the back down) sufficed for complete correction or even reversal of the deformity (Tracing 3).

EXPERIMENT III. Specimen at the Harvard Medical School: This, like the previous specimen, was an adult spine, with an unhealed destructive disease

FIGS. 7 and 8. RESULTS OF HYPEREXTENSION TREATMENT (GOLDTHWAIT).

- (11) At beginning of treatment; (12) same after nine months.

of the third lumbar vertebral body. Here, however, the deformity was very slight (see Tracing 5). Traction in the axis of the spine had practically no effect on the deformity even when great force was applied. On supporting the knuckle from below, however, the mere weight of the upper segment of the spine sufficed to open up a considerable gap at the point of the disease, and a very slight downward pressure at the cervical region brought the spine into an approximately normal correction.

EXPERIMENT IV. The same spine was taken to produce an artificial kyphosis; parts of the bodies of the eighth and ninth dorsal vertebrae were chiselled away and the spine bent into a marked kyphosis (see

FIG. 9. TRACINGS OF A CASE OF FORCIBLE REDUCTION (PECKHAM). (a) Tracing (from profile photograph) before reduction; (b) similar tracing after reduction under ether; (c) direct tracing two and one-half years after reduction. Patient seven years old.

Tracing 4). Staples were then driven in, as the pins were in Experiment I, and between these staples strong rubber bands were stretched. By measuring the length of these bands under the different manipulations, and ascertaining the direct force necessary to stretch them to like length when unstrung from the staples, it was possible to obtain an approximate estimate of the direct disrupting force developed by the different methods of correction. Reduction of the deformity to the line shown in Tracing 5 was found to correspond to a stretching pull at this point of 9 pounds. To develop such a disrupting force by traction in the axis of the spine required a traction of 21 pounds. A 16-pound pull corrected the spine to a tolerably good position only. With the spine steadied by slight traction (the dorsum still upward) a downward pressure of 4 pounds at the knuckle was enough to accomplish a like correction. With the dorsum downward, on the other hand, with the knuckle supported and the lower spinal segment fixed, a downward pressure at the upper end of the spine of but $\frac{1}{2}$ to 1 pound sufficed for full correction.

EXPERIMENT V. The conditions of the last experiment were approximately reproduced in a wooden model (see Diagram IV, Fig. 4) similarly provided with staples and rubber bands; in this case full correction corresponded to a disrupting force of 12 pounds, as measured by the stretching of the rubber bands. To accomplish this by direct pull from end to end required a traction of 20 pounds. With the ends steadied, dorsum up, required a downward pressure at the angle of 3 pounds. With the knuckle and the lower segment supported, and the dorsum downward, a little less than 1 pound sufficed for full straightening.

Anteroposterior pressure corrective force of the type of the Metzger-Goldthwait appliance appears to meet the necessary conditions for correction and application of the bandage more precisely than Calot's method, as the correcting force can be accurately es-

timated by the surgeon and there is less wasted on the secondary curve.

In all methods difficulty is met in preventing an exaggeration of the lumbar curve. Traction is the most efficient way of preventing this, but flexion of the thigh (if the Metzger-Goldthwait apparatus is employed) can also be used to advantage. An advantage will be found in the dorsal over the abdominal recumbent position in a greater facility in the application of the bandage in the front, the position which most needs staying. The pressure plates (padded aluminum plates) can be left in the jacket, or flat steel rods can be used and drawn down and out after the plaster has hardened.

REPAIR AFTER CORRECTION.

After correction it is necessary to retain the spine in a corrected position until the gap made in correction is repaired or supported by ankylosis.

The reformation of bone may, under favorable circumstances, be rapid and considerable. For instance, in a case of Dr. E. H. Nichols, of Boston, where a third of the humeral shaft had been removed subperiosteally, after extensive osteomyelitis, a solid new shaft formed within nine months. A case reported by Dr. H. W. Cushing, of Boston, showed reformation of the tibial shaft (after excision for osteomyelitis) in nine months. Formation of new bone in the spine may be similarly rapid after fractures. Wagner and Stolper report autopsies (with plates) showing firm callus uniting fractured vertebral bodies at ten, eight and four months, eight weeks and even six weeks after the injury.

It does not follow, however, that such repair occurs after the forcible separation of diseased vertebrae. There is really no evidence that such gaps are ever filled up with bone. Ménard's investigations tend to show that the formation of new bone by the periosteum (shown to be essential to firm repair in fracture) is in most cases scanty and late. Drehmann has

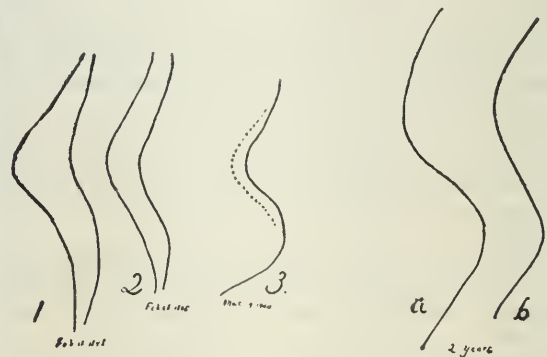

FIG. 10. TRACINGS OF TWO CASES OF FORCIBLE CORRECTION (GOLDTHWAIT).

I. (1) Tracings before and after the first correction under ether; (2) tracings before and after the second correction, ten days from the first; (3) tracings two years later; the dotted line shows the first tracing of Fig. 1; the relapse of the deformity is seen to be almost complete. II. (a) Tracing before correction; (b) tracing two years later.

studied 47 specimens and comes to similar conclusions.

A study of 21 specimens in the Warren Museum in Boston shows in the more recent cases (numbering 10) only slight repair of any sort. Locking of the vertebral bodies by the progressing deformity is usual and in some cases there is partial fusion of the sur-

faces of the vertebral bodies where these come in contact, but there is no formation of new bone in mass. The older specimens show more extensive fusion, in some cases ankylosis of the posterior column, with or without a considerable new formation of bone in this region, but only 6 of the 11 show periosteal new bone at the seat of the disease itself.

Of these 6, 1 is a long-healed kyphosis dating back forty-three years before death. This had healed by fusion of the vertebral bodies, and the considerable masses of periosteal bone evidently belong to an ankylosing osteo-arthritis not limited to the seat of the

FIGS. 11, 12 and 13. TRACINGS IN THREE CASES OF FORCIBLE CORRECTION (GIBNEY).

FIG. 11. (a) Before correction; (b) at four and one-half months; (c) at five months; (d) at fifteen months.

old tubercular disease. A second similar specimen is evidently a long-healed process. The other 4 specimens show periosteal bone formation in small amount supplementing a firm fusion. The tubercular disease in these 4 cases dated back nineteen, fourteen, ten and six years, respectively, before death.

The specimens brought forward in argument by Calot, Krause of Altona, Gayet and others apparently date back as do these to long-healed tubercular disease. The conclusion is inevitable that formation of new bone in mass from the vertebral bodies is not the usual method of repair in Pott's disease, and that such formation only occurs after years, if at all.

As to direct evidence of cases examined after forcible correction, the autopsies reported by Malherbe, Murray (2), Sherman, Brann, Krause and Anders (4), all fail to show any evidence of new growth of bone. The skiagraphic illustrations do not seem to have proved any such new formation. Calot's drawings from radiographs are certainly not convincing.

RETENTION AFTER CORRECTION.

It is manifest that a retention appliance is as important as the correction itself, and it is necessary that careful fixation in a corrected position should be carried out for a long period. How long this period is is a question not yet definitely determined, but it is manifest that the time of the cure claimed by some surgeons is much too short.

It is evident that in small children with short spines and also in high curves adequate retention is impossible and a certain amount of relapse of the cor-

rected curve is therefore unavoidable in many cases.

Unremovable plaster jackets form the most feasible means of immediate fixation, accompanied at first with recumbency which removes the superimposed weight, but as recumbency is incompatible with the healthy condition necessary for repair, the patient should, as soon as possible, be allowed locomotion.³

ARREST OF THE DEVELOPMENT OF THE CURVE.

Where correction is not possible for various reasons, either on account of the situation of the curve or on account of the pathological condition, the treatment by fixation of the trunk with appliances is to be employed with the hope of arresting the development of the curve. The retention of the spinal column in the best possible position is therefore always important even if correction has been attempted. Where fixation treatment is neglected, even if satisfactory correction has been attained, a relapse of the curve will follow.

Preventing an increase of the curve by mechanical means involves a great deal of care and attention to detail, more than is usually possible in large hospital clinics. Increase of curve, therefore, can be checked by a treatment of rectification, using repeatedly the methods of application employed in forcible correction, but with the use of but little force. This constitutes, with proper retention measures, a rational means of treatment in Pott's disease applicable to a large number of cases, but necessary for a long period of time.

What can be accomplished by purely mechanical treatment applied with great care thoroughly for a long period is indicated by the accompanying tracings (see Fig. 6).

The results here shown, obtained through the courtesy of Dr. H. L. Taylor, indicate an unusual degree of success in the practice of the late Dr. C. F. Taylor, of New York. One of the writers had the opportunity to personally examine the cases to verify the

FIG. 12. (a) Before operation; (b) under traction at operation; (c) on removal of jacket fifteen days after operation.

accuracy of the records and later tracings. The treatment was entirely ambulatory in the convalescent stages, and consisted of the most thorough mechanical

³ A description of the variety of effective removable appliances which have been and are employed as convalescent devices would involve a greater amount of space than is allotted to this discussion. Reference is therefore made to the various handbooks on orthopedic surgery.

anteroposterior support carried out persistently through years. In a few cases actual improvement in the curve was observed after years of treatment, as has been shown also by Dr. H. L. Taylor in the *Transactions of the American Orthopedic Association*. In some an increase in the curve resulted; in most, however,

FIG. 13. (a) Before operation; (b) after operation; (c) one month later.

the progress of the curve was relatively slight, often none.

The tracings here presented are selected from a large number as being the most illustrative.

CHECK OF THE LATER INCREASE OF THE CURVE.

After the tubercular process in the spinal column is arrested, and complete bony anchylosis has occurred, and the cure established in a growing child, it will sometimes be found that an increase in the curve may take place in the course of the growth of the child, which is due not to a continuation of the tubercular process, but to a change in the shape of the vertebrae caused by the abnormal direction of superimposed pressure, as rachitic curves in growing children may increase in the long bones, even after the rachitic process itself is arrested. The extent of these secondary curves and their development depend upon

FIG. 14. TRACINGS OF A CASE THROUGH FOUR YEARS, SHOWING THE NATURAL TENDENCY TO INCREASE WHERE TREATMENT IS NOT CAREFULLY FOLLOWED OUT.

the rate of growth of the child and the amount of superimposed weight rather than upon a condition

of osteitis. In order to check this distorted growth it is found necessary to continue the use of supporting appliances longer than the pathological condition would seem to demand. In cases of this sort it is possible to check the increase of the curve only by the use of such appliances as will maintain the proper position.

OPERATIVE MEASURES.

It has been shown that the main support in the diseased spinal column is in the articular processes. Where these are welded together in connection with an anchylosis of the transverse and spinous processes, nature has furnished the most desirable support to a spinal column with diseased vertebral bodies. Attempts to promote solidification of these tissues naturally suggest themselves, but these can hardly as yet be said to present an established method of treatment.

The question of laminectomy for paralysis, as well as that of operative treatment for abscesses or vertebral sequestra, are not considered as coming within the scope of this report.

It may be said in conclusion that the correction or rectification of the curve in Pott's disease is to be considered in every case of active disease with a deformity. The employment of force should depend on the pathological conditions and not on the extent of the curve. Force should be used with great reserve. Improvement of the curve is to be considered in every case, and is to be attempted wherever the spinal column can be made straighter without great force. The main dependence, however, for an ultimate success remains in the surgeon's careful, continued, and thorough employment of retention appliances which hold the spine in the straightest possible position for a sufficient length of time for consolidation of the diseased bony structures. Success is to be won more by careful attention to detail than by an operative attempt.

JOSEPH W. ENGLAND'S FAT-FREE TINCTURE OF DIGITALIS.¹

BY ELBRIDGE G. CUTLER, M.D., BOSTON.

In July, 1899, my attention was called to tincture of fat-free digitalis by Mr. Edward S. Kelley, of the firm of Kelley & Durkee, of Boston. This is a preparation devised by Joseph W. England, chief druggist of the Philadelphia Hospital, Philadelphia, to meet the serious drawback of bulk in the use of the infusion of digitalis when large doses are required to secure the desired needs of action on the heart and kidneys.

Mr. England, in 1892,² presented a paper to the Pennsylvania Pharmaceutical Association on the subject of infusion of digitalis. In discussing the subject of digitalis leaf, he said that the term digitalin had been given to a variety of products, but was generally reserved for the compound obtained by Schmiedeberg in 1875. He found that the commercial digitalins, whether crystalline or amorphous, were varying mixtures of Schmiedeberg's digitalin, digitoxin, digitonin, digitalein, and certain decomposition products. Of these, all except digitoxin were believed to be glucosides. Neglecting the decomposition products, these principles could be grouped best into two classes according to solubility: (1) Those soluble in alcohol and insoluble or almost insoluble in water; (2) those soluble in both water and alcohol. Digitalin and digitoxin would be assigned to the first class, and digitonin and digitalein to the second class, the tincture and fluid extract containing most largely digitalin and digitoxin, with some digitonin and digitalein, while the infusion contained digitonin and digitalein with no digitalin or digitoxin. Hence the difference in clinical value between the aqueous and alcoholic preparations of digitalis leaves. Mr. England spoke of the superior therapeutic worth of English over German leaves and this was ascribed to the fact of the English leaves being carefully freed from nerves and stalks (which had been shown to contain only one-fifth as much digitalin as the leaf parenchyma), thereby reducing the element of variation to a minimum. Since 1892, however, Mr. England (through personal advices from London) found that much of the so-called English leaves are simply very carefully sifted German leaves, and not English cultivated leaves, as was supposed. He also called attention to the fact that the freshly made infusion was feebly acid in reaction, while the tincture gave the acid action more promptly, owing, as he thought, to a greater solubility of the acids of the leaf in alcohol and the presence of a larger quantity in solution. The acids present in digitalis leaves are the odorous antirrhinic acid of Morin (1845) and the fatty digitoleic acid of Kosmann. The percentage of fixed oil obtained by petroleum benzine extraction and spontaneous evaporation was relatively high. In 1887 he obtained about 5%. The oil contained a volatile portion and a fixed oil. It was a dark reddish-brown liquid of heavy, persistently narcotic odor, largely soluble in alcohol, freely soluble in ether or chloroform and not readily inflammable, showing the absence of any trace of petroleum benzine. It left a permanently greasy stain on bibulous paper. Its specific gravity was about .850. Heated for eight hours it lost 5.4%, and also

¹ Read before the Clinical Section of the Suffolk District Medical Society, March 21, 1900.

² American Journal of Pharmacy, July, 1899, pp. 332-344.

lost its peculiar narcotic odor, becoming more fatty, thus indicating the loss of a volatile portion.

Tincture of digitalis, when given any way, sometimes causes profound gastric disturbance, even nausea and vomiting. Mr. England, believing that possibly this might be due in part, if not wholly, to the fixed oil in the leaf and its free acid, prepared some years ago a so-called fat-free tincture in which these two principles were eliminated.

For the past five years the tincture of fat-free digitalis made by Mr. Joseph W. England, to replace the official tincture, has been used in the wards of the Philadelphia Hospital. Dr. Daniel E. Hughes, chief resident physician of the Philadelphia Hospital, makes the following clinical statement to Mr. England, and it is printed in this paper:

"The vast majority of the cardiac and nephritic patients coming to the Philadelphia Hospital have had as a marked and subordinate complication chronic gastric catarrh, and could not stand the administration of the official digitalis tincture, but could take our more bulky infusion. To secure the desired cardiac and nephritic action of this valuable drug required large doses of the infusion, which was a very serious drawback to its use. Mr. England's attention was called to the subject, and he suggested that he might be able to prepare a tincture of digitalis of the same strength as the official preparation, but devoid of the nauseating proximate principles of the latter. He prepared his preparation, and we submitted it to extended employment. After the continued use of this particular preparation of digitalis I can speak of its efficiency and non-nauseating properties. I am confident that it is much more promptly absorbed than the official tincture and this makes the cumulative action of this drug almost, if not altogether, *nil*. Again, more prompt absorption is shown by its quicker action upon the heart, and increase in the flow of the urine.

"The non-irritating properties of this special tincture of digitalis are forcibly shown by its hypodermic use, abscesses having never followed its use, while the official tincture almost invariably causes pain, swelling and abscess formation from hypodermic use."

Mr. England makes his fat-free tincture of digitalis by exhausting the leaves while freshly ground to a No. 60 powder with purified petroleum benzine, either by maceration with solvent in excess for forty-eight hours, if in small quantities, or by maceration and subsequent percolation, if in large quantity, repeating the solvent treatment until all the fat, etc., is removed. The residue is then dried by exposure to air, taking care that no particle of benzine odor remains. While benzine is very volatile, the last portions of it volatilize rather slowly relatively when spontaneously evaporated, especially if adherent to vegetable structure. Exposure of the residue to sunlight, as well as to open air, he says yields the best results.

After the benzine treatment, the dried and powdered leaves are made into a tincture according to the process for the official product, 150 grammes of leaves being used to make 1,000 cubic centimetres with dilute alcohol, with this difference that the reservoir is removed when the total percolation amounts to 980 cubic centimetres, and it is then carefully neutralized with a sufficient quantity (about 10 or 15 cubic centimetres) of the official 10% ammonia water, and the

product is made to measure 1,000 cubic centimetres with fresh percolate or diluted alcohol, or, as he gives it, with the usual weights and measures 1,094 grains of the powdered leaves may be exhausted with dilute alcohol to yield 15½ fluid ounces, and then about 1 or 2 fluid drachms of 10% ammonia water will be required to effect neutralization, after which sufficient percolate or diluted alcohol should be added to make the whole product measure 1 pint. After standing for twenty-four hours the newly made tincture usually precipitates some coloring matter, etc., which should be removed by filtration through paper.

The product as finally obtained is a deep, reddish-brown, almost black, liquid, keeping perfectly for years, of not unpleasant odor and a pure bitter taste. It does not have the acrid odor or taste of the official tincture and, unlike the latter, does not become turbid on admixture with water, but remains transparent with any amount of dilution.

The purposes of this procedure are two-fold: (1) The benzine treatment removes the fat and probably all the nauseating odorous principles; (2) the ammonia treatment neutralizes the free acids present in the leaf, forming the ammonium salts.

It does more than this. The neutralization with ammonia makes all the proximate principles in the tincture water-soluble and not partly so as in the official product. (When the official product is diluted with water, it precipitates.) This is especially valuable for the reason that all compounds before absorption by tissues must first be made soluble before they can be absorbed. By this means absorption is facilitated and assimilation is hastened, as will be shown by pharmacological results later.

"When the fat-free tincture was first made, the object was to obtain a preparation which would not nauseate, and clinical results in the Philadelphia Hospital have shown that this end is very generally accomplished. A short time ago, however, an even more valuable feature of the fat-free tincture became evident. This was the *rapidity* with which the preparation was absorbed and assimilated in comparison with the official product. Observations were then made to determine clinically the relative rapidity with which the fat-free tincture and the official tincture were each absorbed, noting, (1) the time of primary effect; (2) the time of maximum effect; and (3) the pulse reduction or work, both in male and female patients and both hypodermically and by the mouth."

This work was performed by Mr. England with the assistance of Dr. F. A. Sherrer. Great care was exercised in obtaining patients in whom the physical conditions were as nearly uniform as possible, so that comparative results could be had. The cases chosen were mostly rheumatic with endocarditis. Patients were given the tinctures three hours after meals, when the stomach was practically empty, the fat-free tincture one day, the official the next. No food or water was taken during the time of administration. The beginning of each administration was so timed that there was no serious difference between the rate of pulse beats when the giving of each preparation was commenced. At most the primary time was never more than 6 beats. It is obvious that if a heart is beating almost normally one day when one tincture is given, and is beating tumultuously the next day when another tincture is used, that uniform conditions do not exist, and comparative results can-

not be had. The next essential is rest in bed and perfect quiet. No sphygmographic tracings were made to determine the rapidity of absorption and action more accurately, but the preliminary trials made by the mouth showed that primary effects were obtained with fat-free tincture in about fifteen minutes, and primary effects with the official tincture in about thirty minutes. The tinctures were both made from Allen's digitalis leaves. The fat-free tincture was made in January, 1898, the official in September, 1898. The following are some of the results which were obtained:

CASE I. Male patient; tinctures given by mouth; doses, 10 minims.

Fat-free tincture. March 29, 1899.		Official tincture. March 30, 1899.	
Pulse.	Time.	Pulse.	Pulse.
90	3.45 P. M.	86	
88	4.00 "	86	
88	4.15 "	82	
86	4.30 "	82	
84	4.45 "	80	
82	5.00 "	80	

Fat-free tincture.—Primary effect in fifteen minutes, full effect in seventy-five minutes; pulse reduction or work, 8 beats.

Official tincture.—Primary effect in thirty minutes, full effect in sixty minutes; pulse reduction or work, 6 beats.

CASE II. Male patient; tinctures given by mouth; doses, 10 minims.

Fat-free tincture. April 1, 1899.		Official tincture. April 2, 1899.	
Pulse.	Time.	Pulse.	Pulse.
78	3.45 P. M.	80	
74	4.00 "	80	
73	4.15 "	78	
72	4.30 "	76	
71	4.45 "	73	
71	5.00 "	72	

Fat-free tincture.—Primary effect in fifteen minutes, full effect in sixty minutes; pulse reduction or work, 7 beats.

Official tincture.—Primary effect in thirty minutes, full effect in seventy-five minutes; pulse reduction or work, 8 beats.

CASE VI. Male patient; tinctures given hypodermically; doses, 10 minims. Same patient as Case II.

Fat-free tincture. April 17, 1899.		Official tincture. April 18, 1899.	
Pulse.	Time.	Pulse.	Pulse.
58	9.30 A. M.	54	
54	9.45 "	54	
47	10.00 "	50	
46	10.15 "	50	
46	10.30 "	49	
48	10.45 "	51	
48	11.00 "	52	

Fat-free tincture.—Primary effect in fifteen minutes, full effect in forty-five minutes; pulse reduction, or work, 12 beats.

Official tincture.—Primary effect in thirty minutes, full effect in sixty minutes; pulse reduction, or work, 5 beats.

CASE IX. Male patient; tinctures given by mouth; doses, 10 minims.

Fat-free tincture. May 20, 1899.		Official tincture. May 21, 1899.	
Pulse.	Time.	Pulse.	Pulse.
54	10.00 A. M.	54	
48	10.15 "	52	
48	10.30 "	48	
46	10.45 "	48	
46	11.00 "	44 asleep.	
50	11.15 "	44	
52	11.30 "	46	

Fat-free tincture.—Primary effect in fifteen minutes, full effect in forty-five minutes; pulse reduction, 8 beats.

Official tincture.—Primary effect in fifteen minutes, full effect in sixty minutes; pulse reduction, 10 beats.

This is the only case in which primary effect took place in fifteen minutes with the official tincture; as the patient was in an especially quiescent state preparatory to sleeping, the tincture had less work to do than usual, and did it more quickly. The marked reduction of pulse beats is due to the same cause.

In all there were 15 cases examined. The following is a summary of results:

SUMMARY OF RESULTS.

Case.	FAT-FREE TINCTURE.			OFFICIAL TINCTURE.		
	First effect, minutes.	Full effect, minutes.	Work, or beats reduced.	First effect, minutes.	Full effect, minutes.	Work, or beats reduced.
1	15	75	8	30	60	6
2	15	60	7	30	75	8
3	15	60	5	30	90	5
4	15	45	8	30	75	6
5	15	45	6	30	60	5
6 h.	15	45	12	30	60	5
7 h.	15	45	10	30	60	6
8 h.	15	45	8	30	60	8
9	15	45	8	15 l.	60	10

13	15	45	10	30	45	6
14	15	45	3	45	105	6
15	15	60	8	45	45	4
Averages.	15	49	76	31	66	64

h. hypodermic cases; others, by mouth.
l. exceptional case, explained in text.

Twelve of the above patients were male, 3 female. In 12 of the cases the tinctures were given by mouth, 3 hypodermically. Mr. England arrives at the following conclusions: Of these results it may be said that practically the primary effects of the fat-free tincture were manifested in fifteen minutes, and the maximum in forty-five minutes; while with the official tincture primary effects were obtained in thirty minutes and the maximum in sixty minutes. In both cases, however, the duration of effect was the same, thirty minutes. The pulse reduction, or work, was slightly greater with the fat-free than with the official. The most striking difference, however, exhibited between the fat-free tincture and the official tincture was the *much greater rapidity of absorption* and action of the former, showing a speedy assimilation. The time element of direct action is a very important matter in some cases and might readily mean the difference between the life and death of a patient. No especial difference in the time of absorption between hypodermic injections and mouth administrations was observable, but when the tincture was given hypodermically the pulse reduction seems to have been greater with the fat-free tincture, though not extending over any greater length of time.

The short abstract of Mr. England's paper shown me by Mr. Kelley in one of the pharmaceutical journals was so convincing, coming as it did from such an authority, that I was eager to try the preparation, and

Mr. Kelley very kindly placed some of it at my disposal in a few days. This was early in August or late in July, 1899. The first patient to try it was a man of seventy odd, who had been a sufferer from cardiac disease for several years. Of late he had had broken compensation, shown by ascites and great edema of the legs, shortness of breath on exertion, frequent attacks of dyspnea, both by day and night, the latter especially severe, considerable cough, abundant expectoration, passive congestion of liver and spleen as shown by their great enlargement on palpation and percussion, passive congestion of the kidneys and digestive tract. He had no appetite, suffered from gastric oppression and distention after food, and felt generally miserable. He could only take the official tincture of digitalis in small doses for two days at a time with a week's respite, as it had been used for several years, and had frequently been pushed to its full limit of tolerance. Trial of the infusion was equally ineffectual because of the large dose and nauseating character of the preparation. From the very first dose the fat-free tincture agreed with the patient and he has been taking it uninterruptedly to the present time.

In another case where the official tincture of digitalis could not be used at all except for two days at a time, and where the drug was grievously needed, I have been enabled to give the fat-free form three times a day from the time I first began it in August till the present time, with the very best results. This patient was unable to endure even the smell of the ordinary preparation, although to my senses there was little difference in their odors. I have not used the preparation in the Massachusetts General Hospital sufficiently long (only since March 1st) to obtain any new ideas in regard to its action, but my experience of the past seven months has been confirmed with reference to its usefulness. This tincture does not do more than the official tincture will do, but it will not produce nausea or disturbance of the digestion as the latter may and frequently does do. In my experience it fills a place which is a very important one in practice, and I bring forward Mr. England's paper with the hope that the profession will be induced to make a trial of the preparation so as to see if the experience which has been recorded is correct, as seems to be the case now.

KNEE-JOINT SURGERY FOR NON-TUBERCULAR CONDITIONS.¹

A REPORT OF THIRTY-EIGHT OPERATIONS FOR SYNOVIAL FRINGES, INJURED SEMILUNAR CARTILAGE, LOOSE CARTILAGE, COAGULA, EXPLORATORY INCISION, ETC.

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

In presenting this subject it is my hope that from a study of the cases and in the general discussion something may be added to our knowledge of joint surgery. The cases which are presented are those in which the knee joint has been freely opened, either for diagnosis or to render the function of the joint more perfect. The cases in which operations have been performed which would tend to lessen the

normal use of the joint, such as excision or erosion, are excluded, as are also all cases in which the operation has been performed as a part of the treatment of the septic or suppurative processes. All of the cases included in this series were at the time of the operation sterile, so far as the condition of the joint was concerned. In all the knee was the joint operated upon, but while this joint must, from its size and anatomical structure, more often require such treatment than the others, nevertheless the same principles apply to any of the other articulations.

The age of the patients varied from four to sixty-five years, and this fact seemed to be of about the same importance as in other operations.

There is, as you all know, a popular impression that for some reason it is more dangerous to open the large joints than any of the other large cavities, and while this impression is less commonly held than formerly, yet even now because of it operations are refused and patients are condemned to long courses of non-operative treatment, which frequently is not only inconvenient, but may disturb to an irremediable degree the normal character of the joint structures. The reason of this fear is undoubtedly very largely due to the serious results which attended such operations in the pre-antiseptic days, and the statements which are to be found in the textbooks of those days have to a considerable degree influenced the writings of the more recent times. That opening a joint is more feared by the average surgeon than opening the cranium or the abdomen is partly due to these traditions, and is similar to the fear formerly felt in regard to these very operations which are now performed so commonly and so successfully. Similar changes will undoubtedly take place in joint surgery as it becomes more common and better understood, and the occasional unfortunate result will be easily overlooked in the great general good which will result from such work.

It is my personal feeling that there is no more danger in opening the knee or any of the other large joints than in opening the peritoneum. Neither operation should be performed carelessly or without due preparation, but in case the symptoms cannot be relieved in any other way, there should be no hesitation in resorting to the operation. To go still further, if there is any question as to the diagnosis, and the doubt means otherwise a long period of inactivity, with the danger of destructive changes taking place which could be prevented, there should be no hesitation in opening the joint to determine the exact nature of the disease, so that proper treatment can be prescribed. It is practically impossible at times to differentiate between some of the beginning rheumatoid diseases and tuberculosis in the same stage, and yet it is at this very time that it is of the utmost importance to know the exact nature, as the treatment of the two conditions is so radically unlike, and if sufficient time is allowed to elapse for the diagnosis to become clear, the disease is so far advanced that nothing more than imperfect results can be obtained.

In children this question of doubt does not so often arise, as at this time of life the majority of subacute or chronic joint affections are tubercular, and as in these tubercular cases early operative interference is so rarely indicated, the exploratory incision is less often necessary. In adults, however, where the non-

¹ Read at a meeting of the Surgical Section of the Suffolk District Medical Society, and at the meeting of the American Orthopedic Association, held in Washington, May 1, 2 and 3, 1900.

tubercular chronic joint affections are in the majority and as even in the tubercular cases early operation is so much more often the best treatment, there should not, it seems to me, be the least hesitation in determining through the exploratory incision the exact nature of the disease if it is not possible in other ways.

This, I am aware, is an opinion not as yet held by many surgeons, whether in general surgery or in the special branch which constitutes our specialty, but it is an opinion which becomes stronger each year as the results are observed under the different methods, and I have not the slightest hesitation in urging its general adoption. As an illustration showing how impossible it is to differentiate between these different diseases, it has been my fortune during the past year to see one of the most hopeless, helpless cripples from rheumatoid arthritis that I have ever seen. This patient was treated for nearly two years by one of our best orthopedic surgeons for tuberculosis of the knees, first one showing the symptoms and then the other, and not until the other joints gave out was the real nature of the disease recognized. This is mentioned not in criticism, but to show how difficult it is to differentiate in many of these cases, even by those who are specially trained; and also to emphasize the importance of early diagnosis, as I feel convinced, from seeing a large number of these cases in the different stages, that if the exact nature of the disease in this case could have been known in the very beginning the result would have been very different. It is because of this great risk which is run by waiting in these doubtful cases that the exploratory incision is so strongly urged. In my own work before this procedure was adopted there was the same uncertainty, and cases which were supposed to be one disease proved to be another, and harm resulted at times from too little treatment and at other times from too much. In determining the exact nature of the disease with the joint open it has been found necessary to depend more upon the microscopic examination than upon the macroscopic appearance, as more than once a condition which was supposed to be non-tubercular has revealed the characteristic lesions of that disease in the microscopic preparation, and vice versa.

Of the cases which are reported there are 32 patients and 38 operations. In 5 cases both knees were operated upon; in 1 case, with displacement of the semilunar cartilage, a second operation was necessary. Of the 38 operations, 1 was for the removal of several loose pieces of cartilage. This patient was a woman of sixty-five, and the only point of special interest is the origin of the loose pieces. Three pieces, as large as hickory nuts, were removed, and were without question some of the osteo-arthritis nodes which formed a ridge at the edge of the cartilage of the femur, these, because of their size, having been broken off at some time in the joint motion.

Two of the operations were performed upon a case of irreducible dislocation of the patella of many years' duration, in which very extensive plastic operations were necessary to hold the bones in place and restore the function of the joint. This case has been previously reported,² and is here mentioned to show what extensive operations can be performed upon the knees without interfering with the normal

function of the joint. In both knees it was necessary to leave a gap in the capsule of the joint on the outer side fully an inch and a half wide and several inches long. This was closed only by the skin and superficial tissue, and yet one joint is normal in its function, and in the other there is only some limitation of extreme flexion.

In 1 case the exploratory incision revealed a beginning osteosarcoma. In 1 case the operation showed the symptoms to be due to osteo-arthritis nodes. In 5 cases the nature of the disease by incision was shown to be tubercular and appropriate treatment was prescribed. The incision did not change the course of the disease, but that which up to that time had been uncertain as to diagnosis was made clear.

Semilunar cartilage.—Nine of the operations were for the relief of symptoms produced by injury or displacement of the semilunar cartilage. In all of these cases conservative treatment had been thoroughly tried without success for various lengths of time, and the operation was performed as a radical cure. These cases have been of considerable interest especially as contrasted with the cases which have been treated without operation, and a more careful study may not be unprofitable.

All of the patients were young, and with one exception were young men. In all the inner segment of the cartilage was the portion affected, but the cause of the original trouble varied. In some there was severe injury, while in several nothing more than turning quickly or going up stairs was the explanation. The cases which have been brought on by such simple movements have all had lax joints, and the pinching or tearing of the cartilage has undoubtedly resulted from the unnaturally free motion. In a closely "knit" joint, with firm ligaments, apparently considerable force is necessary to make the motion possible that will bring about this result.

The lesion which has been present in these cases has not been, as I had expected, a dislocation of the cartilage due to rupture of the ligament which held it in place, but a crushing and laceration of the cartilage at some point with or without a rupture of the ligaments. In 4 of the cases the ligaments were intact at the time of the operation, the lesion being a crush or tear of the inner edge of the cartilage. In 2 of the cases there was a tear one-quarter of an inch long into the cartilage from the inner edge, and this inner edge commencing at the tear was folded over onto the rest of the cartilage, forming a ridge on which the femur caught in motion. With this condition present it is readily seen that a comparatively slight violence would tear the cartilage entirely across and away from its attachments. Clinically I am sure that I have seen this condition take place, where after occasional slight catches, causing comparatively little inconvenience, there has been a more severe catch associated with the protrusion of the cartilage on the inner side of the joint, which can usually be slipped back by careful manipulation. These cases at the time of the operation have shown a badly torn cartilage more or less detached. In 1 case over an inch of the cartilage was entirely free, except for a small bit of ligament, while in still another, with a piece nearly as large, even this attachment was lacking.

The point at which the crushing has taken place in all of these cases has been at the curve made where

² *Annals of Surgery*, January, 1899.

the anterior portion joins the lateral portion, and if the piece is finally torn free it is the piece anterior to this point. In the operation this anterior portion, which represents about one-third of the whole, has been the part removed, except in one instance, in which, as the result of a foot-ball accident, the ligament was torn more extensively, and the whole inner cartilage was removed.

For treatment, in 2 of the cases the cartilage was stitched into place. One of these relapsed and was entirely removed later. The other case, a woman, when last heard from was well.

In all of the other cases, representing the later cases, the injured portion has been entirely removed, and this I am sure is the better operation. Suture of any kind because of the structure of the cartilage must be uncertain, and at the best necessitates a long course of carefully supervised protection of the joint afterwards. With the excision of the loose fragment the joint can be moved in a few days, and the after treatment ends in from three to four weeks, with no possible danger of relapse.

Synovial fringes; coagula.—In the remaining 19 operations the symptoms were produced by masses of fibrin or unnatural folds of the synovial membrane, and as both conditions were usually associated they are included together in this report.

The folds of synovial membrane or fringes are undoubtedly present in any inflammatory process in or about the joint, and the membrane is thrown into folds simply because of its great vascularity, and that, whenever for any cause the normal supply of blood is increased, the membrane becomes swollen, and as the firm and comparatively unyielding capsule prevents the membrane from increasing its size in its long axis, it must increase vertically and the folds result. The size and extent of the fold depends upon the direct cause of the trouble. The simplest form is seen in the so-called dry joint, so commonly met with at middle life. In this type, in the general relaxation of the structures of the joint and the lack of tone of the muscles, the synovial membrane is relaxed and, as is true of the other parts, the relaxed tissues become passively congested and swollen. The creaking or snapping is due to these folds or fringes slipping over each other, and in these joints there is little variation from the normal amount of fluid. In the large majority of these cases under stimulating treatment that would tend to increase the tone of the part, the membrane resumes its normal condition, the creaking or snapping gradually disappearing as the strength returns.

If, however, this relaxed or swollen condition persists for any length of time, the power of contraction is much impaired, so that recovery is at least prolonged. Occasionally the folds which are near to the patella are caught in the articulation, with the result that the joint is more or less locked (depending upon the size of the fringe), and the fringe itself is bruised by the pinching and becomes swollen. It is readily seen that this swelling would make the fringe larger, so that it is more apt to be caught if motion is allowed. If it is caught or pinched but once, it may retract to its former size, but if this be repeated many times it loses its elasticity and a loose fold of synovial membrane or a true fringe results, which remains after the rest of the swelling has disappeared, as a tab or loose fold hanging from an

otherwise normal membrane. As this pinching in the articulation represents one of the chief causes of these permanent fringes they are, of course, found chiefly about the patella.

After a fringe has once formed it is evident that it may at any time become caught between the bones, and the frequent acute attacks in these cases are undoubtedly to be explained in this way. It is also apparent that the joint may be locked by such a fringe similarly to the action of a loose cartilage, although the catch is not so abrupt or so complete as in the latter case.

After the fringe has once formed the continued irritation which must result from movement of the joint is followed by an hypertrophy of the structural elements of the fringe and results in the papillomatous appearance of what originally must have been a simple tab. As the irritation goes on, however, the hypertrophy due to the overstimulation ceases, and degenerative changes begin following the rule which applies in other parts, that, in processes of degeneration, structures of a higher order are replaced by structures lower in the scale.

The change most commonly seen is fatty degeneration, and this has been seen in varying degrees from a small point of fat tissue to the replacement of almost the whole of the fringe, so that it exists as a lipoma inside the joint. In 1 case six or eight of these small lipomata or degenerated fringes were removed. In 1 case a calcareous degeneration was found and in the membrane there were numerous calcareous bodies, varying in size from the head of a pin to a good sized pea, which on section showed true cartilage and bone cells. These were entirely distinct from osteo-arthritis nodes and were found between the layers of the synovial membrane instead of on the outside of the membrane, as would have been the case had the change been due to that process.

Associated with the fringes in most of the cases were masses of coagulated fibrin, free within the joint, varying in size from small flakes to, as was present in one instance, a mass over an inch in diameter. These two conditions were so often associated and apparently are so similar in etiology that they are considered together.

Whenever for any reason there has been a large increase of the joint fluid, it is possible that instead of the fluid being absorbed as the inflammation subsides, the fibrin of the fluid may separate and form a coagulum. This, of course, has no color, but is simply a mass of white fibrin which moves about in the joint as a foreign body. The nature of the original inflammation does not seem to be of importance in the formation of these coagula, as is shown in the cases of this series. One was a case of acute articular rheumatism, which was referred for treatment because, after the active disease had subsided, the knee joints remained swollen in spite of all ordinary measures. In this case the diagnosis of the condition was made, and at operation the coagula were washed out with entire relief to the symptoms. The condition has also been seen in tuberculosis, in traumatic synovitis, in rheumatoid arthritis, and the largest coagulum of all was removed from a child who had had a small punctured wound of the knee, which had been washed out with hydrogen peroxide through the original small wound.

It is evident at once that these coagula represent a

foreign substance inside of the joint and that they are capable of producing irritation and symptoms similar to other loose bodies. That the motion of a joint may be seriously interfered with by such a substance is not to be questioned, and the only difference between the symptoms produced by it and those produced by a loose cartilage is that which would result from the different density of the two structures.

It is evident also that as this fibrin may produce continued and frequent irritation and that as continued and frequent irritation is the chief cause of the synovial fringes, these fringes are present in most cases where coagula are present. The reverse of this statement is also undoubtedly true, and that as the irritation caused by the presence of these fringes may result in an increase of synovial fluid, the opportunity for the formation of the coagula is presented.

As the operations have been performed the two conditions have usually been associated, but with varying predominance, and in the cases where both knees have been operated upon the two joints in the same individual have varied. In one the fringes have predominated, the coagula being of distinct secondary importance, while in the other joint the exact reverse of this has been the condition found.

Operation.—The operations which have been performed in these cases have varied somewhat with the nature of the trouble. For the exploration or removal of the semilunar cartilage a longitudinal incision about 2 inches long at or near the point of injury of the cartilage has been on the whole satisfactory. In case a more extensive view of the joint is desirable the incision can be enlarged transversely. The point of injury can usually be determined by careful examination before the operation. For the cases in which purely exploratory operations have been performed, an incision 2 or 3 inches long either just inside or just outside the patella has been used and this enlarged as much as necessary to determine the exact nature of the disease. Usually a piece of synovial membrane has been removed for microscopic examination.

Coagula could, of course, be removed through either of the above incisions, but where fringes are present an incision on both sides of the joint is desirable, so that the whole cavity can be explored. The fringes should be trimmed off so that all the irregularities are removed. No attempt need be made to close the wounds that are thus made in the membrane itself, and whatever bleeding there may be from these wounds can be satisfactorily controlled by flushing the joint with hot water. For closing the joint, fine silk sutures have been used for the capsule with silkworm gut for the skin and subcutaneous tissues.

The preparation for these operations has been similar to that for any other sterile operation, the only thing of special importance being rest of the joint for a few days previously in case there is any evidence of acute trouble.

The after treatment, unless the incision has revealed some serious disease, has consisted of complete immobilization of the joint for one week, plaster of Paris being the splint commonly used. During the second week most of the patients have been up on crutches, the dressings being removed once or twice daily for passive motion. During the third week a flannel bandage has been substituted for the stiff bandage, the crutches have been discontinued, and use, to-

gether with stimulating bathing, has been encouraged. During the fourth week all treatment except the stimulating bathing has been discontinued and this has been kept up for varying lengths of time, depending upon the strength of the joint.

Results.—The results in such a series of cases naturally depend upon the nature of the condition for which the operation was performed.

In those in which the operations were purely exploratory, the course of the disease was in no way changed.

The patients with whom the semilunar cartilage was at fault were well and at their usual occupations in four weeks with one exception—a circus acrobat, who waited six weeks before returning to his work; the longer interval being the result of caution rather than disability. All of these patients are, so far as I know, well, with the uncertainty of usefulness, which was present before the operation, entirely removed.

The cases in which the symptoms were due to the coagulated fibrin were naturally relieved by its removal, as was also the case of loose cartilage.

The fringe cases are improved in varying degrees, depending upon the nature of the disease which caused the fringes to develop. Where the fringes were simply the result of the weak or relaxed condition of the joints as the result of the operation and the after treatment the joints are normal. The other cases have been improved in just such proportion as would be expected from the nature of the disease.

One patient with osteo-arthritis is, I think, worse for the operation, which apparently made the disease more active, a condition which has been observed in operations performed upon other parts of the body where this disease is active. This result, together with a similar result which I have seen in the hands of another surgeon, and from my experience with this disease in other parts, leads me to the conclusion that operations should be avoided upon any part where this disease is present, unless it has been for a long time quiescent.

Conclusions.—The purpose of the paper is to show, by considering the results obtained in 38 operations, that operations upon joints need not be feared more than operations upon other parts of the body, and because of this to urge the importance not only of operating to relieve a definitely recognized condition, but also to make use of exploratory incisions in the doubtful cases to determine the exact nature of the disease. Without this it is impossible in many cases to differentiate in the incipient stage between several different conditions, and it is at this very time that the most can be accomplished in the way of treatment if the exact condition is known.

Of the 38 operations, 1 was for the removal of a loose cartilage; 2 were for permanently dislocated patella; 7 were for exploration to determine the nature of the disease; 9 were for removal of an injured or displaced semilunar cartilage; 19 were for the removal of synovial fringes or masses of coagulated fibrin.

No unpleasant results followed the operations except in 1, a case of osteo-arthritis, in which the disease was apparently made more acute. The exploratory incision, with this one exception, did not alter the course of the disease. The cases from which the semilunar cartilage was removed have functionally normal joints. The cases in which the synovial

fringes and coagula were removed are improved in proportion to the nature of the disease which caused the condition to be present.

Medical Progress.

RECENT PROGRESS IN THORACIC DISEASES.

BY GEORGE G. SEARS, M.D., AND JOHN W. BARTOL, M.D., BOSTON.

THE COIN SOUND IN PLEURISY WITH EFFUSION.

MOUSSOUS¹ speaks of the value of the coin sound (*signe du son*) in children as well as in adults in differentiating between pleural effusions and pulmonary consolidations. He says that when the lung is healthy the sound transmitted is obscure, muffled and without metallic quality, but when an effusion, either serous, fibrinopurulent or hemorrhagic, is present in a pleural cavity free from adhesions the metallic sound is perfectly clear. Neither ordinary congestion of the lungs, with the exception of splenopneumonia, nor the different forms of inflammatory and neoplastic indurations are able to produce this sign and it is the same with bronchopneumonic nodules, infarctions, tubercular infiltrations and even encysted pleuritis or fluid effusions in the pericardium, so that, without being pathognomonic, the coin sound gives very valuable evidence of an effusion, while it also allows one to recognize the height of the fluid in pneumonia accompanied by a pleural exudate, as well as that portion of the area of dulness in pleuritis with false membranes which corresponds to the liquid exudate. The only condition in which doubt may arise is in the diagnosis between pleuritis and splenopneumonia, since it is present in both conditions. The idea, however, of an ordinary inflammatory or congested condition of the lung can be immediately dismissed.

MYOEDEMA IN PULMONARY TUBERCULOSIS.

Myoedema is the name applied to the phenomenon occasionally produced by sharply striking the pectoralis major with the tip of the finger, and characterized by a fascicular or nodular contraction of that muscle. Its significance has been variously interpreted. Walsham² has examined 1,000 out patients with pulmonary tuberculosis with reference to the presence or absence of this sign. He found that it only becomes well marked when the wasting has advanced beyond a certain degree, although a suspicion of the fascicular variety, but never the nodular, may sometimes exist in an early case. In fact, the more the wasting, the more marked the myoedema unless the loss of tissue becomes extreme. A blush following the tap on the muscle is almost as characteristic as the contraction. He has found no alteration in the normal electric reactions, although many observations have been made.

He concludes that the phenomenon is nearly valueless as an early sign of pulmonary tuberculosis, since it only becomes well marked when other physical signs leave no doubt about the diagnosis, but it is useful as indicating the condition of the muscular system of the patient and of showing approximately the amount of wasting that has taken place. He has never found it in a perfectly healthy person, but agrees

with West that it can be obtained in other wasting diseases beside phthisis.

THE CAUSES OF IMMUNITY AGAINST TUBERCULOSIS IN HIGH ALTITUDES.

Mitchell and Crouch,³ working at Denver at an altitude of 5,290 feet, found that the tubercle bacillus, expectorated on a sandy soil, has lost but little of its virulence after twenty hours' exposure to the direct rays of the sun, and is still active after thirty-five hours. They therefore believe that Koch's statement that the bacilli, presumably in pure culture, are killed in a few minutes to several hours has given sanitarians a false sense of security. The fact is that sputum expectorated by consumptives, at such an altitude as Denver, has ample time to become desiccated and blown about in the air before it has been robbed of its power for harm. Another explanation for the great degree of immunity from tuberculosis which exists in that region and at that altitude must be found. It probably arises from the effects of the climate on the vital forces of the individual:

(1) By the slight humidity, both absolutely and relatively in the atmosphere, which with the lessened atmospheric pressure and almost constant winds greatly facilitates evaporation. The loss of moisture is very rapid from the pulmonary alveoli, and though these could scarcely become too dry to serve as a nidus for the tubercle bacillus, the constant evaporation may produce unfavorable conditions for its development. Owing to the absence of atmospheric moisture, the heat at high altitudes is not enervating.

(2) The lowered atmospheric pressure causes dilatation of the cutaneous and mucous capillaries. The pulmonary capillaries are dilated, and the blood stream is so slowed that it can better give battle to the invaders. The diminished amount of oxygen tends to increase the frequency and depth of respiration and the thorax is thereby expanded, while the heart's action is also increased for the same reason. The body warmth is continually lost in large quantities, and to replace it, other things being equal, the appetite increases, metabolism is more rapid and complete, and the need of nourishment greater. Evaporation also raises the specific gravity of the blood, and the number of red corpuscles and the percentage of hemoglobin are increased. In other words, the very factors which tend to heal or retard cases of phthisis in high altitudes account for the immunity of those who live there.

MERCURY IN THE TREATMENT OF HEART DISEASE.

Morison⁴ speaks enthusiastically of the value of mercury in certain cases of cardiac disease. Its influence upon the circulation may be said to be chiefly an indirect one. Brisk purgation may withdraw some of the watery constituents of the blood, and thus reduce the weight of the circulating fluid, but this direct action must not be overestimated. As a vasomotor relaxant the effect of mercury on the heart is wholly indirect. By removing an impediment the work of the heart is made easier.

In another way mercury is of value from its action on the kidneys, where it, at times, has so powerful an effect that it might be permissible to regard the diuresis resulting as a veritable renal purgation, the

¹ Rev. mens. des mal. de l'enfance, January, 1899.

² Lancet, January 27, 1900.

³ Journal of Pathology and Bacteriology, May, 1899.

⁴ Lancet, October 28, 1899.

effect continuing for a week or ten days after the calomel has been stopped. This is usually manifested on the fourth or fifth day, and the quantity of urine often amounts to 12 pints in twenty-four hours. It acts better in mitral than in aortic cases, and is useless when there is concurrent nephritis of non-cardiac origin. Its action is often increased by the addition of digitalis, strychnine or arsenic.

THE DIAGNOSTIC AND PROGNOSTIC SIGNIFICANCE OF THE DIAZO REACTION IN PHTHISIS.

Michaelis,⁵ after reminding the reader that the diazo reaction is never present in the urine of a healthy person, and is in no way dependent on the existence of fever, goes on to make four general groups of disease classified according to their relation to this reaction. In the first he puts diseases in which the reaction is practically never found, that is, the chronic affections of spinal cord, of kidney, of the heart (sclerotic origin), malignant tumors, or, in short, all processes not the result of acute or chronic bacterial invasion. If the reaction occurs in such conditions he considers it significant of secondary infection by bacteria. The second group comprises such diseases as ordinarily show the reaction and in which it is of value in diagnosis, that is, typhoid and measles. In the third group he classes diseases like pneumonia and diphtheria, in which the reaction is seldom present and when positive speaks for a grave prognosis. In the fourth group he places by themselves the tubercular processes. In these the reaction is often of diagnostic value; thus, in patients without fever or definite signs, a long persisting diazo is generally significant of tuberculosis; positive reaction in ascites speaks for tubercular peritonitis as against carcinomatous, or liver cirrhosis; its presence in meningitis throws the weight of diagnosis toward tubercular sources; in exudative pleurisy it has a similar value. It is always present in miliary tuberculosis. But a special value is given to it in the prognosis of phthisis, so much so that in phthisis with well-marked diazo the prognosis may be put down as absolutely bad. After a few precautions as to the technique and the necessity of fresh solutions attention is called to the fact that the reaction may be present when naphthalin or chrysarobin is being exhibited and that it may be inhibited by the administration of gallic or tannic acids and their compounds (tannigen, tannalbin, etc.), and also large doses of iodine.

The rest of the paper is taken up with a discussion, statistical and otherwise, of its value in the prognosis of phthisis. Mild and uncomplicated cases of phthisis practically never show the reaction, and its presence is significant of acute accompanying infection, or else suggestive of serious invasion of tubercle bacilli, with few physical signs. On the other hand, the absence of the reaction when the clinical picture is of an advanced stage is suggestive of a slow advance, or else of temporary improvement. As a result of recorded results in 167 cases, he concludes that a very large proportion of phthisical patients showing the reaction will die in less than six months.

PURULENT PERICARDITIS.

Manges⁶ reports a case of pericarditis secondary to pneumonia and due to the pneumococcus, in which,

after the aspiration of 18 ounces of pus, some 40 more were removed by open incision under local anesthesia with eucaine. Recovery was complete, and in six weeks the patient was able to leave the hospital. After the operation pericardial adhesions remained so that at each systole there was a retraction of the overlying tissues. The pulsus paradoxus was also present.

In speaking of the treatment of this condition he says that as soon as it is established that pus is present, pericardotomy should be done, as all the reported cases in which aspiration was thought sufficient have terminated fatally, while out of Roberts's 35 cases treated by incision only 20 died, of whom 10 were distinctly septic beforehand. Even when enormous amounts of pus are found, patients have a reasonable show, if an open operation is fearlessly done.

In speaking of pericarditis as a complication of pneumonia he says that of 500 at Mt. Sinai Hospital, it developed as a complication in 11, of whom 5 died, a mortality of 45%. This probably does not represent the frequency of this complication, as pericarditis during pneumonia is often overlooked.

Dr. Connor⁷ also reports a case following pneumonia, in which 30 ounces of pus were withdrawn by aspiration. As the symptoms did not improve and the patient was in an extremely bad condition, incision was made under local anesthesia and nearly 40 ounces more removed. During the operation, in spite of the utmost precaution, the pleura was slightly incised. It was at once carefully closed, but probably became infected. The patient died of a purulent pneumonia a few days later.

INVESTIGATIONS OF THE HEART AND CIRCULATION IN TUBERCULOSIS.

Regnault,⁸ in his "Thèse de Lyon," shows that atrophy of the heart is not the rule in tuberculosis, in spite of the fact that it is a disease especially productive of atrophy in the tissues in general. Dilatation of the right heart in tuberculosis affects chiefly the auricle and occurs less commonly in the ulcerative than in the fibrous form. It is the result not only of emphysema, pleural adhesions and pulmonary sclerosis, but also of the rapid diminution in the area of circulation.

Lowering of arterial tension is a constant phenomenon in tuberculosis, keeping pace with the fever and the cachexia, but also existing in the cases of slow progress and those without fever. It is the result of a toxin produced by the tubercle bacillus or an associated infection. It has a certain diagnostic value in those cases without physical signs and a prognostic significance in that the tension is found to rise in cases advancing to recovery. The instability of the pulse, so constant a sign, is dependent on the lowered tension, as is also a rapidity out of proportion to the temperature.

Genuine attacks of tachycardia are sometimes observed, due possibly to mechanical or toxic irritation of the sympathetic, possibly to a combination of the irritability of the vagus and the low arterial tension.

THE HEART WALL IN DIPHThERIA, RHEUMATIC FEVER AND CHOREA.

Poynton,⁹ from a study of 18 cases of rheumatic

⁵ Berlin, klin. Wochn., xxxvii, 13.

⁶ New York Medical News, January 29, 1900.

⁷ New York Medical News, January 20, 1900.

⁸ Gaz. heb., No. 26.

⁹ Lancet, May 12, 1900.

heart disease, 4 cases of diphtheria, 1 case of chorea, and 1 experimental case of staphylococcus infection, draws the conclusion that there may be extensive myocardial changes as a result of toxic influence without any demonstrable valvular or pericardial lesions, or any symptoms of nerve paralysis. He explains on this basis those cases in which there is unaccountable breathlessness, precordial pain and other indications of cardiac inadequacy. Dilatation as a result of these myocardial changes he finds much less common in diphtheria than in rheumatism. The practical aspect of the matter is the importance of not waiting for definite auscultation or percussion signs before assuming that the heart is implicated and consequently in need of appropriate treatment; such precaution being especially indicated in children.

THE INFLUENCE ON THE HEART OF MECHANICAL IRRITATION OF THE LIVER.

Heitler,¹⁰ who has already demonstrated the change in the extent of heart and liver dulness with change in size of pulse, — that is, small pulse, increased dulness; large pulse, diminished dulness, — found in an overworked mechanic a marked variability in size of pulse brought about by percussion of liver or by vibrating the anterior costal border. Thus when the pulse was small, percussion or vibration produced an immediate increase in its volume for from 5 to 25 beats or longer; the frequency of the pulse, meanwhile, showed practically no change. That the reflex arose from the liver was shown by control tests in the splenic and abdominal regions. These effects are thought to have a bearing on the recognized association of circulatory disturbances with certain disorders of the liver.

OLIVER'S SIGN IN MEDIASTINAL TUMORS.

Auerbach¹¹ reports 2 cases which, while they discredit tracheal tugging as a sign pathognomonic of thoracic aneurism, at the same time give it added weight as a symptom significant of intimate connection between the aortic arch and the primary bronchus. In both the cases tracheal tugging was exquisitely demonstrated, and in both was found to be caused by a firm adhesion between the arch and bronchus due to malignant growth, evidence of which had been given during life by marked dulness beneath the sternum simulating aneurism, the other characteristic signs of which, however, were absent. In the second case the adhesion was caused by a malignant packet of glands, which was not larger than a walnut.

Oliver's sign, however, still remains in doubtful cases more suggestive of aneurism than new growth, owing to the comparative rarity with which the latter would be so situated as to bring about the conditions necessary for the production of the tugging. The same conclusion holds true with Cardarelli's sign, a modification of the other. The technique for which consists in pushing the thyroid cartilage to the left of the middle line. When the sign is present there will be perceived a slight pulsation of the cartilages toward the right; on the contrary, displacement of the cartilage toward the right results in no such pulsation.

¹¹ Deutsch. med. Woch., xxvi, 8.

THE RELATIVE INTENSITY OF THE SECOND SOUNDS AT THE BASE OF THE HEART.

Dr. Sarah Creighton¹² draws the following conclusions from a study of 1,000 cases:

(1) Accentuation of the pulmonic second sound is almost invariable in young children and frequent in youth.

(2) After the fortieth year of life the reverse is the case, and it is rare then to find a pulmonic second sound as loud as the corresponding aortic.

(3) Between the ages of twenty and thirty years there is no marked accentuation of either sound.

(4) In view of the above facts, it is obvious that when one speaks of an accentuated pulmonic second sound as corroborative of a diagnosis of heart disease, such an accentuation must mean an increase in the loudness of the sound over that normally to be expected at the age of the patient in question. A comparison with the aortic second sound is not sufficient to settle the question.

(5) Further, when we speak of an aortic second sound as accentuated, we must mean (in patients over forty years) more accentuated than it normally is. Once more, the simple comparison with the pulmonic second sound will not settle the question; the comparison must be made with an ideal standard carried in the mind.

(6) In interpreting the meaning of an accentuation of the pulmonic second sound in suspected mitral stenosis, one must bear in mind the age of the patient. The presence of a pathological accentuation of the second sound can be determined only in relation to the degree of accentuation which is to be expected at the age of the patient in question.

THE ACOUSTICS OF THE SECOND PULMONIC.

Hecht¹³ discusses quite at length the conditions influencing the character of the second sounds at the base of the heart, both aortic and pulmonic, but with especial reference to the significance of variations of the latter from a normal standard. The chief interest in his studies is given by the fact that in his investigations the intensity of the sounds was measured with the stethometer. This is a stethoscope with a metallic conducting tube, in the side of which is cut a longitudinal slit situated in the upper half of the tube, and capable of being closed by a diaphragm sliding up over it, the theory being that the intensity of a sound heard through the instrument can be measured by the extent to which the diaphragm is slipped back in order to allow all sound waves to escape through the slit before reaching the ear. Thus, starting the auscultation with the slit entirely closed, the diaphragm is gradually moved downward until the sound disappears; the length of the opening is then read off on the millimetre scale and the sound given a corresponding value. By this method he studied the second pulmonic under a variety of conditions in health and disease and attained results which, if not entirely conclusive, are at least interesting. He does not draw attention to the marked differences occurring at different periods of life, but he notes a distinct increase in intensity during the stage of active digestion.

He investigated after this method the various diseases of the lungs and the functional and organic disturbances of the heart. The chief value of the

¹² Medical Record, January 13, 1900.

¹³ Wien. klin. Woch., xiii, 13.

method, and that perhaps a considerable one, must lie in the possibility of watching the progress of individual cases with regard to increasing or decreasing interference with the lesser circulation, or with regard to the maintenance of the heart's vigor.

THE MOVABILITY OF THE HEART WITH CHANGE OF POSITION OF THE BODY.

Determann,¹⁴ calling attention to the well-known clinical fact that the heart is not a firmly fixed organ and that its change of position can be readily demonstrated, goes on to detail the results of some experiments made by percussion and the Röntgen rays (500 patients investigated). In healthy subjects he found that turning onto the left side produced an average dislocation of the heart of $2\frac{1}{2}$ centimetres to the left and 1 centimetre upward; turning onto the right a change of $1\frac{1}{2}$ centimetres to the right and about $\frac{1}{2}$ centimetre upward. Only exceptionally was a change lacking; in some cases it was quite small, in others as great as $6\frac{1}{2}$ centimetres to the left and 4 centimetres to the right, without distress to the subject.

These greater movements were found, however, to occur as a rule in individuals flabby and ill nourished, and in such were often found also evidence of loosely anchored abdominal organs. There were certain influences of sex, age and occupations; thus, women as a whole have more freely movable hearts than men, especially after child-bearing, or tight stays; children have little sign of it, the newborn scarcely any; old people only slight. Individuals of sedentary occupation and feeble muscular development are especially subject to the condition. The physiological effect of the full stomach is noted and also anything which tends to elevate the diaphragm. During the latter part of pregnancy the heart is much pushed up and compressed, and thus shows very little movability. Immediately after delivery, however, the highest grade is found and the apex may be dislocated on the left side as far as 9 centimetres from its original position.

Of pathological conditions there are, of course, several obviously limiting in their effects on the liberty of the heart's position, such, for example, as emphysema or any abdominal disturbance attended by pushing up of the diaphragm. On the other hand, there are the conditions characterized by relaxed diaphragm and enteroptosis; in such cases we find and may speak of a "cardioptosis." Thus, according to the writer, we may have a secondary cardioptosis dependent on an enteroptosis, or we may have a primary form independent of the latter conditions; such, for example, is very common in neurasthenia and a very striking degree of displacement is often found in chlorosis.

In many of the cardiac neuroses he hoped to find an explanation of the disturbed function in an increased movability, and was able to prove that the two conditions did at least often co-exist.

As the effective causes of cardioptosis he selects laxity of the connective-tissue elements as the most important and concludes as the result of his observation that while cardioptosis, like enteroptosis, may be unattended by subjective symptoms, it may on the other hand make its presence felt by marked disturbances of functional nature.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

J. BERGEN OGDEN, M.D., SECRETARY.

REGULAR meeting, Wednesday, March 21, 1900,
Dr. H. F. VICKERY in the chair.

Dr. E. G. CUTLER read a paper entitled

JOSEPH W. ENGLAND'S FAT-FREE TINCTURE OF DIGITALIS.¹

Dr. GREENLEAF: I think we are much indebted to Dr. Cutler for presenting this interesting account of Mr. England's work. We are all aware of the value of digitalis. We are also aware of the fact that occasionally patients are disturbed by it. The tincture is probably used much more than the infusion in this vicinity, and any measures likely to improve this preparation is certainly desirable. Where patients have been nauseated by digitalis it has been my custom to lessen the dose in the occasional cases where it occurred, or to substitute strophanthus or a similar drug for it. A preparation that will obviate the tendency to nausea is certainly a gain. The greater rapidity of action to which Dr. Cutler calls attention is also worthy of special note.

I think Dr. Cutler's paper emphasizes another fact which, while he did not make this particular point, impressed me as he was speaking, namely, the necessity of much closer relations than we have hitherto borne in the interrelations of pharmacy and medicine. Few physicians know the constituents of digitalis, and on seeing the notice of Dr. Cutler's paper it was natural to say, "What has fat to do with digitalis?" I did not know that fat was a constituent of its leaves and I find that several of the treatises on materia medica do not refer to it. The masters on the subject, however, do mention the presence of fatty acids and essential oils, so that we must look to the pharmacists for increasing our knowledge in this direction, and we should co-operate with them to a greater extent, so that they may be the better prepared to appreciate our needs. We owe this very preparation to a pharmacist. It seems to me we have been remiss in this direction in Boston of recent years. A short time ago I had the privilege of attending a meeting of physicians and pharmacists for the discussion of subjects relating to materia medica, and it brought out a mutually valuable discussion. I have yet to hear of any such meeting in Boston. We miss much in not having a better understanding between medicine and its allied sciences, and I hope Dr. Cutler's paper will prove an inspiration towards this desirable end.

Dr. SMITH: I have been very much interested in this paper of Dr. Cutler's, because about this time last year Mr. Kelley kindly called my attention to this preparation of fat-free tincture. At that time I had a very rebellious case of nephritis due to lead poisoning, with cardiac complications, where I had been unable to make any headway with infusion or the plain tincture, and I began after reading this account of the work of the Philadelphia Hospital to use this preparation, not telling my patient what it was, and I succeeded beautifully with it, in that it created no nausea, and also that I was able to push it a lit-

¹ See page 283 of the Journal.

tle more without fear that I had been able to push the ordinary tincture. I increased the dose of this cautiously, beginning with 5 drops, until I was giving 30 drops three times a day.

I can think of 8 cases in which I have given this preparation a good trial. The second case I saw with Dr. Sawyer, in Gardiner, Me., a physician seventy-four years old, with aortic insufficiency and obstruction and nephritis. There was present general anasarca, with a great deal of delirium at the time, and the dyspnea was so marked it was expected the patient would live but a very few hours at the time I saw him. The doctor had been obliged to give up all preparations of digitalis, and was relying on the other tonics, and we sent immediately for this fat-free tincture, and he began that cautiously with small doses, and increased up to 30-drop doses every four hours, and in one month this physician was riding around the town without any sort of discomfort whatever, and he remained evidently with a well-acting heart up to a few weeks ago, when he dropped dead. Now this could not have been obtained, I am perfectly sure, with any of the preparations of digitalis that we know anything about aside from this, because the doctor had persevered with them in every way at different times during the last two or three years. I felt less anxiety about pushing the drug in the physician's case, because, since an accident which occurred to him in our Civil War, he had been an opium eater, and it has been my experience that opium eaters have a pretty good tonic for their heart, and we can perhaps push some drugs a little more than we otherwise could. In every other case in which I have used it I have found it to work admirably, particularly in not creating nausea, and feeling that I could more fearlessly increase the dose.

DR. VICKERY: I would like to ask Dr. Cutler whether there is any effect upon the amount of urine in the way of diminution.

DR. CUTLER: It has rather seemed to increase the amount of urine. I have not observed diminution in any case thus far.

DR. VICKERY: Does Dr. Cutler know whether that fatty ingredient in the ordinary drug diminishes the amount of urine?

DR. CUTLER: I am unable to say.

DR. VICKERY: It would be an interesting point. Ordinarily we have been taught that nausea and diminution in the amount of urine are danger signals. I should think that this new preparation would be a very welcome addition to our armamentarium. It is a subject about which I have had no practical experience.

DR. CUTLER: The gentlemen have talked of Dr. Cutler's paper. All the conclusions and all the experiments are Mr. England's with the addition of this Philadelphia doctor. I simply have tacked on two or three patients of my own and it absolutely confirms what he has done. I was so struck with the fact in several cases, as the doctor says, where the people could not take the ordinary tincture, I gave this one. The first one I told what it was; those afterwards I did not tell. Every single one was able to take the drug uninterruptedly. I suppose I shall finally come across a case that will be unable to take it, but this fact was so striking that I was very much interested in it. The fat-free tincture can be mixed with water and it does not precipitate, and it can be injected sub-

cutaneously just as it is or diluted perfectly well. Every officinal tincture which I have ever seen, even though it has been assayed, has always, whenever we have added water, precipitated. What the precipitate is I will not undertake to say. I presume it is something soluble in alcohol and not in water. I presume it is some of those fatty products which England took out. The difficulty with the preparation by ordinary pharmacists would seem to be that he does not get rid of his benzine compound. According to Mr. England, that is best done by sunlight and exposure to air. I should suppose, unless very carefully handled, it would be a thing somewhat difficult to accomplish. Of course its inflammability or otherwise would be a point showing as to whether the benzine had been expelled. If not inflammable, or only as any organic matter would be, it would show the benzine was gone. If quite inflammable, or the odor of benzine remained, it would be clear that it had not been taken out. England takes this coarse powder and subjects it to the treatment with the benzine and gets all of the volatile and fixed fats out of it and then gets rid of the benzine. After that he follows the ordinary formula. It certainly is a more elegant preparation than the officinal tincture. At the Massachusetts Hospital I have been using the preparation for a few days wholly, and at my request the apothecary is going to prepare it for my wards and nowhere else, that is, the officinal tincture is to be used elsewhere all over the hospital and the fat-free tincture to be used in my wards for the next four months, and I am not going to draw anybody's attention to the fact that such is the case. We want to see whether our results show anything or not. So far as I have seen in private practice it seems to me it reaches a want we often feel very keenly—something we can give to a person whose digestion is upset, something we can give in a dose smaller than infusion of digitalis. Sometimes you want to give to a patient a quantity of infusion of digitalis which is tolerably large, and he finds the amount of liquid he must take somewhat troublesome to handle; but 30 drops of this preparation is a very small bulk to take several times a day. The largest dose I have seen given had no bad effects on the patient whatsoever. I have never seen very large doses given continuously, only this one dose I spoke of where the person took it by mistake.

What I want is to have a number of gentlemen try it and report the failures or what the limitations of the preparation are, rather than the opposite. I feel convinced that it is very important to have the fat properly removed. I can conceive of a preparation where the fat may be asserted to be removed and where in reality it is not. One apothecary told me that he found a good deal of difficulty in getting rid of the benzine and he consulted Mr. Kelley to find out how it could be done, and I saw a preparation which emanated from another source, and I thought the benzine was not all gone, but that, of course, will be a thing which will correct itself very soon. As I understand it from Mr. Dodd at the hospital, they use now amongst apothecary stores what they call assayed preparations, so that it is a pretty uniform and a quite exact form. I hope Dr. Vickery will be encouraged to try it. I value his suggestions very much.

DR. VICKERY: Dr. Cutler spoke about a large dose; Dr. Smith also. I might perhaps be pardoned for relating an interesting experience that I had. I

saw a case with Dr. Boland, of South Boston, of acute rheumatic pericarditis complicated with pneumonia. The man had been put on medicine put in two bottles, one digitalis, the other acetate of potash. The acetate of potash bottle had become empty, been sent to the apothecary's and erroneously filled with the digitalis prescription, so this man was taking digitalis out of two different bottles. His pulse was extremely slow when I saw him, but very good; and he bore this very severe illness with great equanimity and got well. If it had been a new method of treatment I should have thought it a most brilliant success. I do not know just how big the dose of digitalis was.

DR. CUTLER: I do not by any means wish to have anybody discard the officinal tincture. It is only in those instances where the officinal tincture cannot be taken or produces disturbance that I would urge anybody to try this new one. I do not bring it forward as a cure all. It is only where one finds the necessity of giving digitalis and finds his efforts are blocked, either because the patient cannot take and absorb the officinal tincture, or the dose of the infusion is so large that the patient refuses to take it; if under those circumstances he will remember this preparation I speak of, possibly he will get some advantage from it. I do not want to have it substitute anything else. We all know what a very valuable preparation the officinal tincture of digitalis is and the infusion also, but it is only in certain cases where those cannot be taken that I speak for this.

AMERICAN NEUROLOGICAL ASSOCIATION.

TWENTY-SIXTH ANNUAL MEETING, HELD IN WASHINGTON, MAY 1, 2 AND 3, 1900.

(Concluded from No. 11, p. 267.)

DR. JOSEPH COLLINS reported a

CLINICAL STUDY OF THE REFLEXES,

the object being to determine, if possible, the physiological nature of reflex tendon phenomena and to inquire into their relationship to, and probable dependency upon, muscle tone.

DR. S. WEIR MITCHELL spoke in reference to reinforcement of knee jerks, quoting the literature on the subject and referred in commendatory terms to the work of the American neurologists as compared with the Continental. He dwelt upon the feature of muscle reaction in its different phases.

DR. KNAPP spoke about certain peculiarities of reflexes not mentioned by Dr. Mitchell.

DRS. SACHS and SPILLER closed the discussion on the subject.

SECOND DAY.

The morning session was marked by a spirited discussion on the "Neuron Doctrine in its Relationship to Disease of the Nervous System."

The first paper was a deferred one from the previous day's session by DR. F. X. DERGUM, entitled

AUTOPSY OF A CASE OF ADIPOSIS DOLOROSA, WITH MICROSCOPICAL EXAMINATION.

The patient referred to was a woman who, on first examination, was fifty-one years old and a native of Ireland. There was nothing particularly striking about the family history. She continued well until she was forty-nine years old and was probably ad-

dicted to alcoholic excess. The first that was noticed was enlargement of the arms, accompanied with shooting pains in both shoulders, the sides and chest, but most marked in the upper arms. The skin was not thickened and was not adherent to the adjacent tissues. The muscles were not involved in the swelling. There were slight quantitative and qualitative changes noticed in the muscles and forearms. Cutaneous sensibility was diminished. There was no alteration of gait, but both knee jerks were lost. In two other cases reported by Dr. Dergum there was likewise noticed a loss of knee jerks. In the present case the face appeared pale, as was also the mucous membrane. The features of the patient were well formed and intelligent. Hair dark and fine; mind not impaired; skin dry. Examination of the eyes revealed nothing abnormal save some narrowing of the visual field. Urine and blood negative; no leucocytosis. The patient was under observation for eleven years. Small nodules would make their appearance and the enlargement involved likewise the abdomen, hips, thighs and legs below the knee. The feet and hands were not involved until the last. On several occasions the paroxysms of pain were severe and the patient would be taken with vomiting sometimes containing blood. She suffered from frequent attacks of bronchitis accompanied by dyspnea. At various times she exhibited cardiac trouble, which led to her death from fatty degeneration of the heart, in connection with adiposis dolorosa.

In making the autopsy it was found that the pubic hair was scant and there was none in the axilla. On opening the abdomen it was found that the intestines were distended with gas, but there was nothing abnormal except fatty infiltration. A microscopic study of the various changes did not exhibit anything significant, except the heart muscle, which was found very friable and of yellowish color, with marked change in the muscle itself. The microscopic examination included a study of the subcutaneous tissues, peripheral nerves, spinal cord, pituitary body and the thyroid gland. Earlier in the case small portions of the subdermal tissue were excised and it was thought that the fat was embryonal in character, but such was not the fact; the fat revealed nothing peculiar. There was marked diminution and atrophy of nerve fibres. The spinal cord presented a decided change in the dorsal and cervical regions. The lumbar cord failed to present any change. There was likewise no change in the brain nor in the pituitary body. The thyroid gland was very interesting. Though not weighed it was quite small and the microscopic examination proved it to be abnormal beyond all doubt. There was complete absence of colloid material. It was believed that the derangement of the thyroid gland caused certain substances to be thrown into the circulation of an abnormal character.

DR. BURR said that within the last six months he had had an opportunity of making an autopsy and examining a case of the same character. There was in association a new growth of the pituitary body. He thought that this was merely accidental, as he did not believe that disease of the pituitary body would cause any deposit of fat. There was distinct affection of the thyroid gland and interstitial neuritis within the muscles. There was degeneration of some of the voluntary muscle fibres.

DR. PUTNAM spoke of cases of progressive muscu-

lar dystrophy and congenital blindness occurring in the same family.

The first paper on the neuron theory was by DR. L. F. BARKER, entitled

THE ANATOMICOCYTOLOGICAL RELATIONSHIP OF THE NEURON TO DISEASE OF THE NERVOUS SYSTEM.

The paper dealt with the present status of the knowledge of the units in the nervous system. The history of the neuron doctrine was traced. The conception originated with the pathologist Ford and was supported by the embryological work of His and by histological studies made by Golgi's method. Wald-eier, in 1891, collected the evidence in favor of the view and gave to the nerve units the name "neurons." Barker sees in the neuron doctrine nothing more than the application of the cell doctrine to the nervous system. Until it was shown that the axis cylinder of a nerve fibre and its end ramifications are integral parts of a single cell, it was impossible to apply the cell doctrine intelligently to the nervous system. The retraction theory has never had any adequate basis. The studies of Apathy and Bethe are regarded as extremely important as bearing upon the intimate relations which exist between the nerve centres. They do not interfere in any way with the retention of the units themselves.

The next paper was by DR. W. G. SPILLER, on THE PATHOLOGICAL CHANGES IN THE NEURON IN NERVOUS DISEASE.

He suggested that the most important question is, Does pathology afford any support for the neuron doctrine, or do the changes occur of such character that we can obtain from them the existence of the neuron? It must be shown that the neuron is affected by disease; that is, whether the cell body may become diseased and die without the existence of the axon. It must be shown whether the disease of sensory neurons affects the motor neurons. Degeneration has a tendency to involve groups of nerve cells and processes. To what degree does a neuron become diseased? If we cut an axon, the cell body in which the axon arises undergoes rapid alteration and possibly death. An axon is only partially dependent on the nerve cells for vitality, and if the blood supply is cut off that portion deprived of circulation will die, but the cell body is necessary to the axon. A number of radiographs were exhibited at this point, showing certain pathological changes in the brain. He said that in a Gasserian ganglion which had been removed he found alteration of the nerve cells of that ganglion, but was not able to find any of the sensory root. The destruction of the nerve cells of the spinal ganglion was much less in certain experiments, and therefore it might be expected to find a slight alteration in the posterior root. There is a tendency for the entire neuron to undergo alteration when attacked by disease or injured. A very interesting question is the degree of limitations to one set of neurons. It is certain that a retraction exists, but this is occasionally overcome.

DR. B. SACHS read the following paper:

HOW DOES THE DOCTRINE AFFECT THE CONCEPTION OF NERVOUS DISEASE?

He said that the introduction of the neuron theory promised to bring about a general revolution in the

conception of nervous disease. With a single stroke the mysteries and doubts of years were to be cleared away. Granted that the structure and function of the nervous system can be interpreted much more readily in the light of this doctrine, it still remains a question whether it has been a great assistance to us in determining the cause and development of the various diseases of the nervous system. It has been shown that the nervous system is composed of a series of contiguous, not continuous, units; that in this nerve unit, composed of the cell body with its dendrites, the nerve fibre or neuraxon and the terminal tufts, the cell bodies exercise a trophic influence over the entire neuron; furthermore, that the nerve force, to speak in general terms, could travel from the cell body to the periphery and from the periphery to the cell body. This question of the trophic influence of the cell body had to be discussed before the profession could appreciate the value of the neuron in its relation to the nervous system. The doctrine helped us, of course, very little in our understanding of the cure of inflammatory processes, for such processes do not respect the final structure of the brain or cord, and are generally so destructive that it would matter little whether the nervous system were made up of contiguous or continuous units. *Tabes dorsalis* is to be accepted as a disease of the direct sensory neuron; whatever the nature of the poison circulating in the body may be, the sensory fibre is the part primarily affected. Even if the view could be maintained that the disease began in the spinal ganglion cell, this ganglion cell would not be diseased unless there was something wrong with the peripheral stimuli conveyed to it. It is not necessary to enter upon a discussion of the aid rendered by the neuron doctrine to the interpretation of nerve diseases.

DR. H. H. DONALDSON then addressed the society upon the topic,

THE PHYSIOLOGICAL SIGNIFICANCE OF THE SIZE AND SHAPE OF THE NEURON.

Dr. Donaldson presented interesting data concerning the study of the neuron elements in the white rat. He said that in these animals the examination was made of the cell bodies from the spinal ganglion, which send their axons to form the sciatic nerve. The ganglion cells become progressively larger. At birth the white rat is entirely devoid of any medullated fibres, central or peripheral. During the first six or eight days of life the medullated sheaths begin to appear. The appearance of the medullated sheath about the axons is a very rapid process in the first case.

DR. PUTNAM thought that the notion should be greatly modified or abandoned, that the cell body is the place for the storage of anything particularly standing for the function of the nervous system as a whole. He said that the term is very often used in books on clinical medicine of the storage of memories in the cortex in the brain.

DR. LANGDON said that it seemed to him that to begin at this day to criticise the neuron doctrine and neuron discovery or hypothesis is very much like criticising the architecture of a building of which the plans are not yet drawn. He thought that one could safely say, in regard to the neuron doctrine, that anatomically it had given much help.

DR. VAN GIESEN did not think that the neuron theory needed so strong a defence.

DR. MILLS thought that the term "neuron" in this connection had done harm rather than good in the teaching of the new doctrine, but he said that there could be no doubt that the neuron theory must stand—in other words, there is a certain degree of interdependence of nerve cells that has been demonstrated.

DR. DERGUM thought that it was best to wait until the knowledge on this subject is more complete, until more is known about the details of the relation of the neurons to each other in all portions of the nervous system.

DR. COLLINS said that in discussing the neuron doctrine we were not dealing with theories but with facts. He thought that one of the most valuable points which had been brought out in the meeting was the necessity of using the term "nerve cell" as represented by the neuron, and not speaking of the nerve cell as meaning the cell body. He thought this would bear fruit in the future.

DRS. THOMAS, SMITH and ANGELL expressed their views pro and con upon the neuron theory, its pathological, physiological and anatomical relationship.

In closing the discussion on his own paper, Dr. SACHS said that he did not want it to be construed that he was pessimistic in his belief, and that if it seemed that he was of that opinion it was simply because he was anxious. He simply wanted to show that even in the neuron theory there was some limitation.

DR. BARKER said that his conception of the neuron is not purely morphological. It is based just as much on physiological and pathological results as on morphological. Indeed, he thought there was a tendency to distinguish too much between the morphological and physiological concepts. In reference to diseased conditions and the relation of the neuron doctrine to the study of disease clinically, he thought that it had been of much help.

THIRD DAY.

The first paper presented this session was that by DRs. JAMES J. PUTNAM and E. W. TAYLOR, entitled

CLINICAL AND ANATOMICAL ANALYSIS OF CASES OF DIFFUSE DEGENERATION.

The case in question presented the aspect of pernicious anemia. The writer (Putnam) had seen a large number of cases belonging to that group and will be able to analyze 25. It was held to be a distinct disease, with definite clinical and anatomical characteristics. In the case described there was numbness of the extremities, which was very prominent, and cachexia, ending with anemic softening of the cord. The characteristic lesions are rather inclined to occur in foci. The essential point is that the nerve-root zone is not affected, so that as far as the lesions go they are confined to the spinal cord alone. As to the indications of anemia, as evidenced by large macrocytic corpuscles, they are very common, and it is quite possible that they are universally present in these cases. Another patient with pernicious anemia had shown great improvement in the blood; at the present moment the blood count has come up from 3,000,000 to 5,000,000, but the spinal symptoms continue.

DR. LANGDON said that we have two groups of pernicious anemia, one without this spinal degeneration, so much so that he has followed to the end 2

cases of marked pernicious anemia, and he had an opportunity to test them a few weeks before death without the slightest evidence of spinal symptoms. He recorded a case in his own practice of a lady with a spleen extending down to Poupart's ligament and to 3 inches to the right of the umbilicus; her nervous symptoms were exceedingly vague, and the most careful examination did not reveal any appreciable functional alteration. This patient with marked pernicious anemia, as shown by a thorough blood examination, and marked evidence of degeneration in the posterior and lateral columns, had mucous colitis, and he thought it was interesting to know the connection between the bowel condition and the hematic and degenerative states.

DR. MORTON PRINCE then read a paper entitled SECTION OF THE POSTERIOR SPINAL ROOTS FOR RELIEF OF PAIN IN A CASE OF NEURITIS OF THE BRACHIAL PLEXUS; CESSATION OF PAIN IN AFFECTED REGION; LATER DEVELOPMENT OF BROWN-SÉQUARD PARALYSIS IN AREA AND PAIN IN OTHER AREAS AS RESULT OF LAMINECTOMY.

The case related was that of a man who was struck by a train and received a Colles's fracture of the left wrist and paralysis of the right arm. The paralysis continued, rendering the arm useless from the shoulder down. The paralysis affected the muscles of the forearm and pronators. There was a diminution of sensation over the lateral areas. Pain was present in the thumb, forefinger and back of the wrist. Dr. Prince presented a diagram showing the location of the pains, for which operation was done for relief. The pain was intense, and three operations were undertaken at different times, but none seemed to have been based on neurological principles. Finally an operation was performed which was partially successful for the purposes for which it was undertaken. Six weeks after the accident and before the operation there were areas of anesthesia and analgesia over the radial aspect of the hand, thumb and forefinger, and extending upward over the same aspect of the arm. The reader then went over the nerve and root supply of the hand and arm. In time there gradually developed a severe pain in the neck behind. Even after the discharge from the hospital the man suffered severe pain around the neck and head; it was thought that this might have been caused by injury to a nerve during the operation. The arm was practically useless. His leg was spastic, and he could not support himself on it. There was anesthesia in the right leg. He has a sensation of extreme coldness in the right foot.

DR. S. WEIR MITCHELL asked the date of the operation, which was given as October 20th, and the injury fifteen months or a year and a half before, and the writer further said that the muscles are extremely atrophied, especially the deltoid, and the muscles of the shoulder joint and arm hang down and drag on the shoulder, and this is the cause of the present pain about the shoulder joint.

DR. MEYER said that the profession was again considerably at sea with regard to the anatomical and clinical correlation of the Brown-Séquad paralysis, since Brown-Séquad stated in his last publication on the matter that he had to change his view completely concerning this subject, since on cutting the posterior root he had obtained the Brown-Séquad symptom complex; further by making a second hemisection

lower down, after producing the Brown-Séguard symptoms, he was capable of simply reversing the whole picture in the posterior segments of the body. The question therefore arose whether it was really necessary to assume that the blood clot was concerned in the production of the Brown-Séguard paralysis.

DR. PRINCE said that he never had seen a laminectomy performed for any purpose of this kind without thinking of the possible dangers of an ordinary blood clot being produced.

DR. BURT G. WILDER spoke upon the subject of

REVISED INTERPRETATION OF THE CENTRAL FISSURES OF THE EDUCATED SUICIDE'S BRAIN EXHIBITED TO THE ASSOCIATION IN 1894.

With several charts and specimens of the brain of a suicide, Wilder described the anatomical relationship of the various fissures in the brain. The suicide in question was a dentist who had willed his brain (in writing) to the writer and who, shortly thereafter, killed himself by shooting himself twice, the first ball being deflected and producing no injury, while the second ball penetrated the region of the temple with fatal results. The persistency of the man in trying to take his life was emphasized; that it was a rare condition in a person not known to be a maniac which would force him to actually shoot himself again after the first shot had not taken effect. Wilder said that he had about one hundred well-preserved human brains and had compared them all with reference to the following point: Is there any absolute diagnostic feature of the central fissure on the one hand and the post-central on the other capable of demonstration?

DR. SPILLER asked whether it has been found that the cells of Betz are not numerous in the upper part of the parietal lobule.

DR. MEYER said, in reference to the determination of the fissures, we were too much inclined to speak of having taken a section out of the paracentral lobule, and that at times there is entire failure to find Betz's cells, while in other parts of the paracentral lobule down to the corpus callosum Betz's cells are found.

DR. CHARLES K. MILLS thought that the report of Dr. Wilder's case emphasized the importance of not coming too quickly to conclusions with regard to the duplication of fissures; that he had seen a great many human brains during the last twenty years, and while he could not say frequently, he could say that in a number of instances he had seen an appearance of the duplication of the central fissure. He thought that the conclusion should never be arrived at that duplication of the main fissure like the central fissure was present until other possibilities have been excluded.

DR. WILLIAM G. SPILLER presented a paper entitled

A CASE OF MALARIA PRESENTING THE SYMPTOMS OF MULTIPLE SCLEROSIS, WITH NECROPSY.

The case was one of malaria and disseminated sclerosis. Patient was in good health as far as could be learned. In 1890 he had a chancere. Being a sailor he was exposed to the malaria. In 1892 he lost power in the right side of his body, from which he recovered in four weeks. In December, 1895, he had headaches and vertigo, with feeling of drowsiness, and in the same year suddenly lost power in the left side

of the body. He recovered the power of this side rapidly. In 1896, upon examination, it was found that he stood unsteadily when resting on the right foot. He could not stand alone on the left foot on account of ataxia; ankle clonus on right side. These conditions terminated in death September, 1899. The necropsy revealed an enlarged spleen. Diarrhea, which was severe before death, was probably malarial in character; estivo-autumnal type, resembling cholera. There was moderate sclerotic condition in the cord, not intense, but unmistakable; slightly thickened band of neuroglia tissue. By carmine stain the cells of the anterior walls were normal; no recent degeneration of the spinal cord. Hemorrhage in the brain and symptoms of disseminated sclerosis marked, intention tremor of left upper limb; marked ataxia left lower limb; tendon reflexes exaggerated on right side.

DR. CHAS. K. MILLS said that while this was undoubtedly a malarial case, there was a question after all whether the ataxic symptoms—the unilateral symptoms which led to the diagnosis of disseminated sclerosis—were due to toxemia; were due, in other words, to the unilateral intoxication of the nervous centres. That while the malarial organisms were present in great number, there were also present in considerable number and in irregular location a number of hemorrhagic lesions. He would not attribute the symptoms in a case like this necessarily to toxemia, but rather consider the possibility of small or large disseminated foci—hemorrhagic foci—as the cause of the symptoms.

DR. CHAS. W. BURR, in connection with DR. McCARTHY, read the next paper, entitled

A CASE OF MULTIPLE SCLEROSIS, WITH AUTOPSY.

The patient was an electrical engineer. The first diagnosis was that of tabes, which was persisted in for a year and a half. Case subsequently developed other symptoms, involvement of the cord with marked spasticity, and some bladder trouble. Autopsy showed big patches of sclerosis; the whole spinal cord was affected. Microscopic examination showed the optic nerve to be extensively degenerated. In the acute patches there was marked proliferation of connective tissue surrounding the blood vessels.

DR. ADOLF MEYER spoke briefly of a few reconstructions of parts of the nervous system. He showed specimens and demonstrated the durability of the plates he used to present the specimens. He believed they were less fragile than others.

DR. CHAS. K. MILLS thought they were unusually good for the purpose of teaching the structures or parts of structures and the organs which have to be represented in different planes; by this method he thought the teacher could readily show and the student could readily see and get an idea quickly of parts he would not be able to comprehend.

DR. JOHN JENKS THOMAS read the last paper, entitled

TWO CASES OF TUMOR OF THE SPINAL CORD.

He reported 2 cases of tumor affecting the spinal cord. The first case was that of a young woman, twenty-one years of age, who, during the course of ten months gradually became paraplegic. At the time of the admission of the patient to the hospital the sensory and motor paralysis and the paralysis of the sphincter was practically complete, and certainly

so at a later period. From that time on the patient seemed to have had no pain. Gradually very marked contracture developed, and the patient remained in much the same condition for a period of thirteen years, except for an outbreak of mental trouble with excitement, from which she made a good recovery. Death resulted from exhaustion, from bed sores, diffuse nephritis and chronic cystitis. At the autopsy, besides these conditions, there was found a tumor of the dura in the mid-dorsal region, which had completely compressed the cord beneath it. Microscopic examination of the cord and of the tumor showed the latter to be composed of a mass of cells, which, in character, resembled endothelial cells, among them many small circular bodies, made up of concentric rings, many of which were calcified. The growth was enclosed in the dura, and the author considered it to belong to the endotheliomata. The cord showed at the level of greatest compression a complete destruction of nerve structure, which had been replaced by overgrowths of neuroglia. The cord was atrophied and showed the usual ascending and descending degenerations.

The second case was one of intramedullary glioma in the cervical region in a boy of six years. The symptoms developed two days after a slight injury, beginning with pain in the right hand and arm, the left forearm being congenitally absent, and with pain in the shoulder and rotation of the head to the left. At this time there were no sensory changes. Later the paralysis of the arm became more marked, and there was diminished electrical irritability of the muscles of this arm and slight paresis of the right leg, with increased tendon reflexes in that extremity. Two weeks later, and seven weeks after the onset of the first symptoms, the patient died suddenly with symptoms of interference with respiration. The autopsy showed a glioma of the whole of the cervical enlargement of the cord, into the upper part of which a large hemorrhage had taken place, and another large hemorrhage in the lower part of the growth and in the central part of the cord, extending well down into the thoracic region. Microscopical examinations showed this tumor to be a very cellular growth, but between these cells the characteristic fibres of neuroglia could be made out, while aside from the hemorrhage, to which the author ascribed the sudden death, there was a slight secondary degeneration of the pyramidal tracts in the cord. Sudden death from hemorrhage into the tumor is much rarer in tumors of the cord than in those of the brain, where it not infrequently occurs, though small hemorrhages into the cord tumors are frequent. The case was also unusual because of the rapid course from the time of the first development of the symptoms and because of the youth of the patient. The author thinks the extent of the tumor was too great for it to have developed entirely after the trauma, and he is inclined to ascribe the onset of symptoms after the injury to a small hemorrhage into the pre-existing tumor, similar to the large one which probably caused death, and rejects the idea that the trauma could have acted in this case as a causal factor. The absence of symptoms which could have led to the formation of the diagnosis of an intramedullary growth was probably more apparent than real, and due to the short duration of the symptoms before the sudden and early fatal termination.

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

(Continued from No. 11, p. 271.)

SECTION OF SURGERY.

THE TREATMENT OF INFECTED WOUNDS.

A DISCUSSION on this subject was introduced by Dr. OSCAR BLOCH, surgeon in chief to the Royal Frederick Hospital, Copenhagen. He said Lister's antiseptic method (treatment by carbolic acid) was based on the treatment of infected wounds (compound fractures). Although all surgeons were agreed as to the superiority of this method, it was not long before new remedies were sought more efficacious than carbolic acid. The most remarkable outcome of these researches was the replacement of the antiseptic by the aseptic method. All the experiments on various methods of treating wounds were founded on a considerable number of valuable investigations on all questions relating to the wounds and their complications, for instance, on microbes and their toxins, on the bactericidal qualities of various remedies, the best method of disinfection, ligature, etc. The author shows that the outcome of all these investigations is that, from a practical point of view, every wound, without exception, is to be looked upon as infected, and that infection and its complications are due to the retention of secretions containing microbes. From this it follows that for the efficacious treatment of wounds the surgeon must put before him two objects: To destroy the microbes or their hurtful products and to prevent the retention of secretions. In other words, antiseptics and drainage must be employed. In order to prevent reinfection of a wound so treated it must be dressed rationally; this is the only way to prevent secondary infection. The author dwelt on the want of agreement and conflicting results of different authorities, and concludes that a scientific experiment is incapable of settling the question, what method of treatment is the best; we must have recourse to clinical experience. As the result of his own experience the author holds that every wound must be treated antiseptically, that carbolic acid is the best antiseptic remedy, that wounds should be drained, and that to dress them in a rational manner an unquestionably sterile dressing must be applied and must be made antiseptic at least in part at the moment of application. Moreover, the dressing must be absorbent, so that it dries up the wound and prevents the surplus of the wound secretions from coming into direct contact with the surrounding air, which contains microbes. Lastly, the dressing must be of such a nature as to filter the air which gains admission to the wound and thus purify it from its microbes. Bloch has attained this object by means of sterilized gauze dressings, carbolized water and cotton wool. With regard to internal antiseptics and febrifuge remedies, with a few exceptions he said he placed little reliance on them, and he criticised the value of therapeutic serums, especially antistreptococcus serum. According to Bloch, it will be well, before using these remedies as curative, to wait till experiment has supplied a firmer basis for practice.

M. FELIX LEJARS, of Paris, said that in recent years the treatment of infected wounds had formed the subject of numerous experimental and bacteriologic-

ical researches. They had yielded valuable information, but all required to be controlled by observation. For the profitable study of the problem, which is very complex, it must be considered under two heads.

(1) Recent infected wounds in which the infection has not yet expressed itself in local or general reactions. These might perhaps be better designated recent wounds assumed to be infected. This assumption, however, should in practice be extended to every accidental wound, and bacteriological examinations show that it is well founded. It is known that even operation wounds are far from being amicrobial. On the other hand, there are no means of recognizing in a recent wound by what microbes it is contaminated, what is their virulence and what their ultimate effect. It has been proved that neither the look nor the visible course of traumatic foci are in this respect sufficient guides. Therefore, every accidental wound should be treated as infected. But how is it to be treated? It is known that the absorption of virus through the injured surface is almost immediate; the rapidity of absorption, however, varies with different microbes; moreover, the dose increases with the duration of impregnation. From this may be drawn the conclusion that the cleansing of the wound, in order to be efficacious, should be as early as possible, but whenever it is done it will be useful. Experience has shown (*a*) that we are powerless to destroy all the germs in a traumatic focus; (*b*) that the natural defensive power of living tissues plays a preponderant part in the fight against infection. The very first procedure, therefore, is mechanical cleansing, which should be minute and complete, aided if necessary by enlargement of the wound and removal of dead tissue. Care should, however, be taken to respect the integrity of living cells, which should be helped in their defensive reactions, nothing more. Sterile water, artificial serum, sterilized boiled compresses entirely answer these requirements; it is not the nature of the fluid used but the method of its employment that gives practical results. Hurtful in large doses, antiseptic solutions, when diluted sufficiently not to alter the living cells, have really no other useful effect than mechanical cleansing. Physical conditions of the same order have to be fulfilled by the dressing. It must be aseptic, absorbent, protective and immobilizing, in a degree applicable to the different regions and for a variable period.

(2) Infected wounds, the infection of which is expressed by more or less pronounced reactions local and general. Here, also, two conditions have to be distinguished: (*a*) The clinical signs of infection may be of recent date, and the wound is not suppurating; (*b*) the wound is in active suppuration. In either case specific serum therapy is indicated; this Lejars considers the scientific, natural method, and the method of the future. Unfortunately as yet only antitetanus and antistreptococcus serum are available. The former is only efficacious as a preventive, while the latter has mostly been used in puerperal fever and erysipelas. Against other microbial infections of wounds we have as yet no effective serum, and against associated infections we are powerless. This makes the treatment of the local focus all the more necessary, and, as in dealing with cases belonging to the first category, the surgeon has to set before him a twofold object. The first thing to be done is to cleanse the whole surface of the wound; then it should be dressed

so as to favor exosmosis, continuous drainage of the whole surface, and prevent all stagnation and super-added infection. The object of the cleansing is especially mechanical, while that of the dressing is especially physical. If these conditions are thoroughly fulfilled the surgeon will have, as far as is possible, protected the living cells against the attack of septic agents without hindering their defensive reactions. In dealing with a suppurating wound the same principles must be applied—thorough exposure of the suppurating focus, and complete and continuous drainage. In certain putrid and gangrenous forms, and in burrowing wounds, oxygenated water, which appears to have a powerful effect on anaërobic microbes, is most useful.

(3) Infected wounds with grave general infection—traumatic septicæmia. Here also it is to specific serum therapy that we must look for rational treatment, but its action is much less certain than in the early stages of infection. At present only experiments can be recorded, and even antistreptococcus serum has seldom been used in traumatic septicæmia. Lejars thinks that it deserves to be tried on a more extensive scale in large doses. In the meantime we must use local treatment preceded by thorough cleansing of the focus. On the other hand, artificial serum therapy, by restoring the blood pressure and stimulating diuresis, increases the natural defence and vital resistance of the organism.

(To be continued.)

Recent Literature.

Practical Anatomy. Including a Special Section on the Fundamental Principles of Anatomy. Edited by W. T. ECKLEY, M.D., Professor of Anatomy in the College of Physicians and Surgeons, University of Illinois; Professor of Anatomy in the Northwestern University Dental School; Professor of Anatomy in the Chicago Clinical School, and Director of the Chicago School of Anatomy and Physiology; Member of the American Medical Association, the Chicago Pathological Society, the Chicago Medical Society, etc., and MRS. CORINNE DUFORD ECKLEY, Instructor in Anatomy in the Northwestern University Dental School; Professor of Anatomy in the Northwestern University Woman's Medical School; Professor of Anatomy in the Chicago School of Anatomy and Physiology. With 347 illustrations, many of which are in colors. Octavo. Philadelphia: P. Blakiston's Son & Co. 1900.

This book is a dissecting-room guide to Morris's "Human Anatomy." As such it treats only of the gross anatomy as studied in the dissecting room on the cadaver. It is more thorough and detailed than the average dissecting-room guide and will be found proportionately more useful. The authors have not, however, escaped entirely from the quiz-compend method and unnecessary space is taken up by italicized questions. The illustrations are taken from Morris's "Human Anatomy," and are clear and artistic. The origins and insertions of the muscles are indicated in colors on the bones. The directions for dissection are plain and specific. The book will be found a clear and safe dissecting-room guide.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 20, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

ANOTHER ARGUMENT FOR CREMATION.

IN our editorial of last week on the Galveston disaster we expressed the belief that the suffering induced by disease would not be added to the immediate loss of life through the effects of the storm. This opinion seems to have been borne out by the facts. In spite of what would appear almost insuperable difficulties, which at first threatened to be more than could be successfully met, the devastated city is likely to suffer no further loss of life. The danger no doubt could have been entirely averted had public opinion permitted the immediate cremation of the bodies of the dead. As it was, for the first few days the attempt was made to dispose of the dead by burial at sea and also by hastily made graves on land, although the encroachment of the water had rendered this last undertaking extremely difficult. In spite of heroic efforts, however, the situation was rapidly becoming menacing on account of the impossibility of caring for the great number of dead by such means. Finally the decision was reached, as a matter of necessity, that general cremation should be resorted to, as a protection to the living. Had this decision been reached before there is no doubt that much of the distress and horror of the situation would have been wholly averted. It is hard to conceive the frame of mind which finds a melancholy satisfaction in consigning the body of a friend or fellow being to the sea, or to a rudely constructed grave, and hesitates to permit it to be decently and wholly destroyed at once. Particularly is such a frame of mind unjustified in a situation such as faced the survivors at Galveston. With all due respect to prejudice and established custom, we cannot but feel that the time is rapidly coming when the demands of health and sanitation will require a recognition of the fact that cremation is the only logical means of disposal of the remains of the dead, and especially when the unpleasant necessity comes of the rapid removal of a large number of dead. That popular feeling is awake to the situation is shown by the following excerpt taken from a daily contemporary: "This idea (cremation) has necessarily been of slow growth, though for the last few years it has shown a more

rapid development, and such striking instances of its larger value in an emergency like that at Galveston must act with the force of a general demonstration. Reforms work slowly when there is little to stimulate them, but a convulsion often proves the force and reason that there are in them. In an island located as that is upon which Galveston is situated, there ought to be no more cemeteries should the city again become a place of general residence. And what is strikingly true of Galveston is true in a less degree of all cities. Cremation will become, as the laws of health are better understood and better enforced, a sanitary necessity. With no abridgment of the ceremonies that declare our love and reverence, we shall show a higher regard for the living when cremation takes the place of burial."

SOLITARY IMPRISONMENT.

IT is not our concern to discuss the moral question involved in the justification for capital punishment as opposed to imprisonment for life. No doubt there will always be a difference of opinion on this point, in proportion as the disputants lay stress upon the relative importance of the individual and of the community at large in the social economy. The matter assumes a medical aspect when we stop to consider the possible effect upon the individual of a life imprisonment, to which is added the far greater punishment of solitary confinement. Not long since we noted in a highly reputable daily paper the following statement of the details of Bresci's sentence, the anarhist assassin of King Humbert: "He will be condemned to perpetual labor, but before beginning his toil he will be placed in a cell for ten years of solitary confinement. He will be chained to the wall; he will never see from the depths of his cell a ray of daylight; he will never hear the sound of a human voice. During those ten years of solitude not even a priest can visit Bresci, all occupation is prohibited, and no printed matter of any form ever reaches the eyes of the prisoner, who may not even talk aloud to himself. He receives his food through a little sliding door in his cell, without even seeing the person who brings it."

We are not disposed to place too much credence in these details, if for no other reason than that they are absolutely impossible of systematic execution. The one or two days of solitary confinement meted out to condemned murderers is said to be almost unendurable. To conceive the possibility of such torture extended over a period of ten years is beyond our power of imagination. No human being could endure an immolation which not only cut him off from human companionship, but also deprived him of light and of mental occupation, beyond the entertainment of his own thoughts. Without the slightest question insanity would be the fate of such a man long before the term of his sentence had been reached, and when such an event has occurred the sentence loses its significance wholly. It is well

established that the mere fact of imprisonment under conditions of special hardship is quite enough to upset mental equilibrium in a considerable number of prisoners. How far the law is justified in more or less deliberately bringing about such a result is a matter about which we should suppose there could be but one opinion. It is these possibilities that the advocates of life imprisonment need to take into account when they argue against the "crime" of taking one life as expiation for another. Italy is a country in which capital punishment does not exist, but we may sincerely wish that it did, if anything approaching the punishment described above is possible of execution. It is a variety of torture quite beyond those refined inflictions of physical pain which we are accustomed to regard as relics of a barbarous age and half civilized peoples.

MEDICAL NOTES.

CLAIMS AGAINST THE GOVERNMENT.—It is said that claims aggregating \$2,300,000 or more have arisen in connection with the efforts made, principally in Hawaii, to prevent bubonic plague from securing a foothold in this country and its outlying possessions, by burning a large part of the Japanese and Chinese quarters, where it was thought the disease might find lodgment. Two thousand Japanese residents are said to have lost their homes and practically all their belongings. Their loss is estimated at \$300,000. The Chinese loss was estimated at about \$2,000,000. It appears that there is no fund available by which the United States could pay for these losses, but it is hoped that some satisfactory adjustment may be made. It will be remembered that the area burned in Honolulu was more extensive than had been anticipated.

TYPHOID FEVER IN BALTIMORE.—Last week, as stated in the *Philadelphia Medical Journal*, 39 cases of typhoid were reported in Baltimore, and 4 deaths resulted from the disease. During August the unusually large number of 189 cases were reported, with 37 deaths. An effort has been made by the Health Department to trace the water supply of the sections where fever exists, but it is learned that the water from the different reservoirs intermingles before it reaches the consumer. The cases are confined to the crowded portions of the city. It is thought that the foul gases arising from the harbor, which have been augmented by the warm weather, may be responsible to a certain extent for the prevalence of the disease.

BRITISH CASUALTIES IN SOUTH AFRICA.—The following statistics of British casualties in South Africa are announced: Of the officers in South Africa 72.1 per thousand have been killed or have died from wounds; 30.6 per thousand of the officers have died from disease, while of the men 19 per thousand have been killed or died from wounds, and 31.3 have died from disease. These statistics not only illustrate that while the officers and men have suffered approximately

equally from disease, the risks of the officers in action have been greatly disproportionate, and also that the rate of mortality in South Africa is much greater than it was in the Franco-German War.

NEED OF A PORT HEALTH OFFICER FOR GLASGOW.—The recent appearance of plague at Glasgow calls attention to the fact that the city has no port officer of health. This is said to be due to the peculiar situation of the city with reference to neighboring ports, which must be passed in going by sea to Glasgow. No doubt the present emergency will lead to the appointment of a suitable officer.

SMALLPOX IN PROVINCE OF QUEBEC.—The Province of Quebec is now, according to the *Journal of the American Medical Association*, practically free from smallpox. The last case was disposed of about a month ago.

MEDICAL SCHOOL OF CORNELL UNIVERSITY.—The new building of the Cornell Medical School is not fully completed, but is expected to be ready for occupancy at the opening of the term on October 2d.

EDITORSHIP OF THE "MEDICAL NEWS."—By the retirement of Dr. J. Riddle Goffe, formerly editor of the *Medical News*, Dr. Smith Ely Jelliffe, of New York, assumes editorial control of the journal.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, September 19, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 86, scarlatina 21, measles 4, typhoid fever 32.

DIPHTHERIA IN BROOKLINE AND WALTHAM, MASS.—During the past six weeks 40 cases of diphtheria have been reported to the Brookline Board of Health. The disease thus far has been chiefly confined to children below the school age. The Board of Health has issued and distributed circulars, urging upon the people the importance of reporting all cases of sore throat, in order that bacteriological examinations may be made. As yet no schools have been closed. The two available hospitals for diphtheria are filled with patients, which will necessitate the opening of a third temporary hospital. A sufficient number of cases has also appeared in Waltham to excite some anxiety. New cases are being reported daily among children, many of which are being treated at the hospital for contagious disease.

NEW YORK.

MORTALITY STATISTICS.—The reports of the Health Department for four weeks in August show a considerable reduction in the mortality of the city as compared with four weeks in July, the death rate in August being 18.97 and in July, 22.98. The death rate in August was only very slightly in excess of that for the same period of 1899, namely, 18.11; a very gratifying result when the extreme and prolonged heat of the present season, as compared with the unusual coolness of last year, is taken into con-

sideration. The reduction in the number of deaths was most marked in the class of diarrheal diseases, in which the weekly average was 200 in August, against 313.75 in July. In diarrheal diseases in children under five years of age, the weekly averages were respectively 186.5 and 290.5. The deaths reported from sunstroke numbered 111 for four weeks in August, against 154 for four weeks in July; 88 of these were in the week ending August 8th. The weekly average of deaths from scarlet fever was lowered from 6.25 to 3.25; that from measles, from 16.25 to 5.5; that from pulmonary tuberculosis, from 149 to 143.75; and that from pneumonia, from 101.25 to 78.25. There was a slight decrease in the deaths from diphtheria, whooping cough and bronchitis, while the weekly average of deaths from typhoid fever increased from 10.75 to 14.

OPENING OF PUBLIC SCHOOLS. — The public schools reopened after the summer vacation on September 10th. In the Boroughs of Manhattan and the Bronx the accommodations for the children applying for admission were more nearly adequate than has been the case for many years past, and it is thought that when some new schoolhouses now nearly completed have been opened, there will be ample room for all. Mr. Jasper, who has been superintendent for twenty-one years, states that all the school buildings are in better condition now than at any time since he has held the position. In Brooklyn and Queens the state of affairs is not so satisfactory, and it is stated that in the former borough there are 17,000 and in the latter 10,000 children without adequate accommodation.

THREATENED WATER FAMINE. — The Borough of Brooklyn is threatened with a serious water famine unless there is a considerable rainfall soon. The figures of the Water Supply Department show a reduction of more than one-half in the storage supply in a month, and notwithstanding great economy in the use of water, but a small reduction in consumption. In the Bronx the situation is equally bad, and, according to the statement of Chief Engineer Birdsall, there are five thousand houses there which get water only at night.

PHYSICIANS AND NURSES FOR GALVESTON. — A number of physicians and nurses from Bellevue Hospital have gone to Galveston, and the Salvation Army has also organized a relief party of trained nurses and helpers to aid the sufferers there. The National Volunteer Emergency Service Medical Corps is represented at Galveston by Dr. George Rauchfuss, of New York, Adjutant General and Chief of Staff.

PREVALENCE OF PINK EYE. — At all the hospitals and dispensaries where diseases of the eye are treated large numbers of cases of contagious conjunctivitis, "pink eye," have recently been reported. The outbreak is thought to have originated in the public swimming baths, and extra precautions are now being taken at all the city baths.

Miscellany.

RATS AND PLAGUE.

SOME of the difficulties in the way of destroying the plague-spreading rat are described as follows in the *British Medical Journal*:

"The rat is so commonly associated with the spread of plague, if not with its actual incidence, that the destruction of the animal seems distinctly to be called for as a measure of precaution. The method of getting rid of the rodent is, however, of primary importance. Should poison or fumigation be resorted to, one common effort is to scare the rats in the neighborhood from the locality, and, if they are infected with plague, the consequence will be an increase of the infected area. Another plan is to offer a reward for each rat destroyed. When this plan is adopted the rats are caught and carried to some authorized place, where they are counted and the ratcatcher rewarded. This plan necessitates handling of the rats, and it is possible that the persons who do this become themselves the subjects of plague, or contribute towards the spread of the disease. There is some evidence that it is not the rat itself that is the major source of infection when a diseased rat is handled, but that the vermin which inhabit the rat are themselves inoculated with plague, and as vermin quickly leave a dead rat, the impregnated parasites getting on the clothing of the ratcatcher tend to the diffusion of the disease. It would therefore seem that the only method of killing rats which will do away with dread of their becoming a source of infection is by trapping them. This, however, is a slow process, and one which does not recommend itself to the ratcatcher, who is paid by 'piecemeal.' Even when the rat is trapped the trap should be immersed in a disinfecting fluid if the ratcatcher is being paid according to results, or the rat should be removed from the trap by tongs and burned immediately. The latter process, however, annuls payment by results, as even if the tail is kept as proof of the number caught it will become a possible source of infection by the vermin inhabiting it. The rats, however, might be immersed in a disinfecting fluid, provided the ratcatcher does not handle the animal. It is not safe to attempt to exterminate plague-infected rats by hunting them with dogs or cats, as these animals may catch the disease, or the vermin in the rats may cling to their coats. It might be worth while trying the plan proposed by M. J. Danysz, of the Paris Pasteur Institute, of which an account was given in the *British Medical Journal* of May 19th, 1900, page 1244. Briefly stated, this consists in the introduction into a given rat population of a coccobacillus presenting the general characters of bacillus coli, and thus resembling Löffler's bacillus typhi murium. The plan has been tried with considerable success at Lille, Hamburg, Copenhagen and Tunis, as well as in Paris."

Obituary.

JACOB M. DA COSTA, M.D., LL.D.

By the death of Dr. J. M. Da Costa, which occurred September 12th, the medical profession of America loses one of its most brilliant representatives. He had reached

his sixty-eighth year, though he had suffered for some years from an affection of the heart which finally led to his sudden death. Born in St. Thomas, West Indies, his early education was secured in Germany, whence he came to Philadelphia and was graduated at the age of nineteen from the Jefferson Medical College. After spending two years in study abroad, he returned to Philadelphia and began the practice of his profession. In 1864, he was appointed a lecturer on clinical medicine at the school from which he had graduated, and later was elected to the chair of theory and practice at the same institution. For a number of years he taught in this professorship, and finally resigned to accept the chair of the practice of medicine and clinical medicine. For the past few years he has been professor emeritus. During the active period of his life he was connected with the Episcopal, Philadelphia and Pennsylvania Hospitals, where the foundation of his wide clinical experience was laid. He published a large number of papers on general medical subjects and was the author of a well-known textbook. He was a member of the American Academy of Arts and Sciences, and the American Philosophical Society; he was also one of the organizers of the Pathological Society of Philadelphia, and at one time president of the College of Physicians of Philadelphia, and of the Association of American Physicians. He was a most successful teacher, an able diagnostician and a man much sought as a consultant.

From cerebrospinal meningitis New York 15, Everett 3, Boston 2, Baltimore, Worcester, Somerville, Springfield, Haverhill and Quincy 1 each. From whooping cough New York and Washington 4 each, Boston 3, Baltimore, Springfield, Taunton, Everett and Chicopee 1 each. From scarlet fever New York 2, Boston and Worcester 1 each. From measles New York 3, Washington 1. From erysipelas New York 4.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending August 25th, the death rate was 19.8. Deaths reported 4,404; acute diseases of the respiratory organs (London) 149, diarrheal diseases 883, whooping cough 117, measles 62, diphtheria 50, fever 44, scarlet fever 24.

The death rates ranged from 11.3 in Cardiff to 30.7 in Preston; Birmingham 24.4, Bradford 13.2, Bristol 16.0, Gateshead 25.3, Hull 24.0, Leeds 19.6, Liverpool 22.8, London 19.2, Manchester 19.3, Newcastle-on-Tyne 19.4, Nottingham 19.8, Oldham 22.4, Sheffield 25.9, Sunderland 19.8, West Ham 18.4.

METEOROLOGICAL RECORD.

For the week ending September 8th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

A STUDY OF THE X-RAY PLATES OF ONE HUNDRED AND FORTY CASES OF FRACTURE OF THE LOWER END OF THE RADIUS.¹

BY E. A. CODMAN, M.D., BOSTON,
Surgeon to Out Patients, Massachusetts General Hospital, Ski-
agrapher to the Children's Hospital.

MY object in showing you some lantern slides this evening is to illustrate the value of the detailed study of skiagrams in cases of fracture and in bone diseases. As the subject is a large one, I have chosen Colles's fracture as an illustration, hoping that I may show of what value the x-ray has been in this troublesome lesion. I am indebted to the out-patient surgeons of the Massachusetts General Hospital for the cases and to Mr. Dodd for most of the skiagrams.

The lantern slides which follow those of Colles's fracture are nearly all from cases of bone disease which I have taken this winter for the surgeons of the Children's Hospital. In several of the cases the skiagram led to early diagnosis, and in others it has aided operation in pointing out the exact limits of the diseased area. In osteomyelitis, tuberculosis and syphilitic disease of the long bones it has proved of particular value. In a future paper on this subject I hope to describe the characteristic appearances of these lesions.

Colles's fracture.—For purposes of study, the skiagrams of 140 cases of fracture of lower end of the radius, treated at the Massachusetts General Hospital in the last four years, were taken. It was found that these cases could be separated into ten or more distinct types according to the lines of cleavage and the directions of the displacements. Cases which were not strictly in the lower end of the radius were excluded. The following classification seems to be founded on pretty distinct lines, although it is realized that one type may fade into or be combined with another.

CLASS I. *Fracture through the base of the styloid process of the radius.*—In this type the displacement does not affect the hand or wrist, which are

FIG. 1. Fracture through the base of the styloid process.

still in normal relation with the main part of the radius. The fragment is displaced but little—generally upward and backward by the supinator longus. There is the typical change in relationship of the styloid processes; little or slight backward displacement and no silver-fork deformity. There is crepitus; no impaction; no subluxation of the ulna.

¹ Read before the Boston Society for Medical Improvement, March 19, 1900.

The width of the wrist is increased, but unless the line of fracture extends far inward into the joint the hand does not follow the fragment as in Class VIII. If this is the case fracture of the styloid process of the ulna may occur. There were but 4 cases of this class in my series, in 1 of which the styloid process of the ulna was broken. A plaster strap about the wrist is the appropriate treatment.

CLASS II. *Fracture of the inner angle of the lower end of the radius.*—In this type the fragment usually remains in place or may be dislocated backwards.

FIG. 2. Fracture through the inner angle.

The relative lengths of the styloids are not changed; posterior or radial deformity is exceptional; crepitus is present; impaction is not. There is no subluxation of the ulna unless the styloid is broken. There is increase in the width of the wrist, but no radial displacement of the hand. Of this type there were 3 in the series. In 2 of these the styloid of the ulna was broken. A simple band about the wrist is the only necessary fixation, with splints only for rest.

CLASS III. *Transverse fracture at or a little above the epiphyseal line (in adults) without displacement.*—There are a considerable number of cases of this kind—sometimes slightly impacted, but often not. Owing to the fact that in all my cases I did not have lateral as well as anterior views, the percentage of 11% is probably too large, and some of these cases would more naturally fall into Class VIII. But in this, as in the other types, no hard and fast rules can be set. In some of my cases reduction had probably

FIG. 3. Transverse fracture without displacement.

been effected before the skiagrams were taken. In others the periosteum may not have been completely torn. The relations of the styloids are but little changed. There is no posterior deformity. Crepitus may be obtained as a rule and impaction can only be present in a very slight degree. No increase of width or radial displacement. Of this type there were 16, or 11% of 140, and there would no doubt have been less had those which had been manipu-

lated previous to the x-ray been ruled out. Sixty-six per cent. of these cases had fracture of the styloid of the ulna also.

CLASS IV. The distal fragment is comminuted, either as a simple T fracture or into several smaller pieces. The whole list of classical signs are present. The fragments are generally displaced posteriorly and radially, as in Class VIII, but part of them may go anteriorly. There may or may not be impaction.

FIG. 4. Comminution of distal fragment.

There were 13, or 9%, in my series, and all of these had also fracture of the styloid process of the ulna. The treatment to be described later for Class VIII is most appropriate for this class.

CLASS V. *Separation of the epiphysis of the lower end of the radius.*—These cases often present themselves with the fragment completely reduced, but may show a typical silver fork deformity. As a rule they are easy to reduce and do not tend to become displaced again easily. Fract-

FIG. 5. (a) Separation of epiphysis.

Fig. 5. (b) Separation of epiphysis, lateral view.

ure of the styloid of the ulna occurred in all my cases in which this process was ossified, that is, 6 of the 17. Careful reduction and fixation in splints or plaster for two weeks is almost sure to produce a good result.

CLASS VI. *Separation of the epiphysis of the lower end of the radius with a chip off the posterior surface of the diaphysis.*—This class proves to be quite common, 10 cases in 140, or 7%. Uncomplicated separation of the epiphysis occurred 17 times, or 12%. So that in 27 cases of separation of the epiphysis, a chip out of the diaphysis occurred in 10, or

over one-third of the cases. In these 10 cases fracture of the styloid of the ulna occurred also except in 2, in which the process was not ossified. Fixation

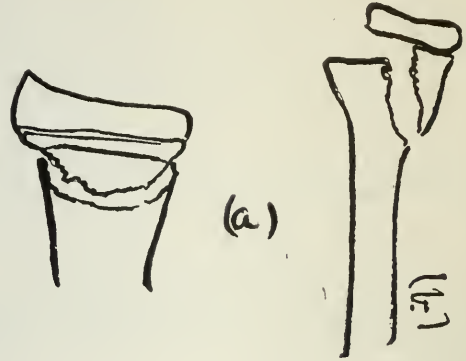

FIG. 6. (a and b) Separation of epiphysis with chip from diaphysis.

between two splints and a dorsal pad over the fragment are enough in most cases. If there is radial displacement also, cross traction as in Class VIII may be employed.

CLASS VII.—*Impaction of lower fragment into the shaft.*—This is a rare class, there being only 2 cases in 140. In one the styloid of the ulna was broken; in the other the skiagram was too indistinct to determine whether it was broken or not. The relations of the styloids are altered. There may be posterior

FIG. 7. Impaction of lower fragment into upper.

deformity. There is impaction without crepitus. The ulna is subluxated when the styloid is injured. There is increase in width and slight radial displacement. Unless contraindicated by age, it is better to break up the impaction and use anterior and posterior splints.

CLASS VIII. This is the typical Colles's fracture and may itself be divided into two forms: That with marked radial displacement of the fragment, and that in which the posterior deformity is more decided. There is usually both—at least to some extent. All the classical signs are present, the amount of crepitus and impaction varying in individual cases.

The lateral view is depicted in Fig. 8 a and the anteroposterior in Fig. 8 b. It is to be remembered in almost all fractures of the lower end of the radius that the hand and wrist bones follow the distal fragment to which the ligaments bind them. In Fig. 8 a the fragment, besides being pushed backwards, is tilted on its own axis, and pierced by the sharp dorsal edge of the diaphysis. It is this which causes the impaction. In the other plane (8 b) the frag-

ment is usually seen tipped to the radial side. This displacement may occur with practically no dorsal dislocation, or vice versa, we may get dorsal with no radial. In the former case it is usual to find fracture of the styloid of the ulna. In the latter it is less common.

In unusual cases the upper fragment pieces the lower almost directly, but, as pointed out by Dr. J. C. Munro, there is always some little tilting towards the radial side. In Fig. 8 *a* it will be observed that the sharp palmar edge of the upper fragment projects anteriorly. Where perfect reduction (which is rare) is not made, this lower edge is left as a menace to the tendon sheaths and median nerve. The author believes that undue pressure against this edge is responsible for many of the unhappy cases of contractures of the hand seen after this fracture. Provision against this is made by an anterior pad extending along the palmar side of the radius to just above this lower edge. The application of this will be de-

FIG. 8. (a) Lateral view, typical Colles's fracture.

FIG. 8. (b) Anteroposterior view, typical Colles's fracture.

scribed below. Of the 140 cases 64, or 46%, fell under Class VIII. In 89% of those in which the styloid process of the ulna could be made out clearly it was found to be broken. Those in which it was not broken were those in which the type was posterior and not radial.

As fractures of Class VIII are the most common and severe, I shall speak of the treatment at more length. The indications are to prevent posterior and radial deformity and to bring the whole hand into normal line with the forearm. The dangers to be avoided are pressure over the sharp edges of the fragments and constriction of the circulation. The parts must first be reduced and then held there.

In reduction it must be remembered that the fracture is in the radius, not in the wrist bones, and that the lower fragment is to be put in place, carrying with it the wrist and hand. *It must be pulled down and shoved over* the angle of the dorsal edge of the upper fragment. A similar and simultaneous move-

ment frees the radial edge. The fragment once reduced can be easily kept in place by the thumb and forefinger, but it has a tendency to slip out as soon as pressure is omitted. To keep it in place, a small pad of sheet wadding or felt is placed over the dorsal surfaces of the lower fragment, and an anterior pad along the front of the radius about three-fourths of an inch wide and one-fourth of an inch thick. This stops just short of the sharp edge and is fastened to the arm by adhesive straps before the splints are applied. A posterior splint to the knuckles of the first phalanges and an anterior to the thenar eminence hold these pads in position. To control the tendency of the hand to become displaced to the radial side, a cross traction method is used (Fig. 11.) Two adhesive straps are looped about the wrist in opposite directions, one tending to pull the ulna toward the radial side, the other to pull the fragment with the hand toward the ulnar side. These are laid in position at the same time as the anterior and posterior pads. The splints are held by an assistant, and after putting a circular strap about the upper end of the splints, traction in opposite directions is put on the lower straps and the ends curled about the splints and caught. This leaves the ulnar side free opposite the lower fragment and the radial side free opposite the upper fragment, and ensures a good circulation. The fingers and thumb are allowed free movement throughout, and the splints are cut off at the wrist at the end of the second week.

As this treatment was evolved by the study of the above cases, I have had but 4 cases in which it has been carried on throughout. These have proved very successful, showing almost complete reduction of the fragments and giving good motion at the end of the fourth week.

CLASS IX. *Stellate fracture of the lower end of the radius, with longitudinal fissures extending into the shaft.*—This fracture was described by Henry J. Bigelow, and a specimen prepared by him is in the Warren Museum. The relations of the styloids are but little if any changed. There is no posterior de-

FIG. 9. Stellate fracture.

formity and but little radial. No crepitus or impaction or subluxation of the ulna. There is more or less increase in width. In 140 cases this form occurred 6 times, or 4%. In 3 the ulnar styloid was broken, in 2 it was intact, and in 1 the skiagram was obscure. A simple band about the wrist is all the fixation required.

CLASS X. *Reversed Colles's fracture, that is, anterior displacement of the lower fragment.*—This fracture has been carefully described by Roberts, of Philadelphia. It is almost exactly the reverse of Class VIII, and is reduced and fixed in a similar

manner, except that the position of the pads is changed. Five cases are included in my series, nearly

FIG. 10. Reversed Colles's fracture.

4% of the whole. In all of them the ulnar styloid was broken.

In describing these ten types the author does not wish to assert that all fractures of the lower end of the radius must fall in one of these classes. The lines of cleavage vary to a great extent, and possibly other forms might have been included, as those cases

FIG. 11. Cross traction method for Class VIII.

in which the anterior or posterior lip of the joint cavity are alone broken. The study is made more with the object of calling attention to the variety of fractures in this region than to lay down absolute rules.

I wish to emphasize the following points :

- (1) That true Colles's fracture formed but 46% of 140 cases of fracture of the lower end of the radius.
- (2) That a knowledge of the position of the fragments is necessary for intelligent treatment.

FIG. 12.

(3) That the application of padding and splints should vary according to the displacement shown in the skiagram.

(4) That if the x-ray shows that marked deformity is still present after the splints have been applied, ether should be given, and another energetic attempt at reduction made.

(5) That concomitant fracture of the ulnar styloid occurred in at least 62% of 140 cases, and if 39 cases in which this process was obscure in the skiagram are deducted, fracture occurred in 86%.

(6) That in true Colles's fracture pressure over the anterior edge of the upper fragment should be avoided and cross traction should be used to correct the radial displacement of the lower fragment.

(7) That statistics of the results of Colles's fracture are not of value unless the pathology of each case is determined by a skiagram.

To illustrate the use of the x-ray in diseases of the bones, the following lantern slides were shown :

BONE DISEASES.

1. Old tuberculosis of knee.
2. Old tuberculosis, showing ulceration of outer condyle.
3. Rheumatoid arthritis, showing sponginess of bone and erosion of joint surfaces.
4. Osteophite of elbow; osteo-arthritis.
5. Early caries of ulna.
6. Tuberculosis of lower epiphysis of tibia.
7. Tuberculosis of lower end of fibula.
8. Tuberculosis at lower epiphysal line of fibula.
9. Tuberculosis of tibiotarsal articulation.
10. Tuberculosis of lower epiphysis of fibula.
11. Osteophite of fibula.
12. Syphilitic periostitis of long bones of leg.
13. Osteomyelitis of femur, showing sequestrum.
14. Tumor albus, showing change in epiphysis.
15. Tumor albus; erosion of outer condyle causing abduction.
16. Tuberculosis in upper epiphysal line of tibia.
17. Old tumor albus; disappearance of external condyle.
18. Osteomyelitis of tibia.
19. Caries following compound fracture of femur.
20. Coxa vera; rickets.
21. Pelvis, acetabulum and head of femur eroded.
22. Sarcoma of humerus, disappearance of bone.
23. Tuberculosis of head of humerus.

ENTERIC FEVER IN LONDON, ENG. — An epidemic of enteric fever is reported from South London. The disease is said to have been brought to England by soldiers sent home from South Africa.

TRAUMATIC JOINTS.¹

BY HOMER GAGE, A.M., M.D.,

Surgeon to Worcester City, Memorial, and St. Vincent's Hospitals.

IN his lectures on the "Principles of Surgery," John Hunter, in discussing injuries to the joints, observes that "sprains are at least seldom perfectly cured," and while I think so strong a statement would hardly be accepted as true today, it must still be acknowledged that seemingly trivial accidents affecting the joints often result in very long, and sometimes even permanent, disability. So that the saying, which must have been truer then than now, is still commonly heard, that a sprain is worse than a broken bone. Whenever the restoration of the function of the joint is long delayed or the pain persistent, the trouble is ordinarily ascribed to rheumatic complications. To what extent this is simply a convenient cloak to hide ignorance, and to what extent such complications do actually exist, it is the purpose of this discussion on diseases of the joints, as far as possible, to explain.

To introduce the subject, I wish very briefly to consider the effects of traumatism upon the joints, the changes which are commonly produced in the structures in and about the joints, how these explain in many instances the delay in the restoration of function, and what may be done to prevent such delays. For the purposes of this discussion I wish to exclude all injuries which are complicated by fractures or dislocations or by external lacerations, and to consider only those which come naturally under the head of sprains or contusions.

The effects of such injuries vary very much according to the amount of force used in producing them, and according to the manner in which that force is applied. But there is one thing common to all injuries which are sufficient to cause a suspension of function, and that is, a laceration of some of the soft parts in or around the joint. It may be from direct violence, as in a bruise or contusion; it may be from indirect violence, as in the stretching caused by a twist or wrench; it may be accompanied by synovial effusion. If severe, it may be manifested at once by the resulting discoloration, or the displacement of cellular structures may be manifest only upon microscopic examination. I believe, however, that as in concussion of the brain, so in sprains and contusions of the joints, impaired function can be produced only by structural change. These changes may affect the cartilages, the ligaments, the synovial membranes, the muscles and their sheaths which lie in proximity to the affected joint, or to the soft parts around and outside the joint; they may affect any or all of these structures. Injury to the cartilages may result in erosion and ulceration, must always be attended by injuries to the more superficial parts, and be slowly and imperfectly repaired. The ligaments, whether torn or stretched, will be thickened by the exudate which is deposited about the torn fibres, may contract adhesions to other structures, or be shortened or distorted by their resulting cicatrices. The synovial cavities may be obliterated by adhesions. Tenosynovitis may cause adhesions which prevent the play of the tendon in their sheaths, or the effusion of lymph in the soft parts about the joint may be so great as to interfere with its motion. The presence

of blood clots in the tissues, with their subsequent organization, furnishes another element to favor the formation of adhesions and the contraction of resulting cicatrices. To a greater or less extent these are the changes following every sprain or contusion according to the severity of the injury. The important feature of them all is the tendency to the formation of adhesions or contractions, and just so far as these are permitted to occur, delayed or imperfect results will be found.

That treatment will be most successful which, while controlling exudation, and permitting repair, provides at the same time for the maintenance of motion. This has been secured by various combinations of rest and compression, with both active and passive exercise. Fixation and compression are certainly the most efficient agents for the control of swelling and the relief of pain, and are therefore especially indicated at the outset. Compression also favors resolution, but does not prevent adhesions and contractions, and both are likely to follow too long continued rest. A healthy joint may be held immovable for a very long time, and yet promptly regain its usefulness; but an injured joint would, during the process of repair, have acquired at least a partial ankylosis, requiring weeks or even months to overcome, varying according to the extent of the damage. Rest and fixation should be continued only so long as is necessary for the relief of pain. They should give place first to the use of carefully applied massage, not indiscriminate rubbing, to stimulate the lymph currents and promote absorption of the effusion, and this should be followed as fast as the disappearance of pain will permit, by some form of active or passive motion to maintain the elasticity of the tissues and prevent the formation of strong adhesions. In the milder cases this may be secured by the method of strapping, revived by Gibney a few years ago, which permits of limited voluntary exercise, and may often be used from the time of the very first dressing. In the severer cases rest and compression must be maintained for a considerable time, but even then after the first two or three days must be supplemented by systematic passive exercise at frequent intervals, such exercises to be increased as fast as the subsidence of pain will permit, and the amount of fixation diminished as rapidly as possible. It is well for us to remember, I think, that the principle of rest, like many other good things, may be carried too far. It should give place to a carefully regulated and controlled use just as soon and just as far as the sensitiveness of the joint will reasonably allow. Keeping this always in mind, I believe that many of the delayed recoveries and imperfect results for which we have felt obliged to fall back upon the theory of some constitutional diathesis may be satisfactorily avoided.

In the neglected cases, in which swelling and stiffness have not disappeared, but, with pain and soreness, continue to interfere with the use of the joint, the problem is a different one. The effused blood and lymph have become partially organized, adhesions have been formed, and ligaments and tendons have already contracted. In these cases of chronic sprain, rest relieves pain, but favors ankylosis. Compression combined with exercise, as in the method of strapping with adhesive plaster, is often useful and sometimes sufficient. It is, however, es-

¹ Read before the Massachusetts Medical Society, June 13, 1900, and recommended for publication by the society.

pecially in these cases that massage with involuntary as well as voluntary exercises accomplishes most, and here we have much to learn from the violent methods of the bone setters and osteopaths. If the ankylosis is thoroughly broken up under ether, and the joint immobilized, the adhesions quickly reform; some rest is necessary for the relief of the pain which follows the operation, but the massage and exercise, to be efficient, must be as vigorous as the patient can comfortably stand—much more vigorous, frequently applied and persistent than in the case of freshly inflicted injury. A single instance from my own experience will, perhaps, best illustrate its necessity. A young man was thrown from a bicycle, injuring the elbow. No fracture was discovered at the time, and when he first presented himself to me five weeks later there was no swelling and no deformity, but almost complete ankylosis. He was advised to have it vigorously rubbed and exercised, and to use it as much as possible himself. Two or three weeks of this plan being followed by no relief, I etherized him, broke up the adhesions, found that there was no bony obstacle to the motions of the joint, and had the rubbings continued, but with no practical benefit. He was sent to a distinguished masseuse in Boston, who advised a continuance of active and passive motion, and assured him, as I had done, that good motion would ultimately be restored. At the end of a year, with the arm still ankylosed, he consulted a natural bone setter, and at the end of a month had a useful arm, which has steadily improved until it is almost as good as it was before the accident. He tells me that the method of treatment by passive motion and rubbing was identical with what we had been doing, but that very much more force was used; that it hurt him a good deal at first, but after a few treatments the pain began to diminish and soon ceased altogether. This and similar experiences have taught me that where tolerably firm adhesions and contractions have occurred, they can be overcome most quickly and most easily by the exhibition of a corresponding force in their manipulation, applied persistently, regularly, and at very short intervals. Recently a new agent has been brought forward to assist in relieving these most obstinate cases, namely, the hot-air treatment, given most easily by the so-called Betz apparatus. It is practically baking the limb in a hot-air oven in which the temperature is carried approximately to 300° F.

From the careful observations and experiments in the use of hot air reported by Frazier in the *Annals of Surgery* for 1897, we learn that when a limb has been subjected to a temperature of 300° F. for an hour, a diffuse hyperemia of the integument may be plainly seen, there will be a temporary numbness of the part, and if there be not complete ankylosis, less pain and more freedom in the movements of the joint. He believes that all the benefits are the results, not of any constitutional effects, but of purely local influences. These he finds chiefly in a locally stimulated circulation, which produces a temporary edema and permits of a certain amount of mechanical stretching, at the same time carrying away and flushing out the fluid that lies stagnant in the tissues. In other words, the hot-air treatment accomplishes, perhaps, a little easier and more thoroughly because the heat is greater, just what has been attempted by the more old-fashioned method of the hot pack or the steaming in hot,

moist flannels. It prepares the joint and puts it in a most favorable condition for massage and active exercises. To this extent it is a useful adjunct to the methods already described, but is of little avail without them.

In conclusion, I desire to express my belief:

- (1) That all injuries to joints accompanied by loss of function are always attended by more or less laceration of the tissues in or about the joint.
- (2) That the delays in the restoration of function are due in most instances not to any complicating diathesis, but to the changes incident to the repair of these lacerations and their effects.
- (3) That such delays are best avoided by an early resort to massage and active or passive motions, and are favored by too long a continuance of rest and fixation.
- (4) When such delays have occurred they are best overcome by more vigorous and persistent manipulation, supplemented by the application of heat or such other agents as may best stimulate the local circulation and favor the elasticity of the tissues.

A CRITICAL REVIEW OF THIRTY CASES OF PYOSALPINX.

BY G. S. WHITESIDE, M.D., AND W. J. WALTON, M.D., BOSTON,
From the Clinico-Pathological Laboratory of the Massachusetts General Hospital.

THROUGH the kindness of several members of the staff of the Massachusetts General Hospital, we are enabled to report a critical review of 30 cases of pyosalpinx; some of them were operated in the Massachusetts General Hospital, some are taken from the records of private cases of Dr. M. H. Richardson, and 2 of them are our own cases. Hence not more than 4 or 5 cases are the results of any one operator's skill. The clinical records are, in 25 cases, taken from the hospital record books, the remaining 3 are from Dr. Richardson's notebook and our own notes on 2 cases. The cases are not picked and chosen with regard to either clinical or pathological results, but are a consecutive series of operations from which *none* have been excluded to either decrease our mortality or improve our statistics. Only those cases have been excluded the specimens from which were received so long after operation that no accurate bacteriological conclusion could be drawn from them.

A study has been made in all cases of cover glasses smeared with pus from the affected tube and of cultures inoculated directly from the same material. These cultures have been taken on ordinary blood serum, plain agar, bouillon, gelatine, litmus milk, potato and specially prepared media with a view to growing the gonococcus. These special media were blood agar, prepared by smearing human blood drawn in a sterile manner over the surface of a sterile agar slant; urine agar, prepared after the manner advocated by those gentlemen who have given the subject such careful attention at the Johns Hopkins Hospital, and also ascitic fluid agar, prepared by the rules laid down by Dr. Hugh Young, of the above hospital. On none of these media were we brilliantly successful in cultivating the gonococcus. Some of these latter tubes, after having proved useless in our hands, were sent by mail to Dr. Young, who grew gonococci obtained in Baltimore upon our tubes and returned them

to us. We followed his directions minutely, but were unable to obtain a second generation.

We have carefully studied both bacteriologically and histologically the cut sections of tubal tissue after being properly hardened. In all cases we have found the histology bear out deductions made from clinical observations. We have become persuaded that the variety of organism concerned, has little, if anything, to do with the severity of the case and the outcome, except in the case of the streptococcus or the tubercle bacillus. On the whole, drainage, by gauze wicks, does not tend to reduce the mortality of the operation. On the other hand, in 3 cases drainage was followed by fecal fistulae, and 1 of these cases proved fatal from this cause alone. One, a tubercular case, never closed up during the lifetime of the patient, the other recovered without a second operation.

The operative mortality in the cases reviewed showed death from fecal fistula as above noted, death from general tuberculous infection one year and a half subsequent to operation in 1 case, death from general streptococcus peritonitis in 2 cases. In one of these the organisms were demonstrated and the peritonitis existed at the time of operation, in the other no organisms could be detected at the time of operation, the peritonitis developing immediately subsequent thereto and closure without a drain. In the fifth case death resulted from general peritonitis within twenty-four hours following operation.

It is clear to our minds from a review of these cases that the gonococcus cannot be proved to be the cause either directly or remotely in as large a number of instances as is generally supposed. Other organisms, which we cannot find recorded as being responsible for such a condition, have been demonstrated by us to be the only living organism present in a considerable number of cases. Among these may be mentioned the bacillus mesentericus, pneumococcus lanceolatus, bacillus tetragenous, and two organisms more commonly demonstrated by other observers, namely, the colon bacillus and streptococcus pyogenes. It cannot be proved that through the action of the gonococcus the normal integrity of these tissues has been impaired, and so made a suitable soil for the development of these other bacteria. Neither can this theory be disproved by such purely negative results as we have obtained.

Several experiments were made by us to demonstrate the possibility of experimentally producing pyosalpinx by the injection of pure cultures of the streptococcus pyogenes, the bacillus mesentericus and mixed cultures of the streptococcus with pus-producing staphylococci, into the uterus of rabbits. The experiments in all cases were entirely negative. One rabbit died of general streptococcus septicemia after an extremely large dose of a very virulent, pure culture of streptococcus. The other animals used developed a purulent vaginitis for a few days. They afterwards, on being replaced in the rabbit pen, became pregnant and bore healthy litters of six rabbits each.

It seems to us that the blood count is not of great diagnostic or prognostic value in pyosalpinx cases, or as differentiating between those having a larger or smaller amount of pus or between those of a more or less virulent type.

From the study of these cases, we believe that the majority of patients afflicted with pyosalpinx, when

first seen by the surgeon, have shown previous symptoms to the ones of the immediate attack, or give a history of former similar crises.

Having given this matter general consideration, let us take the signs and symptoms of the disease more in detail. The average age of the individual so affected is thirty-two, and all were of such an age as to be sexually vigorous.

Seventy-five per cent. were married or widows. In 50% the urine was normal and 50% showed pus, blood and casts. Leucocytosis was present in all those cases where a blood count was done, the lowest count being 8,800 and the highest 32,000. Apparently the amount of leucocytosis was without regard to the organism present or the amount of pus found at operation. The temperature was elevated in all cases. In 17 the temperature ranged from 99° to 101°. In the remaining cases an almost equal number were above and below these figures. The temperature apparently bears no constant relation to the leucocytosis present. Of the pulse, it may be said in general that it was not far from 100 in the majority of cases, and that no direct or definite relation can be established between the rate of the pulse and the leucocytosis. Sixty per cent. of the 30 cases showed acute symptoms referable to the pelvis for more than a year. The remaining 40% were all cases of less than one month's standing. Of these cases 4 were mixed pyogenic infections; the exact morphology of the bacteria present in these we were unable to determine. One contained the pneumococcus in pure culture; 1, the micrococcus tetragenous; 2, the gonococcus, and 2 were entirely bacteriologically negative. One other case of virulent streptococcus infection was probably an acute case, but no record of the duration of the attack was obtained before her death.

Vomiting was present in 72% of cases. All those cases in which it was present were either acute cases or acute exacerbations of a chronic trouble. A slightly larger percentage of individuals were constipated than those whose bowels moved normally. However, an almost equal number had diarrhea. Eighty-eight per cent. showed an abnormally increased bloody vaginal discharge, having more or less dependence upon menstruation. Pain was present in all cases, varying only in character and location. In 80% the pain was severe, being situated on the right or left side in about an equal number of cases. Thirty-three per cent. of these women had either borne children, had miscarriages, or both. In fact miscarriage was possibly a factor in 20%, in causing the disease or in preparing the way for it. Two of the streptococcus cases were post-abortive cases.

With regard to the examination of the patient we noted the following points: The chest examination was negative in all but 1 case, which showed a chronic heart lesion, and 1 tuberculous case in which there were doubtful phthisical signs in the lungs. The general abdominal examination showed a rigidity of the abdominal wall in 40% of the cases. Tenderness was said to be present in all those cases in which any note was taken in regard to this point. This tenderness corresponded accurately with the position of the most acute pain. An abdominal tumor is recorded as having been felt in 4 of 15 cases.

With regard to examination of the genitals themselves, leucorrhœa was present in 80% of cases, some-

times being a simple vaginal discharge and other cases showing stringy yellow mucous protruding from the os uteri. The further vaginal examination demonstrated pain and extreme tenderness of the vaginal vault, especially the posterior cul-de-sac on one or both sides. The most tender spot in the vagina did not always correspond either with the side of greatest abdominal tenderness or with the situation of the tube proved at the operation to be most involved.

With regard to the operation performed in these cases, 4 cases were tapped by vagina and later required abdominal section. In 23 cases both tubes demanded removal. In 2 cases it was impossible to do more than open the abscess on account of very extensive adhesions. In the remaining 4 cases one tube only was removed, all by abdominal section.

The amount of pus evacuated or contained in the tubes was considered as coming under three almost equal headings, namely, small, moderate or considerable quantity. One case showed general peritonitis at time of operation. In the majority of cases the pus was walled off by adhesions which might be characterized as firm and general.

In those cases showing bacteriologically the gonococcus, the bacillus mesentericus, and in all cases where mixed pyogenic infection existed, the abscess cavity contained thick, greenish or yellowish pus in moderate or considerable quantity, except Case 4, which had shown symptoms for only a few hours before operation, and Case 20, which had been previously tapped per vaginam.

With the colon bacillus or the pneumococcus or the streptococcus pyogenes, the contents of the abscesses might be said to be a thin, purulent fluid. Those abscesses containing bloody fluid were all bacteriologically sterile. In more than 75% of the cases recorded the tubes were ruptured and pus set free during removal. This apparently had no bearing on the after history of the case, except in 1 patient who died of a general peritonitis following the opening of two large abscess cavities, in the pus from which the gonococcus was proved abundantly present (Case 24).

Of those cases, 7 in number, which were closed and filled with salt solution after Clark's method, 6

¹ N., negative; P., positive.

² The gonococcus was demonstrated in each of these cases to be present in the pus from the tube. The method used was the usual one of smearing a cover glass and staining by gentian violet and Bismarck brown. In one case the organism could not be shown in this way and was only found by treating a thin section of the hardened tissues with appropriate stain.

³ By "mixed infection" we intend to convey the idea of many organisms existing together. Most of these were possibly the pyogenes aureus or albus or a short, thick bacillus often found in the vagina. It proved impossible to isolate and name these. Perhaps they were dead.

recovered and I died; the death being due in this instance to a general streptococcus peritonitis following the removal of apparently sterile, chronically diseased tubes.

From this series of cases we may draw conclusions as follows: The mortality of the operation taken as a whole is 16%. The greatest dangers to be apprehended are in streptococcus infections from peritonitis, in all drained cases from fecal fistula, in tubercular cases from extension of the disease to other organs.

The foregoing tables will be of possible help in determining the cause of pyosalpinx and defining the symptom complex of the condition.

Clinical Department.

POST-OPERATIVE HEMATEMESIS.

BY KENELM WINSLOW, M.D., GROTON, MASS.

POST-OPERATIVE hematemesis, or capillary hemorrhage from the stomach, following surgical operations and occurring without any visible lesion and without any apparent cause, is very rare. No description of the disorder is to be found in the textbooks, but it has recently received able consideration by Mayo Robson¹ in his Hunterian lectures, and by William L. Rodman² in the oration in surgery delivered by him before the American Medical Association, at Atlantic City, N. J., in June, 1900.

Of fifty surgeons interrogated by Rodman, nine have observed cases of post-operative hematemesis. Finney, of Johns Hopkins Hospital, is not aware of a case ever having presented itself in that institution. On the other hand, Robson has reported 7 cases occurring in his own practice, 2 of which were fatal, and he quotes 6 cases observed by Eiselberg in the Königsberg clinic, and 3 fatal cases related by Reichard in the Free Society of Surgeons, in Berlin, December, 1899. Johnston, of Richmond, has recorded 5 cases, 3 fatal, but accompanied by general peritonitis.

Post-operative hematemesis has occurred after abdominal operations in only 2 instances, when it followed nephrorrhaphy, and in these the peritoneum may have been opened. Thus it has been noted succeeding operations on the peritoneum, omentum, intestines, gall bladder, kidneys, uterus and ovaries. The disorder arises from the second to tenth day subsequent to operation.

While there is no macroscopic lesion or pathological condition visible after death to account for the gastrorrhagia in many cases, in some there are numerous hemorrhages into the gastric mucosa and in others small recent ulcers have been found. The causation I believe to be yet unsolved, although Robson notes that in 6 of Eiselberg's cases there was ligation of the omentum, and in the seventh the omentum was probably contused, also that in an experiment on an animal multiple hemorrhages into the stomach followed twisting of the omentum. Rodman, however, failed to produce any bleeding or even congestion of the stomach in four experiments conducted by him on dogs, in which the omentum was twisted into a rope

¹ Lancet, March 10, 1900, p. 671.

² Philadelphia Medical Journal, June 9, 1900, p. 1313.

and ligated high up, and the liver, spleen, pancreas and intestines likewise subjected to pressure and mechanical violence under the supposition that blood might be forced back into the small veins of the gastric mucosa by these procedures.

Rodman regards sepsis as the etiological factor in post-operative hematemesis, since sepsis favors disintegration of blood corpuscles and predisposes to hemorrhage, and because the gastric mucous membrane is specially prone to congestions both on account of the frequency of vomiting after operations and the tendency of the thin, partially disintegrated blood to settle in the internal organs.

Post-operative hematemesis has occurred after the use of cocaine, and again when vomiting did not follow the employment of general anesthetics, so that vomiting, ether and chloroform may be ruled out as causal factors. There were no evidences of sepsis in most of the reported cases, neither in Mayo Robson's nor in the one detailed below by the writer, and as gastrorrhagia has followed within twenty-four hours of an operation and after simple exploratory laparotomies, it would seem as if sepsis was not an altogether satisfactory explanation of the phenomenon. The relation of a case of post-operative hematemesis following omphalectomy may be permitted.

Mrs. J. was a short, very stout woman, about sixty-five years of age. Her general health had been good with the exception of some shortness of breath on exertion. She had an umbilical hernia as large as an infant's head, which had existed for perhaps twenty years; it had been incarcerated at times, but reduction had spontaneously occurred. The reduction was probably only partial.

I saw the patient for the first time with Dr. Steere, of this town, on the evening of December 24, 1899. There was a history of colic and vomiting for the previous six hours, with unsuccessful attempts at reduction of the hernia by taxis, ice bags, etc. An endeavor on my part did not prove any more satisfactory under ether, and at midnight I operated, assisted by Dr. Steere and Dr. Cowles, of Ayer. Two elliptical incisions were begun in the middle line of the abdomen at a point 3 inches above the hernia and were continued as close as possible to either side of the hernial mass, meeting about 2 inches below it, and dividing all the structures of the abdominal wall down to the peritoneum according to the method originated by Condemin in 1892. The peritoneum was then opened on the left side and the finger introduced into the abdominal cavity and thence into the hernial ring. With the finger as a guide, a knife was introduced into the ring from the abdominal cavity and the sac was completely divided from within outwards by a transverse incision through all the tissues of the wall from the peritoneum to the skin, beginning at a point just to the left of the umbilicus and joining the middle of the left vertical or elliptical incision. The contents of the sac, transverse colon, small intestine and omentum were thus easily exposed. The sac was multilocular and there were many adhesions uniting the bowels, omentum and sac walls. The adhesions were readily separated; a small portion of the omentum was ligated and removed and the intestines were returned in good order into the abdominal cavity. The whole hernial sac and adjacent parts were then excised by dividing the peritoneum through the original incisions. It now appeared that the edges of the

wound could only be approximated with the greatest difficulty and an attempt to suture the peritoneum, fascia and skin was of necessity abandoned on account of the strain on the peritoneum, more particularly in the upper part of the wound. The wound was finally brought together and held in good apposition by interrupted silkworm-gut sutures placed through all the layers of the abdominal wall.

The operation consumed a little over an hour, the patient rallied satisfactorily and was talking with the etherizer before the dressing was fully completed.

The after progress of the case was at first fairly satisfactory, although there was some vomiting following the anesthesia and the pulse was intermittent and not very strong. The temperature was elevated a degree on the second day, but fell to 99° F. on the third; the pulse rate was not high; there was no pain and the patient wanted to sit up on the day following the operation. On the evening of the third day the patient began to vomit, and the nurse noticed for the first time that a dark fluid was frequently brought up in small quantities and without retching. About midnight a messenger came to my house in hot haste, saying that the patient was dying. She was in fact dead on my arrival, in fifteen minutes, having suddenly vomited an enormous quantity of dark blood and then had immediately expired.

At the autopsy considerable dark, clotted blood was found in the stomach and small intestines, but no lesion of the mucous membrane was discovered on careful search. There was no evidence of infection; the bowel was wholly normal; the wound had healed perfectly by first intention and I was surprised to find no sign of tension on the stitches, notwithstanding the difficulty experienced in coaptation of the wound at the time of operation. The lungs were much congested and there were some clots of blood in the bronchial tubes, so that at first sight it seemed as if the hemorrhage had been pulmonary. But there had been no pulmonary difficulty, no coughing, no spitting of bright, frothy blood. The blood was dark and had been distinctly vomited in great quantity just before the end, so that the blood found in the lungs must have been inspired in the latter moments. Nothing else noteworthy was found post mortem.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

CUTANEOUS AFFECTIONS FOLLOWING THE INTERNAL ADMINISTRATION OF ARSENIC.

It is thirty years since Hutchinson raised the question of an arsenic zoster, and Bettmann¹ considers that all are not yet in accord upon this question. He points out that Kaposi, who had previously totally denied that there was a causative connection between the ingestion of arsenic and the occurrence of a zoster, speaks much more guardedly in the last edition of his work. The question, it would appear, must remain one of statistics. Bókai observed 3 cases of zoster among 113 cases of chorea treated with arsenic (that is, in 2.6% of the cases), and this was al-

¹ Arch. f. Derm. u. Syph., 1900, II. 2.

ways after the patients had been on arsenic for a considerable period, and when there had been an essential improvement in the nervous affection. Nielsen reported 557 cases of psoriasis, occurring in 390 persons treated with arsenic, of which 1.9% of the cases and 2.6% of the persons developed a zoster while under observation. On the other hand, no case of zoster was observed in 220 cases of psoriasis which were not treated with arsenic. These figures were an indication, in Nielsen's eyes, of the causative relation of the arsenic. He affirmed also that the appearance of zoster in hospitals was a very great rarity.

It has been affirmed that zoster has occurred with some frequency in cases of poisoning from arsenic. In an epidemic of arsenic poisoning in Reichenstein Geyer estimated its occurrence in from 15 to 20% of the cases. In other instances where large numbers of people have been poisoned by arsenic no association with zoster could be claimed.

Lewin classes arsenic zoster as a dermatitis medicamentosa, and points out that in other drug eruptions the appearances are often confined to certain limited portions of the body, or nerve tracts. The fact that animals treated with arsenic have never been shown to develop zoster is in accord with the infrequency of drug eruptions generally in animals. Attempts have been made by Hutchinson and others to prove that there are special clinical peculiarities that would go to show the existence of an arsenic zoster, but these have not succeeded.

Bettmann reports the case of a woman of fifty, who was suffering from malignant lymphomata, who was taking moderate doses of arsenic both internally and subcutaneously, and developed, together with severe constitutional symptoms, a typical herpes zoster, as well as a generalized vesicular eruption. The latter affection, although not fully clear, seemed most probably due to the arsenic also. In the further course of the affection there appeared a hyperkeratosis of the palms and soles. The writer was able to find in the literature several cases of generalized herpetic eruption, somewhat similar to his own, following the use of arsenic. In his case, and not in the others, the mucous membranes were affected.

Keratosis from arsenic may be regarded as a comparatively rare occurrence, and it has not yet been definitely established that a keratosis from this cause has any characteristic clinical symptoms (? Rep.). In the case reported by Bettmann there was a splintering of the nails also. It is impossible to draw a strict line between an infectious zoster and toxic erythematata of the type of zoster such as we have in this case.

MERCURY IN RESORBIN.

Ledermann, of Berlin, has lately introduced into dermatological practice an ointment base which he has named resorbin. It is an emulsion formed by incorporating water with almond oil and wax, with the addition of small amounts of soap, etc. In this emulsion the fat drops are so finely divided that they readily penetrate the skin. It has been recommended as a cooling ointment on account of its large percentage of water, in pruritic skin affections, and on account of its penetrating properties in softening crusts and in ichthyosis.

A combination of resorbin and mercury, as a substitute for the ordinary mercurial ointment, has been

recommended, and tried with much success in Neumann's clinic in Vienna.² Whereas, in the ordinary mercurial ointment the globules of mercury are very varied in their size, some being so large that they cannot penetrate the skin but are left to set up an eczema, in resorbin the globules are finely divided and closely incorporated with the fat. Lanolin, fluid vasogen, myronin, mollin, etc., were previously tried with indifferent result. The mercurial ointment with resorbin as a base has a bluish-gray color, and contains 33 $\frac{1}{4}$ % of mercury. It smells slightly of almond oil. It is easily rubbed into the skin, and while an ordinary inunction requires from twenty-five to thirty minutes, by the use of this preparation the ointment is found to have disappeared under the hand in eight minutes, leaving a dull-gray mirror on the skin, which feels perfectly dry. This diminishing of the time of inunction by one-third is an essential advantage, especially in private practice, where the person has not the time or patience to give to it, or in the case of pregnant women, or weakly and anemic people.

Ledermann maintained that the action of resorbin mercury was at least equal to that of the official ointment. Corresponding to the quicker absorption of the mercury, there was a more frequent exhibition of slight stomatitis, which necessitated an occasional suspension of the treatment. Seventeen cases, representing the various forms of syphilis, were treated by this remedy at Neumann's clinic. No disagreeable general or local appearances were observed, and especially no cases of eczema. Stomatitis occurred only once in 17 cases, which does not bear out Ledermann's assertion that it is relatively more common. The duration of treatment was less than with the ordinary preparation, and in certain cases the disappearance of symptoms was remarkably quick. In a case of primary lesion of the gum the ulcer was completely healed after fourteen inunctions, and the exanthem had entirely disappeared. In another case the patient was dismissed from the hospital cured after twelve inunctions, and in 4 cases after fifteen inunctions. There were no recurrences during the short observation period of three months. The reporters conclude that this treatment was successful in all the cases tried. It has the advantage over ordinary mercurial ointment of shortening and simplifying the inunctions, and diminishing the duration of the treatment.

FUNGOID BROMODERMA.

Pini,³ of Bologna, proposes the term bromoderma for the various cutaneous manifestations caused by the ingestion of preparations of bromide, as more appropriate than that of bromide exanthem, or bromide eruption. The multiformity of the lesions due to this drug is referred to, Brocq having described eleven different forms. An instance of the anthracoid or fungoid form that came under Pini's observation gave an opportunity for pathological investigation. The case was that of a woman of fifty-one, who had taken bromide during a period of fourteen years for epileptiform attacks, in varying doses, without causing any cutaneous outbreak. Fifteen days before she was seen she had experienced malaise, loss of appetite and pruritus of the whole body, and on the following day red, painful nodules appeared on the

² Wien. med. Woch., No. 8, 1900.

³ Arch. f. Derm. u. Syph., May, 1900.

backs of the hands. These increased in number, and made the hands painful and almost immovable. The eruption was found to be limited to the backs of the hands and wrists and to be quite symmetrical. It was made up of lesions of different form and size, some of which had seropurulent contents, while others were quite firm. The former lesions were scattered about between the fingers and along the ulnar border of the right hand, and were surrounded by a deep red areola. They were either conical or flattened. On both hands there were also large elevations which projected 5 to 8 millimetres above the surface of the skin, of a violet-red color and pasty consistency, punctured with from two to five openings, from which more or less thick pus was expressed. Under treatment and stopping of all bromide, the lesions gradually disappeared, leaving thickening and pigmentation of the skin. After a time the bromide was resumed, but without further cutaneous lesions.

The fact that the patient had taken bromide for fifteen years without any symptoms was somewhat cleared up by the discovery that she had taken far larger quantities of the drug of late, varying from what would cover the point of a knife to half a handful in a small quantity of water. The writer believes, contrary to many, that within certain limits there is a relation between the size of the dose and the degree of reaction on the part of the skin, not on theoretical grounds, but from clinical experience.

The writer's histological studies of one of the larger nodules, which he excised, showed that the epidermis had lost its normal appearance almost everywhere, being greatly hypertrophied and dipping deeply down into the corium, with interlacing septa in every direction. The papilla, which were greatly increased in size, were filled with numerous capillaries of double the normal size, and with a greatly thickened endothelium, surrounded by a few leucocytes. Beneath the papilla there was a diffuse mass of polynuclear leucocytes and a few lymphocytes, which were separated from one another by their connective-tissue septa, which contained numerous blood vessels. The middle layer of the corium was thickly packed with leucocytes, so that the collagenous and elastic fibres had entirely disappeared, and hardly a fixed connective-tissue cell could be seen. There were no plasma or mast cells in the region of the infiltration of leucocytes. Just above the subcutaneous fat tissue the leucocyte infiltration became less thick, and large cells, of endothelioid appearance, and varying form, oval or spindle-shaped, were seen, which were in intimate connection with the fibrous connective tissue. Everywhere, both in the upper and the lower layers, the vessels were found with thickened intima, and proliferation of the outer coat. As a whole, it may be said of this lesion that three zones are to be distinguished in the corium: an upper, composed chiefly of dilatation and proliferation of the vessels; a central, the most pronounced, composed of an infiltration of leucocytes, and therefore hematogenous; and a lower zone, composed of the elements of both upper and middle, and especially rich in connective-tissue cells. At the same time there is an epidermidosis vegetans, and in places a periendoarteritis, and a periendothelitis.

In order to prove that bromine was actually the cause of the lesions, several interesting experiments were made. No free bromine was found to be given

off by the skin of the affected patient, and examination of the pus from the lesions gave a similar negative result. An examination of the urine, on the other hand, on the fifth day after the drug had been stopped, gave a positive result. Examination of the blood showed a slight leucocytosis at the acme of the cutaneous disturbances, as well as an increase in the eosinophiles. The eosinophiles were also found increased in the pus from the large fungoid nodules.

The writer believes that the bromide causes an angiodermatitis by its irritative action on the vessels of the skin, which for some reason at one time takes the form of a glandular inflammation, at another of a bullous inflammation, and again of a hemorrhagic or nodular infiltration. Under this hypothesis it is unnecessary to invoke the agency of a neuropathic or bacteriological cause. Furthermore, bacteriological investigation proved fruitless.

GENERALIZED VACCINIA.

Dr. Gustav Paul, director of the Vaccination Bureau in Vienna, contributes an article on the etiology and pathogenesis of so-called generalized vaccinia in subjects with preceding healthy or affected skin.⁴ He considers it necessary to make a strict division of the complications of vaccination that have been loosely classed under the heading "generalized vaccinia," reserving this latter term for those cases of general eruptions occurring after vaccination in which their vaccinal character has been proved by experimental inoculation on man, or on animals susceptible to vaccinia. The polymorphous, erythematous eruptions which so frequently follow vaccination are to be considered analogous to the drug eruptions.

It is very common to find isolated vaccinia lesions, either in the vicinity of or at a distance from the point of inoculation, caused by the transference of the virus to excoriated, but otherwise normal, parts of the skin. This has been called *Nebenpocken*, *Beipocken*, etc., and usually has a favorable course except when the eyelids or conjunctiva, for example, are affected. Such chance inoculations on the vulva have been mistaken for syphilitic lesions at times.

Eczema and prurigo are considered the most common cutaneous affections to be complicated with vaccinia. In the case of prurigo the vaccinia lesions are naturally seen on the extensor surfaces, the seats of predilection of the prurigo lesions. In the case of pre-existing eczema when complicated with vaccinia the first symptom observed, about the third or fourth day after infection, is a general increase in the eczema. An eczema previously dry takes on an acute phase and begins to weep, with increasing redness and swelling, and places which had been healed take on an exacerbation. When situated on the face, there may be great tumefaction. At the borders of the eczema, often on parts where the skin was normal, are seen numerous solitary and confluent pustules, which have the character of true vaccinia lesions. Toward the centre these pustules become more and more confluent and at the centre are converted into ulcerated surfaces. There is very seldom scarring. The affection never oversteps the boundary of the original eczema. As a rule, the eczema, even if of long standing, disappears. There is usually a high fever, corresponding in intensity and duration to the extent of the local process. In unfavorable cases there may

⁴ Arch. f. Derm. u. Syph., Bd. lii, H. 1.

be vomiting and diarrhea followed by delirium and death. In some of these cases a considerable similarity with variola may be traced, but variola can be excluded by the localization, and absence of prodromal symptoms and lesions upon the mucous membranes. Writers are not all in accord as to the way in which these cases are produced. Some think that an especial virulence of the vaccinia material must be supposed, others that there is an absorption of the virus into the lymph and blood vessels by means of the eczematous surface. Paul is in accord with those who believe that the eczema is not only an easy door of entrance, but also an especially favorable soil for the reception of the virus which has been brought in contact with it.

The following conclusions are reached: It is advisable that children who are suffering from extensive eczema should not be vaccinated, unless there is urgent need, until the eczema is wholly healed. When vaccination becomes imperative in such cases, it should be carried out with especial care, under a protective dressing. It is to be noted that the favorable influence that has frequently been observed in eczemas as a result of vaccination cannot justify the inoculation of eczematous children, in view of the often dangerous character of the artificial infection. Even in the cases that pursue a favorable course scarring is quite likely to result.

THE VISCERAL LESIONS OF THE ERYTHEMA GROUP.

Osler⁵ returns to this subject, which has interested him before. In 1895 he published an account of 11 cases, similar in many respects to those previously grouped by Hensch and Couty, which were characterized by (1) multiform cutaneous lesions; (2) multiform visceral lesions, and (3) arthritic manifestations. The skin lesions comprised acute circumscribed edema, urticaria, purpura and ordinary exudative erythema. The visceral lesions consisted of circumscribed serous or hemorrhagic exudation in the walls of the stomach or intestines which gave rise to attacks of colicky pain, hemorrhages, acute nephritis and certain rare pulmonary and other lesions.

In this paper Osler details 7 additional cases, together with the subsequent history of Case II of his first series, making a group of 18 cases, of which he presents an analysis of the symptoms. The second case was interesting from the great variety of the symptoms. A boy had, in his tenth year, severe attacks of colic, cough, and one attack of urticaria. In his eleventh year he had colic with an outbreak of urticaria and purpura, and soon after a circumscribed edema of the back of one hand, signs at the apex of the right lung and enlargement of the spleen. In the thirteenth and fourteenth year there were emphysematous symptoms, and he died in his fifteenth year with emphysema, dilatation of the heart and pericarditis. Osler justly remarks that as far as the skin lesions were concerned, a physician seeing him in but one of the attacks might have diagnosed urticaria, purpura with urticaria, angioneurotic edema and exudative erythema.

It may be of interest to copy Osler's summary of the 7 cases of his second series:

CASE XII. Neurasthenia; dilatation of the stomach; colic for two years at intervals; exudative erythema; leucocytosis.

CASE XIII. Attacks of colic every week or ten days for six months; on admission typical lesions of erythema multiforme; high fever; improvement; recurrence; pains in the joints; arthritis in one joint of finger.

CASE XIV. Physician, fifty-seven years; from twentieth year, every few months, attacks of nausea, vomiting and abdominal pain, associated with outbreaks of urticaria; no hemorrhages from the mucous membranes; final attack with purpura and urticaria.

CASE XV. Physician, twenty-nine years. When a lad one attack of hemiplegia with aphasia lasting for a week; within a year five or six attacks of transient hemiplegia; history of migraine in 1896, and a mild attack of rheumatism; angioneurotic edema of the upper lip; outbreaks of urticaria; in 1897 attack of abdominal colic, with pains in the legs, and an outbreak of purpura and urticaria; in 1898 hematuria and albuminuria.

CASE XVI. Boy of eleven years. For three months attacks of pain in the abdomen with vomiting; swelling of the joints; purpura; recovery.

CASE XVII. Man, eighteen years. Following influenza, in January, attacks of arthritis with cramps in the abdomen and an outbreak of urticaria; eight attacks between January and May; during stay in hospital, swelling of wrists and back of hand; erythema; urticaria, spontaneous and factitious; no purpura; recovery.

CASE XVIII. Girl of seven years. During first year swelling of knees; from second to seventh years, frequently recurring attacks of pain in the abdomen, with vomiting and swelling of the knees, but no skin rash; following vaccination attack of great severity, with extensive lesions of erythema, purpura and urticaria; melena; recovery; recurrence of the skin lesions; enlargement of the spleen.

(1) *The gastro-intestinal crises.*—In discussing this feature Osler finds that the attacks may be characterized by colic alone, oftener colic and vomiting, colic with vomiting and diarrhea, and lastly colic with vomiting of blood or the passage of blood in the stools. Usually, but not always, there are cutaneous manifestations with the crises. In Case XIV the relationship between urticaria and the gastro-intestinal crises is well shown, and Osler thinks it reasonable to suppose that the abdominal pain is due to urticarial lesions in the mucous membrane of stomach and intestines. In support of this, Packard has recently shown that there are numerous instances of the formation of wheals in the mouth and throat, although the lesions have not been actually seen in the stomach and intestines. In the 18 cases reported urticaria was present in 8 at some time or other.

(2) *Hematuria and nephritis.*—Acute nephritis occurred in 6, chronic nephritis in 1 of the cases. In 2 of the cases death was directly due to this complication.

(3) Hemorrhages from the mucous surfaces occurred in 6 cases; from the bowels in 5 cases; from the nose and gums in 1, from the stomach and kidneys in 2 each.

(4) Cerebral symptoms were present in 2 cases.

(5) In only 1 case were there marked pulmonary symptoms.

With regard to the skin lesions purpura alone was noted in 4 of the cases. In the other 14 cases exu-

⁵ British Journal of Dermatology, July, 1900.

dativ erythema, urticaria, or urticaria with purpura, acute circumscribed edema or typical erythema multi-forme were observed. Acute circumscribed edema occurred in 3 cases, associated with other exudative lesions. The different forms of skin lesions may be present in the same case in recurrent attacks, as in Case II, where there was an urticaria in the first outbreak, urticaria and purpura in subsequent ones, and later angioneurotic edema and exudative erythema.

Swelling of the joints or synovial sheaths occurred in 10 of the cases. It may be transient or of great intensity. In some of the cases the swelling was chiefly along the tendons, in others a whole extremity was involved.

It is pointed out that precisely similar skin lesions may result from a variety of causes, as is well shown in the case of purpuric lesions, which may appear precisely the same, whether caused by iodide of potash, scurvy or variola. Furthermore, the same cause may give rise to a great variety of skin lesions in the same subject. So that etiologically Osler is unable to offer us much aid with regard to this group of symptoms. Two of his cases suggest a relationship with migraine, others some gastro-intestinal poison, combined with individual susceptibility. One following gonorrhoea he thinks belongs among the acute infectious erythemas. He does not regard the arthritis as necessarily indicating rheumatic poisoning.

WINTER AND SUMMER RECURRENT ERUPTIONS.

Under the title, "A Clinical Study of Some Winter and Summer Recurrent Eruptions," Crocker⁶ describes 7 cases of eruptions recurring in winter and 14 cases of those that recur in summer. Under the winter eruptions he describes a papulopustular eruption of the hands, of which he cites three examples. The hands alone are affected, especially about the knuckles, and the lesions are indolent indurated papulopustules, isolated, and few in number at a time, appearing as a succession of lesions throughout the winter and early spring. The most beneficial treatment is that directed to improving the circulation of the extremities. Crocker thinks that *aerodermatitis pustulosa hiemalis* would be an appropriate name for this affection. He is not sure, however, that it may not be a variety of the folliculitis of the French, differing from the latter affection by its limitation to the fingers, its connection with a poor circulation and its occurrence solely in cold weather.

Other examples of winter recurrent eruptions are a recurrent pustular eruption of the hands in a boy of twelve, a recurrent erythema of the face in a young woman of nineteen, an acniform eruption in a man of twenty-three, and a diffuse erythematous and finely papular eruption of the face in a woman of thirty-five. It is to be emphasized that in some of these cases exposure to the sun was also an exciting factor and that in all the cases the parts of the body covered by the clothing were spared.

The class of essentially summer recurrent eruptions is made up of *hydroa estivale*, of which Bazin's *hydroa vacciniforme* is a variety, and the recurrent summer eruptions described by Hutchinson. Of the 14 cases described by Crocker, 9 are grouped in the same class and are characterized by their vesicular, vesiculopustular and erythematous lesions, by their tendency to commence at any time from infancy to puberty, and

to get well at the age of twenty to thirty. By far the most frequent localities affected were the face, neck and hands. There were 2 adult cases of much the same character, which Crocker thinks better to keep apart for the present at least. His Cases XII and XIII were those of diffuse erythema and diffuse urticaria, respectively, and are regarded as vasomotor neuroses of a pathology similar to the preceding cases. In both of these the eruption was confined to the face and hands.

[The relationship of many of these cases, especially those of the vesicular type, to *hydroa estivale* and *hydroa vacciniforme* would seem to be a very close one. Dr. Crocker says he hopes to take up a consideration of the cases that come under the head of *hydroa estivale* on a future occasion. It seems probable that some of the cases of summer eruption here reported are mild forms of that affection. — REP.]

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting, March 19, 1900, DR. E. H. BRADFORD in the chair.

DR. E. A. CODMAN read a paper on

THE STUDY OF THE X-RAY PLATES OF ONE HUNDRED AND FORTY CASES OF FRACTURE OF THE LOWER END OF THE RADIUS.¹

DR. SCUDDER: I have only a word to add to what Dr. Codman has already said, from my personal experience in the study of these plates, as a great many of the cases have occurred in my services at the hospital. It seems to me — and I think Dr. Codman would agree — that we must withhold any final classification until the number of observed cases is much larger than those under discussion. Probably other varieties of fracture will appear, and the percentages, which are extremely interesting, will increase and decrease in certain classes, and a later classification will be much more satisfactory. Practically I have found that the x-ray has helped materially in preventing the use of undue force and in properly directing the force in setting fractures at the wrist. If we remember the old-fashioned method of reduction of Colles's fracture, by grasping the hand and making traction on the wrist, it will appear that that method must necessarily have led to an additional sprain of the wrist and possibly to additional damage to the wrist. The x-ray demonstrates that gentle force is often sufficient to reduce the fracture. In certain cases where great force is necessary the x-ray shows how such force may be intelligently employed. I have been very much impressed by the early consolidation of the fractured bone in these cases of fracture of the lower end of the radius. After about one and one-half to two weeks a fracture is firm enough for very little more than a short dorsal pad of about 2 to 3 inches long and an adhesive plaster strap with a small pad placed in the anterior radial arch. That has been my method of treatment for the past four or five years. The x-ray

⁶ British Journal of Dermatology, February, 1900.

¹ See page 305 of the Journal.

shows that the fragments remain in their proper position when treated in this simple way. The hand is left free and there is very much less of the stiffness of the fingers and loss of motion at the wrist than in cases treated by long immobilization. There almost always is a little broadening of the wrist following a Colles's fracture.

In connection with the disease in bone which Dr. Codman referred to, I personally had an illustration of the value of the x-ray a week ago in the case of a man of thirty years of age, who had an osteomyelitis of the femur. He came to the hospital with a sinus in the middle of the thigh. An x-ray was taken to determine if the disease could be localized. The x-ray plate showed a distinct area, about the size of a quarter of a dollar, in the centre of the enlarged femur, which was different in appearance from the rest of the bone. That area was found to be at the bottom of the sinus. Upon laying the sinus open the area seen in the plate was found to correspond with a well-defined osteomyelitis. The softened bone was entirely cleaned out as a dentist might clean out a cavity in a tooth. The acute symptoms subsided. The x-ray plate localized the disease very definitely.

DR. LUND: I wish to speak of the great interest I have felt in Dr. Codman's excellent and interesting classification of these cases, and I can add my testimony to what he has said about the slight posterior displacement after efforts at reduction being masked by the filling in of the soft parts until such time as the swelling has gone down, when the surgeon finds he has a poor result. I think that reduction of the antero-posterior deformity is the most important thing, because it is that which causes the neuritis and stiffness of the hand, and I also believe that this anteroposterior displacement can be reduced even in cases where there is destruction of the bone. Where there is destruction of bone, or comminution of fragments, which cannot be got back into place, your radius has got to be shorter than the ulna, and you cannot prevent lateral deformity, but that lateral deformity does not in my experience complicate the final functional result to any extent.

I had a rather interesting experience in regard to short immobilization of the fragments. Some years ago I got along very well with a large number of Colles's fractures by taking off every splint after two weeks. Then I had 1 or 2 cases in which I tried that in which deformity returned and I concluded that I must immobilize them all three weeks. Now by the aid of the x-ray it is easy to decide what cases can be treated by early removal of the splints and those that require them to be kept on longer. In simple cases in which there is no destruction of bone the deformity will not tend to be reproduced and the splint can be removed early. I always apply an anterior and a posterior splint, then remove first the posterior splint at the end of five days to a week, and the other splint generally at the end of two weeks. Cases in which there is comminution and non-union will require a longer immobilization, but it is unnecessary to get a stiff wrist because you keep up a longer immobilization of the fragments by a splint. From the very first day the fingers are moved. I always apply a carved wooden splint, either Dr. Bolles's splint or a similar one, to the front of the hand, which allows flexion of the fingers, so that the fingers can be moved from the very first day of treatment without

disturbing the fixation of the fragments. Early mobilization of the fingers prevents the later stiffness of the wrist and hand. I think the x-ray has given us very great help in diagnosis, prognosis and treatment of these fractures.

DR. MURRO: There are a number of things I should like to take up tonight in detail and talk about, but I will only speak of the widening of the wrist in Colles's fracture. These seventeen radiographs passed around are from 30 or 40 routine cases. In the Medical and Surgical Report of the City Hospital for 1896 the Surgical Out-Patient Department published some statistics of measurements in Colles's fractures, that is, measurements of the elevation of the styloid and the widening of the lower end of the radius and ulna. I have kept on measuring wrists ever since, and have measured probably 200 separate fractures, each one being measured many times, and I have accurate statistics of 85 hospital cases that I gathered at random from the records yesterday. Of these 85 cases of so-called Colles's fracture there was radial displacement in 79; in other words, if the wrist is carefully measured, there is a widening easily detected by measurement by calipers in probably 90% of all fractures of the lower end of the radius. In all but 1 or 2 of Dr. Codman's cases shown tonight there is what I should call a radial deformity, and I think if he had measured those wrists and compared the width with the opposite wrist he would find the typical widening. Many and many a wrist entered in the records as having no widening shows at least $\frac{1}{2}$ inch widening and a displacement toward the radial side. If a line is drawn, extending the longitudinal axis of the forearm through the radio-ulnar joint, that line will be seen to pass through the ulnar side of the unciform quite a distance from the os magnum in cases of fracture. The widening has interested me very much and I have tried for a good while to find some definite explanation. At first I thought it was simply from the wedge-like action of the upper fragment driven into the lower fragment and pushing the ulna away from the radius. That does not seem to be the explanation except in certain cases. There is another point that appears to explain it after studying the x-ray pictures and measuring it with the calipers carefully from the time of the injury up to months or years afterwards. One practically always finds the deformity and I believe it is produced in this way. If we take an ordinary radius and make a longitudinal section we will find that on the ulnar side the cortex of the bone is pretty thick and straight, but thin and angular on the radial side about $\frac{3}{4}$ inch from the tip of the styloid. All the central portion is weak and spongy. When a man falls on the extended hand, he falls almost always on the radial side. Practically in all these cases there is more or less impaction and a driving upwards and radialwards of the styloid process. The anteroposterior displacement I will not take up. In the large majority of cases careful measurement shows that that styloid remains higher than on the other side in spite of treatment. You cannot pull it down to normal and keep it there except in a very small proportion of cases. What happens I think is this: In the fall the force is transmitted in two directions, directly upwards through the shaft, and also, because of the cup-shaped obliquity of the radial half of the surface, the force must be transmitted against the radial side. That is, the force is transmitted directly against the

cortex on the ulnar side of the bone, which does not give way so much as does the weaker radial cortex. By careful measurement one finds that as the radial half of the surface is forced upwards the distance from the ulna to the radial side of the styloid is increased at least $\frac{1}{8}$ inch; in other words, you have an isosceles triangle which rotates on a pivot placed in the ulnar cortex of the radius, roughly speaking. I believe that is nine-tenths of the explanation of the widening at the wrist and the shortening of the styloid in these fractures. The ulnar cortex gives way also, but being stronger it does not crush so easily and hence does not move upwards as far as the thin radial cortex and medulla.

Most of these 85 cases show more or less impaction. Occasionally there is apparently no impaction. Now the width of these 85 wrists varied from $\frac{1}{16}$ to $\frac{6}{16}$ of an inch as compared with the width of the healthy side. The large majority, 57 out of 85, showed $\frac{1}{8}$ to $\frac{3}{16}$ of an inch widening. That is almost the routine increase in width one finds, and inevitably in those cases there is deformity just as plainly to be seen as can be if one is looking for it. In 13 of the 85 there was widening through the wrist of $\frac{4}{16}$ to $\frac{6}{16}$ of an inch, but these were very bad fractures, one of them an extremely bad fracture, much comminuted, difficult to get in place and with a very marked tendency to radial displacement; another was a bad case; one of the $\frac{4}{16}$ widenings was an earlier case when I had not mastered the trick of measuring accurately and probably overmeasured in this case. There were 4 cases out of the 85 in which there was no widening to be found and I think it is worth while to speak of those in detail. In 1 there was no shortening of the styloid at all and it was considered a doubtful case. Probably it was not a Colles's; no x-ray was taken. In the second the fracture was 1 inch above the styloid; no shortening of the styloid; possibly a cross strain Colles's, without impaction, or fracture of the shaft, which does not count. The third was a fresh case; at the time of injury $\frac{1}{8}$ inch widening, crepitus; in two and a half weeks the $\frac{1}{8}$ inch widening had diminished; in five and a half weeks there was no widening. Then we discovered there had been an injury to the other wrist which had been called a sprain, and probably was an old Colles's; in other words we found the same measure on both sides; it was a widened wrist after all. The fourth case was a young girl who fell with the hand under the body in acute flexion. There was no shortening of the styloid, but much swelling. At that time I could get no accurate measurement of the widening. Six weeks later Dr. Bottomley found $\frac{1}{8}$ inch and it seemed to me possible that this was one of those cases of cross strain where there had been separation without impaction, and with a tendency to radial displacement which I believe occurs from the pull of the muscles on the radial side.

Some of these cases at first and later on showed a difference in measurements, the width being reduced, which may have been due to swelling of the soft parts or inaccurate measuring. There was much synovitis in one of this group and the fracture was simply through the styloid tip, so that very likely the difference may have been explained in that way. In a patient with separation of the epiphysis there was no widening at all. The epiphysis slid off and then back again and stayed in place without producing widening, which I think helps out the theory that in the large

majority of cases there is a rotation towards the radial side of the lower fragment.

In addition to the 85 cases, there were 2 cases of reversed Colles's that are interesting. One of these was a man who fell first on the palm, producing a Colles's, then he rolled over and produced a reversed Colles's. He came in with slight shortening of the styloid and $\frac{1}{8}$ inch widening. Another case I have called a reversed Colles's. It is the only case I have seen where there was narrowing instead of widening—a young girl who, when fifteen years of age, was fooling with another girl and the wrist was twisted. She came in three years later with the typical deformity of a reversed Colles's. Dr. Barrell, with a wrench, partly reduced it under ether. I took measurements and there was $\frac{1}{8}$ inch narrowing. I have always supposed that there was some injury of the epiphysis and consequent lack of development; no x-ray was taken.

I have never seen any case of fresh Colles's that required the great force for reduction under ether that Dr. Scudder speaks of. I have tried to break up old unrecognized Colles's fractures that occurred years before and came with a fresh sprain, but the ordinary Colles's fracture breaks up, in my experience, without the least difficulty under ether, and I still stick to extension over the knee, pulling down and manipulating the fragments into position.

On the question of splints every man has his own hobby. I use the palmar splint with the hand curled over a pad, the fingers being left out and I let them use the fingers as soon as they wish. The only pad that I am careful about is the pad to preserve the anterior arch of the radius. I still believe in a certain amount of adduction, because it does tend to reduce the radial displacement, but I do not believe that in the large majority of cases the radial styloid can be brought down to normal and held there; at any rate I have rarely seen it done.

The process of measuring for lateral widening is not difficult with a little practice and is approximately very accurate in most cases. As a means of diagnosis I consider it invaluable. To measure, both wrists are held in exact degrees of pronation with the hands naturally and easily flexed. With a pair of graduated calipers the greatest width of the normal side is found and noted; then the width of the injured side is found, noted and compared. Except in rare cases the difference in thickness of the soft parts does not and cannot account for variation in measurements. Of this I am very positive after long experience in this procedure and with this possible factor constantly in mind.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

FOURTEENTH ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 1, 2 AND 3, 1900.

FIRST DAY.

THE association was called to order by the president, DR. JAMES BELL, of Montreal. After a short business session the scientific programme was taken up at 10 A. M.

DR. J. P. BRYSON, of St. Louis, read a paper upon CHRONIC UNILATERAL PYELONEPHRITIS AND ITS PATHOGENIC RELATION TO DISEASE OF THE OPPOSITE KIDNEY.

This question is becoming of greater importance as the diagnostic and prognostic value of urine segregation is recognized, and there is ground for hoping that the question may thus be solved. Observations need to be extended over considerable periods of time, as single tests are misleading. Notes of 4 cases were given, in 3 of which there was evidence that trouble had been caused in the opposite kidney, though the conclusions in 1 were rendered uncertain by the presence of tuberculous areas in both epididymes. Conclusions reached were: (1) Post-operative observations confirm the belief that long-continued pyelonephritis, suppurative or not, has an effect on the opposite kidney; (2) the pathogenic effect is manifested in the tubular epithelium, causing a parenchymatous nephritis; (3) suppuration adds amyloid change to the other; (4) the mechanism of the involvement is not yet determined; (5) the benefit of frequently segregating the urine is not only to localize the disease, but to warn the surgeon when to operate.

DR. FRANCIS S. WATSON, of Boston, reported

SOME CASES OF RENAL SURGERY.

An interesting case was that of a man who had been the subject of traumatism over the right kidney at five different times, hematuria following each. A blood clot was removed from the pelvis of the kidney and the organ gave no further trouble. In a second case of simulated renal colic the kidney was opened; no stone was found, but entire relief followed. The capsule was thickened, which would confirm the belief that such cases were due to pressure of the capsule. In a third case, in which nephrotomy had been done on a tuberculous kidney and fistula followed, the upper half of the kidney was removed in three pieces.

DR. KEYES has split the capsule of kidneys with the relief of pain even when no calculus was found. Relief was given in 1 case of chronic granular kidney by splitting the organ. He is in favor of splitting the kidney in cases of intractable pain simulating colic.

DR. BRYSON stated that a displacement of the kidney or ureter sufficiently great to produce symptoms of colic might exist without the operator recognizing it in these cases unless it was sought for particularly. Such cases would be cured by fixation.

DR. A. T. CABOT, of Boston, gave

SOME OBSERVATIONS UPON HYDRONEPHROSIS.

A case which brought out several interesting points was the basis of his remarks. The patient was a boy of eleven years, who had had symptoms of hydronephrosis since he was one and a half years old. When operated upon, a sac containing dark-colored urine was opened, when a mass, which proved to be the kidney, was seen at the bottom of the sac, the condition proving to be one of a ruptured hydronephrotic sac with a pseudohydronephrosis around it. The rent in the kidney was closed, but the ureter did not act and the kidney again dilated. The sac was reopened and a tube introduced. After continuous drainage for two years relief was sought from the fistula. To increase the urine before operation diuresis was instituted for five days. Not only did the sound kidney increase its output, but the urine from the affected organ rose from 9 to 30 ounces. This is

considered an evidence that the surgeon should seek to restore the outlet of the ureter even when the kidney substance is thought to be destroyed. Operation in this case showed the ureter looped in an S-shaped manner over an accessory renal artery, and nephrectomy was performed, as the ureter could not be probed after the artery was cut. After operation the urine fell from 40 to 15 ounces on the third day. The point emphasized was that preliminary diuresis is of the greatest importance before any operation which is to bring increased stress upon the kidney.

DR. BANGS stated that he had removed a kidney on which nephrotomy had been performed one year previously for hydronephrosis, the opposite kidney showing signs of irritation. Shock followed and saline solution was given by the rectum. The remaining kidney secreted 98 ounces of urine during the first twenty-four hours after operation. He prefers Mayo Robson's incision for reaching the kidney. In seeking the cause of renal colic the x-rays have given very unsatisfactory results in proving the presence or absence of a calculus.

DR. BRANSFORD LEWIS, of St. Louis, read a paper upon

THE PATHOGENY OF GONORRHEAL NEPHRITIS,

and exhibited a specimen. The condition of the kidney was that of an acute interstitial nephritis added to chronic nephritis. Gonococci were demonstrated in pus found in the kidney. Dr. Lewis does not understand why an infection of the kidney by gonococci alone should be a rare occurrence, and thinks it is not so rare as supposed. He believes that infection of the kidney by means of the lymphatics which accompany the ureter, and by metastasis through the blood vessels, is also much more common than has been thought. Infection without bladder involvement, which has been found, would rule out ascending infection by continuity. Cultures of gonococci have also been made from the blood of a patient suffering from gonorrhoeal arthritis.

DR. YOUNG, of Baltimore, reported a case of chronic cystitis and double pyonephrosis which was due to infection by the gonococcus alone. He has aspirated the bladder suprapubically over 100 times, and thinks it the only way to get a pure culture from the urine. The gonococcus may be the cause of cystitis, but cannot be cultivated unless the medium in the bladder is favorable to its growth. In one case the gonococcus was demonstrated to be present in the bladder for five years without giving rise to marked symptoms. In a second case the patient had had chronic cystitis for seven years, this following typhoid fever. A pure culture of the typhoid bacillus was obtained from the bladder. Afterward a gonorrhoeal infection was added with no aggravation of the symptoms. The gonococcus drove out the typhoid bacillus, as a short time afterward only the former could be detected in pure culture.

DR. W. K. OTIS, of New York, read a paper on

THE MODERN URETHROSCOPE.

Several improvements upon his most recent instrument were described, the principal ones being that it is smaller, the lamp is of low tension or a "cold" lamp, and a conical diaphragm cuts off some of the light.

The following papers were read by title: "General

Sepsis following Gonorrhœa," Dr. G. E. Brewer, of New York; "Radical Treatment for Curvature of the Penis," Dr. Eugene Fuller, of New York.

(To be continued.)

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

(Continued from No. 12, p. 300.)

SECTION OF SURGERY.

INTESTINAL AND GASTRO-INTESTINAL ANASTOMOSES.

DR. ROUX, of Lausanne, opened a discussion on this subject. He said experiments on dogs did not give a faithful picture of what was observed in man, whose digestive canal presented a material more manageable and less untrustworthy. Anastomosis had for its object the turning aside of the course of the food, whether on account of the dangers or inconvenience caused by its presence, or its passage over certain points of the gastro-intestinal canal, or on account of one or more obstacles which it would be impossible, dangerous or inopportune to remove. It is a procedure palliative in appearance, but has often a curative effect. In regard to risk, technique and results, it stands midway between fistulæ (jejunal fistulæ, enterostomy and preternatural anus) and radical operation (pylorectomy, excision of tumors or diseased loops). Anastomosis is effected by lateral apposition. It is the most practical of intestinal unions (*a*) because it requires less strict precision; (*b*) because it allows a larger junction without risk of forming a diaphragm or valve; (*c*) because it allows an opening of unlimited length which is less subject to later contraction; (*d*) because it is independent of the calibre of the tubes to be united. It is also the procedure most within reach of all operators.

Entero-anastomosis.

Acute affections.—Anastomosis is contraindicated: (1) When the state of the patient does not allow more than enterotomy; (2) when the state of the intestine demands, under penalty of death, the immediate removal of one or more loops; nevertheless it may be combined in some cases with extraperitonealization of these loops (for instance, strangulated hernia); (3) when the state of the patient and that of the intestine, together with the skill of the operator, allow something better to be done. Anastomosis is indicated: (1) When the re-establishment of a channel for the feces is alone in question, especially if a more radical operation appears to be too long or too dangerous; (2) even after the success of a disinvagination or untwisting, if fear is entertained for the peristaltic function.

Chronic affections.—(1) Anastomosis should be preferred in cases where there are numerous adhesions, where it offers a better chance, leaving out of account the nature of the disease. (2) It should be the operation always chosen: (*a*) In cases of inoperable tumors; (*b*) in presence of certain complex, multiple, inaccessible inflammatory foci (tuberculosis with burrowing, actinomycosis). (3) Recourse should be had to anastomosis as a preliminary operation: (*a*) In cases of operable tumors in very debilitated patients (for instance, in commencing occlusion); (*b*)

in cases of inflammatory affections with deep furrowing, external pyostercoral or genital fistulæ, etc., which are often cured by this first intervention if care has been taken to combine anastomosis with unilateral exclusion, a procedure which only takes two or three minutes, and which is suitable for all cases of Classes 2 and 3. Life is compatible with 1 metre and 50 centimetres of jejunum and the half of the colon, the rest being excluded. The surgeon therefore need not be afraid to operate on healthy loops at a distance from the focus of disease.

Gastro-intestinal Anastomosis.

Gastro-enterostomy, as being less dangerous, should precede pylorotomy as a preliminary operation when the condition of the patient makes it desirable. It may replace it if the tumor is inoperable. It should always complete it (Billroth's second method) so as to give the patient at once the benefit of the radical and of the palliative operation when recurrence takes place, by making a new pylorus at as great a distance as possible from the old one. In non-cancerous affections of the pylorus and the stomach, for which an easier evacuation of the gastric contents is desirable, gastro-enterostomy should be preferred to pylorotomy and pyloroplasty, because it is easier and equally efficacious whether in its ordinary form or as duodenostomy. Gastro-anastomosis is very much superior to gastroplicatio and gastropexy; if done by the Y method it is an ideal operation. For the surgeon who is equally handy with the scamstress's needle and with the more or less automatic approximation apparatus, suture will remain the method of election, because it alone gives reunion of the mucous membrane by first intention, and because it allows easy post-operative treatment, an important matter in all cases. Murphy's button, the best thing of the kind, should be reserved for cases — and they are too numerous — where minutes have to be counted. It gives unlooked for results. In all these operations a surprising proportion of deaths from pneumonia takes place; these are not sufficiently explained by the necrosis.

DR. SOULIGOUX, of Paris, said: Intestinal anastomosis constitutes most frequently the principal operation in the treatment of cancer and of stricture of the intestine; or the operation may be complementary. In presence of a case of acute or even chronic intestinal obstruction, intestinal anastomosis must yield precedence to preternatural anus, even if one has to intervene by a secondary procedure later. In case of retardation in the flow of feces without obstruction, if the surgeon finds himself in presence of a movable tumor which can easily be taken away, it is enterectomy that should be practised; but the operation should be completed by anastomosis, either lateral or terminolateral, operations which are more simple, more rapid, and more certain than circular enterorrhaphy. If the tumor is adherent, and its removal greatly complicates intervention, anastomosis is the only operation to be performed. It is of slight gravity, and, although only palliative, gives a fairly considerable survival. In cases of stricture or cancer of the cecum it should consist of turning of the ileum into a sigmoid flexure, and in the rest of the large intestine of a junction of the parts of the colon situated above and below the obstacle. In the case of strangulated hernia it may be either a preparatory or

a definite operation, much simpler and more certain than a circular enterorrhaphy. Souligoux summarized his conclusions as follows: The stomach has become an organ essentially belonging to surgery. Only dyspepsia of nervous origin lies outside the sphere of intervention. In cases of cicatricial stenosis of the pylorus or of the first part of the duodenum gastro-entero-anastomosis is the operation of choice, indeed the only one admissible, since it is almost free from danger, it provides against all accidents, and thanks to it, patients recover flourishing health. Moreover, it is less serious and more sure than pylorotomy or gastropasty. In cases of stenosis of cancerous origin it is also gastro-entero-anastomosis that in the present state of opinion, both of medical men and of patients, will be most frequently employed. Pylorotomy is to be preferred to it only in cases of commencing cancer, without adhesions to the liver, pancreas or colon, without involvement of the pre-aortic, pancreatic and hepatic glands, and of course when there is no trace of generalization; in a word, when it is easier of performance, and provided the surgeon adopts the technique recommended by Hartmann and Cunéo. Gastro-entero-anastomosis will most frequently be the necessary complement of pylorotomy when extensive resections of the stomach and duodenum have been performed. In the case of gastric ulcer in process of evolution gastrojejunal anastomosis will still be useful, not to stop hemorrhage, but to place the organ in a state of repose, and to allow cicatrization of the lesion to take place. In bilocular stomach of cicatricial origin gastro-entero-anastomosis is the operation of choice; it is much superior to gastropasty. In cases of dyspepsia when no improvement has been brought about by medical treatment, when phenomena of retention of food with violent pains causing contraction of the pylorus persist, it will be the operation of necessity. Done early it is not very serious, and allows the stomach to get well by establishing a means of escape for the gastric contents. Von Hacker's method is much the best when it is feasible. The anterior route should be followed only when it is impossible to perform posterior anastomosis. The operation which is physiologically the most complete is that of Roux. Nevertheless the posterior route, which provides against most of the accidents of *circulus vitiosus*, appears preferable to Souligoux. Whether carried out with the help of suture, of anastomotic buttons, or of crushing, as he has recommended, it is the most rapid and therefore the least dangerous. In cases where phenomena of obstruction by adhesion may occur, one should not hesitate to perform a secondary jejunojejunal anastomosis as Ricard himself and many others have done.

EXPLORATORY OPERATIONS ON THE STOMACH.

MR. A. ERNEST MAYLARD, Glasgow, presented a communication on this subject. He said its object was threefold: (1) To indicate those conditions for which the operation of early exploration is of special value; (2) to make clear the safety and simplicity of the operation, and (3) to demonstrate the best method of performing it. With regard to the first point, early direct digital examination, with visual inspection would, in obscure cases, determine whether the disease was innocent or malignant. If the former, the appropriate treatment would be suggested, and the

patient's mind relieved of all doubts and fears, so distressing and harmful in their indirect effects; while in the latter the growth might be removed at such an early period of its development that its eradication might prove complete and permanent. With regard to the second point—the extreme safety and simplicity of the operation—the greatest encouragement may be held out to the patient to submit to the operation. When no harm can follow even if no practical result can be obtained, there need be no hesitation on the part of the practitioner in advising the operation, and none on the part of the patient in submitting to it. The third point concerns the operation itself. Upon the thoroughness with which this is executed to a large extent may depend the value of the procedure. The steps of the operation, including the fore and after treatment, are as follows:

(1) *Preparation of the patient.*—Lavage is practised for two days previously; the diet is simple; the bowels are well emptied. A nutrient enema and a subcutaneous injection of liquor strychnine are given just prior to operation.

(2) *Abdominal incision.*—In most cases the median incision above the umbilicus is sufficient. In some cases, however, the left oblique (Fenger's) is necessary.

(3) *External examination of the stomach.*—The mobility of the organ is first noted to determine the presence or otherwise of adhesions. The anterior surface is palpated, and the posterior, by tearing to the required extent, through the gastrocolic omentum. Bidigital palpation should also be practised.

(4) *Internal examination of the stomach.*—This is effected, first, by direct inspection, and, secondly, by digital exploration. To render inspection efficient, the stomach must be completely cleared of its contents through an incision in its anterior walls. This is effected by a specially devised siphon apparatus. Fluid is introduced as required, and withdrawn until the cavity of the organ is perfectly clean. All proper protective measures are taken to guard against infection of the peritoneal cavity. As soon as all fluid is withdrawn the speculum is introduced. The specula employed are of special sizes. They resemble the ordinary large-size glass-reflecting vaginal specula (Fergusson's), only are much longer, and cut both obliquely and transversely at their ends. By means of these, and either direct daylight or reflected artificial light, a perfect visual inspection of the mucous membrane is obtained. Digital exploration follows visual, and is executed by the index finger of the right hand, coupled with, if necessary, the external manipulation of the stomach with the fingers of the left hand.

(5) *After treatment.*—The gastrotomy wound is closed by a continuous Lembert, and the abdominal incision united in three separate layers. The patient is fed for the first forty-eight hours by nutrient enemata. Of various illustrative cases cited the following is a good example: A lady had suffered for years from dyspepsia. Various medical opinions had been expressed, and the commonest conception of her troubles was that they were due to antecedent ulceration. She was much depressed by the various opinions expressed as to the cause of her complaint, and the more or less apparently useless effects of the innumerable drugs administered. An exploratory op-

eration revealed a chronic gastric catarrh. So far as the operation itself was concerned the patient suffered not the slightest ill effects, while the result mentally upon the patient was of the very best. To her all doubts in her case were settled, and, aside altogether from the use of appropriate drugs and suitable food, the beneficial effect of the mind upon the body seemed to have most to do with her comparatively rapid and complete recovery.

GASTRO-ENTEROSTOMY.

DR. A. MONPROFIT, of Angiers, presented a communication on gastro-enterostomy, which, he said, at first used solely in the treatment of inoperable tumors of the pylorus, may also be employed as a palliative in malignant tumors of the stomach not involving the pylorus. Such patients are relieved and their life is prolonged. Gastro-enterostomy and gastrotomy should not be opposed to each other, but an endeavor should rather be made clearly to determine the limits where one and the other of them stop. There is at the present day less tendency to remove, at the cost of considerable mutilations, large extensive and adherent tumors. These cases derive much more benefit from gastro-enterostomy. On the other hand, limited small movable tumors of the pylorus can be removed with excellent results. The procedures that have been successively used have been anterior gastro-enterostomy by Wölfler's method, which does not always give good results; then the methods most employed are those of von Hacker and Roux. The procedures of apposition by means of Murphy's button or by the method of Souligoux have each their partisans. Monprofit has always employed sutures with excellent results. He does not produce coprostasis, but contents himself with carefully protecting the abdominal cavity. When the stomach is much distended with liquids, he empties it by means of an india-rubber tube introduced through a puncture made in the mucous membrane before complete incision. Following the example of Roux, he feeds his patients as early as possible, giving them first liquid, then solid food within the first few days.

DR. BOURGET, professor of clinical medicine in the Cantonal Hospital, Lausanne, read a paper based on 100 cases of stricture of the pylorus, in 46 of which gastro-enterostomy had been performed. The communication was presented to the Section of Medicine, but an abstract of it may conveniently find a place here. His conclusions may be summarized as follows:

(1) Gastro-enterostomy is required whenever the calibre of the pylorus is insufficient to allow the free passage of food from the stomach into the intestine.

(2) To warrant the performance of the operation the cause of the stricture must be permanent or definitive in character, either tumor band, cicatrized ulcer or fibrous ring.

(3) It is contraindicated in cases of temporary narrowing of the pylorus, as by pyloric spasm in neurasthenic persons, and in gastric stasis from ptosis or atony of the walls.

(4) It should be done only after a careful study of the mechanical working of the stomach, which should be examined in different stages of digestion by means of test meals, these being strictly the same by each examination. In cases where a transient cause of stricture (neurosis) is suspected similar explorations

should be made, but should be repeated more frequently on account of the variability in the results. The effect of a prolonged tepid bath, bromide of potassium and even suggestion should be tried.

(5) Insufflation of the stomach is necessary to obtain information as to cases of gastric ptosis or as to the importance of the dilatation.

(6) Gastro-enterostomy is a curative operation in cases of pyloric stricture from cicatrized round ulcer, fibrous ring, or peripyloric adhesions.

(7) It is palliative in cases of malignant tumors involving the pylorus, but it may prolong the life of the patient to an altogether remarkable extent.

(8) The results of the operation have not been satisfactory in neurotic patients or in those who are the subjects of ptosis.

(9) After the operation the chemical function of the stomach is but slightly influenced, although the standard of acidity is lowered.

(10) The mechanical work of the stomach is considerably modified. The evacuation of the gastric contents is ensured; it is performed in a normal and rhythmical manner, as if it were regulated by a normal pylorus. The duration of work of gastric digestion in a patient who has been operated on (after healing of the surgical wound) is the same as in the normal individual.

(11) The stomach gradually regains its normal size and position.

TRANSPLANTATION OF THE TENDONS IN TREATMENT OF PARALYSIS.

DR. OSCAR VULPIUS, privat docent of surgery at Heidelberg, read a paper on this subject. He said that the transplantation of tendons had come into use only in recent years, although the idea of replacing the action of paralyzed muscles by that of healthy muscles was sufficiently obvious, the procedure not very difficult, the danger infinitesimal, the results good, and the occasion of operating frequent. He based his communication on 160 operations done in his clinic. Thanks to the most rigorous asepsis, including the use of gloves and a mask, he had had a series of 130 transplantations without any trace of infection. He prefers what he calls the "descending" method; he sacrifices no muscle, but brings the distal end of the divided tendon into connection with the neighboring muscles. In this way he benefits the paralyzed muscles without damaging the healthy muscles which are to replace them. The most important indications for the operation are: Destruction of muscles, tendons and nerves by injury and spinal paralysis, foremost among them being infantile spinal paralysis. In partial paralysis the operation is distinctly indicated; in total paralysis the surgeon must choose between it and arthrodesis. Transplantation has shown that total paralysis is in truth more rare than is believed. As regards results, success should be instantaneous in this sense that, at the end of the operation, a normal position of the articulation should have been obtained. Vulpius's 160 operations have shown that this improvement of position is permanent, and that it is followed by a return of more or less normal mobility. The success is sometimes increased to a surprising extent under the influence of post-operative treatment. The more circumscribed the paralyzed territory, and the nearer healthy muscles having a similar function are to be found, the

more brilliant will be the success of the operation. In spastic paralyses success consists not only in correction of the attitude but in disappearance of the spasm. The results also depend on the localization of a paralysis. The most favorable part for the operation is the leg, the thigh is less so; the musculature of the forearm presents greater difficulties, although Vulpinus has had some very satisfactory results. Complete failures are very rare if there has been no defect in technique. Relapses have become much more rare as experience has increased, and in such cases a second operation may correct the first. On the whole, Vulpinus thinks himself justified in warmly recommending transplantation of tendons in the treatment of paralysis. A rational combination of the various modern methods may at least make life worth living for thousands of poor paralyzed sufferers.

SURGICAL TREATMENT OF HYDATID CYSTS OF THE LIVER.

PROF. THOMAS JONNESCO, of Bucharest, said that at the present time four kinds of operations are performed for hydatid cysts of the liver: (1) Puncture, whether or not followed by parasiticide injections; (2) marsupialization; (3) incision followed by evacuation and suture of the cyst; and (4) enucleation and extirpation of the cyst. The last operation, which is ideal, is so rarely applicable that it can hardly be taken into account unless as an exceptional intervention. Puncture should be given up as uncertain and even dangerous. Marsupialization, in view of the duration of the treatment, remains an operation of necessity applicable to suppurating cysts, and to those in which the calcified adventitia no longer allows retraction of the pouch to take place. The operation of choice consists in incision of the cyst, which is emptied of its liquid contents, daughter cysts and germinal membrane, and suture; the pouch is left without drainage or fixation of the cyst to the abdominal wall. Jonnesco has operated in 6 cases of cysts varying in size from that of a man's fist to a diameter of 20 or 30 centimetres, and always with success. The effusion of bile into the cyst is not a contraindication. He has cured 1 case of this kind. In a woman operated on by him he was able in the course of a second intervention for a fresh cyst to observe the result of the first operation two years afterwards. The pouch had completely disappeared, and in its place there remained only a hard cicatrix adherent to the under surface of the liver.

ANESTHESIA BY SUBARACHNOID INJECTIONS OF COCAINE IN THE LUMBAR REGION.

DR. SEVEREANU, of Bucharest, said he had induced surgical anesthesia about 70 times by injecting hydrochlorate of cocaine into the spinal canal. This method seems to him to have certain drawbacks which he considers it important to point out. The amount of cocaine which he used varied from 1 to 4 centigrammes. In all the cases he observed a general weakness lasting one or two days, and sometimes causing great anxiety. There was very frequent vomiting, with headache, which was generally very severe. Independently of the dangers of the use of cocaine, he finds there is a very serious inconvenience attaching to this particular procedure—namely, that it allows the patient to witness the operation.

M. TUFFIER said he had performed 125 operations,

among them 58 laparotomies, after cocaine anesthesia by Bier's method. The phenomena which follow the injection are nausea, which may go on to vomiting when too large a dose has been injected; pallor of the face, respiratory distress, increase in the frequency of the pulse on the day after the anesthesia; there may also be some vomiting, and more or less violent headache lasting fifteen to twenty-four hours is practically always observed. Of the 125 patients operated on, 5 died; in 4 of these the method of anesthesia could not be held responsible for the result. The other patient died on the very day of the operation. Post-mortem examination showed the existence of a heart lesion complicated with pathological condition of the lung, and M. Tuffier thinks that in that case, too, the injection of cocaine had nothing to do with the death.

M. V. NICOLETTI, of Naples, said he had been able to show by numerous experiments on the rabbit and the dog that there is no histopathological lesion of the nervous system following subarachnoid injections of cocaine in the lumbar region. This appears to warrant the inference that the anesthetic property of cocaine results solely from its action on the vascular system of the spinal cord. He has been able to produce anesthetic effects in animals by subarachnoid injections not only of cocaine, but of ergotin, antipyrin and quinine.

M. RACOVICIANU-PITESCI, of Bucharest, said that, like M. Tuffier, he had operated on 125 patients after anesthesia by Bier's method, using doses varying from 1 to 4 centigrammes. In 80 cases he noticed symptoms of slight intoxication which sometimes lasted four and even five days. In 3 patients the symptoms were so severe as to necessitate artificial respiration and subcutaneous injections of ether. He further stated that he knew of 2 cases in Roumania in which death had followed cocaine anesthesia produced by injection in the lumbar region. He does not think, therefore, that this method can replace chloroform anesthesia.

PERICARDOTOMY THROUGH THE THORACIC INSERTION OF THE RECTUS ABDOMINIS.

DR. A. VOINITCH-SIANOJENTZKY presented a communication on this subject, in which he said that pericardotomy by a single longitudinal incision through the thoracic insertion of the rectus abdominis is a perfectly simple procedure. The incision corresponding exactly to the anatomical axis of the anterior mediastinum makes it possible to penetrate the pericardium without touching the pleura, and this can be done with perfect certainty, whatever may be the size of the pericardial effusion. This procedure should always be preferred for cases of small pericardial effusions or when it is impossible to diagnose the size of the effusion. The longitudinal incision can be enlarged without difficulty downwards to the bottom of the pericardium as soon as that has been laid bare: in consequence of this the best drainage can always be obtained. The tubercle of the left sixth chondrosternal articulation is a landmark in the incision and in the puncture of the pericardium.

SURGERY OF CANCER.

J. L. FAURE, of Paris, holds that cancer is a local disease which can be cured by a local operation. It is necessary that the operation should be complete, going far beyond the limits of the disease. Every incomplete operation is invariably followed by recur-

rence or rather continuation of the disease, for "cancer does not recur, it continues." While removing the disease, therefore, the surgeon should take no heed of how the breach is to be filled up—the wound must be dealt with afterwards as may be possible. Taking these principles as his guide, M. Faure has during the last five years operated on a considerable number of cancers in all regions—face, tongue, jaw, pharynx and larynx, thyroid body and glands of the neck, branchial remnants, stomach and intestine, testicle, ovary, breast, uterus and rectum, scapula, femur and ilium. He groups together all kinds of malignant tumors, whether epithelioma or sarcoma, as he holds that the same rules should apply to both these affections. He does not include in his statistics any case dating from less than a year back. Under the conditions defined he has had 93 cases of cancer in every situation and of every degree of gravity. In 18 no recurrence occurred within a space of time varying from twelve to forty-seven months. Of these, 2 who had extensive epithelioma of the upper jaw and of the floor of the mouth died, after twenty-four and forty months, respectively, of an intercurrent malady without sign of relapse. This gives in round numbers 20% of cures. Faure admits that the period mentioned is not sufficiently long to justify him in speaking of definite cure, although he has never seen, at least in external cancers, recurrence take place after a year of apparent cure; but 14 of his patients, or 15.05% of the whole number who were discharged from the hospital cured, have disappeared and cannot be heard of, and Faure assumes that among them there have been some other instances of prolonged freedom from recurrence. He regards his statistics of 20% of cures, which include favorable, moderately favorable, and extremely unfavorable cases, as "truly consoling," and as enforcing the conclusion that it is wrong to despair of curing cancer and that we have the right, and should consider it a duty, when confronted with this disease to "undertake everything and dare everything."

CANCER OF THE CHEEK.

M. MORESTIN, Paris, said that 12 patients suffering from primary cancer of the cheek had come under his observation. Of these 1 was a woman and 10 of the 11 men were smokers, while the eleventh, who did not smoke, chewed. All had very bad teeth, and some had leucoplasic patches in the immediate neighborhood of the tumor or on the opposite cheek. In 10 of the 12 cases the growth started in the immediate neighborhood of the lower gingivogenial cul-de-sac, extending afterwards on the one hand to the internal surface of the cheek, and on the other invading the mucous membrane of the alveolar portion of the jaw. The glands became enlarged early, they became fused with each other and with the submaxillary gland and soon became adherent to the jaw. The upper gingivogenial cul-de-sac is not involved, and below it there remains a band of healthy mucous membrane. The floor of the mouth, too, generally remains intact for a fairly long time. The prognosis of cancer of the cheek is always very grave, its evolution takes place in a few months, and it soon gets beyond surgical treatment. In the cases in which intervention is possible the most general plan will be to remove

en bloc the tumor of the cheek, the submaxillary glandular mass, and the corresponding part of the maxillary bone. Of the 12 cases reported by M. Morestin, 7 were inoperable. In the other 5 he operated, and 1 of the patients, who was absolutely cachectic, died the same day. The other 4 bore the operation well; in 3 relapse occurred, death occurring in from three to eight months; the fourth was lost sight of.

(To be continued.)

Recent Literature.

Saunders's Question Compend No. 3. Essentials of Anatomy, including the Anatomy of the Viscera, arranged in the form of Questions and Answers, prepared especially for Students of Medicine by CHARLES B. NANCREDE, M.D., Professor of Surgery and Clinical Surgery in the University of Michigan; Senior Vice President of the American Surgical Association, etc. Sixth edition, thoroughly revised by FRED J. BROCKWAY, M.D., Assistant Demonstrator of Anatomy, Columbia University, New York. Philadelphia: W. B. Saunders & Co. 1899.

When medical students learn by study of the part itself and not by memorizing from a quiz compend, and when they are passed in courses on the basis of the actual practical knowledge and ability to describe things put before them and not on the amount of quiz-compend material they can spread on paper in an hour or more, then the quiz compend will have fulfilled its function. May the time soon come! If we must use a quiz compend this is a rather satisfactory one, though it seems inconsistent in a book where conciseness is sought to the extent of leaving out "a's," "an's" and "the's," space should be given to the definition of such terms as "schindylesis" and "gomphosis," which certainly seem non-essential. Why it adds to a description of the thoracic nerves to have "Describe them" in coarse print precede their description in fine print, or why it is necessary even for a quiz compend to adopt the cumbersome form of question and answer it is difficult to see. Certainly a very material reduction in the size of the book could be made by leaving out the coarse-print questions.

Heavy type headings are useful in a book of this sort, but the book has already enough of them without the questions and commands to describe the various organs.

The Treatment of Fractures. By CHARLES LOCKE SCUDDER, M.D., Surgeon to Out Patients, Massachusetts General Hospital, etc., assisted by FREDERIC J. COTTON, M.D. Pp. 433, with 585 illustrations. Philadelphia: W. B. Saunders & Co. 1900.

This carefully written volume is an interesting treatise on the subject of fractures. The book is written to serve as a guide to the student and practitioner in the treatment of this class of injuries, and an effort has been made to introduce the additional knowledge of the subject contributed by skiagraphy and the methods made possible by modern surgery. The book deals only with specific fractures, each of which is considered anatomically, its prognosis stated,

and the details of its treatment described. The text is profusely illustrated, many of the pictures being of especial interest. While one might differ with the writers in regard to some minor details, the book as a whole appears to be an excellent piece of work, which is the result of a careful study of the subject. It contains information (specific data) relating to the actual prognosis, rapidity of repair, treatment and "end" results frequently much desired but often not found in such works. It is well arranged, and is concisely and systematically written. The facts stated are derived from an extensive bibliographical study, as well as personal clinical experience. The volume will well repay a careful perusal.

Lectures upon the Principles of Surgery. Delivered at the University of Michigan. By CHARLES B. NANCREDE, A.M., M.D., LL.D., Professor of Surgery and of Clinical Surgery; Emeritus Professor of General and Orthopedic Surgery, Philadelphia Polyclinic; Senior Vice President of the American Surgical Association; Corresponding Member of the Royal Academy of Medicine of Rome; Member of the American Academy of Medicine; late Major and Chief Surgeon, U. S. V., etc. With an Appendix containing a Résumé of the Principal Views held concerning Inflammation. By WM. A. SPITZLEY, A.B., M.D., Senior Assistant in Surgery, University of Michigan. Illustrated. Philadelphia: W. B. Saunders & Co. 1899.

All things considered, Dr. Nancrede's work on the "Principles of Surgery" is a very satisfactory book to place in the hands of students. The work has been done in a thoroughly scientific spirit. The book is the course of lectures that Dr. Nancrede gave at the University of Michigan, and it is a pleasure to read it.

The strong point in Dr. Nancrede's writing is that, while the recent scientific research is presented, the theory of a given subject is always offered from a practical standpoint. The writer does not sink his individuality in presenting many of the vexed questions, for he clearly states where his views diverge from those of other teachers. It is a book that may be highly recommended to both surgeons and medical students.

Surgery. A Treatise for Students and Practitioners. By THOMAS PICKERING PICK, Consulting Surgeon to St. George's Hospital; Senior Surgeon to the Victoria Hospital for Children; Her Majesty's Inspector of Anatomy in England and Wales. London, New York and Bombay: Longmans, Green & Co. 1899.

We have delayed a little while before writing a review of this book that we might submit it to the test from time to time of using it as a reference book. The more we use it the better we like it. The author states that the book is the substance of his lectures on surgery delivered at St. George's Hospital for fifteen years, and it is evident that, as the author says, "the work may be regarded as an outcome of the experience of a hospital surgeon and teacher for nearly thirty years." It is of necessity dogmatic, but it clearly states the author's views of the nature of the various injuries and diseases that are discussed. The book is perhaps a little too large, 1,176 pages, but we can readily understand that the author has condensed on every page. It is a treatise,

but would serve very well for a textbook. Many of the illustrations are excellent, in that they are new and not meaningless "process" work. We feel that Dr. Pick is to be congratulated, for this work is evidently the result of a life labor. It reflects the greatest credit upon the author.

A Treatise on Appendicitis. By JOHN B. DEEVER, M.D., Surgeon in Chief to the German Hospital, Philadelphia. Illustrated. Second edition, thoroughly revised and considerably enlarged. Philadelphia: P. Blakiston's Son & Co. 1900.

This new edition of 300 pages is a volume of convenient size and attractive appearance. The author states that the book has been virtually rewritten; that every chapter has been carefully revised and much new material introduced. This is especially the case with the section relating to the Pathology of Appendicitis, which has been written by Dr. A. O. J. Kelly, Director of the Pathological Institute of the German Hospital. These additions have increased the size of the book. The plates seen in the former edition relating to operative technique have been omitted, and a series illustrating the histology of different varieties of the disease are substituted. The plates illustrating the ileocecal, ileocolic and subcecal fossæ are new. The volume contains 22 full-page plates, many of them colored. The subject of appendicitis has been well classified by the writer and extensively studied. A full index and a bibliographical table are appended.

The Microtometist's Vade-Mecum. A Handbook of the Methods of Microscopic Anatomy. By ARTHUR BOLLES LEE. Fifth edition. Philadelphia: P. Blakiston's Son & Co. 1900.

Five editions of this now well-known book have appeared since 1885. This latest edition has been thoroughly revised, in part rewritten, and obsolete methods have been omitted. This latter change is most highly to be commended, and we wish had been carried a little further. The unnecessary multiplication of histological methods is always to be deprecated, and particularly when the suggested modification is merely different from, but no better than, established procedures. In general this new edition, while keeping within the bounds of size prescribed by earlier ones, contains much that is new and excellent. The book will, no doubt, long stand as one of the best manuals of histological technique in the English language. Much care has been taken in the making of the volume; the binding and type are altogether satisfactory.

Quiz Compend. A Compend of Gynecology. By WILLIAM H. WELLS, M.D., Adjunct Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic; Instructor of Clinical Obstetrics in the Jefferson Medical College; Fellow of the College of Physicians of Philadelphia and of the Gynecologic Section thereof; late Assistant in the Out-Patient Gynecologic Department of the Jefferson Medical College Hospital, etc. Philadelphia: P. Blakiston's Son & Co. 1899.

This handy little manual is exactly what it implies in its title, the briefest possible extract of a textbook on gynecology. It is a good specimen of its class.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 27, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS

THE HYGIENE OF CHURCHES.¹

DR. REMLINGER,¹ chief of the Military Laboratory of Hygiene of Tunis, in an excellent article on the hygiene of churches, calls attention to the fact that the hygiene of almost all other edifices and public establishments (schools, theatres, prisons, hospitals, etc.) has received careful attention, while the hygiene of churches has been much neglected. He treats of their general sanitary condition, fire protection, liability to the spread of contagious diseases, preventive measures, and to the peculiarities of the churches of different sects, especially those of the Mussulmans.

He pictures an ideal sanitary church very much as follows: "The future sanitary church will be without a nave, or low side walls. There will be an open space below, which may be used as a crypt, or not. The floor made of marble, cement or tiles. The windows large enough to admit abundance of light, the glass of such a character as to admit the sun's rays freely." He suggests that electricity be employed to furnish the heating, ventilation and the artificial lighting at night. Otherwise he prefers steam or hot water for heating, in place of hot-air furnaces. The seats should be of light material and easily movable. He would forbid the use of carpets, mats, wallpaper, gaudy decorations, and other material liable to collect dust and to increase the danger of fire. The doors should be sufficient in number and should open outwards.

Cuspidors placed at a convenient height (*à hauteur d'homme*), and containing an antiseptic, should be placed at the entrance, along the walls, and upon the pillars of the church. Inscriptions in plain sight should call attention to these, especially to those at the entrance of the church, stating that "Out of respect for the holy place, and as a sanitary measure, spitting upon the floor is forbidden."

He also advises the protection of the holy water

from the pollution which it must necessarily receive from filthy and diseased persons.²

The condition of the confessionals also receives his condemnation and measures are suggested for their improvement.

The sweeping and dusting of churches should not be allowed, but wiping with damp cloths should be used instead. Sawdust moistened with an antiseptic is also advised.

The author also gives suggestions as to the correction of evils in churches already existing.

He states that great pains have been taken to ascertain the amount of carbonic acid in the air of school-rooms, factories, etc., before and after their occupancy by large numbers of people, but never to his knowledge have such examinations been made in the churches.

He compares Notre Dame, at Paris, to a dark cave, where the visitor has difficulty in adapting his vision to the gloomy interior, and on the contrary, the sudden change to the brilliant outdoor sunlight is still more painful to the eyes.

He cites the investigations of Casagrandi and Mazza with reference to the practice of kissing the statues of the saints. They had examined such statues at Rome and Turin, and found the bacilli of Koch and Löffler, etc., upon them. These customs, however, are not peculiar to Christianity, since the pilgrims at Mecca are accustomed to kiss a black stone which is said to have fallen from heaven, and those who cannot touch it with their lips touch it with their hands, which they afterwards kiss. At first thought the remedy suggested in the case of the holy water is the addition of an antiseptic to the water, and he naively adds that "there cannot be found in the Holy Scriptures a text forbidding the addition of an antiseptic to the holy water." A new difficulty here presents itself, however, on account of a popular belief in certain places that a dose of holy water administered to the sick is attended with miraculous results. The addition of the bichloride of mercury to such water might perhaps interfere with such miraculous action. The author tells the story of a man who, after an operation for appendicitis, was in a fair way for recovery, but being desirous of hastening his convalescence, swallowed a draught of some filthy holy water, which had been kept in a cupboard for several years. He was taken soon afterward with an infectious bronchopneumonia, of which he died. He cites two recent inventions which have been made to obviate this difficulty, one of Dutch and the other of Italian origin, the principle consisting in the use of a faucet or siphon in such manner that no person can come in contact with water which has been once used by another. Such appliances have already been adopted in some parts of Italy.

¹ Les églises au point de vue de l'hygiène, par le Dr. Paul Remlinger, médecin major, chef du laboratoire militaire de bactériologie de Tunis.

² See the investigations of Abba, at Turin, upon samples of holy water taken from the cathedrals. (Sur les conditions déplorablement bactériologiques de l'eau bénite dans les églises, Revue d'Hygiène, October 20, 1899, and May 20, 1900.)

With reference to the dust which accumulates upon the floors of churches he presents a graphic picture of a visit to St. Peter's, at Rome, on an evening of Holy Week, when as many as 80,000 persons attend the services. He says, "The immense nave was filled with a cloud of dust, so dense as to obscure the architectural details of the edifice. What becomes of this dust? On the following night it settles upon the floor, the altars, statues, and the thousand and one projecting points of the interior. At daylight, when the air of the church has become clearer, the sweepers and dusters make their appearance. With brooms, dusters and brushes of various shapes, they stir up the dust. It arises again throughout the church, and again fills the air. It settles once more, only to be stirred up again by the crowd of attendants."

Measures for the correction of some of these evils have already been taken by at least two Italian ecclesiastics, the bishops of Fano and Reggio.³ The latter says in a communication to the local health authorities in his diocese: "The greatest natural blessing which man can enjoy in this world is good health and the preservation of his life. He should, therefore, employ all the resources of hygiene for this purpose. The Divine Founder spent his life in doing good to mankind, and in restoring health to those who had lost it." The bishop, therefore, issues a series of practical hygienic measures to be adopted in the churches of his diocese.

THE BABINSKI PHENOMENON.

IN matters of diagnosis relatively few new signs stand the test of time, and prove themselves of permanent value. This, however, cannot be said of the reflex phenomenon which bears the name of its earliest describer, Babinski. Not only to the neurologist, but also to those working in the more general fields of medicine, this sign should prove of great value, because of the simplicity of its execution, and also because it is likely to form an important determining factor between so-called functional and certain organic disorders of the central nervous system. The test, in its simplest form, consists merely in an extension of the toes, best observed in the large toe, when the sole of the foot is irritated. It differs from the ordinary plantar reflex in that the toes are extended and not flexed, as occurs under normal conditions. A further interest is added to the test, because of the fact of our relative ignorance of the significance of cutaneous reflexes in general. A solution of the difficulty seems in part accomplished by the work inaugurated by Babinski, and carried out since his publication in 1896 by a considerable number of other investigators. The plantar reflex at least should no longer be taken in a purely routine way, regardless of its significance, as the habit has been in the past. The final establishment of the principle, however, that extension of the toes indicates a distinct disturbance

³ Rivista d'igiene e sanita pubblica, May 16, 1900.

with the function or structure of the pyramidal tracts of the brain or cord, demands a very large number of carefully taken and tabulated observations. These are by degrees coming in, and already a number of excellent papers on the subject have appeared. Among the most recent is one by Walton and Paul, of Boston, published in the June number of the *Journal of Nervous and Mental Disease*. These writers have examined seven hundred patients with special reference to the Babinski phenomenon and have reached certain conclusions of value to the general subject, among which are the facts that the Babinski reflex obtains in about seventy per cent. of cases of hemiplegia and diplegia, and in approximately the same percentage of cases with disease involving the pyramidal tract in the spinal cord; that the reflex is never present in health; that it is often the earliest to appear in pyramidal tract disease, and that it very exceptionally appears in cases not conforming to recognized types of pyramidal disease (meningitis, hydrocephalus, poisoning, as by alcohol or uremia). These general conclusions are certainly of great value in themselves, and as a basis for further work, particularly in the type of case last described, and in various obscure affections of other organs, as well as of the nervous system, accompanied with cachexia and a general lowering of the physical condition from whatsoever cause. The matter is clearly of sufficient diagnostic importance to justify continued study.

MEDICAL NOTES.

MEDICAL CORPS OF THE NAVY.—A naval medical board of examiners for examination of candidates for admission to the Medical Corps of the Navy is now in session at the Naval Laboratory, Brooklyn, N. Y., and will remain in session for several months. There are now seventeen vacancies in the list of assistant surgeons. Congress at its last session passed a law taking assistant surgeons out of the steerage and making them ward-room officers as soon as they entered the service, giving them the rank of junior lieutenants and the pay of assistant surgeons in the army. Candidates must be between the ages of twenty-one and thirty. Circular of information can be obtained on application to the Surgeon-General of the Navy, Navy Department.

AN "ANTIEN FISH-LIKE SMELL."—A correspondent of the *Medical Press and Circular* sends the following as "a fact": A poor fellow in bad health was taken from the London slums to the top of Hampstead Heath. He fainted soon after, not being used to fresh air. A bystander with great presence of mind placed a stale fish under his nose. The effect was immediate. The poor fellow opened his eyes and exclaimed with a sigh of relief, "Ah! that smells like home!"

CIVILIANS FOR THE ROYAL ARMY MEDICAL CORPS.—According to the *Medical Press*, civilian

medical men at present serving with the troops in South Africa are to be offered commissions in the Royal Army Medical Corps, by which means it is hoped to fill some, at any rate, of the numerous vacancies in that service. It remains to be seen to what extent advantage will be taken of the opportunity. It is quite possible that experience at the front will have a deterrent effect on those who have been exposed thereto. In any event more elaborate measures will be required if the service is to be maintained in a state of efficiency.

A MONUMENT TO THE LATE PROFESSOR KÜHNE. — It is proposed by the friends and students of the late Prof. Willy Kühne to erect a suitable monument to his memory, to be placed in the lecture room of the Heidelberg Physiological Institute. To this end funds must be raised, which it is hoped may be forthcoming from the numerous friends, students and colleagues of the distinguished physiologist. Contributions may be sent to the Oberrheinische Bank in Heidelberg, with the statement that they are to be used for the "Kühne Monument."

TUBERCULOSIS DECLARED AN INFECTIOUS DISEASE IN IOWA. — According to the *New York Medical Journal*, the Iowa State Board of Health has placed tuberculosis on the list of infectious diseases, and recommended that persons afflicted with it and infected premises be dealt with accordingly. In a pamphlet just issued are numerous suggestions and instructions for dealing with the disease.

DEATH FROM CIRCUMCISION. — A fifteen-day-old infant died from hemorrhage following circumcision by a rabbi in Philadelphia last week, according to the *Medical News*. A physician was called after unsuccessful efforts to check the hemorrhage had been made for two hours. The child died five hours after the physician was called to see the case.

STATISTICS OF MOLOKAI. — The leper colony at Molokai contains 1,100 persons — 625 males and 475 females. Of the entire number 984 are Hawaiians, 62 are half breeds, 37 are Chinese, 5 Americans, 4 British, 3 German, and 6 Portuguese. — *Medical Age*.

DR. OCHSNER. — Dr. A. J. Ochsner has been appointed professor of clinical surgery in the Medical Department of the University of Illinois (Chicago College of Physicians and Surgeons).

PLAGUE IN GLASGOW. — An occasional case of plague is still reported from Glasgow.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, September 26, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 121, scarlatina 21, measles 8, typhoid fever 25.

SMALLPOX AT STRAFFORD, N. H. — Several cases of smallpox have recently been discovered in a French-

Canadian family at Strafford, N. H. It is thought that the disease will not spread, owing to the fact that the affected family lives in an isolated part of the town. The disease will probably be traced to Pittsfield, where there are a number of convalescents from the disease in the contagious hospital.

A CASE OF SMALLPOX IN MALDEN, MASS. — A case of smallpox has been discovered in Malden, in a negro woman recently arrived from Richmond, Va. It will be difficult to make provision for her in the town, since the building formerly used to isolate such cases has been devoted to other purposes.

NEW YORK.

COURSE FOR TRAINED NURSES AT COLUMBIA UNIVERSITY. — At the request of the American Society of Superintendents of Training Schools for Nurses, the authorities of Columbia University are about to establish a special course in "hospital economics," to be given at Teachers' College. The aim of the course is to fit persons who are already trained nurses for the responsible duties of superintendents of hospitals and principals of training schools for nurses. It is intended to present the practical problems of hospital administration and to give students systematic instruction in the organization and management of training schools. The prescribed course of study will include general psychology and its application in teaching; methods, practice, organization and supervision of hospitals and training schools, biology, physiology, hygiene, the production and manufacture of foods, home sanitation and management, bacteriology and household chemistry. A series of special lecture courses has also been arranged.

ELECTRIC AMBULANCES. — The Roosevelt Hospital has been presented with two electric ambulances, costing about \$3,000 each and capable of travelling sixteen miles an hour. It is also stated that the firm which manufactured them is now constructing similar ambulances for the New York and the Presbyterian Hospitals. Up to the present time the only hospital in the city that has had a vehicle of the kind is St. Vincent's.

TWO CENTENARIANS. — Mr. Bernard Aronson, of New York City, reputed to be one hundred and five years old, is dead. He was born in Germany in 1795 and came to New York about forty-eight years ago. Mrs. Anna Baumle, a native of Kurschin, Austria, died in Newark, N. J., on September 15th, at the reputed age of one hundred and three years and seven months.

BEQUESTS TO HOSPITALS. — Among the institutions receiving \$5,000 each under the will of George D. Sweetser are the following: The New York Skin and Cancer Hospital, the New York Infant Asylum, the Society for the Relief of Ruptured and Crippled, the House of Rest for Consumptives, the Woman's Hospital and the Home for Incurables.

Obituary.

LEWIS A. SAYRE, M.D.

DR. LEWIS ALBERT SAYRE, one of the most striking figures in the profession in America, and unquestionably the most widely known orthopedic surgeon in the world, died at his residence in New York, on the 21st of September. For many years he had been a sufferer from rheumatism, and for the last twelve months he had been confined to his room the greater part of the time. His death was due to a gradual failure of vital powers. He was in his eighty-first year.

Dr. Sayre came of old Colonial and Revolutionary stock and was born at Bottle Hill, now Madison, N. J., on February 29, 1820. He was a precocious child, and at the age of four recited verses of welcome in the presence of Lafayette, when the latter was revisiting the Revolutionary scenes of New Jersey. He was graduated from Transylvania University, Lexington, Ky., in 1839, and from the College of Physicians and Surgeons, New York, in 1842. He married, in 1849, Miss Eliza Ann Hall, a daughter of Charles Henry Hall, an influential citizen of Harlem, and had four children, Dr. Charles H. H. Sayre, Dr. Lewis Hall Sayre, Dr. Reginald Hall Sayre and Miss Mary Hall Sayre. Of these, Dr. Charles Sayre died in 1880 and Dr. Lewis H. Sayre in 1890.

Immediately on his graduation he was made prosector to the professor of surgery in the College of Physicians and Surgeons. In 1853 he was appointed surgeon to Bellevue Hospital and in 1859 to the Charity Hospital on Blackwell's Island. In 1873 he became one of the consulting surgeons to the latter institution. He was one of the principal founders of the Bellevue Hospital Medical College, of the New York Academy of Medicine, the New York Pathological Society and the American Medical Association.

In 1860 he was appointed by Mayor Fernando Wood to the position of resident physician of New York, in control of the Health Department of the city, and he continued to fill this office with marked ability and success during the administrations of Mayors Gunther and Hoffman. In this capacity he showed great vigor in combating smallpox, cholera and other infectious diseases, in his efforts in behalf of compulsory vaccination and in dealing with the evils of tenement-house life and other sanitary problems.

When the Bellevue Hospital Medical College was organized in 1861 he became a member of its first faculty, as professor of orthopedic surgery, fractures and luxations, and he continued to fill the chair of orthopedic surgery until 1898, when the college was consolidated with the Medical Department of the University of the City of New York. He was then made professor emeritus, while his son, Dr. Reginald H. Sayre, was appointed clinical professor of orthopedic surgery in the University and Bellevue Hospital Medical College. Dr. Sayre's achievements in the special field which constituted in a large degree his life work are of world-wide renown.

While he has impressed his original genius upon the progress of this entire branch of surgical knowledge, he will no doubt be best known to posterity for his achievements in connection with the exsection of the hip joint and his treatment of Pott's disease and lateral curvature of the spine by means of suspension and the plaster-of-Paris jacket. His first operation for the cure of hip-joint disease was performed as early as 1854, and the gratifying result attracted widespread attention. In 1871 he went abroad and demonstrated his method in a number of the principal European hospitals. During this tour he treated a member of the royal family of Sweden, and King Charles IV created him a Knight of the Order of Vasa. He was also made an honorary member of the British Medical Association, the Medico Chirurgical Society of Edinburgh, the Surgical Society of St. Petersburg, the Medical Society of Norway and other scientific bodies. At the International Medical Congress in Philadelphia in 1876 he performed an

exsection of the hip in the presence of the concretion, and in 1877 he visited England again and demonstrated his new method of treatment for spinal disease before the British Medical Association at Manchester. He also gave clinical lectures on the subject in London, Edinburgh, Liverpool, Dublin and other cities, and in recognition of his flattering reception, published while in England "An Illustrated Treatise on Spinal Disease and Spinal Curvature," which he dedicated to the medical profession of Great Britain.

Dr. Sayre's principal literary work was his "Lectures on Orthopedic Surgery and Diseases of the Joints," which is remarkable for its terseness of style and the great practical utility of its illustrations, nearly all of which are taken from actual photographs. In preparing the revised edition of the work he was assisted by the late Dr. Wesley M. Carpenter, and for several years before his death it was a matter of great regret to Dr. Sayre that the condition of his health and the demands upon his time prevented him from making another revision, embodying the latest fruits of his experience and observation. Dr. Sayre also published "A Practical Manual on the Treatment of Club-Foot," which passed through a number of editions, and a large number of monographs on other special topics.

In 1866 he was elected a vice president of the American Medical Association, and in 1889, when it met in New York, president of that body. He was also at various times president of the New York Pathological Society and other societies. At the time of his death he was consulting surgeon to Bellevue Hospital, St. Elizabeth's Hospital, the Home for Incurables, and other institutions. Among the societies officially represented at his funeral, held September 23d, at Grace Church, were the New York Academy of Medicine, the Pathological Society, the Medical Society of the County of New York, and the New York County Medical Association.

Dr. Sayre was of a most commanding presence. He had a powerful voice, under admirable control, and as the play of emotions upon his strongly marked features was remarkable, he was a most impressive speaker. His language was not always polished, but it was invariably vigorous. In his lectures, and in speaking before societies, he brought out the points which he desired to impress with the utmost clearness and force, and as he had a rich fund of anecdote and an unusual gift of mimicry, he was always sure of carrying his audience with him. Truly a notable person has passed away in Lewis A. Sayre, and the news of his death will be received with sincere sorrow not only throughout this country, but all over the civilized world.

FRANK W. GRAVES, M.D.

RESOLUTIONS OF THE MIDDLESEX EAST DISTRICT MEDICAL SOCIETY.

Whereas, We are called under the dispensation of Providence to mourn the sudden death of our most highly esteemed professional brother, Frank W. Graves, of Woburn, Mass., the Middlesex East District Medical Society, in regular meeting assembled, hereby

Resolve, That we share in the great grief of the many who knew Dr. Graves in his private and business relations, to whom his useful life and manly character were open and familiar, and who loved him for the genial and noble qualities with which his personal friendships were brightened and dignified, and that we join in the regret and conviction of general loss which always follow the death of an honorable and successful man and citizen. But, as fellow members of this society and as his associates in the medical profession, we feel even more deeply the deprivation of his cheering presence, his kind and efficient counsel and assistance, his courtesy, honor and integrity and brotherly relation to each and all of us.

That, as physicians, we testify to the skill, foresight and wisdom with which he won such signal success in the ranks of our profession, and hereby make record and public ex-

pression of our sorrow for his demise and the great bereavement which has fallen upon us as individuals and as a society.

C. C. ODLIN,
S. W. KELLEY,
CHAS. DUTTON, } *Committee.*

ALFRED STILLÉ, M.D.

THE death of Dr. Alfred Stillé is announced, who for nearly twenty years had been associated with the University of Pennsylvania as professor of the theory and practice of medicine. He was born in Philadelphia in 1813, and was graduated from the University of Pennsylvania as A.B. in 1832 and as M.D. in 1836. He was made resident physician at the Philadelphia Hospital in the latter year. He subsequently studied in Europe for two and a half years. He was resident physician at the Pennsylvania Hospital from 1836 to 1841, and lecturer on general pathology and practice of medicine in the Philadelphia Association for Medical Improvement from 1845 until 1859. From 1854 to 1859 he held the chair of theory and practice of medicine in the Pennsylvania Medical College. He was elected to the corresponding chair in the University of Pennsylvania in 1864. In 1849 he was appointed physician to St. Joseph's Hospital, and in 1854 he was elected professor of theory and practice of medicine in the Pennsylvania Medical College. He held that chair until 1859, when he was chosen to occupy a similar chair in the University of Pennsylvania. This position he held until 1884, when he became professor emeritus. He was president of the American Medical Association in 1867, of the Philadelphia College Medical Association in 1862 and of the College of Physicians of Philadelphia in 1885. From 1865 to 1867 he was physician and lecturer on clinical medicine in the Philadelphia Hospital. He received the degree of LL.D. from the Pennsylvania College at Gettysburg in 1876. Among his publications were "Medical Instruction in the United States," "Elements of General Pathology," "Unity of Medicine," "Humboldt's Materia Medica," and a systematic treatment on the action and use of medicinal agents.

HUNTER H. MCGUIRE, M.D.

DR. HUNTER H. MCGUIRE died in Richmond, Va., September 19, 1900, at the age of sixty-five. He had never recovered from a paralytic stroke, which occurred six months ago. During the Civil War, Dr. McGuire was a prominent medical figure in the Confederate Army. He served as the head of the medical department under General Stonewall Jackson, and operated on that officer at the time of his fatal wound. Since the close of the war Dr. McGuire had established an enviable reputation as a surgeon. He was educated at several medical colleges, among them the Jefferson Medical College of Philadelphia. He held the chair of anatomy in the Medical College of Virginia from 1856 to 1853, when he removed to Philadelphia. In 1865 he was called to be professor of surgery in Virginia Medical College, where he remained till 1880. In 1885 he was made professor emeritus in that institution.

Dr. McGuire organized St. Luke's Home for the Sick, with a training school for nurses, in Richmond. He was president of the Association of Confederate Medical Officers in 1869 and of the Virginia Medical Society in 1873, vice president of the International Medical Congress in 1876 and of the American Medical Association in 1881, and president of the American Surgical Association in 1887. The University of North Carolina in 1887 conferred upon him the degree of LL.D. He was a contributor to Ashurst's "International Cyclopaedia of Surgery," Pepper's "System of Medicine" and the American edition of Holmes's "Surgery."

RECENT DEATH.

ROBERT FRANCIS FORREST, M.D., M.M.S.S., of Cambridge, died in Watertown, September 18, 1900.

REMARKS UPON OBSCURE NON-TRAUMATIC TUMORS OF THE LOWER ABDOMEN SUDDENLY APPEARING WHERE NONE HAD PREVIOUSLY BEEN DETECTED.

BY MAURICE D. RICHARDSON, M.D., BOSTON.

THE sudden appearance of abdominal tumors should suggest to the observer a lesion that demands intervention; for nearly, if not all, are curable only by surgical means. Moreover, intervention in most of the tumors under consideration must be prompt to be successful. It is from this point of view that I invite attention to a class of abdominal lesions so hard to understand that they must be called obscure. Indeed they are of such uncertain origin that no man, skilful and experienced though he may be, can more than hazard a guess as to their nature. Fortunately these tumors present symptoms that of themselves demand early operation. A differential diagnosis, interesting as it may be, is impossible from the very nature of things.

A wide experience in abdominal surgery may not afford a single example to illustrate my subject; a narrow one may afford several. Most of the cases upon which I base my remarks have come under observation within the past four months. In every case the patient's life was saved by operation performed as soon as the urgency was clear. In but one was a correct diagnosis made before exploration; that exploration demonstrated in all the lethal nature of the lesion.

By sudden and obscure tumors I mean those which are so small that they escape observation one day, and so large that they cannot be overlooked the next: so small that bimanual examination fails to detect them at one examination, and at the next so large that they may even bulge the abdominal wall.

My attention was particularly attracted to this subject by the detection of a large ovarian cyst with twisted pedicle in a woman whom I had examined a short time before without finding any tumor whatever. My interest in this case was especially acute because my failure to detect the tumor was shared by one experienced in such examinations, who, even under anesthesia, had been unable to discover anything abnormal in the lower abdomen.

CASE I. The patient, a woman of forty, had suffered for some six months with sudden attacks of pain in the left side of the abdomen. The first attack in August, 1895, came on five days after confinement. Between that time and February, 1896, there had been six attacks. It was supposed to be a nephritic colic, and the history in detail certainly justified that diagnosis. The pain was controlled by morphine. The patient was examined under ether. *Nothing could be detected in the pelvis.* The urethra was dilated and the bladder examined. Nothing abnormal could be felt anywhere in the abdomen. Two days later, without any apparent reason, she became suddenly collapsed. There was no sharp pain — only a "sinking feeling." The nurse could feel no pulse. I first saw and examined the patient on the evening of this day, and could detect nothing. The temperature was 99.4°; the pulse 170. No operation was advised.

Three weeks later the patient presented symptoms so strongly suggestive of an acute appendicitis that a medical consultant after careful examination advised that a surgeon be sent for. I was then able to diagnosticate and to re-

move an ovarian tumor with twisted pedicle, the whole filling the abdomen as high as the umbilicus. The patient made a good recovery. The explanation of this case, as demonstrated by the operation, seems satisfactory. There was a flaccid cyst of moderate size, which escaped detection owing to an unusually thick abdominal wall covering it; the collapse was due to hemorrhage into the cyst at the beginning torsion. At the time of operation the tumor had become large and tense enough to be easily detected.¹

The first and most natural criticism in considering this case is that the examination was not thorough; that skilled examiners could not have failed to detect such a tumor. But such a criticism, I maintain, can be founded only upon ignorance or upon inexperience, for there can be no doubt that tumors suddenly appear in regions where the most painstaking and experienced examiners have failed to detect any.

The first and most common of the suddenly appearing tumors, and, I may add, the most likely to be overlooked, is the over-distended bladder. If the whole truth were told, not a few instances would be recorded in which the operator has exposed a normal bladder in a state of extreme distention — some in which he has actually opened it. Such a mistake is common with certain acute lesions, more especially appendicitis with abscess. I recall one case in which the tumor of the appendix was so closely connected with a full bladder that I opened the latter. Fortunately no harm was done. Taught by this experience, I have by catheterization avoided several fluctuating tumors which proved to be the full bladder fastened to the right side of the abdomen by contiguous appendicular inflammation.

In such cases, however, there is no sudden and unexpected development of a tumor; moreover, the causative lesion is always apparent. It is rather the uncomplicated tumor, elastic, fluctuating and symmetrical, that must be carefully scanned. Even with the most painstaking examination such a tumor may deceive us, unless we continually bear in mind the possibility of a full bladder. We shall be especially liable to mistake if we are unaware of the suddenness of development, for the bladder may have been over-distended some time before the first examination. In one instance I was about to open the abdomen for supposed ovarian cyst. I found it filled by a fluctuating, symmetrical tumor. The patient was a woman of twenty-six, who had complained for two months of pain in the right lower abdomen. The attending physician had made a diagnosis of ovarian cyst and had asked me to operate. Vaginal examination confirmed the diagnosis of ovarian cyst. I advised operation. The patient was placed in the Trendelenburg position, and the cut was about to be made, when something, I forget what, suggested bladder. I found that just before operation, she had passed her urine voluntarily and easily and had not been catheterized. The tumor escaped through the catheter.

In pelvic surgery especially it should be an invariable rule to catheterize the patient just before operation. This rule should apply particularly to women. Failure to empty the bladder by the catheter will often cause the annoyance of a partly filled bladder interfering with one's work; sometimes catheterization will prevent the performance of a totally unnecessary abdominal exploration.

I have twice been astonished to find, a few days

¹ The Medical Register, Richmond, Va., October, 1899.

after simple operations upon the lower abdomen, a large fluctuating tumor extending to the umbilicus. The most serious and impossible complications were immediately suspected, particularly hematomata. In each instance the catheter solved the diagnosis and relieved the patient.

On the other hand, the tumor does not always prove so easy of diagnosis.

CASE II. On January 30, 1900, I saw with Dr. George E. Thompson, of Boston, Mary M., a girl of fourteen, who had been taken with pain in the lower abdomen ten days before. The illness began with diarrhea, followed by vomiting, distention and general tenderness. There were some constitutional signs, but of moderate extent. The attack began just at the close of her first menstruation. She had been greatly frightened by the flow, not understanding it, and she had kept about her work, had got wet, and had taken cold. The lower abdomen was dull and apparently fluctuating. Her general condition was good. The whole abdomen was much distended, but soft.

I advised the passage of a catheter, and was greatly surprised that nothing came through it. The lesion was quite obscure, but it seemed probably a subacute peritonitis, probably connected in some way with menstruation. I sent her to the hospital, where she was kept under careful observation. On March 2d I operated upon the tumor in the lower abdomen which had gradually developed, and found what I had never suspected — a pelvic abscess from appendicitis.

The tumor which at first I thought might be a full bladder was a localized peritonitis with gradual thickening walls. The true diagnosis was never even suspected. Though in this case no bladder complications were found, the passage of the catheter as a means of diagnosis was clearly indicated. Attention is at once directed to the bladder whenever there are urinary symptoms, especially dribbling. Fluctuating tumors in men suggest bladder, even when urinary symptoms are not mentioned. No more common condition is overlooked by the general practitioner than the distended male bladder, even when dribbling of urine calls the attention directly to it. The female bladder is even more likely to be overlooked, for it may be enormously distended without giving rise to a single symptom or even to an inconvenience. The obvious lesson is that in all fluctuating tumors of the lower abdomen, before opening the abdomen, the catheter should be passed. Many tumors will by this means of diagnosis disappear.

A second variety of rapidly forming tumor may be the idiopathic dilatation of the colon — the so-called phantom. A suddenly appearing tumor dependent upon this cause possesses characteristics quite different from all other varieties considered in this paper. The ordinary phantom tumor, though it may be called obscure, can hardly be called suddenly appearing; it should rather be called a suddenly disappearing tumor. It is a well-known and persistent tumor, disappearing only under anesthesia. The dilated colon, however, may suddenly become twisted or obstructed and show itself as a well-marked tumor. Such a condition of the colon may have given no signs whatever of its existence. A remarkable case of this kind came under my observation some years ago.²

CASE II. The patient, a man of forty, under the care of Dr. Hardy Phippen, of Salem, became suddenly distended to enormous proportions. The bowels were completely obstructed. Violent peristaltic movements were visible through the abdominal walls. There was no es-

pecial tumor other than that of an enormously distended coil. It was clear that there was a violent effort in the large intestine to empty itself, and this effort showed itself in a tense and dilated coil. I found the abdominal cavity filled with the sigmoid flexure, twisted about its mesentery and completely obstructed. I untwisted and fastened the sigmoid flexure, in normal position, to the abdominal wall. This was on March 22, 1897. On August 9th, the twist having recurred, I resected the whole coil with permanent success.

The diagnosis in this variety of suddenly appearing tumor is limited to those lesions of intestinal obstruction which are attended by the presence of an isolated and distended coil. The disease most commonly found is an intussusception or a volvulus, though I have seen the intestine just above a stricture excessively distended and forming a pear-shaped tumor, sagging with retained liquid feces. The common forms of intussusception, volvulus, and simple obstruction need not be considered in the rapidly appearing intestinal tumors, for they are, as an almost invariable rule, small or hard of detection. In the case just mentioned the coil was so large that it filled the whole of the abdomen.

CASE IV. A recent case of the so-called phantom tumor without obstruction — in some respects more remarkable than the first — was that of Mary K., who entered the Massachusetts General Hospital for a supposed case of chronic appendicitis. The appendix was removed with temporary benefit. When she first came under my observation she presented a rounded, symmetrical, tympanitic tumor filling the lower abdomen. Dr. Fitz made the diagnosis of idiopathic dilatation of the colon. The tumor belonged to the so-called phantom class, for under ether it entirely disappeared. On recovery from anesthesia the tumor immediately reappeared. On May 5th I removed the whole sigmoid flexure — 14 inches of excessively dilated bowel — and joined the descending colon to the rectum in a straight line. On April 19, 1900, she presented the same appearance as before. I have recently explored again and found at the site of the suture an excessive dilatation with thickening of the bowel. A second sigmoid flexure has appeared. The second tumor must be regarded as an idiopathic dilatation of the descending colon and upper rectum, for at my previous operation no sigmoid flexure was left. There was no obstruction to the fecal stream and the recurrence of dilatation to me is inexplicable.

Dr. F. B. Harrington has had a similar case recently reported by Fitz. In a personal communication Dr. Harrington has given me the facts of a third case. A woman of seventy suddenly developed a tumor rather above than below the umbilicus, with complete obstruction. The tumor was tympanitic, resistant and tender. Exploration showed it to be an enormously distended sigmoid flexure.

In some instances in explorations of suddenly appearing tumors comparatively large collections of clear fluid will be found in close connection with such lesions as salpingitis and even with appendicitis. Small cysts are often noted upon the Fallopian tubes or upon fibroids. An extreme development of these collections of fluid explains the large pseudocysts of sudden appearance. I recall one case in which a bulging tumor between the caput coli and the bladder proved to be an encysted collection of serum dependent upon a recurring abscess two years after the removal of a gangrenous appendix. In another instance, to be reported later in this paper, there were several localized collections about a single large cyst filled with blood. In numerous patients I have found, confined behind the uterus, low in the pelvis, very considerable collec-

² Transactions of the American Surgical Association, 1897, p. 585.

tions of clear, sterile fluid. Such collections may form in a short time. When they are high up in the pelvis they may, in a night, cause a bulging of the abdominal wall. On the other hand the collection of fluid about recently inflamed tubes may be of considerable extent and yet be impossible of detection. On March 23d I opened the abdomen in an obscure pelvic case, supposed to be either salpingitis or extrauterine pregnancy, and exposed a flaccid encysted peritonitis which I had been unable to feel under anesthesia by bimanual palpation. Such a cyst tensely filled would have bulged the abdominal wall. Had its thin-walled vessels given way the patient would have presented a suddenly appearing obscure tumor filled with blood where none had previously been detected.

Tumors of this origin must be considered in attempting to make a diagnosis. They do not appear, however, without being preceded or accompanied by physical signs easy of detection. The appendicitis, the salpingitis, the fibroid, the pelvic peritonitis, all present sufficient evidence upon which to base an opinion.

The next lesion is so unusual that little can be said to throw light upon its probable origin or upon its exact nature. I venture to say that few would be able in the illustrative case to hazard a guess as to the lesion. I will give the case in some detail from the records of the Massachusetts General Hospital. It may be interesting for the reader to make his diagnosis before going on to read the description of what was found at the operation.

CASE V. The patient, a girl of nineteen, had been under the care of Dr. Fitz in the medical wards of the Massachusetts General Hospital. The only gastric symptom was discomfort after eating. This had lasted a year and was supposed to have been caused by a "blow upon the stomach" from a fall upon a curbstone. There had been frequent vomiting and much belching, but no hematemesis.

The patient gained under medical treatment which was directed to her general condition — one of neurasthenia with dyspepsia. Repeated examinations of the abdomen were negative. On February 14th at noon she began to vomit. In eighteen hours she began to complain of pain in the left abdomen. She soon became collapsed. On February 15th, at noon, twenty-four hours after the vomiting began, she was seen by Dr. Mixer and myself. The left side of the abdomen was much more prominent than the right, and flat from the pubes to the ribs. The tumor was fluctuating and tender. The patient was collapsed. There was a leucocytosis of 22,300. She was then transferred to the west surgical division.

I found a large, fluctuating, tender tumor filling the whole lower abdomen. Vaginal examination showed that the tumor pressed upon the bladder and filled the upper part of the pelvis. The patient was in extreme collapse. Though it seemed hardly possible that the tumor could be a dilated bladder, I advised first the passage of the catheter. It was not a bladder. The symmetry, tenderness, fluctuation and dulness strongly suggested an ovarian cyst with twisted pedicle. I therefore made careful inquiries as to the previous examinations. I found that repeated examinations by Dr. Fitz had shown the abdomen "negative." I was yet inclined (in the light of Case I) to regard the tumor as an ovarian torsion. The real lesion was not for a moment suspected. Dr. Mixer kindly operated for me and found an excessive dilatation of the stomach. This organ filled the lower abdomen, sagging it in the shape of an enormous pear. There were several gallons of fluid dragging the stomach into the lower abdomen, where it formed, as I have already described, a dull, bulging, symmet-

rical, fluctuating mass. No stricture of the pylorus or other cause was found for this condition. It was impossible to relieve the stomach by way of the esophagus, Dr. Mixer not being able to pass a tube into the stomach in that way. An anastomosis was therefore made between the stomach and the jejunum. The patient gradually failed and died three days later.

The symptoms in this case were largely gastric, but no physical signs of dilatation were detected. No tumor of the lower abdomen or pelvis was ever apparent. The lesion, evidently of the gravest character, showed itself by the sudden appearance of a large, symmetrical, tender, fluctuating tumor of the lower abdomen. The chief constitutional signs were those of collapse. The aggregation of symptoms pointed as much to an ovarian tumor with a twisted pedicle as to anything else, — indeed rather more, — and not at all to the real lesion. Fortunately they indicated the necessity for surgical relief, and the course taken was the only one making recovery possible, for even with the abdomen open it was impossible to drain through the esophagus.

The inference to be drawn from this case is that in the tumors under consideration the stomach is not too remote to be a possible cause of the unexpected tumor. Another case, though not as extraordinary as this, illustrates the subject.

CASE VI. Isabel McL., age twenty-one, single, entered the accident room of the Massachusetts General Hospital on February 10, 1900. There was a past history of indigestion and constipation for three years. During the last days of June, 1899, she had an attack of pain in the right iliac region and pain in the back. She vomited a great deal. She went to bed and stayed four days. Two months ago she had had another attack of pain in the same place, without vomiting. She did not then go to bed. Two weeks before entrance she had an attack of pain in the right iliac fossa. She vomited frequently and the bowels were constipated. There was tenderness in the right iliac region in all of these attacks. The menstruation was slightly irregular. The last period was two weeks ago. She was well developed and well nourished; the heart and lungs were negative. There was tenderness in the right lower abdomen. The rectus was more rigid on the right side. Examination by rectum showed a slight tenderness in the right side of the pelvis. It was impossible to make a vaginal examination. There was a blood count of 6,000. The next day she was more comfortable. She could not pass the urine and she had to be catheterized. She complained of attacks of pain during this day — not very severe — starting in the right hypochondrium, and extending down the median line towards the pubes. There was no vomiting.

On the 16th she was more comfortable. The pain was less severe. The tenderness was more marked in the right iliac fossa and above the pubes. No mass could be felt in the abdomen. The urine in twenty-four hours was 18 ounces. On the 17th her condition was the same. On the 18th white count was 20,000. It was now deemed advisable to open the abdomen. Within the last twenty-four hours a tumor had appeared to the right of the median line, pretty well filling the right lower abdomen. I was extremely surprised to find a large, tender and elastic tumor where none had been felt the day before. The diagnosis seemed very obscure.

On opening the abdomen I found a tumor of the right ovary, about the size of a small cocoon. There was a twist in the pedicle which impeded the venous return, though it did not entirely shut off the circulation. The cyst was tensely distended with the exudation from the obstructed vein. There was in the left ovary a small cyst, about the size of an egg, which I dissected out with the blunt dissector, closing the rent in the ovary by an inter-

rupted fine silk suture. The patient has made a perfect recovery.

The most common tumor, probably, which suddenly attains considerable dimensions is the ovarian tumor with twisted pedicle. The obstruction to venous return, which begins before the arterial supply is closed, causes, first, engorgement of the tumor walls as well as its cavity. In many instances this engorgement results in hemorrhage into the cyst. When the cyst is distensible, the shock and collapse depend chiefly upon the hemorrhage. More infrequently the tumor is due to the rupture of blood vessels, and hemorrhage into the distensible cyst, without any twist in the pedicle whatever. In many cases the symptoms of hemorrhage and collapse are so characteristic that the attention is at once drawn to the examination of the pelvis, and the tumor is found. In many other cases the tumor is already known to exist. In the tumors which suddenly appear without warning, without pain, and without hemorrhage—signs so characteristic of ovarian torsion—the diagnosis and explanation are somewhat more doubtful, as in the following case:

CASE VII. Ada McD., age eighteen, White River Junction, Vt., entered the Massachusetts General Hospital on February 6, 1900. The history was negative up to two years before admission, when she had what was supposed to be a peritonitis. For a year before admission she had been having weekly tampons in the vagina, with no marked improvement. The symptoms were chiefly connected with the menstruation. The flow was painful and rather scanty. The chief complaint was pain in the left side low down in the pelvis—a dragging down sensation, and backache. The chief point in this case was that in my first examination I was unable to find anything whatever in the pelvis. I was not satisfied with this examination, however, and on February 9th I etherized the patient. Under ether I made a most thorough bimanual examination. I found the uterus anteфлекed—in a state of normal anteфлекion—and a mass extending on either side, rather more to the right than to the left. It seemed to be either a small fibroid or an enlargement of the tube. In a word, the girl had a tumor which was somewhat difficult of detection.

On the following Monday morning I found a tumor filling the whole lower abdomen, going as high as the umbilicus. It was fluctuating, not especially tense and not especially tender. I was so surprised to find this tumor that I hesitated a long time before opening the abdomen, thinking that I might possibly have overlooked a pregnant uterus. Finally, under bimanual examination, I felt something rupture, and then I knew at once that it was a cyst or a portion of a cyst which had given way during examination. There was no indication of hemorrhage, and yet the girl was rather pale. I opened the abdomen and found a very thin-walled ovarian cyst of the left side filling a large part of the lower abdomen. The cyst was multilocular, one cyst being much larger than all the rest combined. This one was aspirated and bloody fluid was withdrawn. The right tube and ovary were normal. The patient's condition was very poor at the end of the operation, but she made a good recovery. An immediate cover-glass examination was made, with negative results. The culture from the peritoneal cavity was sterile. Further examination showed that the initial lesion was a "tuberculosis of the Fallopian tubes."

In this case the cyst was distended by a fluid composed mostly of blood. The source of the hemorrhage was undoubtedly the thin-walled vessels of the interior of the cyst, ruptured probably during the manipulation of the bimanual examination. The patient was somewhat pale, but presented no other signs of hemorrhage. With a tender, resistant tumor, and with signs

of hemorrhage, attention would have been immediately drawn to the possibility of an ovarian torsion.

The most frequent cause of unexpected tumors seems to be, as in Case I, the result of sudden enlargement of a flaccid tumor due to a twisting of its pedicle. The common occurrence of this mechanical lesion has for some time attracted my attention. The frequency with which the physician fails to recognize so grave a lesion might seem inexcusable were it not that the mistake is sometimes made by the most experienced diagnosticians. The trouble is that the effects of twisting are often observed in patients who have never known or suspected that they had a tumor. Moreover the lesion may occur in the course of other diseases or conditions which cannot but mislead the observer.

Nothing could be easier than the diagnosis when a well-known and perhaps often-observed tumor becomes suddenly painful, tender and resistant, and especially when accompanied with vomiting and collapse with rapid pulse and subnormal temperature. Such an aggregation of symptoms cannot but suggest a sudden shutting off of the blood supply to the tumor, with distention of the tumor either by blood or by serum, and beginning gangrene of its walls. But suppose that pain, tenderness, vomiting and collapse take place, and that under ether nothing is discovered by the most careful bimanual examination, would not the examiner be surprised to know that these symptoms were due to a twisted pedicle, as proved two or three weeks later by the successful removal of a tumor filled with blood large enough to occupy the whole lower abdomen (see Case I)? Or suppose a mild and frequently recurring appendicitis, so evident that neither physician nor consultant deemed a vaginal examination necessary, would not the operator be surprised to find a small ovarian cyst, strangulated in the pelvis, shut off completely from its pedicle and nourished by adhesions? Or even after repeated observations upon a painful and tender fibroid, would he not be surprised, in beginning a hysterectomy, to find an ovarian pedicle twisted enough to shut off the venous return, while still permitting the arterial supply? He might well be surprised, and I might add that I have been surprised under these very conditions, for all these supposititious cases are taken from my own records. Fortunately, the indications for operation were clear and all the patients were saved.

The chief necessity in connection with the suddenly appearing ovarian torsion is the early recognition that something has occurred within the abdomen which urgently demands exploration. Refinements of diagnosis, however desirable in ordinary cases, must be condemned if they consume precious time. Sudden, sharp and severe pain in the lower abdomen, followed by symptoms of shock, with tenderness and tumor, mean a serious lesion, and demand exploration. The surgeon may find an extra-uterine pregnancy, an ovarian torsion, an acute salpingitis, or even a perforated appendix.

Tumors of hemorrhagic origin, suddenly appearing, are usually coincident with the initial pain, and for this reason are apparent at the first examination. In case the patient is examined before the pain—the initial sign of hemorrhage—appears, it is evident that nothing will be discovered. The sudden development of the hemorrhage is not unlike that of the tense and blood-filled cyst of the ovarian torsion or of

simple hemorrhage. Early examination in suspected pregnancy will show that no considerable tumor is present, even in ectopic gestation; in most cases only an enlarged ovary or tube will be detected. When in a suspected pregnancy a tumor suddenly appears coincidently with sharp abdominal pain, the chances favor the ruptured sac of an extra-uterine pregnancy with confinement of the blood within the layers of the broad ligament. At times the tumor is a hematoma or a hemocele confined in the pelvis. The diagnosis between the tumor of an extra-uterine pregnancy and ovarian tumor with twisted pedicle is often dependent upon the history of a possible pregnancy, for the principal symptoms of onset are identical. When the cyst becomes filled with blood, in both there is a sudden pain with faintness and collapse; in both there is a tender, elastic and suddenly appearing tumor; in both there are symptoms of peritoneal irritation, nausea, vomiting and distention; in both, low temperature and high pulse. When there is a history of irregular menstruation, of tender breasts, and of morning sickness, the chances favor an extra-uterine pregnancy. In the absence of all signs pointing towards pregnancy, the elastic, tender tumor suggests an ovarian tumor with twisted pedicle.

The ovarian tumor with twisted pedicle is usually tense and tender; the hematoma is not. If the hematoma is tense, it is seldom tender. Many examples of suddenly appearing blood tumors of the lower abdomen might be given here to illustrate the foregoing remarks. They differ materially from the encysted hemorrhages of ovarian tumors, whether with twisted pedicle or not. The importance of distinguishing between the hemocele and the ovarian tumor is great, for the former often do well without operation and the latter always demand it. One distinguishing feature not mentioned is the gradual development of the hemocele. Yet I have seen one develop suddenly. I recall the case of a married woman of thirty-four who had gone over her menstrual period one month. There was nausea. Pain in the abdomen came on suddenly, and was accompanied by vomiting. I found a tumor as large as a child's head extending from the pubes nearly to the umbilicus. On exploration this proved to be a thick-walled sac containing clotted blood. The walls of the sac were stitched to the wound and the blood was removed by irrigation. No evidence of fetal structure could be found. Convalescence from this operation was rapid, but a sinus remained for some time. About four weeks after the operation the patient was seized again with pain, the attack being very similar to the first. A tumor then rapidly formed to the left of the uterus, as in the first attack. No intervention was attempted. The swelling subsided gradually, to appear on the right side some weeks later. The appearance of the last tumor was sudden and was accompanied by the same symptoms as the first. The patient was kept quiet in bed for some weeks, and was discharged July 11, 1892.⁴ In another case of suspected extra-uterine pregnancy I found the whole abdomen filled with a tumor evidently containing blood. The patient was improving at the time that I first examined her, and no surgical operation was performed. She made a perfectly good recovery.

Among the remotely possible sources of suddenly appearing pelvic tumors are the distended gall blad-

der and the intermittent hydronephrosis. A consideration of the distended gall bladder seems hardly appropriate, because it is impossible for a gall bladder, from its very nature, to acquire in a few hours such dimensions as to encroach upon the pelvis. In all the tumors of the gall bladder that I have seen the largest has been due to a chronic obstruction of the common duct, from cancer of the pancreas. I have reported one case in which the tumor came down to the brim of the pelvis. This was not, however, a suddenly appearing tumor; on the contrary, it was a tumor of very gradual development. It was recognized at the very beginning. As I have already stated, the gall bladder, from its very situation and structure, is an organ that does not permit of the excessive dilatation necessary to reach the pelvis. It is somewhat different in another class of tumors—the sudden dilatation of the pelvis of the kidney. I have seen and reported a case of intermittent hydronephrosis in which a tumor filled the right hypochondrium. Such a tumor, though impossible of detection one day, and bulging the abdominal wall the next, occupies a place in the abdomen far removed from the pelvis. It is conceivable, however, that the kidney may be displaced, and give rise to a suddenly appearing tumor, either at the brim of the pelvis or in the pelvis itself. The intermittent hydronephrosis is in itself a rare tumor. It would be almost inconceivable to have a tumor displaced in the pelvis, and at the same time the seat of this unusual condition. In a differential diagnosis the dilated gall bladder and the intermittent hydronephrosis may be eliminated from their very rarity. On the other hand, the acute dilatation of the stomach cannot, for this lesion is certainly more common than either acute dilatation of the gall bladder or acute dilatation of the pelvis of the kidney. Moreover, the stomach, being a large and distensible organ, may easily be sagged into the regions of the ovarian tumor and of the extra-uterine pregnancy. Indeed, I have been struck by the frequency with which the stomach appears below the umbilicus in the median incision. It is a very common occurrence. Such a stomach, even with the patient in the Trendelenburg position, appears below the umbilicus. When distended in the horizontal position, or in the erect position, it is easy to see how such a stomach might cause an obscure tumor. I have seen several instances in which the dilated stomach has shown itself low down in the left side of the abdomen. In these cases the stricture of the pylorus and the dilatation or sagging were so gradual that there was no difficulty whatever in the diagnosis. These tumors could hardly be called either suddenly appearing or obscure tumors, for they appeared gradually and were not obscure.

The foregoing consideration, then, applies chiefly to the sudden dilatation of a flaccid ovarian cyst, either by hemorrhage from its walls or by an obstruction to the venous return from a twisting of its pedicle. It applies to the sudden enlargements of the chronic dilatations of the sigmoid flexure; to the sudden appearance of encysted peritonitis, accompanying salpingitis or other inflammatory conditions of the pelvis, and finally to the large collection of blood due usually to the rupture of an extra-uterine pregnancy. In all these lesions the importance of their recognition is obvious. The diagnosis of these suddenly appearing tumors is a matter of great interest and importance, for upon a clear recognition of the necessity of surgi-

⁴ *Annals of Surgery*, December, 1894.

cal intervention depends in many instances the life of the patient. A clear recognition of the nature of the lesion will prevent also the danger of an unnecessary, not to say a meddling, operation.

From the cases already detailed it appears that, in my experience at least, an exact diagnosis is often impossible. It appears clear, however, that a lesion essentially fatal, if unrelieved, presents symptoms so suggestive as to form a conspicuous guide to the surgeon's hand; symptoms that lead him to the sure relief of the tumor with twisted pedicle or the hematomata of ectopic gestation, but which also call him to stay his hand in the sudden and painless tumors of the overdistended bladder.

In most of the tumors under consideration pain is the first, the most important and enduring symptom. Pain alone demands careful examination of the pelvic viscera. Discomfort in the lower abdomen, if not amounting to real pain, may reveal on examination a pelvic tumor the nature of which will become clear only upon the appearance of other symptoms and signs.

The great emergencies of pelvic surgery attended by the sudden appearance of tumors are ovarian torsion and extra-uterine pregnancy. In rare instances, perhaps, the perforation of an appendix may give rise to a tumor of considerable dimension. Appendicitis and salpingitis, too, might be included in the present consideration. Both these diseases, however, present such definite histories and such definite physical signs — physical signs so definitely follow the initial pain — that the tumor so invariably associated with them can hardly be called obscure or unsuspected. A consideration of these common lesions is therefore beyond the scope of this communication. The tumors of an ectopic gestation, on the other hand, may attain in a few hours a size that is extraordinary, so also may the tumor of an ovarian torsion, a dilated and obstructed sigmoid flexure, a suddenly distended ovarian cyst, an acute dilatation of the stomach, and a full bladder.

The mistake of opening a full bladder by laparotomy is so inexcusable that I may be pardoned for saying a few words upon the diagnosis of a full bladder. It cannot do harm to repeat that the full bladder often causes grave mistakes, no matter how experienced the diagnostician. Presenting, as it does, a smooth, symmetrical, fluctuating tumor, who is to be blamed for thinking it a simple ovarian cyst, especially if there have been no urinary symptoms whatever, no pain, no overflow, but on the contrary natural and easy micturition at the usual interval? He would be inexcusable perhaps who should open a bladder when urinary discomfort and dribbling of urine pointed clearly to the bladder in a state of overdistention, though I have been called to operate upon many such tumors, the nature of which was conspicuous. But should he be blamed for exploring such a tumor in the total absence of urinary symptoms? I think he should be, when by the use of the catheter a sure means of diagnosis is at hand. The catheter, therefore, should be used in all fluctuating tumors of the lower abdomen as a means of eliminative diagnosis. As a matter of routine the catheter should be used just before laparotomy.

The diagnosis of an acute dilatation of the stomach may be said to be impossible; a correct one in the case mentioned would have been mere guess work.

Even in the light of exploration it is difficult to see what the symptoms meant. In a second case precisely like the first I should feel quite as much in the dark. Those who were familiar with this case would probably suggest the possibility of a dilated stomach. They would use the stomach tube as a means of diagnosis. As the catheter will solve the question of the full bladder, so will the stomach tube that of a dilated stomach. Yet it would seem absurd to say that the stomach tube should be passed in all fluctuating tumors of the lower abdomen. Indeed it is absurd unless the stomach is in some way suggested as the possible cause of the tumor.

The large bulging tumor of the dilated colon, with or without symptoms of intestinal obstruction, gives signs which I am sure will hereafter suggest to me the true lesion. If the tumor subsides under anesthesia, if it is tympanitic, resistant and tender, if it is rounded and symmetrical, if the obstruction is acute, and if there has been no gradual cachexia, the dilated colon is strongly indicated. The suddenness of the appearance of the tumor and of the symptoms rules out the dilated coils of a chronic obstruction, such, for instance, as are due to cancerous stricture.

The diagnosis of extra-uterine pregnancy is usually easy. Pain in the course of irregular menstruation, with dribbling of blood from the uterus, always suggests it. With the sign of hemorrhage the diagnosis is almost sure. With any other confirmatory signs of pregnancy it is about certain. Most cases of extra-uterine pregnancy are unaccompanied by any tumor of considerable size. The tumor, if any is found, is small. It is often buried up in the free blood of the pelvic cavity. Even if a tumor is felt it may not be that of the fetal sac. Recently a friend and gynecologist sent me at the Massachusetts General Hospital a patient with extra-uterine pregnancy, in whom under ether he found the fetal tumor on the right side, where under ether I also found it. The exploration showed a tubal pregnancy too small for bimanual palpation, on the left side.

There are, however, tumors connected with extra-uterine pregnancy and hemorrhage, and of very considerable size, as I have already stated. Those found in the case of an extra-uterine pregnancy are preceded by pain, and accompanied by the usual signs of pregnancy. They are collections of blood in the layers of the broad ligament, or encapsulated in the pelvis.

The diagnosis of ovarian tumor with twisted pedicle is easy when a tumor is known to exist. Where one has not been found previously it is very difficult. It depends upon sudden pain, with or without signs of hemorrhage. The tumor is elastic and tender. The signs of strangulation, gangrene, peritonitis, are often obvious. The diagnosis of ovarian tumor with twisted pedicle must always be suggested by these symptoms.

In spite of difficulties of diagnosis the signs point the right way — towards surgical intervention. It matters little whether the diagnosis of extra-uterine pregnancy is wrong if the surgeon is guided to the relief of an ovarian torsion, or if, expecting a torsion, he finds an extra-uterine hemorrhage; or if, expecting an ovarian tumor, he finds a dilated stomach; or if, expecting an internal strangulation or an intestinal obstruction, he finds a dilated and twisted sigmoid flexure. It does matter, however, if, expecting to find a serious lesion, he finds a full bladder, or if, ex-

pecting an ovarian torsion, he finds a normal pregnancy.

Fortunately the call for relief is a loud one in the serious lesion; the surgeon makes few mistakes who quickly responds. It is not a loud cry in trivial cases; it is a suggestion for careful study, or even for prolonged observation, under which the true nature of the phenomena can be accurately determined.

In summing up the matter of these acute abdominal emergencies which constitute the greater portion of obscure and suddenly appearing tumors, I am led to remark that here, as in all medical and surgical practice, the chief aim should be to view the whole with common sense; to consider carefully the history, to weigh carefully the symptoms, to apply all reasonable methods of examination, and finally if it is determined that intervention is necessary, to proceed to operation without unnecessary delay.

In all suddenly appearing tumors of the lower abdomen, however obscure they may be, intervention is demanded if the symptoms are the least urgent. A tumor that has attributes of sudden formation, of tenderness, of hemorrhage, of profound constitutional disturbance, demands immediate intervention. Tumors, however, which do not possess the attributes of urgency may be watched, especially if the local symptoms are subsiding, and if the patient's strength is returning. From their very nature, however, they all require surgical intervention sooner or later.

A CASE OF INFLAMED PERITONEAL CYST SIMULATING OVARIAN CYST WITH TWISTED PEDICLE.¹

BY AGNES C. VIETOR, M.D., BOSTON,
Assistant Surgeon, New England Hospital.

Mrs. A., thirty-six years old; mother of two children, youngest seven years old. Family history negative. Personal history negative, except that menstruation has not been perfectly regular as to time; occasionally the intervals between periods would be prolonged, varying from five weeks to six or eight months. Patient, then, was subjectively a well woman till seven years ago, ten weeks after the birth of her last baby, when she had an attack of what was called peritonitis, which attack was ascribed to mental anxiety and catching cold. Ever since this illness she has been compelled to be careful not to get overtired, overdoing being always followed by discomfort in both iliac regions, lasting from a few hours to several days, and relieved by rest. Four months after this initial illness, she miscarried spontaneously at three months, convalescing without complication. About this time she is said to have contracted malaria. Three years later she had an attack, diagnosed as appendicitis, from which she recovered, but which left her with an occasional feeling of discomfort in the right side of the abdomen.

Patient came under my care in January of the present year. She gave a history of overexertion all the month of December, preparing for the holidays. The exertion brought on the usual pain, which increased in severity, as she did not rest. She menstruated the last week in December, the period being unusually painful. When I saw her,

the first week in January, the flow had ceased for several days, but the pain continued in both inguinal regions, in the back and extending down the backs of the thighs; she also complained of headache and great nervousness. She refused to let me make any examination, and insisted that all she needed was rest and a little medicine for "rheumatism in the back." I prescribed for her and directed her to go to bed. She did not go to bed, but rested a little more than usual and felt better. Four days later she saw me again, and reported that she was better except for frontal and occipital headache, that she was very weak and that her "malaria" was troubling her again, as the night before she had an attack of vertigo with palpitation, followed by prolonged chilliness and cold sweat.

Upon my declining to assume further responsibility for her case without a thorough examination, she finally consented to let me examine her, and I found the following condition: Temperature 101.3°, pulse 80, respiration 22. Heart, lungs, liver and spleen negative. Urine contained large amount of albumin. Vaginal examination showed that the uterus was slightly enlarged, anteflexed, tender and rather soft. The right broad ligament was resistant, swollen, and contained irregular masses, but was too sensitive to permit the appendages to be distinctly outlined. The left pelvis was filled with an elastic, tender cystic tumor extending up into the abdomen, midway between the symphysis and umbilicus, and from near the median line to about midway to the anterior superior spine of the ilium. Behind and below this tumor, near the cul-de-sac, was a small, irregular, firm, exceedingly tender mass. A diagnosis of acute exacerbation of a chronic salpingitis, with possible presence of pus, and probable left ovarian cyst, was made.

The patient was warned of the seriousness of her condition, but she still resisted going to bed. During the night she had a repetition of the chill and sweat. The next morning she had a chill lasting two and a half hours; I saw her just as the chill was subsiding and found her face flushed, conjunctivæ injected and an icteric tinge of the skin. Temperature 103.3°, pulse 92, respiration 20. Examination showed no change in the findings of the day before, but the patient looked much more ill. In the evening I was sent for in haste, and found intense abdominal pain over the region of the tumor; the abdomen was tympanitic and markedly sensitive, and there was some rigidity of the walls. The patient had been delirious at times the past few hours, and was vomiting at intervals. Temperature 104.8°, pulse 96, respiration 24. I made a diagnosis then of pyosalpinx with probable twisted pedicle of the cyst (ovarian?), and urged celiotomy.

The next morning I hastily curetted the uterus, hoping to leave that organ, and then performed celiotomy. On opening the abdomen and detaching the adherent omentum, there was escape of a small quantity of bloody serum. After walling back the intestines with gauze, the pelvis was seen as follows: Uterus in position, slightly enlarged, especially longitudinally, fundus forward. To the left of the uterus was a tumor which nearly filled the left pelvis and projected upward, into the abdominal cavity; its walls appeared roughened, dark red in color and had enlarged veins running over the surface. The left tube, slightly enlarged, was seen to be stretched out over

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 7, 1900.

the upper anterior surface of the tumor. This tumor seemed everywhere adherent, except on its upper surface. In separating the adhesions at the bottom of the pelvis, the tumor was ruptured, giving exit to a serous fluid. It then became exceedingly difficult to follow, but finally a pedicle was formed for the removal of the remains of it and the left tube. The left ovary was found below and behind the tumor, as palpated from the vagina, and was largely converted into a series of hematomata. It could not be entirely enucleated from its bed of adhesions without dangerous delay, and a small, apparently healthy portion was left in the stump.

On the right side the appendages were completely hidden in a mass of dense exudate, to which the intestine and the tip of the appendix were closely adherent. The appendix was separated, and being found otherwise normal, the raw surface was closed in by peritoneum with a catgut suture. The intestine was then separated, but in one place the adhesions were so dense that in separating them the wall was damaged. This was repaired by a Lembert suture. At the point of this adhesion was a small cyst, 2 by 3 centimetres, filled with a serous fluid, that at first seemed to be the occluded and dilated extremity of the right tube. Further dissection, however, showed that it was a peritoneal cyst. With great difficulty, the right tube was found buried in the dense exudate, was enucleated and removed. It contained about 2 drachms of pus. The right ovary was buried still deeper in the pelvis and could not be entirely brought up. It was almost impossible to make a pedicle for these appendages, but eventually we succeeded in making rather a broad one. Except for the exudate burying it, the right ovary was apparently healthy and a small portion of it was left in the right stump. The peritoneal cavity was washed out with normal salt solution, a portion of which was allowed to remain, and the abdomen was closed.

While all the acute local symptoms were referred to the region of the tumor on the left side, you will see by the temperature chart that the constitutional reaction was due in large part to the condition on the right side, as the temperature and pulse subsided only gradually, though steadily, seemingly with the absorption of the exudate. The vomiting, delirium, chills, sweats and all abdominal symptoms ceased with the operation. Except for the nephritis which continued for over six weeks to give albumin in the urine, the convalescence was uninterrupted.

The specimens which I show do not convey an adequate impression of the pathological condition, except to one who has seen similar cases. The tumor, as you will see, is represented here only by those shreds of membrane, the greater part of it remaining firmly adherent to the tissues of the left pelvis. Dr. W. F. Whitney kindly examined the specimens for me, and pronounced the tumor a peritoneal cyst. It was the outcome, no doubt, of the repeated attacks of peritonitis from which the patient had suffered during the past seven years. The roughened and congested surface of the cyst where it rose into the abdominal cavity showed an acute inflammation of this portion of the cyst wall. I have mentioned a smaller, similar cyst on the right side, but the characteristic of the right side was the dense exudate which hid and blanketed the appendages. This exudate varied from 1 to 2 centimetres in thick-

ness, it was freely supplied with blood vessels, and made the dissection of the tube and ovary very difficult. The operation was so lengthened by these complications, and the patient's condition was so precarious, that, as the appendix appeared normal, it seemed the less of two evils to free it and leave it rather than risk even the few minutes necessary to remove or invert it.

NOTE. — The post-operative history of this patient is interesting. During convalescence she had several nervous paroxysms of an emotional type, the most marked being during the week when menstruation was due, though it did not appear. After returning to her home she improved for a few weeks and felt at last she was a well woman. Naturally, she was tempted to overdo, and one day after a five-mile walk she began to feel not so well; she had occasional discomfort in the region of the right stump, she grew "nervous," mentally depressed and "tired," suffered from insomnia and began to lose flesh and strength. She did not improve greatly under treatment and I advised change of scene. She returned home in a fortnight much worse, the picture of acute melancholia with suicidal tendencies. I then had her remain in town and gave her positive suggestion every other day, inducing a light hypnosis. She improved steadily under this treatment, the insomnia disappearing after the first séance. After ten days I again sent her out of town, giving her the suggestion in writing, to use as needed. Her improvement was steady and at the present writing she is perfectly well and the picture of health.

SERUM THERAPY IN PNEUMONIA.¹

BY WILLIAM H. SMITH, M.D., BOSTON.

In 1892 Friedländer discovered in a case of croupous pneumonia a capsule bacillus, which he considered to be the etiological factor in the production of this disease. In 1883 Talamon found in a consolidated lung a diplococcus, which he called the pneumococcus; but it was not until 1886 that Fraenkel isolated the pneumococcus from a sufficient number of cases of acute croupous pneumonia to show that it had an etiological bearing in the production of this disease. He was able to cultivate the organism and to study its methods of growth and its characteristics. Since this time numerous investigators have confirmed the observation of Fraenkel — Netter, Weichselbaum, and more recently, Pearce at the Boston City Hospital, and Wright at the Massachusetts General Hospital, and from the data gathered it may be said that the etiological factor in the production of acute lobar pneumonia, in from 90 to 95% of the cases, is the pneumococcus. The organisms which take part in the production of broncho and lobular pneumonia are more varied, and today it is well recognized that any of the following organisms may produce a lobular or broncho pneumonia: the tubercle bacillus, the diphtheria bacillus, the bacillus mucosa capsulatus, the bacillus of bubonic plague, and the influenza bacillus, or the various forms of cocci — streptococcus pyogenes, staphylococcus pyogenes, and the pneumococcus. One case is recorded where sarcinae seemed to be the original invaders.

If, however, we eliminate the lobular or broncho pneumonias occurring in the course of the acute infectious diseases, and those secondary to an inflammatory process elsewhere, in a majority of cases the organism found, either alone or in association with other organisms, is the pneumococcus.

Since, therefore, in 90% to 95% of all cases of acute croupous pneumonia, and in a large number of the uncomplicated broncho or lobular pneumonias, the

¹ Read before the Massachusetts Medical Society, June 12, 1900, and recommended for publication by the society.

etiological factor is the pneumococcus, we shall, in our discussion of the serum therapy in pneumonia, limit ourselves to the antipneumococcus serum. As soon as Fraenkel's work upon the pneumococcus became recognized, and the methods of isolation and cultivation of this organism became known, investigation by means of animal inoculation became rife. As early as 1886 Fraenkel observed that rabbits inoculated with attenuated cultures of the pneumococcus withstood an otherwise fatal dose.

In pursuance of their investigations these observers used practically everything containing pneumococci. Attenuated cultures, glycerin extract of agar cultures heated to 60°, heated bouillon cultures, filtrates and precipitates from cultures, dried organs of animals dying from pneumococcus infection, were used in these investigations, or infusions of the same in sterile water. Sputum, collected at the time of the crisis in cases of pneumonia, either fresh or after heating, was employed in these experiments; while the pleural exudate following croupous pneumonia was also used.

The results obtained from this line of investigation seemed to show that certain animals could, by the injection of pneumococcus cultures or exudates or secretions containing pneumococci, be rendered immune for a longer or a shorter time to an otherwise fatal dose of the pneumococcus. After this artificial immunity had been discovered, the next line of investigation was to determine if the serum of the immune animals was protective when inoculated into another animal, and, according to Mennes, Foa and Carbone were the first to establish the fact that a mouse remained alive after inoculation with 2 to 4 drops of blood from an immune rabbit when this was followed by a fatal dose of pneumococcus culture. This is the first experiment in serum therapy against the pneumococcus.

It remained for Emmerich and Fowitsky to show that the mouse remained alive if the immune serum was injected after the pneumococcus culture—a fact also proved by the Klemperers.

The etiological factor in the production of pneumonia having been found, the fact that animals could be rendered immune for a longer or shorter time having been shown, and the immunizing property of such sera demonstrated when further inoculated into animals, it remained to discover the practical application of these facts.

At varying intervals there have been reported cases of pneumonia treated by the antipneumococcus serum. The Klemperers treated by subcutaneous injection a series of cases with apparent benefit, as shown by fall of temperature, slowing of pulse and respiration.

Lara reported the results in 10 cases of pneumonia, the sera used being obtained from immunized dogs, rabbits, or glycerin extracts of organs of refractory animals. He considered the results encouraging.

In Naples in 1897, Professor Pane reported that he had obtained antipneumococcus serum from a donkey and a cow that he had successfully used in treating a number of cases of pneumonia—23 cases in all, with 2 deaths.

In 1898, before the Italian Medical Congress in Turin, Massalongo and Francheni reported upon Pane's antipneumococcus serum. They had used his serum in 10 cases of the most severe type on alcoholic subjects with weak hearts and nephritis. They con-

cluded that better results in this class of cases were obtained than if treated by the ordinary method.

De Renzi reported on a series of 10 cases in 1898 treated by antipneumococcus serum. Severe cases were selected for the treatment. A cure resulted in every case.

Wiesbecker reported 5 cases treated by serum obtained from human subjects recovering from pneumonia. All 5 recovered, and there seemed to be a diminution of the subjective symptoms. The serum from blisters from pneumonia patients has also been used, but with little effect. Most recently Washbourne has succeeded in producing immunity in a pony after nine months' treatment with living and dead cultures, and has obtained a serum which seems to have powerful immunizing properties. The difficulty which all investigators had experienced up to this time was in their inability to keep the pneumococcus culture which they were using virulent. Washbourne applied the method of Pfeiffer of streaking agar cultures with sterile blood of rabbits and by this means and keeping the blood at a temperature of 37.5° C. it was found possible to maintain the virulence of the pneumococcus at a given level for a period of sixty days. The minimum fatal dose of the culture used by Washbourne was .000001 of a loop which held 5 milligrammes. The serum was mixed in varying amounts with a tenfold fatal dose of the culture and the mixture injected into the peritoneal cavity of rabbits, control experiments always being made with a minimum fatal dose. The smallest quantity of serum which would protect the animal under these conditions he considered equal to a unit. The strongest serum yet obtained from his pony, equal to .03 cubic centimetres, protected against a tenfold fatal dose; a cubic centimetre, therefore, equals 33 units. Sera from normal rabbits and guinea pigs would protect against the minimum fatal dose, but not against a tenfold fatal dose. Washbourne treated 6 cases and had no deaths. He considered that the serum should be inoculated as early as possible and at least 600 units should be injected twice a day.

Spurrel, Hartnett and Cook have reported cases treated by Washbourne's serum. Mennes has recently succeeded in obtaining a powerful immunizing serum from a horse. Neither Mennes nor Washbourne, however, wish to state positively that their serum is of value without further investigation. Certain subjective disturbances have been reported following these injections of the serum, such as excitement following the use of dog serum, agitation following the use of rabbit serum, and urticarial rash.

As the question stands today, it may be stated that, experimentally, animals may be rendered immune, that their sera has protective property, and that continued investigation is doing away with some of the difficulties which previously harassed the early investigators. But the fact still remains that in dealing with the pneumococcus we are dealing with an organism capable of many variations and degrees of virulence, and that the sera obtained under such conditions must of necessity vary both in strength and character. Washbourne's method of cultivation seems to be a distinct advance, inasmuch as he maintains life and virulence in the culture over a longer period than have other observers. His investigations are recent, and it is too early to state what the result will be. Experimentally, antipneumococcus serum seems to be of value. Practically, that it is of any great

value does not at present seem to have been demonstrated, as the reported number of cases are too few; the series of any one observer too small. What the future of the serum therapy in pneumonia will be it is too early to say.

Clinical Department.

CASE OF PATENT FORAMEN OVALE IN ADVANCED LIFE.

BY WILLIAM L. WORCESTER, M.D.,

Assistant Physician and Pathologist, Danvers Insane Hospital.

ABRAHAM H., apparently a full-blooded negro, said to be fifty-seven years of age, was admitted to the hospital, February 25, 1898, suffering from general paralysis. In the notes of the physical examination, made at the time of admission, the following statement is made as to the condition of the heart: "Apex beat in sixth interspace, under nipple; no heart sounds heard; a long, loud murmur, systolic in time, can be distinctly made out at apex." During the patient's stay in the hospital, no indications of embarrassed circulation were noticed. On account of the color of his skin it is perhaps likely that cyanosis, if it had existed, might have passed unobserved. He died May 13, 1900, of exhaustion from a series of convulsions.

a. Foramen ovale. b. Communication between ventricles.

At the autopsy the heart was found to be moderately hypertrophied, weighing 375 grammes; the cavities, especially the right ventricle, were dilated. The valves were healthy. The foramen ovale was present, measuring $2\frac{1}{2}$ by 2 centimetres in diameter. It was divided into two unequal parts by a small tendinous cord. Immediately under the right aortic semilunar valve was an opening forming a communication between the ventricles. On the side of the left ventricle it was about 1 centimetre in its longest diameter; on the side of the right ventricle, not more than 2 millimetres in diameter. So far as could be judged from appearances, this was probably a congenital defect.

The patient was a pensioner on account of disability alleged to have been contracted during the Civil

War. This, as well as his advanced age, seemed of interest in view of the condition of his heart. I accordingly made inquiry at the Pension Office in regard to his military and medical history, and also of his mother, who is still living, as to his health in early life. His mother, in reply, denied that he had ever suffered from shortness of breath in childhood, and said he always had good health until he went into the army. A communication from the Pension Office states that "the records show that the soldier enlisted February 28, 1865, and was discharged on surgeon's certificate of disability March 31, 1866. On muster rolls to August 31, 1865, he is reported present; September and October absent without leave; from October 31, 1865, to February 28, 1866, present. The certificate of disability is not on file, but the records of the regiment show treatment in the regimental hospital for valvular disease of the heart at various dates from November 3, 1865, to April 15, 1866. The first medical examination held in the case was made December 7, 1887, but the condition of the heart was not reported until his second examination, August 6, 1890, when the board described a pronounced and remarkably distinct musical mitral systolic murmur heard over the entire left chest, the location of the organ being normal."

It is hardly probable that the examination at the time of enlistment was very rigorous, but it seems rather singular that such a disability should not have been discovered on the most superficial investigation, and still more so that the patient should have lived to be fifty-nine years of age without any striking cardiac symptoms, dying at last of a disease entirely independent of his malformation.

Both of the abnormal openings can be seen in the above photograph.

Medical Progress.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., AND WM. DUDLEY HALL, M.D., BOSTON.

ORBITAL COMPLICATIONS OF EMPYEMA OF THE ETHMOID CELLS.

VIEUSSE,¹ in these numbers, gives a very complete account of the subject. The first article contains a very good description of the anatomy of the ethmoidal labyrinth followed by a clinical history of 14 cases. In the second article the symptoms are taken up in detail. It is more than probable that the starting point lies in the os planum of the ethmoid rather than by infection through the agency of the veins. As the orbit becomes invaded by products of inflammation we notice swelling of the lids, exophthalmus and a tumor at the inner angle of the eye. This latter varies in size from a small pea to even a hazel nut, may be round or diffuse, firm or fluctuating and painless. Pressure may cause a flow from the nostril and there may be a sense of crepitation. Proptosis may be slight, the deviation down and out with but little impairment of motion. The edema may be limited or diffuse, and there may or may not be diplopia. The fundus changes suggest a mild neuritis and the vision may fall to .2 if there is pressure on the nerve. The third article discusses the etiology, and has spe-

¹ *Rec. d'ophtal.*, March, April, May, 1899.

cial bearing upon the various forms of rhinitis, although, of course, it may be the sequel of almost any general infectious disease. At a late period of the disease extension is apt to take place from one to another of the various sinuses, but at the earlier stages a differentiation is easier. To discriminate between frontal and ethmoidal disease is difficult at any stage. Localization of pain and tenderness over the frontal is suggestive. A projection of the bony wall in the orbit suggests disease of the ethmoid rather than frontal. Symptoms due to compression of the eyeball are the same in both cases. Pus in the middle meatus may come from either the maxillary, frontal or anterior ethmoidal cells; pus in the superior meatus from the posterior ethmoidal or sphenoidal sinuses. To diagnose between the former, catheterization of the frontal and puncture of the maxillary may be employed. In each case if pus immediately appears after irrigation it probably comes from the ethmoid. Transillumination may show the ethmoidal cells of one side to be more opaque than those of the other side. By ausculting the frontal sinus, expiratory râles may be determined. Frequently differential diagnosis is merely a matter of conjecture. The early occurrence of compression of the optic nerve would favor disease of the posterior ethmoidal rather than of the sphenoidal. With care there is little danger of mistaking it for dacryocystitis. Malignant growths and osteomata, though rare, must be thought of. Drain through the nose, orbit or both ways. The incision may be along the upper, the internal, or the internal and inferior margins of the orbit. Gruening's operation is as follows: Incision along the internal margin of the orbit to the periosteum. Strip up the periosteum internal to the lachrymal sac. Divide the attachment of Horner's muscle, laying bare the os planum. Press the orbital contents to the outside with spatula. Curette the os planum. Introduce a drainage tube from the orbit into the nose and suture in the incision.

THE ORDER OF DEVELOPMENT OF COLOR PERCEPTION AND OF COLOR DEVELOPMENT IN THE CHILD.

W. A. Holden² believes that the order of development of perception, and the order of attractiveness of colors in the young infant, in whom the order of selection is almost instinctive or physiological rather than the result of training or reflection, support by analogy singularly well the Gladstone theory of the development of color perception in the human race, so that this theory may have a certain value as a general evolutionary theory, although we must go down much lower in the mammalian scale than to primitive man to find the beginning of color perception. What are the functions of the various colors in nature, and why does the child react to colors differently at different ages? The predominating nature colors are the blues and greens and the yellows and reds; the complementary colors to these background colors serve to call attention to particular objects, as, for example, fruits and flowers, and may be called accent colors. The colors of the red end of the spectrum are exciting or irritating when presented in large masses, whereas the greens and blues are more restful. The young infant responds to the exciting colors, choosing instinctively those of the red end instead

of the blue. As the psychological development proceeds, and the child becomes more distinguished from the animal, and mental processes dominate the earlier more physiological reactions, we find, first, an indifference to all colors and a little later a dislike for the more exciting reds and yellows, and a preference for the blue end of the spectrum. This typical change takes place in the order of attractiveness as the child grows older, and occurs without respect to environment or training. In a certain number of children the change from red to blue preference is not so direct, and after a period of greatest indifference to all colors, at the age of two or three, there is for a time a modified indifference in which one or more of the middle and most luminous colors — orange, yellow and green — is preferred. At the age of eight, blue or violet preference is almost universal, but red has begun to advance from the lower end of the scale. Adults prefer end colors, while they dislike the middle colors.

TREATMENT OF DETACHMENT OF THE RETINA.

In 1895 R. Deutschmann³ published the result of his operative method of treatment of 16 cases of detached retina, and since that time he has continued these operations subject to some modifications, and now has completed the treatment of 101 cases. A full account of all these cases, some of which have been under observation for more than five years, is now given, and they form a collection of clinical histories worthy of careful study. He now transfixes the eye far back with a two-edged knife, entering at the outer and lower part of the sclera, passing across to the corresponding point on the inner side the counterpuncture, involving all the coats except the conjunctiva. On withdrawal, the blade makes a slight curve towards the centre of the eye, thus perforating the retina in two places, and allowing two openings for the escape of preretinal and subretinal fluid. He no longer thrusts about in the hope of cutting real or imaginary bands. Rabbits' vitreous is next injected into the vitreous by means of a combination of a knife and canula. Young rabbits' vitreous is stirred up in a neutral salt solution under antiseptic precautions, and allowed to settle; it is then injected and is, Deutschmann believes, a very important addition to his method of treatment. He reserves the injection for those cases not benefited by the double puncture operation. Of the 101 cases he claims to have "cured" 26, and to have more or less benefited 34. Of the remaining 41 he considers that 7 were at first greatly improved but afterwards relapsed, while 34 either showed no improvement, or, for various reasons, were unsuitable for or did not remain long enough under treatment. This percentage is much better, in his opinion, than that obtained by rest or by simple puncture. The best results were in cases of traumatic origin or in young persons.

SUCCESSFUL TRANSPLANTATION OF THE CORNEA AND SCLERA IN AN EYE WHICH WAS BLIND FROM PHTHISIS OF THE CORNEA.⁴

Wolffberg⁴ cites this case: The patient, female, lost the right eye from an injury in childhood, and lately injured the other by a blow causing dislocation of the lens, cataract and iridocyclitis. The cornea

³ Beitr. z. Augenheilk., xl, 1899.

⁴ Woch. f. Ther. u. Hyg. d. Auges, August 24, 1899.

² Archives of Ophthalmology, May, 1900.

became atrophied, and after the extraction only light perception remained. The eye of a sparrow was bisected and the part in front of the iris was used. As it seemed irrational to the operator to bring the anemic sclera in contact with the anemic anterior portion of the blind eye, an artificial hyperemia was induced by undermining the conjunctiva around the cornea, then passing a thread after the manner of a purse string along the border of the opening, and by its closure covering the atropied cornea by some chemotic vascular conjunctiva. On the next day the cornea of the blind eye was trepanned ($3\frac{1}{2}$ millimetres) through its entire thickness without escape of vitreous. The sparrow's cornea, with its scleral border, was then introduced and the border well tucked under the overlapping conjunctiva. Almost no reaction; sutures were removed at the end of five days. The transplanted sclera soon lost its opaqueness, and soon became as transparent as the cornea. The patient can now, at the end of a month, go about a well-lighted room unattended.

IRIDECTOMY IN GLAUCOMA SIMPLEX.

True and Chauvin⁵ give results obtained in 14 cases of simple glaucoma, which have been under observation for from six months to five years and a half after the iridectomy. They consider this operation and anterior sclerotomy only as worthy of retention, giving their preference in favor of iridectomy. They believe in an early operation, although the process may have been without pain and the vision good. Full recognition is given of the difficulty of making a diagnosis between a simple glaucoma and optic atrophy, with excavation when there is no rise in tension. If after use of myotics there is an increase in the vision and an enlargement of the field, benefit by making an iridectomy may be hoped for. Chronic glaucoma is so apt to be bilateral that the field of the apparently sound eye should always be examined, and if there is shown to exist a characteristic loss, an operation should be undertaken, even though the central vision should be perfect. Although this procedure is not infallible, it may be safely said that no other method promises so well.

(To be continued.)

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

F. G. BALCH, M.D., SECRETARY.

REGULAR meeting, Wednesday, March 7, 1900, DR. J. W. ELLIOT in the chair.

DR. J. C. MUNRO presented a

PATIENT AFTER THORACOPLASTY FOR SARCOMA, PROBABLY OF THE DIAPHRAGMATIC PLEURA.

About eight months before operation the patient was on the medical side of the City Hospital; considerable bloody serum was aspirated from his right chest and he was discharged relieved. He re-entered in November, and Dr. F. H. Williams made a definite diagnosis of tumor by x-ray examination. Under ether a large part of the third to the seventh ribs, in-

clusive, was resected, and a mass covering the diaphragm and pushing the lung up to level of second rib was removed. Owing to severe shock a small nodule was left on the diaphragm behind the costal cartilages. A few weeks later a second operation was done, the growth having increased rapidly, pushing up alongside the spine and into the posterior angle of the ribs. All of the growth could be removed except a nodule which lay so far posteriorly that it could not be safely reached without making an opening through the posterior wall. Practically no shock followed this operation. Recurrence has of course taken place, and the patient is practically in the same condition as in November last. He is to start on Coley's treatment at once.

DR. ELLIOT: In this connection I would like to mention a case I had the other day where I removed a large part of the chest wall and a part of the lung on the left side for a sarcoma which extended from the sternum in front round under the scapula in the back. The patient, a man of thirty-three years, had noticed a growing tumor on his left chest for a year. I turned up a large flap of skin and muscle from the front of the chest and removed the tumor with nearly the whole of the second, third and fourth ribs. The tumor was found to have extended through the chest wall and to have invaded the lung, so that it was necessary to remove a large surface from the lung. The lung wound was clamped and stitched. The lung did not collapse owing to adhesions and to traction with my clamps. The patient suffered severe shock from the operation, and in spite of transfusion died on the second day.

DR. MUNRO also presented a

PATIENT AFTER PYLOROPLASTY.

Trouble began about three years ago with tenderness in the epigastrium when the patient twisted his body in certain directions; two and a half years ago he complained of distress without sharp pain or vomiting of blood or anything pointing to ulcer of the stomach. He had a specific history. Vomiting and emaciation increased, and after treatment at various hospitals he finally came to the City Hospital. Was in the hospital on the medical side three months, and while there very careful examinations were made of his stomach contents by Drs. Sears, Smithwick, and others, and finally brought to me for operation. He was then a skeleton. At the time of operation there was a large residue in the stomach with very much lactic acid and no hydrochloric acid. At the operation I found simply a constricted pylorus, the lumen admitting only a director. I performed the ordinary pyloroplastic operation, which was in November. Since then he has gained 80 pounds and is now all right. Dr. Smithwick has examined his stomach within a day or two and reports no residue, no fermentation, and the stomach is practically normal. For a while after operation there was considerable residue with fermentation, and Dr. Sears felt discouraged, fearing that there would have to be another operation. I think it was simply overcoming a habit that had existed for a number of years. The hydrochloric acid has not reappeared, but probably will in time.

DR. RICHARDSON: I have found that after linear pyloroplasty the lumen is not always satisfactory. Some months ago I published in a paper on this sub-

⁵ Arch. d'ophthal., January, 1900.

ject the results in a few cases. If I were going to operate again for stricture with thickening of the whole pylorus, I should make a partial V-shaped resection instead of a linear incision. There is no special advantage in the straight line, and closure is often difficult. The tissues are frequently thickened and lack the pliability necessary for a satisfactory operation; yet, as time goes on, the cicatrix becomes softened and the tissues thinned, so that the new opening is sufficient. In many cases, nevertheless, I feel sure that a more or less complete resection of the cicatrized pylorus will give better results than the conversion by suture of a longitudinal cut into a transverse one.

DR. ELLIOT: What was the narrowing due to?

DR. MUNRO: There was a specific history. There may have been a gumma that ulcerated, leaving a scar. There was no history of acute pyloric ulcer and nothing to be felt in the mucous membrane at operation. I think in another case I should adopt Mayo's suggestion of anchoring the pylorus down so as to bring the drainage of the stomach lower.

DR. MAURICE H. RICHARDSON read a paper entitled

REMARKS UPON OBSCURE NON-TRAUMATIC TUMORS OF THE LOWER ABDOMEN SUDDENLY APPEARING WHERE NONE HAD PREVIOUSLY BEEN DETECTED.¹

DR. MUMFORD: Mr. Chairman, I will not weary you with descriptions of twisted ovarian tumors that I have seen. Dr. Richardson has covered that subject so thoroughly that there is little to be said. Indeed many of his cases came under my own observation at the hospital. But the title of his paper is very interesting and striking. I believe that these suddenly appearing tumors are not so rare as might be supposed. Many of them, most of them indeed, are urgent and require immediate operation, but this is not true of all; and I refer especially to enlargements of the kidney. Within the past year I have seen 2 such cases which might be added to Dr. Richardson's list. Both were kidneys, very movable, engorged, appearing suddenly low in the abdomen, causing great pain and discomfort, puzzling at first to the surgeon, and most alarming to the patients. In both cases nephrorrhaphy gave permanent relief.

DR. MARCY: I have been deeply interested in Dr. Richardson's paper. It opens up a whole subject on which it would be easy to write a book. There are a variety of things that come to us the older we grow in our experiences which make us less sure in diagnosis. I am very certain, in abdominal diagnosis, I know less about making a clear, distinct, positive diagnosis than I thought I did ten years ago, because there are many more things we know may be possible, and many things that in the earlier period we would have ruled out we now consider. Dr. Richardson has hardly given the emphasis some of us would give to extra-uterine fetation, although he has referred to it two or three times in his paper. I remember a case I operated on some time ago which I supposed to be ectopic pregnancy, and it was an extra-peritoneal hematoma, impossible to diagnose before operation.

The only thing, I think, that has not been referred to is the very first case of dropsy, as it was then

called, of the gall bladder, which was opened by an American surgeon in Indiana, with the full belief that he was about to operate on a cystic tumor of the ovary. That goes on record as the first operation in the world upon the gall bladder. In the case of twisted pedicle you know how sometimes a comparatively small tumor rapidly becomes large, and yet it is not the classical case such as we used to know and was described in the earlier days of twisted pedicle. Let me give two or three instances:

A woman, of perhaps sixty, had been under observation a considerable period with a large fluctuating cystoma of the ovary. I advised operation, but she declined it, saying: "No surgeon will ever see the inside of my abdomen." Perhaps a year went by, when I was suddenly summoned to New Hampshire to operate upon this woman. In the meantime she had been congratulating herself that the tumor was going away, the lessening size of the tumor making rotation easier. I found a necrosed cystoma weighing about 30 pounds; the pedicle was twisted twice and all the circulation was cut off.

I remember another case, a comparatively small tumor of about 15 pounds, in a woman in middle life. She went to the Massachusetts Hospital, where she was examined by the physician in attendance, who found a cystoma that seemed so characteristic that, according to her statement, a dozen of his pupils examined her. She went home in much pain. That night her physician was called, and two days later I opened the abdomen. I found a necrosed cystoma with two and a half times twisted pedicle, which it seemed fair to assume had been acquired at the hands of the students.

It is only a little time ago I saw a much more obscure case, where a woman had a pretty evident history of impregnation. It was believed by her physician that she was three months pregnant, which was found to be correct, but there was an x factor in the problem demanding immediate surgical intervention. At the operation I found an ovarian tumor pedicle, twice twisted, the cystoma not larger than a large cocoon.

Such are cases worth reviewing. Some of these curious things, as dilated stomach, won't happen very often, and yet I have lost, I am quite sure, 2 patients on the table by overlooking a dilated stomach in laparotomy. How? On recovery from etherization, with a dilated stomach distended with thin fluid, there came regurgitation of fluid that caused the death of the patient by drowning in his own fluid. Had I washed out the stomach before operation I should have saved this complication.

As to the dilated bladder, I am sure some of our younger friends would rather smile when they look upon the wise Dr. Richardson and say: "Is it possible he makes a mistake?" One of the wisest physicians I know thought he knew the character of the disease, for he had watched it in its development, and seen the patient from day to day and felt sure she had a large cystic ovary. He sent her to me for operation. I drew away 40 to 50 ounces of urine from the bladder, and then it was apparent that there was no tumor for removal.

I am quite certain discussion of this sort is of the largest possible good to us all, and I am sorry Dr. Richardson has not a much larger audience to profit by his paper.

¹ See page 333 of the Journal.

DR. MUNRO: I recall three tumors suddenly appearing: one an aneurism of the thoracic aorta, that appeared in the upper part of the pelvis; another, a tubercular peritonitis, that appeared four weeks after Cesarean section; a third, similar to that which Dr. Richardson speaks of — a sigmoid in a low grade peritonitis due to an appendicitis.

DR. ELLIOT: In these cases of twisted pedicles I have always been impressed with the symptom of pain. I have been called to such patients in great pain, and usually they have taken morphia without relief. I was surprised when I listened to Dr. Richardson's account that, although collapse was noticed, there had been so little pain, especially in the ones described as suddenly gangrenous, especially the last one in which the twist must have occurred within a short time. I have no doubt from the look of these pedicles that the torsion in some of the cases is very gradual. The twists are glued in their position. I have seen twists three and four times round that must have been there months. In the last case the drawing and everything shows it was a very acute case, and I am surprised that it was not associated with greater pain. I happen to have had a case exactly like Dr. Richardson's dilated stomach case two or three years ago. It was a young man, I think about nineteen or twenty, who came to the hospital. I was called at night to see this man with a large tumor. No one present had any idea what it was. At the operation I found the stomach absolutely filled the abdomen, and it hung so heavily on the pylorus that it made an intestinal obstruction. I emptied the stomach and relieved the obstruction, but the man died in two or three days.

DR. AGNES VIETOR: I saw Dr. Boldt operate on a patient in whom no tumor whatever was palpable. He operated because the diagnosis of ovarian cystoma had been made some time before, and he considered the diagnosis reliable, and while a careful examination at the time showed nothing, still celiotomy disclosed an ovarian tumor.

Dr. Vietor then reported

A CASE OF INFLAMED PERITONEAL CYST SIMULATING OVARIAN TUMOR WITH TWISTED PEDICLE.²

DR. MARCY: In this connection I would like to report a case, and its peculiarity, I think, lies in the patient's age, fifty-one, married about twenty-five years, never pregnant, and well until lately. When I saw her in consultation it was thought altogether likely that the case was an acute form of malignant disease of the pelvis. Uterus enlarged, fixed. To the right side of the uterus was a mass pressing the uterus forward and apparently blended with it. According to the description of its development by Dr. Forbush, of Charlestown, it had come on in the last six or eight weeks. I do not believe any one would be warranted in making a diagnosis and I hesitated about making a laparotomy, but quite to my surprise we found a very thick-walled cyst, that is to say, the right Fallopian tube had developed into a pus pocket quite the size of a large cocoon, with a thick wall, and the left tube contained also an ounce or two of pus. The uterus owed its enlargement to small multiple fibroids, and was removed along with the other diseased organs. I think the case is worth putting on record because of the late period of life in

which the disease occurred, fifty-one years, never pregnant, married twenty-five years, and no special reason why she should have had an infection of the tubes. This is the first case of infectious salpingitis which I have ever met after the cessation of menstruation. She had passed the menopause six or seven years in what was believed to be a normal way, and in other respects had been a strong, healthy woman all her life.

DR. RICHARDSON: I have nothing to add, except that the case of Dr. Vietor seems very much like one of the cases that I report — a suddenly appearing, thin-walled cyst with hemorrhage in it. Gall-bladder tumors large enough to be felt in the lower abdomen cannot, from their very nature and origin, belong to the category of suddenly appearing tumors. Examination could not fail to have detected them long before they could reach the pelvis. It must be remembered that this communication deals with tumors which escape skilled examiners one day, and which are conspicuous the next.

DR. ELLIOT: It has been my experience to find that a thin-walled ovarian cyst is very difficult to feel every day — some days you feel it and some days you cannot feel it. I think it is very easy to miss a thin-walled cyst. Cysts go up and down for various reasons; some days you cannot feel a cyst above the pubes, and the next day you can feel it 2 or 3 inches above. I suppose the condition of the bowels, whether empty or full, or the condition of the abdominal wall, may cause this; at any rate, sometimes you can feel them and sometimes you cannot. I do not believe that ovarian cysts appear suddenly. The explanation for their sudden appearance is simply that they have been previously overlooked.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

FOURTEENTH ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 1, 2 AND 3, 1900.

(Concluded from No. 13, p. 322.)

SECOND DAY.

THE first part of the session was devoted to the discussion of

THE BEST METHOD FOR OBTAINING URINE DIRECT FROM THE URETERS FOR DIAGNOSTIC PURPOSES.

DR. F. TILDEN BROWN, of New York, stated that the attributes of an ideal instrument were: (1) Its equal applicability to both sexes; (2) no contamination from the other gland or from extraneous materials; (3) a minimum amount of discomfort to the patient and of harm following its use; (4) a simple technique. From these standpoints three types of instruments were discussed: Kelley's, Harris's and the ureter cystoscope. The advantages of Kelly's method are: (1) The instrument is the simplest in construction; (2) the mucous membrane around the orifice of the ureter can be cleansed; (3) it is the only instrument that can be used in some conditions of the bladder. Its disadvantages are: (1) It is essentially limited to the female; (2) the introduction of a flexible catheter is difficult; (3) the urethral tube is large enough to cause a temporary incontinence of urine; (4) displacement of the catheter is liable; (5) more

² See page 359 of the Journal.

assistants are needed; (6) the knee-chest posture is disagreeable to the patient; (7) general anesthesia is more generally indicated. The Harris segregator deserves commendation, but is contraindicated in a number of conditions. Its advantages are: (1) It can be used by any one who is expert in using a catheter; (2) small cost; (3) separate urines can be obtained synchronously; (4) it is easily sterilized; (5) there is not the danger of infecting the kidney. Its disadvantages are: (1) The difficulty of introduction, the discomfort to the patient and the danger of after effects; (2) the advantages of cultures made from the urine obtained is practically *nil*; (3) the uncertainty as to its trustworthiness in separating the urines. The advantages of the ureter cystoscope are: (1) It permits the ascertaining of the condition of the bladder; (2) the operator can satisfy himself that the specimens of urine are from separate kidneys. Its disadvantages are: (1) It is not applicable where the capacity of the bladder is limited or where the fluid is not transparent; (2) it is relatively expensive; (3) its details require more study and experience. Dr. Brown concluded that the ureter cystoscope was the safest and best instrument for obtaining separate urines.

Dr. OTIS, of New York, believes there is a tendency to think that catheterizing the ureters is a simple operation, when the truth is that it is a decidedly difficult procedure. He prefers the direct or convex ureter cystoscope. Dr. Otis exhibited

(a) A NEW ELECTROCYSTOSCOPE.

(b) A CYSTOSCOPE FOR THE CATHETERIZATION OF BOTH URETERS.

Dr. M. L. HARRIS, of Chicago, present by invitation, discussed the various instruments. He stated that catheterization of the ureters is frequently a failure, even in the hands of the most expert operators. Some of the errors from this method are the presence of blood and epithelial cells in the urine due to traumatism of the ureter, and the fact that all the urine does not pass through the catheter in some instances. The chief danger is infection of the kidney and this is a very grave objection. He has demonstrated that his segregator will accurately divide the bladder by cases where only one kidney was present, where blood was coming from one kidney and by autopsy findings. To prevent vesical hemorrhage he uses suprarenal extract, 50 to 60 cubic centimetres of a 5% solution being allowed to remain in the bladder for ten to fifteen minutes. Local anesthesia is secured by placing 15 to 20 cubic centimetres of a 2% solution of cocaine in the bladder for six minutes. Partial anesthesia of the rectum is secured by the use of antipyrin and tincture of opium.

Dr. BRANSFORD LEWIS, of St. Louis, demonstrated

A URETER CYSTOSCOPE (FOR MALE OR FEMALE)
BUILT ON A NEW MODEL.

One of its chief advantages is its simplicity. General anesthesia is seldom necessary. The catheter is introduced while the patient is in the knee-chest position, the cystoscope is withdrawn and the patient then placed in the dorsal position while the urine is collected. A cold lamp is used and complete control is had over the inner end of the flexible catheter.

Dr. BANGS stated that he has found difficulty in

passing a straight instrument even in young men. In others the instrument when introduced cannot be deviated from the middle line sufficiently to find the openings of the ureters. In certain cases he has not been able to see the openings of the ureters. In making investigations regarding this point he has found the same condition in cadavers, not being able to find the openings without a careful search with a fine probe. He has also caused small traumatism near the opening of the ureters in efforts to introduce a catheter. This may explain infection in some cases. He prefers to use the Harris segregator unless in very exceptional instances, and thinks this the best instrument for ordinary surgical diagnosis.

Dr. BRYSON stated that from the practical standpoint of the operating surgeon the Harris segregator was the best instrument. He always precedes its use with cystoscopy, as the knowledge of the interior of the bladder removes the main objection to the instrument. A great advantage of this method is that it can be used frequently over a long period of time — more than a year in 1 of his cases. Patients will object to this use of the other methods under discussion.

Dr. EUGENE FULLER, of New York, read a paper upon

ANTERIOPOSTERIOR SUBDIVISION OF THE BLADDER;
AN IMPORTANT ANOMALY.

Dr. Fuller has met with 2 cases of this anomaly, one specimen of which he secured post mortem. The partition was just in front of the ureteral orifices, an aperture connecting the anterior and posterior chambers of the bladder. The symptoms, which began in early life in both cases, were those of frequent micturition and slowly increasing difficulty in urination. The bladder walls were greatly hypertrophied. The prostate was not hypertrophied in either case and in the specimen secured the gland seemed rather atrophied.

Dr. RAMON GUIERAS stated that he had frequently met with difficulty in cystoscopy by the instrument seemingly entering the bladder and then refusing to enter further. On moving it about an opening was found and the bladder really entered. He had attributed this difficulty to an enlarged condition of the prostatic urethra and suggested that such was the case in this instance.

Dr. FULLER replied that the condition of the prostate in the specimen would not admit of that explanation.

Dr. FULLER then read his paper of Tuesday's programme,

RADICAL TREATMENT FOR CURVATURE OF THE PENIS.

The case was that of curvature following an internal urethrotomy. The fibrous urethra acted as a bowstring to the organ. The urethra and spongiosum were divided obliquely and separated, about three-fourths inch being left between the two portions, and tissues stitched over this gap. The patient is now in good condition, one and one-half years after the operation, and normal intercourse is possible.

THIRD DAY.

Dr. E. L. KEYES, of New York, opened the session with a paper upon

THE THERAPEUTICS OF UROTROPIN.

Several cases were detailed to show the satisfactory effects obtained by the use of this drug. One case of persistent anuria following an external urethrotomy was relieved at once by the exhibition of urotropin, the symptoms again appearing when the drug was discontinued. Dr. Keyes uses urotropin in all cases where urinary chill is present or is threatened. His conclusions are: (1) Urotropin seems to be almost a specific in acute catarrhal pyelitis; (2) large doses may be necessary at first, these being followed by long-continued smaller doses; (3) the centrifuge and the microscope may be necessary to detect the change in the urine following its use; (4) dysuria, etc., may be caused by irritation, and irritation may be caused by small doses in some cases; (5) it is a valuable prophylactic against urethral chill; (6) good results follow its use after operations; (7) urine passed during its administration occasionally has an escharotic effect on wounds with which it comes in contact.

Dr. BRYSON stated that in cases of tuberculous disease which had been operated upon he had seen instances in which urotropin produced changes which retarded the healing of the wound.

Dr. OTIS has used cystogen a great deal because of its cheapness. He always uses urotropin for several days before catheterizing ureters, if this is possible.

Dr. KEYES stated that he had given a patient 67½ grains of urotropin daily for months. In that case an enlarged prostate became lessened in size, the amount of residual urine diminished, and the patient was made thoroughly comfortable. The fact of sloughing from the effects of urotropin having been questioned, he gave 3 instances in which weak solutions of formalin had produced such untoward effects, the wounds becoming healthy when the formalin was stopped.

Dr. RAMON GUIERAS, of New York, reported several cases of

PROSTATIC DEFORMITIES DUE TO LOSS OF TISSUE.

He had often detected deformity of the prostate by rectal examination and found no explanation for it. Attention was finally called to a case where tuberculosis had caused an abscess of the seminal vesicle and eventually an abscess of the prostate. Evacuation of this left a depression. Many chronic cases, where there is a morning drop of discharge and a few shreds, will be found due to the results of abscess in the prostate. In some of these cases rectal examination reveals depressions and cavities in the prostate or bands extending across the gland. In other cases the gland is almost wholly destroyed, the ejaculatory ducts in one instance being felt as cords extending from the vesicles. These conditions usually result from abscesses which have ruptured into the urethra. A pyogenic membrane is left in the prostate and pus forms for a long time afterward. Some cases are no doubt attributed to tuberculosis and gonorrhoea. The remains of these abscess cavities may cause the most intractable cases of chronic discharge. The treatment must consist principally in rectal massage and irrigation and urethral irrigation.

Dr. E. E. KING, of Toronto, read a paper on

PRIMARY CANCER OF THE PROSTATE,

and exhibited specimens. A feature of one case was the discharge of a large quantity of blood, at one time, with great relief of the symptoms. Pain was felt only when the bladder was distended with urine. The

whole gland appeared to be involved in all cases before relief was sought, showing the insidious nature of the affection. Frequent micturition with some dribbling of blood were the common symptoms. Four members of the family of one patient had died of cancer. Especial points noted were: (1) The very advanced state of the disease before found; (2) the relief experienced when the capsule of the gland ruptured; (3) the small amount of metastasis present.

Dr. JOHN P. BRYSON, of St. Louis, considered

THE DIFFERENTIAL DIAGNOSIS OF CIRCUMSCRIBED LESIONS OF THE UPPER, MIDDLE AND LOWER PARTS OF THE URETER.

Cases were detailed to show the symptoms referable to calculi in the parts of the ureter mentioned. In cases of irritation in the pelvis of the kidney or the upper third of the ureter, the subjective symptoms are referred to the kidney, the pain radiating toward the middle of the abdomen. When the irritation is in the middle third of the ureter the genitocrural nerve is involved. In the lower third of the ureter there is increased frequency of micturition, but no vesical tenesmus.

Dr. CABOT stated that he had seen involvement of the kidney produce symptoms referable to the neck of the bladder. He depends more upon local tenderness found upon thorough examination of the ureter than upon subjective symptoms for localizing the trouble, as subjective symptoms are often misleading.

Dr. KEYES stated that he had seen a case of retention from vesical spasm due to stone in the kidney, no other condition to account for the spasm being present, as the bladder was perfectly normal.

Dr. BRYSON stated that it was very common to find a lesion at the lower end of the ureter along with kidney involvement. In cases like the one just referred to this lesion if present would be sufficient to cause the bladder symptoms. When this lesion was not present he believed no bladder symptoms would be found in connection with kidney involvement.

Dr. CHAS. L. SCUDDER, of Boston, reported a case of

ACUTE ABDOMINAL SYMPTOMS ASSOCIATED WITH A CONGENITAL MALFORMATION OF A URETER IN A CHILD.

The symptoms resembled those of intestinal obstruction. Enemata, however, secured fecal evacuations. A tumor was felt in the right iliac fossa. Operation showed the tumor to be retroperitoneal. The condition of the child prevented further operation and the patient died soon after. Autopsy showed a normal right ureter and also an abnormal one, the latter being greatly dilated and sacculated.

Dr. GEO. K. SWINBURNE, of New York, read a paper upon

BACTERIA ASSOCIATED WITH A DIVERTICULUM OF THE BLADDER.

A number of calculi have been obtained from the bladder. A catheter can be introduced a short distance, one-quarter of an inch, into the diverticulum, the mouth of which can be seen, photographs having been made of it. The diverticulum is supposed to contain a calculus.

The following papers were read by title: "Prosta-

tectomy for the Relief of Enlargement of the Prostate," Dr. Samuel Alexander, of New York; "Rupture of the Urethra," Dr. J. R. Hayden, of New York.

The association elected the following officers for the ensuing year: President, Dr. Samuel Alexander, of New York; Vice President, Dr. W. T. Belfield, of Chicago; Secretary, Dr. J. R. Hayden, of New York.

The association then adjourned to meet at Old Point Comfort, April 30, 1901.

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

(Concluded from No. 13, p. 326.)

THIRD GENERAL MEETING.

THE third general meeting, which took place on August 9th, was also the closing ceremonial of the Thirteenth International Medical Congress. The large amphitheatre of the Sorbonne, containing Puvion de Chavannes's masterpiece, a large allegorical painting representing "The Sacred Grove," was well filled, when, soon after two o'clock, the band of the 115th Regiment of the Line began the stirring strains of the *Marseillaise*. The audience instantly stood up and cheered when the band stopped playing.

The president of the congress, Professor Lannelongue, who had at his right hand Professor Julian Calleja, the Dean of the Faculty of Madrid, and at his left Professor Virchow, then rose, and having declared the meeting open, introduced PROFESSOR ALBERT, of Vienna, who now read his paper on

THE ARCHITECTURE OF BONES IN MAN AND ANIMALS.

The extemporized pulpit from which the professor delivered his address was placed at the end of the platform, close to the gallery in which the regimental band was seated, the seats reserved for the press being near the far end of the platform. The members of the band were doubtless highly edified at the words of the learned scientist; the medical men in the body of the hall moved along opposite the speaker; the press, unfortunately, could not do likewise, and consequently heard not a word.

AWARD OF THE CITY OF MOSCOW PRIZE.

After the address of Professor Albert, the PRESIDENT rose and called to the minds of his audience that at the last International Congress the city of Moscow had offered a prize of £200, to be given at the Paris Congress, to the author of the best work in recent years in the domain of medicine and hygiene. After a careful consideration of the merits of the various candidates, the committee had decided that it would be preferable to award the prize to one of the younger generation, and thus stimulate the work of those who had not yet reached the highest position. The committee had finally unanimously selected M. Ramon y Cajal, professor of histology and pathological anatomy in Madrid, for his magnificent work on the nervous system.

THE NEXT CONGRESS.

When the applause had subsided, the president announced that the committee of the honorary presi-

dents had accepted the invitation of the Spanish Government, and that the Fourteenth International Congress would be held in Madrid. Owing to climatic reasons the congress will meet about Easter, 1903, and will be under the presidency of M. Calleja, Dean of the Faculty of Medicine, with M. Fernández Caro, Inspector-General of the Spanish Navy, as general secretary. The regimental band at once played the Spanish National Hymn, which was listened to by the entire audience standing, and was greeted with great applause.

PRESIDENT'S FAREWELL ADDRESS.

M. LANDELONGUE then rose and delivered a somewhat lengthy speech of farewell. He thanked his collaborators who had helped to bring the work to such a successful conclusion, naming especially M. Chauffard (the general secretary) and M. Dufloey (the treasurer), and MM. Weber and de Massary (the secretaries), adding the name of the regretted editor, M. Georges Masson, who had always considered the publication of the congress as an honor for his house. After thanking the French committee and the foreign national committees, the president emphasized the fact that during the last century the idea of nationality had been growing in importance. The result has been a certain isolation of the different states, each with its own distinct life. The rôle of the International Congresses is counter to those isolating tendencies; they throw into relief the simple truth that science should have no territorial limits, and also another important fact that there are a certain number of productive forces that one can only study by seeing them at their seat of origin. But in addition to the scientific work and communications which appear to be the basis of these meetings, there is also the need for the workers in different countries to know each other. Contact alone enables us to see that after all there is everywhere less coldness and egotism than one believes, that the notion of ingratitude does not exist between us, and that there is an absolute equality in our mutual intercourse. One might perhaps discuss the advisability of continuing this enormous collection of medical sciences as a composite whole, or whether it would not be preferable to hold a certain number of congresses of specialists. A certain number of sections have such an independent existence, and were with difficulty persuaded to form part of the general scheme. Specialization is certainly a narrowed domain, but it is none the less certain that the era of specialization has produced a much more rapid advance in the number and precision of the results obtained, especially in the matter of technique. One might in fact say that specialists contribute the most to the advance of science. But this is not a sufficient motive for the specialists to remain isolated. As it is the sections retain their autonomy. Many of them, even of their own initiative, meet in subsections. We must not forget that all specialities have a common origin, and the field would soon be exhausted did they not from time to time receive general ideas, doctrines coming from a wider and different source, without whose influence false doctrine might creep in. Special sections, such as physiology, chemistry, comparative anatomy, which seem so far away from us in their origin and methods, have none the less the most useful rôle in our knowledge, just as we, too, place at their disposal a field of application which contributes

largely to their development. Electricity, which began so modestly, is now called upon to take an important part in the rôle of nervous transmissions, and perhaps in the cure of many diseases, even those of an infectious nature. The separation of the so-called specialities would quickly create an isolation, which would ere long be harmful to their progress, and unfavorable to the genesis of new ideas in them all. "In a few moments this congress will have concluded its task. Whatever may be the opinion or feelings you carry away of France and of us, whether for political or national reasons you judge us with generosity and cordiality, or rather with strict equity, be certain that, faithful to our historical traditions, we keep a lasting souvenir of your visit. We shall never forget that in spite of the difficult times in which we live, with war and massacres in China, and war in South Africa, that more than 6,000 of you have come and brought your work, which will be the honor of the congress. If in the future circumstances lead us in our turn to visit you, we shall be happy to renew again old friendships, and we shall go as one goes to visit those who are bound and united to us by a common bond. This bond is the love of science, for itself first, and then for its higher and nobler application to the common weal—I mean the material and moral amelioration of the lot of the people, to whom we wish to devote ourselves without reserve. Gentlemen, I only bid you *adieu*, the better to say to you *au revoir*."

CLOSE OF THE CONGRESS.

When the applause had ceased, PROF. JULIAN CALLEJA, the president of the next congress, rose amid great cheering. In the sonorous Spanish tongue and with the deepest emotion, he thanked the president and the members of the committee for the honor conferred on him, saying also how greatly he had been touched by the compliment of the playing of the Spanish National Anthem when Madrid was announced as the next place of meeting. He assured everybody a hearty welcome.

M. CORTÉJAVENA, the National Director of Health, and member of the Royal Academy of Medicine in Madrid, reading in French, then briefly thanked France, the president and organizers of the congress, in the name of the foreign nations, and congratulated them on the great success they had achieved.

THE PRESIDENT then declared the meeting closed, and everybody went away with regret to the strains of the military band.

GREAT FÊTE GIVEN BY THE PRESIDENT OF THE FRENCH REPUBLIC AT THE PALACE OF THE ELYSÉE.

On Friday afternoon, August 10th, at 4.30 P. M., the President of the Republic and Madame Loubet received the members of the International Medical Congress in the salons and gardens of the Elysée. Invitations were also issued to members of the Congress of Hygiene and Demography, to members of the International Congress of the Medical Press, and of the Congress of Medical Ethics and Deontology. The members of the Congress of Students were also invited, and it is estimated that ten thousand invitations had been sent out. Before 4 P. M. the guests began to arrive, and soon a long single file

of carriages and cabs lined the Faubourg St. Honoré. As progress was slow by this means, many got out and walked to the gate of the Elysée, where they found the street filled with guests awaiting admission. Batches of about fifty were allowed in at a time, and after passing through one of the two cloak rooms, they entered the salons of the palace, where, after being greeted by the President, they passed out into the large garden. The guests, however, arrived more quickly than early arrivals could gain admittance, and soon the street was filled with guests on foot. This was the state of affairs when, just before five o'clock, the Shah of Persia arrived with his suite and the escort of cuirassiers which always accompanies him since the attempt on His Majesty's life. The guests before the palace gateway had to make room, and there was much crushing and expression of feeling, mingled with the screams of the ladies. Some of the horses were frightened, and for a few minutes the position of affairs was distinctly dangerous. The afternoon was fine on the whole, though two little showers caused some temporary anxiety, without, however, having the effect of driving the guests indoors.

The stage was set up under the stately trees at the far end of the lawn, which, being concave in shape, allowed the guests to get a splendid view of the stage. The arrangements were in exquisite taste, and the stage, flanked with porticos of green trelliswork, bearing large ornamental vases filled with flowering plants, had a most harmonious and pleasing effect. At the foot of the stage, behind a bank of shrubs and flowers, was seated the entire orchestra from the Grand Opera House. The lawn was covered with carpet, and in the front row of the seats sat the Shah of Persia on the right hand of the President, Madame Loubet being next His Majesty, while behind the crimson and gold chair stood one of the Persian officials in his high astrakhan cap, holding an umbrella; his only duty during the afternoon was to hand his master a glass of iced orangeade.

The performance had been arranged by M. Gailard, the director of the National Academy of Music. The programme, which was illustrated by Jules Chevet, consisted of four acts, representing barbarian, Greek, French and modern dances, executed by members of the *corps de ballet* from the Grand Opera. Before each act one of the actors or actresses of the Comédie Française, dressed in appropriate costume, recited verses describing the dance that was to follow. M. Leitner described the barbaric dance; Madame Bartet in Greek costume followed, the scene represented being Athens, with the Acropolis and the blue Mediterranean in the distance. This was certainly the most beautiful and effective act. M. Bouchier, with powdered wig and in the dress of a "*petit marquis*," introduced the minuet and French dances of the seventeenth and eighteenth centuries. The last scene represented the views in the Champ de Mars portion of the exhibition looking from the Eiffel Tower to the Château d'Eau. Madame Brandes recited the verses introducing modern ballet dancing, which terminated the performance. Everybody, including the Shah, who often led the applause, was delighted with the performance, which was beautifully conceived and carried out.

The Shah, with the President and Madame Loubet,

walked slowly back to the palace, and it was 6.30 p. m. before the band in the courtyard, playing the Persian National Anthem, announced the departure of His Majesty. The numerous guests, however, lingered much longer in the beautiful gardens, or wandered through the salons, admiring the carved wood and gilded panelling, the fine bronzes, and the priceless tapestries. A picturesque note in the crowd was provided by the variety of the costumes of the guests: at night evening dress is obligatory, but during the afternoon some were in evening dress, many in frock coats, others in the military uniforms of different nations, with numerous orders and decorations. The members of the Students' Congress wore every variety of national dress, Hungarians in velvet coats, etc., and each nation seemed to have a different head-gear, including the mortar board, velvet students' caps with colored ribbons of different faculties, the Turkish fez and the peaked cap of the Scandinavian, with white linen crown, being among them. The Cambodian princes wore white pith helmets, coats of cloth of gold, and black silk stockings. In fact, every nation on earth seemed to be represented except the Chinese.

RECEPTION BY THE MUNICIPAL COUNCIL AT THE HÔTEL DE VILLE.

On Saturday afternoon, August 11th, the members of the International Medical Congress were received in the Hôtel de Ville by the Municipal Council of the City of Paris. The salon on the first floor had been reserved for the members of the congress and their wives. Two orchestras played and numerous buffets were provided. M. Gribaudo, the President of the City Council, received the guests, who had a delightful afternoon looking at the numerous pictures by modern French artists and listening to the music.

STATE BANQUET AT THE ELYSÉE.

The President of the Republic invited the presidents of the sections and the foreign official delegates to the International Congress to a state banquet at the Elysée on Wednesday, August 8th. The President and Madame Loubet received the guests, who numbered 250. The dinner was served in the large dining room, hung with beautiful Gobelin tapestry, the table being beautifully decorated with flowers. There were no speeches, and the band of the 29th Regiment of the Line performed a selection of music during the evening. The dinner was followed by a reception.

Recent Literature.

Embryology of Invertebrates. Textbook of the Embryology of Invertebrates. By DR. E. KORSCHULT and DR. K. HEIDER. Translated from the German by MATILDA BERNARD. Revised and edited by MARTIN F. WOODWARD. Vol. II, pp. ix, 375; Vol. III, pp. xii, 441. New York: McMillan & Co. 1899.

These two volumes bring measurably near completion the English edition of Korschelt and Heider's "Embryology of Invertebrates." It is a publication deserving the most cordial recognition from the scientific world on account of its great merit. The origi-

nal German edition was in all respects a manual of the first importance and value, not only because it is the only comprehensive summary of the immense discoveries of recent years in the domain of invertebrate development, but also because the summary has been made after thorough and laborious study both of the literature and of the actual material. It is almost a revelation to see the enormous extent of embryological knowledge, but the authors have kept their subject matter under control with master hands, and have displayed most sound judgment in estimating investigations and in the formulation of the general results, the presentation of which is one of the most valuable and original features of the work.

The English edition was begun by Professors Mark and Woodworth, of Harvard, who prepared Vol. I. The present volumes fully equal their predecessor in the accuracy and smoothness of the English rendering, and Miss Bernard is to be complimented upon her share of the work. Mr. Woodward, as editor, has added greatly to the value of the manual by his notes, which are always distinctively indicated and which direct attention to important discoveries made since the issue of the German edition. He has also made extensive additions to the bibliographies, which are thus rendered more helpful.

That there should be mistakes in a book of this kind is inevitable, but such errors may be well passed by in a brief notice, in order to better emphasize the fact that we have to do with a treatise planned and carried out according to very high scientific standards. Two general defects may however be noticed, first, the disgraceful printing of the illustrations in the English edition, second, the vexatious crudity of the bibliographical references—we have hunted in vain for a single one properly completed. May we not hope that in the concluding volume these inexcusable blemishes may be corrected? Surely it is time for English publishers to rise above their very low standard of book illustration, for as regards scientific books, at least, it is the lowest in the world, and surely, too, it is time for English scientific men to learn the rudiments of bibliography, of which most of them are ignorant.

Martin and Rockwell's Chemistry and Physics. A Pocket Textbook of Chemistry and Physics. By WALTER MARTIN, M.D., and WILLIAM H. ROCKWELL, JR., A.B., M.D., of the College of Physicians and Surgeons, New York. 12mo. Pp. 366, with 137 illustrations. Philadelphia and New York: Lea Brothers & Co. 1900.

This work is divided into two parts. The first part, comprising 182 pages, takes up the subject of chemistry, both inorganic and organic. The second part is devoted to the subject of physics, and occupies 177 pages of the text. It is needless to state that in a volume of this size two important subjects have been very briefly and incompletely considered. The book is intended for the use of medical students and graduates of medicine, but, to quote from the preface, "The general plan of the book is, one may say, purely 'chemical and physical,' as may be instanced by the introduction of 'wireless telegraphy' in the section on physics." It is evident, therefore, that the work would best meet the needs of those preparing for a medical course rather than of those already engaged in medical studies or of graduates of medicine.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, OCTOBER 4, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS

THE OPENING OF THE MEDICAL SCHOOLS.

EACH new year in all of our institutions of learning shows certain marked improvements over the methods of instruction heretofore practised, and certainly this is nowhere more true than in medical education. The last few years have seen a growth in the conception of the true meaning of medical teaching which is quite out of proportion to anything that has gone before. The realization has gradually impressed itself upon the profession that teaching in medicine, as in other fields of knowledge, is not only a means to an end, but an end in itself; that a man may well devote his most serious attention to the art of teaching, quite regardless of the secondary benefits likely to accrue to himself from association with men who are soon to be his fellow practitioners. The eagerness of young men, fresh from their own studies, to teach, and the opportunities which are now being given to such promising men, is one of the most hopeful signs of the times as regards the general elevation of the standard of medical instruction. It is a foregone conclusion that many of these young men will never rise beyond the most subordinate positions, but in the meantime a healthy rivalry is being established between various departments and within the same department, and those few men who show a special aptitude for teaching are sure to emerge from the throng, well equipped for higher positions of greater responsibility. This increase in the number of subordinate teachers is fostered and in fact rendered absolutely necessary by the tendency now everywhere observable to minimize didactic and increase personal teaching. Small sections demand many teachers. A glance at the recently issued Harvard Medical School Catalogue shows upwards of sixty assistants in the various departments for the ensuing year. Many of these men are very recent graduates in medicine, whose reputations are still to be made, and who, no doubt, will put a degree of enthusiasm into their work which will react most favorably upon the student body.

Another tendency which we think is observable is a general effort to bring into closer relationship the so-called scientific and practical sides of medicine. The first step toward the newer education was the recognition of the essentially independent character of the fundamental branches of medical science, and the establishment of appropriate professorships, entailing adequate salaries in those departments, thereby permitting and encouraging the incumbents to devote their whole time to the development of their individual branches. The result of this, as every one knows, has been most beneficent; it has dignified medicine as a science, and, if properly understood, in no way belittled it as an art. The side of medicine popularly known as "scientific" has established a definite place for itself in all our better medical schools, and has in the minds of some usurped a somewhat more important position than the needs of a practical medical education demand. However this may be, the fact remains that the scientific side, as represented by the laboratory, has come to stay. The need of the future clearly will be, so far as the individual average medical student is concerned, to adjust the theories of the laboratory to the requirements of the future practitioner. We are under the impression that this has not been adequately done in the past; that far too great a gap has existed in the student's conception between the scientific and practical physician. The teaching of the subjects which deal with the theory of medicine has been too distinct from those which deal with the immediate problem of the care of the sick; he has had no broad point of view regarding the interrelation of the branches of medical knowledge as seen in the laboratory and at the bedside. All this is an entirely natural consequence of the artificial separation which has been going on within the last few years between the science and the practice of medicine. Growth in such matters takes place for a time only through apparent divergence, and the accompanying insistence upon the significance of the separate fields of work. Hence has arisen the extraordinary spectacle of men, confessedly striving toward the same general end, arrayed against each other, as if they represented two opposite tendencies, which they have been pleased to call on the one hand "scientific" and on the other "practical." Such an anomalous and unnatural state of affairs is impossible of continuance, and has ceased to be a factor in the older seats of learning in Europe. We may see the dawning of a more rational feeling here; if we look with care through the lists of courses now being offered, for example, at the Harvard Medical School, we find a growing tendency to bring into closer union the fundamental theoretical branches of medicine and the immediate problems offered by the sick. The laboratory is now an essential adjunct to the wards of a properly equipped hospital, and the time is rapidly coming when the converse will likewise be true. It is absurd to suppose that such a union will inter-

ferre with the prosecution of original scientific research; it will, on the contrary, supply the very problems which it is in the province of the scientist to investigate.

The beginning of another year of medical study is sure to see a very decided improvement in the methods and the efficiency of teaching, and, we are equally sure, a growing appreciation of the fact that accuracy of observation, wherever applied, represents the true scientific side of medicine. We are confident that we shall see a more complete co-operation than ever before between the various departments of medical knowledge, and as a natural consequence, a more rational instruction of the medical student, for whom after all, the medical school essentially exists.

THE NEW YORK STATE HOSPITAL FOR CONSUMPTIVES.

THE trustees of the proposed State Hospital for Consumptives in New York State have selected a site at Big Clear Lake, in the Adirondaeks, for the institution. In what seems to be a very well-considered editorial the *New York Tribune* takes exception to this selection. It points out, in the first place, that the average taxpayer will be inclined to protest at the lack of business sagacity displayed, since it will cost at least \$20,000 to purchase or condemn the necessary land here, when the State already owns thousands of acres of Adirondack lands, as beautiful, as healthful and as convenient to a railroad. He will be even more astonished, the article goes on to say, to learn that the chance of saving from 25 to 40 per cent. on the cost of construction is being deliberately thrown away, almost if not entirely for sentiment. The prison commission, as recently mentioned in the *JOURNAL*, wished the trustees to select a site near Clinton Prison at Dannemora. There the State owns a large tract of land, admirably situated, with gravelly soil, sloping to the south, with picturesque views and excellent and plentiful water. The hospital could be built out of sight of the prison, far enough from it to have a separate railroad station and a name of its own, which would avoid confusion and unpleasant suggestion to the patients and their friends. At the same time it would be near enough to utilize the labor of the convicts, saving the State a large sum, and furnishing a much needed outlet for their energies, dangerously restricted by the present prison labor laws. The convicts have just been building near Dannemora a hospital calculated to cost \$26,000, which, owing to their work, cost only \$19,000. The relative superiority of this region is then pointed out. There is 15 per cent. more rainfall at Big Clear Lake than at Dannemora, and the average winter temperature is 10° lower. The air at Dannemora is dry and clear, and the experience with consumptive prisoners who are regularly sent there has been entirely satisfactory, while Big Clear Lake, though doubtless reasonably suited by climate for consumptives, is subject to mists

over the water. There may very likely be other locations equally well suited for such an institution, but the Dannemora district has been shown to be specially adapted to this specific purpose. The plans of the hospital trustees are subject to the revision and veto of the Forest Preserve Board and the State Board of Health, and it is urged that these bodies should be very cautious about giving assent to a scheme unnecessarily elaborate and expensive and one which is likely to subject the State's new charitable work to criticism, and prejudice taxpayers against the further development of the consumptive hospital system.

MEDICAL NOTES.

AN AMERICAN COLONY QUARANTINED. — It is reported that many members of the American summer colony at Murray Bay, in the Lower St. Lawrence, have been quarantined because of the appearance of scarlatina. It has been suggested that the infection came through rugs and homespun cloth, manufactured by French Canadians, and sold to the summer residents. The cases are not serious.

AVOIDANCE OF YELLOW FEVER IN SANTIAGO. — Through the strenuous efforts of Colonel Samuel M. Whiteside, commander of the Department of Santiago and Puerto Principe, no yellow fever has occurred since December. The greatest possible precautions have been taken by cleanliness and disinfection to prevent the disease, which the result has amply justified.

PLAGUE AT GLASGOW. — On September 29th 2 additional deaths from plague were reported from Glasgow. One of the victims is said to have been a child born of a woman who was suffering from the disease.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, October 3, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 144, scarlatina 25, measles 17, typhoid fever 38.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending September 29th was 190, as against 203 the corresponding week last year, showing a decrease of 13 deaths, and making the death rate for the week 17.67. Of this number 84 were males and 106 were females; 167 were white and 3 colored; 133 were born in the United States, 55 in foreign countries and 2 unknown; 41 were of American parentage, 127 of foreign parentage and 22 unknown. The deaths from consumption were 17, pneumonia 8, whooping cough 2, heart disease 14, bronchitis 5 and marasmus 10. There were 7 deaths from violent causes. The number of children who died under one year was 60, the number under five years 73. The number of persons who died over sixty years of age was 39. The deaths in public institutions were 56.

OPENING OF WILLARD HOSPITAL.—The Willard Hospital, at Bedford, Mass., for the treatment of dipsomania and narcomania, was formally opened last week. The house contains thirty rooms and is situated in extensive grounds (175 acres), with every opportunity for outdoor amusements. The question of inebriety is always an important one. Last year Mayor Quincy appointed a special committee to investigate the subject. One of the recommendations of this committee was that cities should have institutions like the Forel institution in Switzerland. To this end the Willard Hospital has been established. Dr. Edward Everett Hale is president and Dr. S. B. Elliot medical director.

THE SHARON SANITARIUM.—We are requested to inform our readers that members of the medical profession with friends are cordially invited to inspect the new buildings of the Sharon Sanitarium, on Thursday, October 11, from 11 A. M. to 1 P. M., and from 3 to 5 P. M. Trains leave the Back Bay Station for Sharon at 10.19 A. M. and 2.19 P. M.

DIPHTHERIA AT NEWTON, MASS.—It is reported that about a dozen cases of diphtheria have been reported to the Board of Health of Newton since the opening of the public schools. Most of the cases are in West Newton near the Waltham line.

DEATHS IN WORCESTER, MASS.—According to the mortality report of the Worcester, Mass., Board of Health, the number of deaths in August, 1900, was 244, as against 171 for August, 1899.

NEW YORK.

CLOSING OF STRAUSS MILK DEPOTS.—Mr. Nathan Strauss has closed for the season his twelve depots for the distribution of pasteurized and sterilized milk in the parks and on the recreation piers, and there now remain open only the three permanent depots. Since the beginning of this charitable work in 1893 the infant mortality of the city, in the reduction of which this is, no doubt, an important factor, has steadily diminished. In Manhattan and the Bronx (the former New York) during the months of June, July and August of 1892 there were 6,612 deaths in children under five years of age and the death rate was 136.1, while in the same period of 1900, notwithstanding the great increase in population, there were only 4,562 deaths in this class, and the death rate was 78.1. The nearest approach to this was in the cool summer of last year, when the death rate was 81.8.

IMPROVEMENTS IN CARNEGIE LABORATORY.—At the first meeting this season of the Executive Committee of the Council of the University of the City of New York, which was held on September 24th, it was announced that through the generosity of Mr. Carnegie, extensive improvements had been made in the Carnegie Laboratory during the summer. Under the supervision of Dr. Wm. H. Park, associate professor of bacteriology, the upper stories have been re-

fitted for elaborate bacteriological research, while all the remainder of the building is to be devoted to histology. It was in this laboratory that Drs. Dunham and McAlpin prepared their pathological exhibit for the recent meeting of the American Medical Association at Atlantic City, which proved so acceptable that such an exhibit was made a permanent feature.

FRAUDULENT USE OF SOFT COAL.—Since the rise in the price of anthracite coal incident to the strike numerous manufacturers in the city have resorted to the use of soft coal. On September 25th the president of the Board of Health ordered the sanitary superintendent to have a special inspection made for the purpose of finding out who the offenders were, and on the 28th seven persons were arrested and arraigned in the police courts. The statement was also made that warrants had been issued for nearly a hundred other violators of the law.

MEETING OF AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.—The tenth annual meeting of the American Electro-Therapeutic Association was held at the New York Academy of Medicine on September 25th, 26th and 27th, with Dr. Walter H. White, of Boston, the president, in the chair. At the opening session the members of the association were welcomed to the city by the president of the Municipal Council, and responses were made by Drs. Charles Dickson, of Toronto, and Louis F. Bishop, Secretary of the Academy of Medicine.

AN EXCURSION FOR NURSES.—Mr. Elbridge T. Gerry recently took a party of seventy nurses from the New York Hospital School on an excursion up the Hudson on his steam yacht *Electra*.

PURCHASE BY STATE FOREST PRESERVE BOARD.—The State Forest Preserve Board has just purchased 16,000 additional acres in the Adirondaeks, at prices ranging from \$1.50 to \$6.50 an acre.

Obituary.

SAMUEL SMITH PURPLE, M.D.

DR. SAMUEL SMITH PURPLE, a former president of the Academy of Medicine and one of the most venerated members of the profession in New York, died at his home in that city at midnight on September 29th. He was born at Lebanon, Madison County, N. Y., on June 24, 1822, and was graduated from the Medical Department of the University of the City of New York in 1844. From 1846 to 1848 he was physician at the New York City Dispensary. During the epidemic of cholera in 1849, he did excellent service as ward physician under the Board of Health. He was an original member of the New York Academy of Medicine. From 1870 to 1875 he was a vice president of that body, and from 1876 to 1880, its president. Dr. Purple was the founder of the great library of the Academy, which was started by a gift of four thousand volumes from him. He was also one of the founders of the New York State and County Medical Associations. He was formerly a prolific writer for the medical press, and at the time of his death he owned one of the finest private libraries in New York. Dr. Purple was unmarried.

Correspondence.

SOME REASONS FOR THE HIGH DEATH RATE OF PUERTO RICO.

SAN JUAN, PUERTO RICO, September 25, 1900.

MR. EDITOR:—The high death rate of Puerto Rico is now attracting the attention of the public press. The causes for this have been engaging the thoughts of Americans since the invasion. When chief surgeon of the District of Ponce, the late General Henry at my request convened a board of survey, October 12, 1898, consisting of an engineer officer, Captain Elliot, and a medical officer, Assistant Surgeon Proben, to report upon the water supply of Ponce and its possible contamination by typhoid germs.

The prevalence of typhoid fever in the city of Ponce and the suspicious character of its water supply came under my observation on assuming charge of the office, September 30, 1898. The board was called to see what measures, if any, could be taken for prevention and improvement.

The members of the board deserve great credit for the interest they took in the subject and the thoroughness of their investigation in the limited time at their disposal.

The reservoir for the supply of Ponce was reported open to various sources of contamination, and the aqueduct was sagged at various points, admitting water from the outside. The unsavory condition of the river above the intake is best given in the words of the report: "All told there are 143 huts along the stream; of these, 20 are along the branches and 123 along the main stream. All are within 300 feet of the river; there are 49 within 50 feet; some directly within 20 feet. Where the roads cross the river habitation is always marked and here the greatest source of pollution occurs, especially within 3, 5, and 7 miles above the dam. Forty-seven such huts were counted, which were situated almost directly on the stream, and these form a very prolific source of contagious elements of pollution. These small huts are entirely devoid of sanitary arrangements; they contain on an average four to five persons each, who dispose of their excreta directly into the river. They use the water for washing their clothes, etc., and for watering their cattle. All refuse of any character is thrown directly into the stream. We have been unable to find any water closet, except one . . . that is extremely filthy. . . . Along the watershed we have been able to count forty pigs and a number of dogs. Four or five places had pigpens directly near the river edge."

This lengthy extract will serve to show the terrible contamination to which the water supply of Ponce is exposed. Yet it must be remembered that only the larger towns have any attempt at a water system. The other towns dip the water in gallons or barrels from the river in which hundreds of women are washing clothes, entrails of animals, etc., and which receives the excreta of hundreds, nay thousands, of people living along its banks, for we must not forget that Puerto Rico is about the most thickly populated country in the world, and that a privy of any kind is practically unknown in the country districts.

Since this report was made the ancylostoma has been found in a large percentage of the inhabitants, which has been stated to be the cause of the anemia to which the majority of the deaths are due in the tropics. These parasites' eggs are discharged with the excreta, find their way into the water, which is drunk by the inhabitants, so that few escape it.

The proceedings of the board were endorsed by me, recommending a system of sand filtration that had been considered some years previous as the only reliable means of purification. This suggestion, because of its cost, was not adopted, but since my departure from that city I learned that a system of filtration was built across the river. This, as was natural to suppose, was carried away by the first heavy rainfall, so that today there is no system of filtration worthy of the name in the whole island, and the water supply is drawn from rivers of which the board describes one of the purest.

Add to this that no city except San Juan, and that so im-

perfect as to be unworthy of the name, contains a system of sewerage; that in towns where any kind of water closet exists it is only partitioned off from the kitchen, or next door to it, and that, finally, poor families in towns live nearly always in single rooms, without ventilation and as crowded as sardines in a box. In towns as large as Cayey many of the houses have no kind of closet and the people have to attend to the wants of nature the best way they can.

While in Ponce I went to investigate an epidemic of smallpox in the neighboring town of Penuelas. There were 30 cases, with several deaths. Similar epidemics were prevalent all over the island. I was one of the directors of the five districts into which the island was divided for vaccination purposes. I accounted for 160,000 people in the District of Guayaman and the other directors did better in their districts. Since then, according to returns, there has not been a death from smallpox on the island.

Now if the *Alcaldes* will only spend the money of the towns for a pure sand-filtered water supply instead of for the miserable politics of Puerto Rico; if they will provide sufficient closets for their districts and some adequate system of excreta removal; if sufficient habitations will be provided for the poor, then we can expect to hear as little about high death rate as we now hear about smallpox.

Many and many a time since my arrival in Puerto Rico I have concluded that were it not naturally one of the most healthy sites on the globe, all the people would long since have been dead from some epidemic or other.

Very truly yours,
P. R. EGAN, M.D.,
Surgeon U. S. Army.

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, SEPTEMBER 15, 1900.

Deaths reported 2,382; under five years of age 1,111; principal infectious diseases (smallpox, measles, diphtheria and croup,

cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 800, diarrheal diseases 419, consumption 223, acute lung diseases 136, typhoid fever 67, diphtheria and croup 45, whooping cough 19, cerebrospinal meningitis 12, scarlet fever 8, measles 5, erysipelas 2.

From whooping cough New York 9, Boston and Pittsburg 3 each, Baltimore, Worcester, Springfield and Gloucester 1 each. From cerebrospinal meningitis New York 6, Boston, Worcester, Lowell and Marlboro 1 each. From scarlet fever New York and Boston 3 each, Baltimore and Lynn 1 each. From erysipelas New York and Worcester 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending September 1st, the death rate was 21.7. Deaths reported 4,824; acute diseases of the respiratory organs (London) 138, diarrheal 1,156, whooping cough 97, diphtheria 49, fever 48, measles 45, scarlet fever 24, smallpox (Liverpool) 3.

The death rates ranged from 11.9 in Halifax to 33.6 in Sheffield: Birmingham 27.9, Bradford 14.1, Cardiff 14.2, Derby 19.3, Gateshead 21.0, Hull 30.6, Leeds 21.4, Liverpool 25.4, London 20.2, Manchester 25.7, Newcastle-on-Tyne 19.1, Nottingham 19.6, Portsmouth 22.5, Sunderland 17.7, Swansea 20.3, West Ham 21.1.

SOCIETY NOTICES.

VERMONT STATE MEDICAL SOCIETY. — The eighty-seventh annual meeting of the society will be held at Rutland, October 11 and 12, 1900.

THE TRI-STATE MEDICAL SOCIETY OF ALABAMA, GEORGIA AND TENNESSEE. — The twelfth annual meeting of this society will be held in Chattanooga, Thursday, Friday and Saturday, October 11, 12 and 13, 1900, following the meeting of the Mississippi Valley Association at Asheville.

Those desiring to read papers should send titles to the secretary, Dr. Frank Trester Smith, Chattanooga.

THE MEDICAL SOCIETY OF THE MISSOURI VALLEY. — At the annual meeting of the society at Council Bluffs, September 20th, the following officers were elected: President, Dr. V. L. Treyner, Council Bluffs; First Vice-President, Dr. B. B. Davis, Omaha; Second Vice-President, Dr. F. E. Sampson, Creston; Treasurer, Dr. T. B. Lacey, Council Bluffs; Secretary, Dr. Chas. Wood Fassett, St. Joseph.

RECENT DEATH.

JAMES HART CURRY, M.D., a well-known physician in Westchester and Putnam Counties, New York, died on September 24th. He was born in New York and was a graduate of the Medical Department of Yale University. During the Civil War he served as surgeon of the 18th Regiment, New York Volunteers. He was an ex-president of the Westchester County Medical Society and also of the Yale Medical Alumni Association. He had practised for nearly fifty years in the town of Shrub Oak and is survived by five children, one of whom is Dr. Stanton Curry, of Peekskill.

THE MODIFICATION OF MILK IN MILK LABORATORIES.¹

BY T. M. ROTCH, M.D., BOSTON.

In considering the question of the different methods of milk modification each one of us must definitely formulate in his own mind what degree of modification as to exactness is needed, and how important we may deem the dangers which surround the handling of milk for any purpose and in any way according to the individual case which we are dealing with. Thus for those who hold that exact modification, small changes in the percentages of the milk, and the administration of fractional percentages of the fat, sugar and proteids, are always unnecessary, it is useless to be burdened with a discussion as to how these conditions are to be accomplished, for it is not the method of obtaining the finished product which is of interest to them, but the question of whether such production when obtained is desirable. To many of us who have been engaged in the endeavor to advance practically and scientifically the use of milk as a food, has come the opinion that the most intelligent manner of approaching the subject is to think and work in percentages. It would certainly seem that, with our knowledge of how greatly different creams and milks vary, the only satisfactory and intelligent way of dealing with the solids in milk is not by giving for certain ages so many tablespoons or teaspoons of this varied product, but to think of what percentages we wish to give, and then to give them as exactly as possible.

In a somewhat extended experience in the modification of milk both in the homes and in the laboratories, no doubt has been left in my mind that even when perfectly fresh, clean, and bacteriologically pure milk is used, there are many cases where the modification of the percentages and special combinations of these percentages are often necessary for a successful treatment, and this in no way argues that modification is all that is needed, for in many cases I have often found that modification entirely failed when applied to old milk, dirty milk, and milk bacteriologically impure.

The modification of milk for all ages, but especially in the early months of life, is extremely important, and too much attention cannot be given to it by those whose practice makes it necessary for them to deal with the difficult problem of infant feeding. This modification, however, has many different phases and possibilities, and there is no doubt that improper and inexact modifications may do great harm. In quite a number of cases a somewhat macroscopic rather than microscopic modification of the elements of the milk may be sufficient for the range of the individual digestion, and for the nutrition of the especial case, but it has been my experience with a very large number of infants, whose vitality was low and whose malnutrition was excessive, to find that the lives of these infants could only be preserved by gradual and minute changes in the percentages of the different elements of the milk and their combinations. We, therefore, in a certain number of cases cannot be too particular in assuring ourselves that we are using a milk modification which

is as precise as our knowledge up to the present time has made it possible to be.

As to which form of modification, home or laboratory, should be employed, it has always seemed to me a matter to be determined by the conditions surrounding the especial case, and in using both forms, as I am continually doing, I decide as to which I shall use by the same general rules, determining in which form in the especial case there may be the majority of the factors which are favorable for a successful modification product. If the patient cannot afford, or is too far away from the laboratory, then the same rules and precautions which are used at the laboratory should as nearly as possible be carried out in the home. The same method should be followed in each case. It is the details which usually differ, simply because it is often impossible to get what is best and most exact. The word *possible*, therefore, is a very significant one in the modification of milk. Milk for modification should be as fresh as possible, as free from dirt as possible, from a herd of as well cared for cows as possible, the Jerseys and Guernseys perhaps not being so fitted for infant feeding as those grades which correspond to the Holstein, Devon, Durham, Swiss and Bretonne. As to the especial method of getting the percentages, it is essentially mathematical, and in my experience, while there are certain individuals who have mathematical minds and like to calculate, the average busy physician has neither the ability, time nor inclination to work out the complex problem involved in a milk modification where a low proteid is needed with milkman's milk and a gravity cream. There is no reason, however, why this should not be done, provided the prescriber has a mathematical mind and knows exactly what the percentages of the milk and cream used each day in his especial families are. Even for such a physician, however, this is not an easy task, and requires constant vigilance and much care. He must thoroughly appreciate the dangers and difficulties he is encountering, for in spite of these he may think in percentages and think he is dealing in them, but in fact is working empirically. It is important, therefore, for the physician to appreciate the danger of working with uncertain materials. He must know in making his calculations that he can with certain percentages in the cream he is using only obtain a limited number of percentages of the proteids, and perhaps with the cream he is using to obtain a certain percentage of proteids it would not be possible to obtain the decided change of proteids which he might wish to give to the infant on successive days. He must therefore remember that to change his formula he must avail himself of a number of different creams in cases where, as I have so often found, frequent and even great changes are needed.

It should be clearly understood what a milk laboratory ought to mean. It should be a place where clean, fresh milk, handled by men trained to do so in the best way, is modified in any way that the physician demands. In our Boston Laboratory the physician's patient can receive on his order a mixture with the percentages called for made up of either separated cream, or gravity cream, separated milk or whole milk. The separated cream and the whole milk are taken from a rather late morning milking, and are modified in time to be delivered on the same afternoon within reasonable limits, and early the next morning (6 to 8 A. M.) in the suburbs and at greater distances.

¹ Read before the Obstetrical Society of Boston, April 16, 1900.

There are arguments for and against both the separated and the gravity creams. In my experience up to the present time I prefer to use a separated cream as being a number of hours fresher, but I am aware that a number of others prefer the gravity cream, and it is possible, so far as the percentages are concerned, for the physician, by giving a few hours' notice to the laboratories, to have used in making up his prescription a gravity cream of a specified fat percentage, and tested each day before it is used. I will presently refer to the disadvantages and difficulties arising from the use of gravity cream in home modification. In my laboratory modifications I use separated cream and whole milk. This milk, which is handled with unusual care and intelligence on the farms connected with the various laboratories, presents a remarkable freedom from large numbers of bacteria. Especial experiments have lately been made with the bacteriology of these milks at the Pepper Laboratory in Philadelphia, with the milk coming from the Chestnut Hill Farm. The experiments covered a period of three hundred and fifty-four days from September, 1898, to September, 1899. An average of 354 examinations for the year was 1,550 bacteria per cubic centimetre. In only twenty days was the average over 10,000, and the average of the remaining three hundred and thirty-four days was 1,530 bacteria per cubic centimetre, and in the autumn and winter was from 1,150 to 1,195. When we take into consideration that 10,000 bacteria per cubic centimetre is the maximum for good milk, it is clearly shown what an advance has been made in providing a pure milk supply.

The number of colonies of bacteria in the cubic centimetre of city milk commonly used often amounts to a million or more. In this connection it may be said that while the milk laboratories may be trusted to practically preserve the original purity of their milk supply during the process of its modification, yet it is especially in home modification where originally clean milk may be rendered unsafe by careless work in the kitchen or nursery. Thus the handling of good milk may make it unsafe and bad.

In regard to the question of heating milk, sterilizing and pasteurizing, with such milk as we may hope to obtain from the care which is bestowed upon it in the laboratories, there will usually be no need of prescribing any heating in our modifications, and I personally am in the habit of prescribing it unheated, excepting in very warm weather or where it has to be transported a long distance. Where, however, milk is used in our home modifications, where pathogenic organisms have already developed their toxins, sterilizing by heat does not destroy the chemical effect of these poisons. Milk which has been full of bacteria and then has been sterilized may be dangerous, because toxins of a poisonous nature may remain in it and act as poisons. This is my chief protest against the use of unknown milks and creams, and the careless handling of good milk. The physician should, therefore, whenever possible, know how good or how bad a milk he is obliged to use if he expects to judge correctly of the success of his modifying prescription. A milk, however, is not only unsafe in a bacteriological sense, for I have seen many instances where serious symptoms arose when a pure milk became dangerous from some unusual modification arising from a lack of knowledge of the modifying materials used.

In fact, unless the physician knows not only the percentage of fat in the cream which he uses each day, but also within what limits he can obtain, when using such cream, the other percentages, such as that of the proteids, he is forced to prescribe inexactly. He must also run the risk arising from not knowing whether he is dealing with an infant who may or may not be one especially susceptible to variations in the percentages and combinations of the elements of milk in its food. An improper modification of milk may be very unsafe for the patient, and in fact may lead to something worse than indigestion, namely, infantile atrophy, rhachitis or scorbutus. For instance, if we examine the food which was given in the earlier modifications of milk by simply diluting with water, we shall see why such dilutions failed to produce good results, simply because the nutritive quality of the milk was in large measure taken away from it by reducing the fat and sugar to such an extent that nutrition was impaired and rhachitis easily induced. After these simple dilutions with water came the many so-called "cream mixtures," which failed to produce the results expected from them, because the prescribers seldom knew what percentages or what combinations they were giving, having entirely overlooked the fact that there is no stable milk or cream, and that while they supposed they were using the same materials every day, they were in fact using many different materials, which combined in the same proportions every day necessarily resulted in many different foods. For this reason what might agree with the infant one day would disagree with it, unless by some peculiar good fortune, on many of the following days. My experience with these indefinite cream mixtures led me to investigate what the cause of their failure was and forced upon me the conclusion that it was to a great degree the lack of determining for the special infant the percentages and combinations which that infant needed, and my conclusion was that every infant must have its food adapted to its especial digestion and power of absorption, with resulting nutriment. This again led me to endeavor to perfect a means by which we could vary the percentages and combinations of the elements of milk to the greatest degree. Here I would state, as my experience may be of some possible value to other investigators on this subject, that in dealing with the proteids of cow's milk, I have found that where the proteid digestion is weak, and in those cases where we ordinarily would have supposed that it would be well to predigest the proteids, I had greater success in adapting the proteids to the especial infant by starting with a very low percentage and gradually increasing the percentage up to a point which would be of the proper nutritive value to that especial digestion than by attempting to predigest a high proteid.

By studying the following tables it will of course be seen that if a modification is indifferently done with reference to the quantity of the cream or milk employed, there will be serious differences in the percentages of all the constituents in the mixture, but if the same quantity of such a cream is employed without reference to its percentage of fat, there may be produced a radical difference in the food. It is therefore necessary not alone that the original formula shall affirm the exact cream to be used, but also that all changes be made by an experienced hand. Most persons, and among these qualified chemists, may easily

forget the great difference in the results of a mixture, even when its ingredients do not differ very markedly. It is not strange, therefore, that the modifier should not know that the extra teaspoonful of cream or milk added to a formula mixture may change its whole character as to percentages, and of course as to its feeding value. Thus suppose that we have had made a mixture of 20 ounces, with the percentages and changes as shown by the following:

Twenty-ounce mixture.— (1) Fat 3%, sugar 6%, proteids 1%. Adding 5 tablespoonfuls of milk, becomes (2) fat 3.50%, sugar 6.50%, proteids 1.50%.

Here it is seen what changes 5 tablespoonfuls of milk may produce when added to a 20-ounce mixture of a formula representing fat 3%, sugar 6%, and proteids 1%; namely, that the proteids have been raised from 1% to 1.50%; the fat to 3.50% and the sugar to 6.50%. Also to substitute in modification a heavy cream for a light one, the difference not being discernible to the eye but only to the fat tester, may change in a 20-ounce mixture a prescription for 4% fat to 10% fat. For instance, if a formula is made up for the employment of 10% cream (top milk), and 20 ounces is prescribed for the percentages of fat 4%, sugar 7%, proteids 1.50%; and in another day's mixture be put the same number of ounces of a similarly appearing cream, but containing 24% of fat, the change will be made from 4% fat in the mixture to 10% fat in the same mixture. In like manner when cane sugar is added, as is so often carelessly done to formula mixtures, the percentage of sugar may be doubled, and in some cases has been known to have been raised to even 30 in a home-made mixture. In short, great accuracy is needed in employing the ingredients so as to produce the proper constituents, and we can formulate our ideas on this subject by saying that slight changes make great errors. Although in a large proportion of cases the inaccuracy of milk modification results from the physician's lack of appreciation of exactly what material he is using, yet in many cases these inaccuracies are vastly increased by an insufficient oversight on his part when he orders the food to be mixed at home.

The dangers and difficulties of modifying milk both at home and at the laboratory although of the same nature are much greater at home. Constant vigilance, much time, and honest, exact work are equally necessary in both. It is merely a question, in which case all the factors of the problem can best be solved and all the dangers avoided, or rather the greatest number of the factors and dangers. I will now state a few of the dangers and difficulties which arise in prescribing specified and exact percentages and combinations at the home. Suppose that the percentage of fat in the milk used is 5 (in this case the milk is supposed to be from a Jersey cow), and that in the mixture made from this material we make our calculations in such a way as to obtain a 2% fat, the resulting proteids will be 1.60%. On the other hand, if we use the milk from a Holstein cow, the milk of which contains only 3% of fat, and if the same proportion of materials is used as in the first case, the resulting proteids will be 2.66%; hence, unless an ascertained and accurately defined milk is used, the proteids may vary, even when the same quantities of materials are used, from 2.66% to 1.60%, the variations depending upon whether the milk contains a 5%

or a 3% fat. These results are shown in the following table:

Milk containing fat.	Fat prescribed.	Resulting proteids.
5%	2%	1.60%
3%	2%	2.66%

As still further illustrating what different results regarding the percentage of the proteids may arise from using the various creams, I have had calculated and arranged the following table:

Cream to work with.	Fat in mixture.	Lowest possible proteid.
10%	2%	.75%
10%	3%	1.13%
10%	4%	1.50%
24%	2%	.31%
24%	3%	.47%
24%	4%	.63%

Here it is shown that unless the cream used is of known definite percentage, the mixture may show proteids varying from .31% to 1.50% as the lowest possible, even where the right quantity of cream is employed.

There are certain difficulties which arise in using creams in which the percentage is known, such as one which can be obtained with the greatest exactness by the separator, and also by setting a milk with a certain known percentage of fat for six or eight hours. I give a 10% cream as an example, because where milk is set for cream over a more prolonged period in order to get a heavier cream, it is manifestly not so fit for use as when it is fresher. It is impossible in using a 10% cream to obtain certain percentages of the proteids. The variation of limitations of the percentages of the proteids with a 10% cream are as follows:

With a 2% fat we obtain	.75% as the lowest possible proteids.
3%	1.13%
4%	1.50%
4.5%	1.82%

Therefore, as is often the case, where we wish to use a 3% or 4% fat, and yet a fractional percentage of the proteids, or, at least, as low as 1%, it will not be possible to make this modification with a 10% cream. Even if the cream is 12% the following variations will emphasize the same principle. Thus

With a 2% fat the lowest proteid is	.63%
3%	.94%
4%	1.25%
4.5%	1.41%

It is thus seen that if a low percentage of proteids is needed, a higher percentage cream is necessary than can usually be obtained by setting milk for six or eight hours. Still greater difficulties arise when we are dealing with a gravity cream in our home modification, for gravity cream depends as to its percentage very widely on the quality of the milk used, as well as the number of hours of setting and the other conditions, such as temperature and handling. Suppose we wish to prescribe a milk modification demanding 3% fat, 6% sugar, and 2% proteids, and that we used a cream with a supposed 10% of fat. If this cream should vary so that its fat was 8%, we should have a mixture with only 2.4% of fat instead of 3%. On the other hand, supposing the per cent. of fat in the cream was 12 instead of 10, using the same formula we should obtain a mixture with 3.6% fat in place of 3%. If, however, the physician had tested the fat in the cream, and found it contained but 8% instead of 10% fat, and had used a sufficiently larger quantity of this cream to produce 3% of fat in the mixture, he would find the proteids had been increased to 2.50% instead of 2%. On the other hand, if the

cream, after having been tested, had been found to contain 12% of fat, and the physician had put in a less quantity to get a 3% fat in the mixture, he would have proteids 1.66% instead of the 2% desired.

This at once brings up the question of the variations which take place in gravity creams not only from the milk of one herd but of many herds, for it will, of course, be necessary for the physician who is modifying at home to see whether his patients are all being fed from the same herd, or if from different herds what the percentage of fat is in the milks of the different herds, and what the percentage of cream from the same herd is on different days. I have just had some experiments made where the milk was bought at different places, and therefore probably came from different herds. After setting under the same conditions for eight hours at about 38° F. the top quarter was carefully poured off, giving the following results :

A gave a cream with a percentage of	6.2
B " " " "	7
C " " " "	10
D " " " "	11

E on two successive days gave a cream with a percentage of 12. It is thus seen that the milks of different herds vary decidedly in the creams which they produce under the same conditions.

I have also had some experiments made with the milk from the same milk company on a number of successive days under the same conditions :

A on the first day gave a cream with a percentage of	6.2
" " second " " "	8
" " third " " "	7.50
B " first " " "	7
" " second " " "	7
" " third " " "	7
C " first " " "	10
" " second " " "	9
" " third " " "	11
D " first " " "	11
" " second " " "	13
" " third " " "	12
E " first " " "	12
" " second " " "	12
" " third " " "	12

In all these experiments the temperature of the milk was kept at 36° to 38° F., and the time of the setting was eight hours.

A few facts in regard to milk taken from herds under different conditions will be of interest in this connection.

In cases where milk can be obtained at once upon milking, the per cent. of fat in the top quarter of milk which has been setting for eight hours will vary according to the per cent. of fat in the milk, as the following experiment will prove. One quart of milk from one cow testing 3.30% fat after setting eight hours at about 36° showed that the upper quarter contained 8% fat. One quart of milk from another cow testing 5.4% fat after setting eight hours at about 36° showed in the upper quarter 14.2% fat, making a difference in the per cent. of fat in the two upper quarters of something over 6%. Cows which give these extremes are not unusual in a mixed herd, in fact in almost any large, well-mixed herd it is likely that this difference could be found. In the same way the mixed milk of different herds varies between very nearly the same limits, as is shown by the records of the Experiment Station at Durham, N. H., which shows that in about 100 herds in the country around Durham the per cent. of fat in the mixed milk varied from 3 to 6, which would make a variation of the per cent. of fat in the top quarter of milk from the

various herds after it had set eight hours at about 36° F. of about 6%.

The following table shows the variation in the per cent. fat of the milk of six miscellaneous herds in the country around Durham, N. H., containing from 8 to 20 cows in each herd, and the college herd, containing about 30 cows. These were not picked herds, but taken indiscriminately. All were well cared for and there were few or no changes of cows in each herd.

TAKEN FROM THE RECORDS FOR THE YEAR 1899 OF NEW HAMPSHIRE AGRICULTURAL COLLEGE, DURHAM, N. H., TESTS MADE EVERY TWO WEEKS FOR NINE MONTHS OF THE MIXED MILK OF EACH HERD. PERCENTAGES OF FAT :

Herds.	July.	August.	September.	October.	November.	December.	January.	February.	March.
L. Thompson.	4.4	4.3	4.3	4.2	3.8	4.2	3.8	4	4.5
Deacon Meserve.	4.4	4.2	4	3.8	4	4	4	4.6	4.4
	4.8	4.2	4.4	4	4.6	4.4	4	4.7	4.9
	4.8	4.6	3.8	4.6	5	4.3	4.4	4.6	4.5
Chesley Bros.	4.2	3.8	3.2	4	4.2	4.3	4.2	3.8	4.2
	4.2	4	4	4.3	4.3	4	3.8	4.2	4.2
G. Demerritt.	4.4	4.4	4.2	5.2	5.6	4.5	4.2	4.7	5.2
	4.2	4.2	4.8	5.2	5.6	4.8	5.2	5	4.6
A. M. Dalton.	4	4	4	4.4	4	4.8	4.4	3.8	4.6
	4	4.2	4.2	5	5.2	4.8	4.7	4.4	4.2
H. H. Dame.	3.8	3.4	3.2	3.3	3.7	4	3.4	3.8	3.9
	3	3.2	3.2	3.8	3.2	3.3	3.8	3.6	3.8
College Herd.	4.4	3.7	4.6	4.5	5	5.5	5.8	5.1	4.6
	4.6	4.3	4.6	5	5.5	5	6	5.1	4.7

In all the herds the lowest fat test was 3% ; the highest fat test was 6% ; the variation was 3%. In one herd during the nine months (college herd of 30 cows) the lowest fat was 3.7%, the highest fat was 6%, the variation was 2.3%.

The variation in the herds is apt to be considerable, as the owner very often has a preference for one or another kind of stock, and often has a larger portion of that particular kind in his herd. This makes it evident that while in one herd, or even in several herds, very nearly the same result might be obtained, it is necessary, in order to be sure of getting even approximate results as to percentages, to make careful tests of the quality of the milk in each herd from which the milk is supplied. In testing the milk, if the sample obtained is not obtained from a careful mixing of the whole of the milk of the herd, it is likely to be misleading, containing too little or too much per cent. of fat, according as it may have been produced by the richer or the poorer cows of the herd. The same mixing of the whole herd milk is also necessary before the delivery of the milk to the consumer. Besides the variation in different herds, and from not being thoroughly mixed, it is well known that the per cent. of fat from the same herd will vary in the course of a year often as much as 2%, as will be seen from the above records from the New Hampshire Agricultural College. This is due to the different conditions of the cows and of the feeding during the year, and to the fact that the fresh cows which are giving the large quantities of milk will at times happen to be cows giving a low per cent. of fat, while at other times the large milkers will be cows which give a high per cent. of fat, so that the per cent. of fat of any herd which is not cared for with special attention to producing a certain per cent. of fat in the milk is constantly varying. If it is necessary for the physician to use different herds in prescribing for different children, in order to give the same percentages it would be neces-

sary to use a *different formula* for each herd, or if he should use the same herd in order to get the same percentages, it would be necessary to use a *different formula at different periods*. These are under the most favorable conditions and where the milk can be obtained at once after milking. If the milk is set after it is delivered by the milkman, the same rule for obtaining 10% cream will not apply, as the cream will have partly risen when the milk is delivered, and if it has set for eight hours after that, a twenty or twenty-four-hour cream may be the result. It is objectionable to set a milk for eight hours if it may be twenty-four hours or more old when it is received. It is well known that where the milk is obtained from large herds it is difficult to mix all the milk each day, and for this reason a variation will appear in the percentages of fat in the milk of one herd.

Therefore, there is no one formula which, by using ordinary gravity cream, can enable the physician to prescribe all the modifications which are necessary when certain variations in such percentages are needed.

It is important in prescribing to have the assurance that the patient receives what is prescribed. It has happened that innumerable instances have come under my observation where physicians have prescribed what was best, and yet where there was no doubt that a very different combination of percentages was actually given to the patient. In this way not only unlooked-for results would be obtained, but a very serious obstacle arises as to our judging from experience whether the proper combination has been given for the especial case. If a physician has decided that an infant is to be fed on some modification of milk, and believes that from time to time changes in the percentages of the mixture will be of value, he should recognize the danger which might arise from an unsafe milk, and the difficulties in making proper calculations unless his materials are known each day. Unless this is done he cannot know, when the patient is doing well, what it is that is causing the improvement, and if doing badly he will not know the reason, and thus will not be able to make the proper changes.

The difficulties and dangers which I have enumerated are practically dealt with and obviated when we simply ask the laboratory to give us the percentages and the materials which we deem necessary for the especial case, and thus all these different phases of a correct milk modification are much simplified when our modifications are made at the laboratory, where all these questions are practically solved for us, and the technique of modification is carried out by clerks trained for this purpose.

BREAST FEEDING.¹

BY A. WORCESTER, M.D., WALTHAM, MASS.

OUR most commonplace possessions sometimes get lost. Individually and collectively we occasionally lose sight of truths and facts which were dearly bought in the hard school of human experience. And perhaps the medical profession, in its enthusiasm over new discoveries, is especially liable to forget inherited knowledge. In matters purely medical this tendency to forget is not very dangerous; the new-fangled

drugs, after all, may not be much worse than the old standbys. But in the larger responsibilities of medical practice, as, for instance, in the direction of the nursery hygiene, the physician must be very wary of fads.

There never can be any doubt that breast milk is far and away the best possible food for infants. Other foods are valuable in the degree that they resemble this ideal food, and methods of artificial feeding are valuable only in so far as they closely imitate the natural method. So trite are these self-evident truths that it would seem superfluous even to mention them. And yet in practice no other foundation principles need more emphatic reiteration. For among the many retrograde tendencies of advancing civilization, there is none more dangerous than this tendency to shirk the various obligations of motherhood; and during later years there has developed the pernicious custom of cheating helpless babies out of their birthrights, by giving them, through false nipples, ingenious imitations of their rightful food.

The causes of this physiological crime are not obscure. The social demands upon modern mothers conflict with their babies' rights. In the log cabin the mother, though slaving single handed for a large family, was not too busy to nurse her children as they came. But the modern mother, with a house full of servants to help her, has not the time to nurse her babies or to take the ordinary care of them. In olden times mothers expected to stay with their babies; nowadays too many mothers expect to be free for outside duties and pleasures, and even for occasional vacations from family cares. Is it any wonder that the gynecologist is employed to treat the subinvolved uterus, and the neurologist to ward off neurasthenia, while the pediatricist struggles with the hopeless complexity of cow's milk modifications? Indeed, is it not possible that the medical profession is somewhat to blame for the present alarming fashion of the artificial feeding of infants? In this age of specialists, when young physicians are so completely equipped with methods for relieving both mother and child of the pathological consequences of this violation of nature, I, for one, cannot help thinking that the medical profession, instead of stemming the tide, is in reality largely responsible for this wrong drifting.

It is sad indeed if the result of splendid efforts to mitigate the evil effects of the occasional necessary loss of natural nursing is the increase of the evil itself. When the young mother whom Dr. James Jackson had counselled against weaning her baby triumphantly displayed her bottle-fed prodigy, the good old physician wisely said, "Ah, yes! But your success will lead other babies to their graves."

Among the regrettable evidences of pernicious medical leadership are the prevailing ideas that modern mothers are becoming physiologically unfit to nurse their babies, and that chemists by analyzing pumped-out samples of breast milk can expose its unsuitableness as a food for infants. It is hard to be patient with such presumptuous pseudoscience! How can it be supposed that the chemical analysis of chance samples of a living fluid, which we know undergoes subtle natural changes according to the mother's varying conditions and even emotions, should warrant such a defiance of nature as is involved in substituting for it any howsoever skilfully sterilized artificial food? Of course it is easy to fatten a baby

¹ Read before the Obstetrical Society of Boston, April 16, 1900.

by giving it food richer in fat than was its natural food. But who can estimate by scales and balances the most desirable growth of the child? Or who can supply by artificial incubation the natural human warmth and comfort that a breast-fed baby receives? Doubtless it is possible to train the newly-born to an immediate independence of motherly lovingness, and we will not dispute the skill of modern nurses in making babies behave themselves; but are mothers so relieved any the more willing to bear more children? Certainly not. Nor is it strange that modern women thus defrauded of the loveliest compensations of motherhood, which would have come to them in the natural satisfying of their deepest cravings, are so anxious to escape all maternal responsibility.

Both for the mothers' sakes and the babies' sakes, physicians are in duty bound to urge the vital importance and the otherwise unattainable advantages of breast feeding. My purpose this evening is to point out how these obligations can be met by calling attention to some of the steps that must be taken.

And first let us consider the question of wet nurses; a most unpopular subject, as we all know. The underlying objections to this time-honored method of feeding infants deprived of their own mothers' breasts ought not to be stronger today than they were in days gone by when wet nursing was not so unfashionable, and indeed some of the objections now have distinctly less foundation. For instance, it is possible nowadays with scientific precision to eliminate the danger of latent infectious diseases in the wet nurse that in former times could be eliminated only partially by unscientific opinion. And surely the question of the expense of the best possible nourishment of the infrequent and occasional baby is not a more pressing question than it used to be in the days of normally sized families.

The supply of wet nurses herabouts is very limited, it is true, but that is mainly because the demand is small. Where working women, in spite of their bounteous breasts, lose their babies, and where it is known that breast milk is in more or less constant demand, it is not so very difficult to arrange their employment as wet nurses. Several shifts about may be necessary, but whatever trouble is thus occasioned is small in comparison with the benefits likely to accrue to all concerned. The main supply of wet nurses, however, is from the class of illegitimate mothers. Were there less falsely virtuous scorn for such unfortunates it would be far easier than it now is to secure good wet nurses and at the same time to save these girls from future ruin. The common prejudice against letting legitimate babies thrive on the breasts of illegitimate mothers is unworthy of civilized people. Cows are not such moral animals as to warrant their preference over human mothers, whose misfortune is generally due to a combination of their ignorance and over-developed motherliness. Of course if the alternative to wet nursing were for the poor illegitimate mother to stay in some proper home nursing her own child, then there would be no propriety in persuading her to serve as a wet nurse. But that is not the alternative for nine out of ten. Unless persuaded otherwise, these girls will sacrifice their breast milk and for a time they will strive to support their babies in some wretched baby farm, whereas if employed as wet nurses they might earn better support for them-

selves and their babies, to say nothing of the gratitude and kindly interest which better than anything else will help them to rise above their misfortunes. A larger employment of illegitimate mothers as wet nurses would thus be a great moral as well as a great physiological gain to the human race. And physicians alone have the opportunity to bring about this improvement.

Let us turn now to the physician's opportunities and duties in inducing mothers to nurse their own babies. Much to this end can be done during pregnancy in teaching women what to expect. In this way the prevailing false notions can be offset by explaining the great advantages of nursing and by exploding groundless fears. But before pregnancy and even before marriage women ought to be taught to admire this really most beautiful function of womanhood. Girls should be taught to guard their breasts and nipples from the injury false fashions of dress impose. Better far the present grotesque fashions in dress, which make young girls look like wet nurses, than the opposite extreme of straight dress fronts we used to see and probably shall see again in vogue, which doubtless in past years caused many of the cases of inverted nipples we now have to deal with. Let us be thankful that girls today do not suffer mortification because bountifully endowed. Girls should also be taught that the sebaceous film is the natural and proper protection of the nipple's tip. Pregnant women should be taught to reinforce this coating with cerates, and not to damage the tender skin with alcohol and tannin. There will then be a fairer chance of a painless and naturally easy establishment of lactation.

It is, however, just at this point, when the baby is first put to the breast, that the physician's largest chance of service comes in. His unstinted time and patience are then needed. Many a mother loses her breast milk because the baby is allowed to chew off the ends of the nipples before the breasts begin to fill. Nursing then becomes an agony instead of the pleasure it is when properly begun. From the facts that the milk does not usually come until the third day, and that about that time is needed for the baby to get rid of its meconium, it might reasonably be supposed that nature does not intend nursing to be begun much earlier. And it is as mistaken kindness to prevent the baby from the exhilaration of crying by stuffing it with food as it is to upset its digestion with cathartics the day afterwards. If the baby is put to the breast for a few minutes only, and only a few times during the second twenty-four hours of its existence, then on the third day the baby will be hungry enough to ease the aching breasts. Were mother and child alone in the woods during these days, the natural process of nursing would undoubtedly stand a good chance of favorable establishment. And in practice it is plainly our duty to follow as faithfully as we can natural methods.

After turning the mother well on one side, and placing under her body some support so that she will not lie on lower level than her baby, then it is well to leave them alone together. If the baby will not take hold, it may be well to start the milk running by gentle coaxing manipulations. This is the physician's business unless he is perfectly sure of his nurse's knowledge and ability. Breast pumps, it must be remembered, are dangerous things, and in-

terfering husbands and ignorant friends are worse. One of the greatest helps when the breasts fill to uncomfortable heaviness is the "double Y" bandage invented in the Boston Lying-In Hospital. It is right in principle and serves beautifully in practice, but great skill is needed in applying it, and so the abominable straight-jacket bandage still is too often used.

In caring for the nipples of the nursing mother great harm is often done by mistaken methods of cleansing. Nasty-tasting lotions are often applied by stupid nurses, who then wonder why the babies hate to take hold. No washes are allowable. Olive oil or lanoline should be used instead. And then for a protecting dressing tallow and beeswax or the raw white of egg should be freely employed. Cracks and excoriations will then be astonishingly infrequent, but if either torturing accident occurs immediate attention is demanded. After thoroughly disinfecting with boracic-acid lotion (5%), and anesthetizing with cocaine, the crack and raw surface should be treated with a 10% solution of silver nitrate, then dried by pressure of absorbent cotton and painted over with egg albumin. For the next few nursings a glass-bell nipple shield should be used. Thus by scrupulous care mothers can be saved from tortures that they too often suffer, and then it becomes far easier to persuade them to continue nursing their babies in accordance with the design of the Creator.

If the baby does not thrive, and some modification of its food seems desirable, before weaning and attempting with the chemist's help to improve upon nature, it is certainly incumbent upon the physician to try in every way to better the mother's milk by building up the mother. This often can be done by bettering her conditions, by not keeping her in bed so ridiculously long as too frequently is done, by getting her out into the open air, by allowing a more generous diet, by saving her from every other fatigue than the natural and milk-inspiring company of her baby. And let us never forget to fight with all our might the falsely alluring patent baby food commercial corporations, whose impudent advertisements ought rightly to be decorated with tiny coffins rather than with portraits of fat-misshapen babies.

HOME MODIFICATION OF MILK.¹

BY CHARLES W. TOWNSEND, M.D., BOSTON.

A KNOWLEDGE of the percentages of the food components is very desirable in infant feeding, enabling the physician to intelligently modify the food to the individual case. On this account milk laboratories would at first sight seem to be the ideal way of feeding infants, and their establishment has indeed constituted a great step in advance, but however useful this method may be in some cases, it is more or less limited in its usefulness. Thus the expense and the fact that the laboratories are confined to a few large cities necessarily limit their sphere. Even where these limitations do not exist, however, it is still preferable to use in some cases food for the infant prepared at home, for it is certainly a fact that laboratory modified milk will not agree with all, even with skilled adaptation of the formula, and it is not an uncommon experience for infants to thrive vigorously on a home modification ar-

ranged to duplicate the formula it was previously taking from a laboratory on which it had not thrived. Just what the proportion of babies is who do not thrive on laboratory modifications I cannot say, but it does not seem to me as large as stated by Starr² in a recent article. The reason that laboratory modified milk does not agree in some cases I have always believed to be due to the fact that this milk is in the majority of cases first divided into two parts by the centrifugal process, one containing practically all the fat, the other part nearly free from it. These two portions are then recombined together with water, sugar of milk and lime water in proportions to meet the formula required, and the mixture is churned up in transport.³ The breaking up of the natural emulsion by this process, although not to be detected at first even by the microscope, is shown by the large oil globule generally found floating on the top of the bottles when delivered at the house of the infant.

In milk modified at home the cream should be obtained by natural separation by standing — the gravity process — and the mixture is not churned up by carting about, and no oil globule is to be found on top, even where the milk is pasteurized. I have been unable to produce the globule in this milk, even by churning it up by transportation.

Another objection to laboratory milk, which may prove serious unless the greatest care is used, is the danger of contamination from the more extended handling and transportation to which the milk is necessarily subjected. On this account pasteurization at 157° to 167° F., or sterilization at 212° F., is more frequently needed, especially in hot weather, and when the distance of transportation is great, or the express service requires long waits, or a double amount is to be sent on Saturdays to last till Monday.

If the milk is fresh from cows proved free from tuberculosis, and in the absence of danger of contamination by typhoid or other infectious diseases, it is, I believe, much better not to either sterilize or pasteurize it. Besides the danger of scurvy, which is slight, there is great danger of loss of appetite, interference with digestion and consequent lack of gain in weight in infants fed for a long time on milk heated to 212°. Such infants are apt to be very pale and sometimes show slight tenderness on handling, both early symptoms of scurvy. On the other hand, some infants will thrive for months on carefully sterilized food, showing how difficult it is to lay down one rule for all infants. Pasteurization at 157° is far less objectionable, but a change from even pasteurized to fresh milk often shows the great advantage of the latter.

I have described in a former article, published over a year ago,⁴ a simple method of home modification of milk by which it is possible to easily calculate the percentage of fat, sugar and albuminoids in the food. This method has continued to prove very satisfactory and has the great advantage of simplicity, which I believe is essential if it is to be commonly used by physicians. The complicated methods so often recommended demand too much mathematics for most men. My experience also leads me to believe that the nurse or mother prepares the food at home with such con-

³ Remarks on Infant Feeding, with Special Reference to the Home Modification of Milk, by Charles W. Townsend, M.D., in Boston Medical and Surgical Journal, March 23, 1899.

⁴ Loc. cit.

¹ Read before the Obstetrical Society of Boston, April 16, 1900.

scientific care that the product is uniform and fairly accurate, probably much more uniform than breast milk, and accurate enough for satisfactory results.

The analyses of top milk made for me by Dr. Charles Harrington on four successive days showed an extreme variation of only .68%, or only .27% omitting the one where the milk stood an hour longer. We also found that the top milk obtained by pouring off the upper quarter from a quart contained practically the same amount of fat as that by siphoning off the lower three-quarters, the difference being less than $\frac{1}{10}$ of 1%. The simpler method of pouring off the upper quarter is therefore to be preferred. This top milk contains about 10% of fat if it is poured off after the milk has stood six to eight hours. With this 10% top milk it is evident that 1 ounce in a 20-ounce mixture would give a percentage of $\frac{1}{20}$ of 10, or $\frac{1}{2}$ of 1 of fat. In the same way the percentage of albuminoids would be $\frac{1}{20}$ of 4, or .2, and the percentage of sugar would be the same as that of albuminoids. I have found that an even tablespoonful of sugar of milk weighs $3\frac{1}{2}$ drachms, and that each tablespoonful added to a 20-ounce mixture raises the percentage of sugar 2.

With this preliminary explanation, this simple rule may be formulated: *Each ounce of 10% cream in a 20-ounce mixture represents .50% of fat, .20% of albuminoids and .20% of sugar; and each even tablespoonful of sugar of milk added to this mixture raises the percentage of sugar 2.*

Thus, if we order top milk 3 ounces, water 16 ounces, lime water 1 ounce, sugar of milk 2 tablespoonfuls, we are making a formula of fat 1.50%, sugar 4.60% and albuminoids .60%. If we order 8 ounces of top milk, 11 of water, 1 of lime water (always making a total of 20 ounces), and $2\frac{1}{2}$ tablespoonfuls of sugar of milk, we are making a formula of fat 4%, sugar 6.60%, albuminoids 1.60%, or about the average composition of woman's milk. Of course this extremely simple method gives a fixed relation between the fat and albuminoids, the fat being two and a half times as much as the albuminoids, the normal relation in human milk.

In cases of difficult digestion it is almost always desirable to reduce both fats and albuminoids, so that this method is generally satisfactory in practice, and a resort to the addition of the lower milk or of richer cream is rarely necessary. In these cases where the constituents are all reduced the nutritive value of the mixture can be greatly increased without taxing the digestion by adding raw white of egg. Thus, 1 ounce of top milk, 18 ounces of water, 1 ounce of lime water and $1\frac{1}{2}$ tablespoonfuls of sugar of milk, giving the formula of fat .50%, sugar 3.20%, albuminoids .20%, can be made much more nourishing by the addition of the whites of one or two eggs, and will be retained where an increase of the milk would not be. A case from private and one from hospital practice will perhaps best illustrate this method.

A. O., six months old, weighed 5 pounds and 12 ounces at birth; now weighs 9 pounds and 12 ounces and has gained nothing for the last month. The infant had been fed on various cream and milk mixtures, generally sterilized, and patent foods, but no milk had been used with the patent food for the last six weeks, as the child seemed unable to digest any. This is, of course, a common and typical story. The infant was pale and emaciated, and was put on the following pre-

scription: Top milk 3 ounces, water 16 ounces, lime water 1 ounce, sugar of milk $2\frac{1}{2}$ tablespoonfuls.

This gives a formula of fat 1.50%, sugar 5.60%, albuminoids .60%. Six feedings were given daily of 6 ounces each at 6, 9 and 12 A. M., and 3, 6 and 10 P. M. As this needed 36 ounces, double the quantity of the above prescription was put up, or top milk 6 ounces, water 32 ounces, lime water 2 ounces, and sugar of milk 5 tablespoonfuls. The strength of this was increased every day by adding $\frac{1}{2}$ ounce more top milk and decreasing the water correspondingly. One-half ounce in the double mixture would be equal to only $\frac{1}{4}$ ounce in the 20-ounce mixture, so that it will be seen that the increase in fat daily was $\frac{1}{4}$ of .50%, or .12%, and the increase in albuminoids was $\frac{1}{4}$ of .20%, or only .05%. This change was so slight and so gradual that the infant was able to manage the food perfectly. At the end of sixteen days the strength of the food had reached: fat 3.50%, sugar 6.40%, albuminoids 1.40%. In the first week the infant lost a few ounces, in the second week gained 6 ounces, in the third week and for several weeks after she gained 12 ounces a week. At the end of a month the strength of the food reached: fat 4%, sugar 6.60%, albuminoids 1.60%, and it was kept at this point for several weeks, the amount in each feeding being gradually increased so that the infant took about 1 ounce for each month of age. A little later, as her appetite was not so good, barley water was put in three of the bottles in place of some of the water, leaving out the lime water and sugar, the prescription reading as follows: Top milk 8 ounces, water 3 ounces, barley water 8 ounces. She liked this so well, she was given barley water in all her feedings when she was eight months old, and the proportion of milk was increased to two-thirds of the upper half of the quart and one-third barley water.

An analysis kindly made for me by Dr. Harrington, of top milk consisting of the upper half, after standing eight hours, showed 7.18% fat. Therefore, a mixture of two-thirds of this upper half and one-third water gives an analysis of fat 4.80%, albuminoids 2.66%. At a year the child weighed $20\frac{1}{4}$ pounds, and was strong and vigorous, with a good color.

The following case was treated in the Out-Patient Department of the Children's Hospital during my last service:

R., two months old, said to have weighed 10 pounds at birth. He had never been breast fed, but had been plied with condensed milk, various patent infant foods, crudely modified cows' milk, fresh and pasteurized, and milk and barley water. He vomited frequently, and the movements were hard and undigested. The child lost weight steadily, weighing when first seen 6 pounds, and presenting a marked atrophied appearance. The face was wrinkled and senile, the skin was dry and hung in folds, and the extremities were mere pipe stems. The child was put on a fat 1%, sugar 4.40%, and albuminoids .40%, by ordering 2 ounces of top milk, 17 ounces of water, 1 ounce of lime water, and 2 tablespoonfuls of sugar of milk. Two ounces were given every two hours, and 10 drops of brandy four times daily. As the child was too feeble to suck well, a Breck premature feeder was used. The vomiting ceased and the stools began at once to improve. The strength of the food was cautiously increased, being guided by the character of the

stools and the general condition of the child, so that in two weeks he was taking fat 4%, sugar 6.60%, and albuminoids 1.60%. The wrinkles on the face filled out and the child appeared bright and vigorous. The gain in weight was regular and a little over 4 ounces a week. Thus, on November 13, 1899, he weighed 6 pounds; November 23d, 6 pounds, 8 ounces; December 11th, 7 pounds; January 2, 1900, 7 pounds, 8 ounces; January 18th, 8 pounds, 4 ounces; After this he ceased coming, but we heard he continued to do well. For a baby so feeble as to need the protection of an incubator, yet brought in winter to an out-patient department, this record is certainly satisfactory.

The criticism can of course be made that, unless the top milk is analyzed, it is impossible to say exactly what the per cent. is in a given case, and may have been quite different in these 2 cases. In the first case it was analyzed and found to average 11.40% of fat, being particularly good and uniform milk. In the latter case it was probably more nearly 10%. It seems fair to take 10% as the average, and it is to be noted that a difference of even 1.40% either way would make a difference of only .07% of fat with each ounce of the top milk in the 20-ounce mixture.

The variation in gravity cream obtained at home is much less than in centrifugal cream obtained from unreliable dealers. It is the physician's duty to investigate the milk supply and refer his patients to reliable dealers. The firm that advertises its ideal milk farm and then makes up deficiencies by buying indiscriminately outside is of course to be rigidly avoided, if disastrous consequences are to be escaped.

The use of cereals as diluents in the first case brings up an important question. The argument that no starch should be put in the infant's food because the mother's milk contains no starch seems at first logical and conclusive. It is to be remembered, however, that the albuminoids of cows' milk are quite different from those of woman's milk and the same argument would lead to their exclusion.

Test-tube experiments have been made over and over again to explain the frequently observed clinical fact that cows' milk modified with barley or oatmeal water will often be digested where the same formula without the cereal will give trouble. The curd formed where the cereal is used is finer and more easily broken up. On the other hand, those who deny the clinical fact say that there is no difference shown in the test-tube experiments between cereal solution and water, and they also add that barley water is little more than water.

The evidence of the advantage of barley or oatmeal water in certain cases, explain it how we may, seems so convincing that it must be considered, and outweighs any theoretical conclusions. This opinion is a very old one, and is, it seems to me, sound in its conclusions. At the last meeting of the American Pediatric Society, in 1899, in the discussion of a paper by Dr. H. D. Chapin on this subject, there was but one dissenting voice to the opinion that barley water and oatmeal water were sometimes of advantage, and it has certainly been my experience. I have fed infants most carefully and systematically on laboratory modified milk and on home modified milk, who have failed to thrive until cereals were added. Why this should be so in some cases and not in all it is hard to say, but it goes to show that babies

are not mathematical machines and that they cannot always be treated as such. Clinical experience as well as theory are both useful. I believe that most infants do better by the addition of barley or oatmeal water as a modifier when they reach the age of six to eight months, but that although the majority do not need the cereal before this age, there are some cases that do better with it.

The conclusions may be summed up as follows:

(1) The modification of cows' milk, with a knowledge of the percentages, is preferable to guesswork feeding of infants.

(2) Percentage feeding can be carried out by a milk laboratory or by home modifications.

(3) Milk laboratories are unavailable to many by reason of their absence or an account of the expense.

(4) Laboratory modifications do not, in the experience of the writer, agree with infants as often as home modifications.

(5) Laboratory modifications are necessarily subjected to more handling and transportations than home modifications.

(6) Milk that is fresh, clean, and from cows free from tuberculosis is preferable uncooked, or, in other words, pasteurization and sterilization, although sometimes essential, are to be avoided if possible.

(7) The method of home modification and of calculating percentages should and can be made extremely simple, and such modifications are sufficiently accurate and uniform.

(8) The addition of cereals to the milk in the form of barley or oatmeal water is generally advisable after the seventh month, and is desirable before that age in some cases as an aid to the digestibility of the milk.

Clinical Department.

NOTES FROM THE NEUROLOGICAL DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

III. LESION OF CHIASM; TEMPORAL HEMIOPIA, OPTIC ATROPHY; PROBABLE PITUITARY TUMOR, WITH GIGANTISM AND DEFECTIVE DEVELOPMENT (PRELIMINARY REPORT).

BY S. A. LORD, M.D., BOSTON,
Assistant Physician, Department for Diseases of the Nervous System,
Massachusetts General Hospital.

PATRICK M., age thirty-two, laborer, came to the clinic on December 20, 1899, during the service of Dr. Putnam, referred from the Eye and Ear Infirmary with the diagnosis of double optic atrophy, not consecutive. His chief complaint was of blindness in the left eye.

Family history.—Great stature, amounting to gigantism in the medical sense, is the rule in the family. The parents were nearly related, and though themselves rugged, all the children were pale and "ailing" in one way or another. An aunt died in an asylum. A sister was melancholy for a year. A brother was likewise "nervous and melancholy" for a year, and had fits of crying. All the brothers and sisters were subject to headache. Otherwise the family history is good. The wife is well and has had six children, of which four died almost immediately after birth (protracted labors, no reason to suspect

syphilis). Two are living and well, the youngest being two years old.

Personal history is unimportant up to a period of three years before the patient came to the hospital. Since that time he has been growing nervous, has been easily frightened, and on that account is thought "childish-like" by his wife. He has not been wholly temperate; he began to smoke at ten, and has used tobacco excessively since he was fifteen. He drank hard for several years when a young man. There is no history of venereal disease.

Closely following the onset of symptoms of emotionality just mentioned there was an attack, neuralgic in character, of severe pain in the legs and knees, lasting several days, intermittent, and unattended by swelling. Failure of sexual power and appetite then began; this has been progressive. Coincidentally appeared two additional sets of symptoms; the one digestive, including abdominal pain part of the time, but without vomiting, and the other referable to catarrh of the nasopharynx. These nasal and pharyngeal symptoms persist but do not increase.

A year later there was a return of pain in all the limbs, described as severe and shooting in character, and there was "stiffness" of the ankles and knees. There has been until this winter tenderness of the calves. (Doubtful history of slight swelling.) At this period it was difficult to open the hands in the mornings. No paresthesia. After persisting a year these symptoms grew less and have been insignificant of late.

About a year after the beginning of the illness, before the second attack of pain, left amblyopia ensued; it is not now remembered whether hemiopia was perceived. The onset of amblyopia was accompanied by tinnitus and vertigo, with sensations of blue and yellow in the field. The tinnitus was a "drumming noise," perceived only at night and only on the left side. This winter there have been signs of optic nerve irritation on the left, of added interest on account of their rarity. They are in the form of bright flashes, and have grown much "smaller" recently. Perhaps the color sensations belong in this category. Seven months before coming to the hospital there ensued dryness of the skin, sensitiveness to cold, thirst, and severe headache, the latter of sudden onset, localized chiefly behind the left eye but felt also in the left temporoparietal region. It was continuous, lasting through the night. No vomiting, nor any cerebral symptoms besides those mentioned. According to the patient the tinnitus and vertigo disappeared with the onset of headache, while the previously merely amblyopic right eye became forthwith blind (the explanation of this in view of the lack of evidence of glaucoma ophthalmoscopically, must be that of vascular lesion). It is stated further that the vision of the right eye improved gradually for a while, and eventually with suddenness and to marked degree on the subsidence of headache, which occurred after a persistence of ten weeks, when a leech was applied. At about this period strabismus was first noticed; it has not increased. Three weeks after the pain stopped there occurred brief epistaxis and the discharge successively of several lumps, partly of very firm consistency, each of considerable size, from the nasopharynx, apparently. Preceding each discharge was mild discomfort in the left side of the head, relieved promptly by the discharge. There has been occasional

slight hemoptysis without cough; this probably originated from the mouth itself. Two months before coming to the hospital the left ear began to "stick out," with no apparent cause, and has since remained much more prominent than the right. In cold weather the ear droops especially. There has been some recent tendency to sleepiness in the daytime, and there was loss of speech of a few minutes' duration, with no loss of consciousness or other cerebral symptoms. In the last year or two the patient has lost strength, has now a "weak back" and has become very pale. He has lost 30 pounds in four years, 20 in the last six months, the maximum weight having been 215 pounds. He is now nervous, easily worried and frightened, particularly at night. Apart from this undue emotional mobility and the attacks of causeless fear there has been apparently no mental failure. There have been no paresthesia, no numbness, no spasm or paralysis (excepting the strabismus), no diplopia, no bladder symptoms. The hands and feet

Normal hand shown for comparison.

have always been large and have not increased in size, nor has there been any alteration of the features, except that of the left ear, the significance of which remains wholly in doubt (possibly beginning acromegalic enlargement).

Status.—The man is just under 6 feet in height, weighing about 186 pounds, heavily framed and large featured, with marked pallor of skin and mucous membranes; his appearance is peculiar and striking. The gait and station are normal, but there is an air of uncertainty explained by his blindness. Memory excellent, mind intact. Subcutaneous fat of face and neck small in amount, normal skin wrinkles well indicated. Speech normal. Expression depressed, somewhat apathetic and unintelligent—it calls to mind suffering and blindness. The beetling brows and projecting supra-orbital ridges, the retreating forehead, the prominent malar bones, long nose, and especially the long, powerful chin, contribute to the remarkable physiognomy. No prognathism. The ears are rather poorly mod-

elled. The left is unusually prominent, projecting 4.1 centimetres, while the right projects but 2.3 centimetres; the left is 7.4 centimetres long, the right 7 (the change in position of the ear it will be remembered is recent). The hair is thin and dry. The occipital protuberance is very large and the ridge extends far around on each side. In the skiagraph it strikes one as immense (there was nothing else unusual). The teeth are normal in arrangement. Palate narrow. Tongue rather small. Lips and nose not thickened; they are well cut. The breadth of the head at the malar bone level is remarkable; rapidly narrowing above this the head assumes a marked cone shape, which is obscured in the photograph, however, by hair. Over the limbs and body panniculus well developed; the skin everywhere dry and pale, nowhere abnormally thickened. There is noticeable absence of hair—it is very scant on the face and pubes. The penis and testicles are extremely small, the scrotum only partially developed. The

hemipic pupillary reaction. The vision on the left is almost *nil*; there is slight light perception. The acuity on the right reduced in remaining half field. Temporal hemiopia, as in Diagram No. 1. No central color scotoma. Both the superficial and deep reflexes are normal, except that there is excessive general response, of neurotic character. Wrist and triceps jerks well marked.

Urine contains no albumin nor sugar; sexual power said to be entirely absent. A cover slip of the blood showed moderately decreased hemoglobin.

The diagnosis of lesion of the chiasm, from a probable tumor of the pituitary body, was made at the first visit; there seemed to be no doubt that a general disorder of nutrition—speaking broadly—had begun and both acromegaly and myxedema were considered. Nux and thyroid tablets were given, but were soon changed for iodide of potassium, in the hope that the lesion might possibly be specific. Slight improvement in general condition followed, the pallor grew

DIAGRAM NO. 1. Showing temporal hemiopia, right eye. Dividing line unusually oblique.
 ——— Field for white.
 - - - - - Field for blue.
 x x x x x Field for red.

DIAGRAM NO. 2. Temporal hemiopia, right eye. Progressive concentric loss in the remaining half field, greater for colors than for white; perception for red wholly lost.
 ——— Field for white.
 - - - - - Field for blue.
 x x x x x Field for red.

hands are very large and thick, but are not "over outlined" as in acromegaly. The fingers are wide, thick and square tipped. The feet are also very large, not so much in length as in circumference; the big toes are disproportionately large, are in fact immense, extending unusually far forwards, with squared ends. No rheumatoid joint changes. Though the size of the extremities cannot be said to be beyond the limits of an individual of this stature, the type evidently is that of gigantism.

The thyroid could not be palpated. No thymus dulness. No lymphatic enlargement. The breath is foul. All movements, including those of the eyes, made normally. The grasp is of fair strength, but leg movements are weak. Sensation is everywhere perfect, including sense of position; no Romberg symptom. Pupils regular, left larger than right. Reaction to light extremely sluggish on left. On the right, the pupil reacts a little less slowly, when light is thrown on the temporal half of the retina. No reaction when light is thrown on the nasal half—

less extreme, and the patient thought the eyesight had improved. In February, 1900, he had a chill, and felt very hot afterwards. He was troubled for a while with intense general itching, which disappeared. All pain disappeared from the head. He spat a little blood. He lost flesh, and more recently gained six pounds. Had considerable nasal discharge and persisting gastric catarrhal symptoms. Frightened and crying sometimes at night.

In February a small degree of divergent strabismus was noted. Examination of the nasopharynx at this time by Dr. Coolidge was practically negative in result and did nothing to explain the previous pharyngeal symptoms. In March there was no essential change for the better. Examination of the visual fields and acuity showed distinct progression of the disease—despite the patient's statements as to improvement in sight—in the form of concentric limitation of the remaining half field of the right eye for white and color. It is to be noted that the loss of color vision was much more rapid than that for white,

perception of red being totally abolished. Diagram No. 2 shows these changes. There was no perception of light by the left eye. At the time of writing, April, 1900, there is no conspicuous alteration of condition; pupils almost equal in size; to light right reacts sluggishly, left does not react. Sense of smell present. Palms slightly moist. Temperature 99.6°. Given strychnia and thyroid. Examination of the ears brought out nothing new.

The interest of the present case lies in the occurrence of optic chiasm disease, of a type referable to a tumor in the sella turcica, in an individual born of consanguineous parents, with family history of gigantism and neuropsychopathic tendencies, this individual himself presenting evidence of gigantism and signs of degeneracy and of defective development. The individual is, moreover, the evident subject of profound vital disturbances, the manifestations of which — though here of obscure origin — resemble in suggestive manner some of those seen in acromegaly and myxedema: pains in the limbs, weakness, pallor, sensitiveness to cold, loss of sexual power and desire, somnolence, mental deterioration; the polyuria and thirst being more significant of possible pituitary (acromegalic) disorder, and the dry skin of myxedematous change. Further, there have been symptoms strongly suggestive of brain tumor, the whole picture being complicated, indeed somewhat obscured, by gastric and peculiar nasopharyngeal symptoms.

There can be no doubt of the existence of a chiasm lesion in the present case, the trouble having first involved the fasciculi of the left optic nerve and subsequently, in succession, the fasciculus cruciatus and fasciculus lateralis of the right. From the concentric limitation that is now affecting the remaining half field it would seem that the peripheral fibres in front of the chiasm are being first involved. Though there are no certain evidences of tumor, the presence of new growth is rendered very probable indeed, for the following reasons:

(1) The important conditions, other than tumor, causing these visual symptoms, namely, tabes and strictly local changes — exostosis, meningitis, primary interstitial inflammation of rheumatic (?) origin — can be eliminated, the former with reasonable certainty on account of the very great rarity of such special involvement of the chiasm in the tabetic process, and because of the presence of the knee jerk; the latter — primary circumscribed pathological process — with probability, on account also of rarity and the lack of definite history of rheumatism, and because there have been symptoms which could not be the results of a lesion so essentially local, which symptoms began in fact before the visual phenomena made their appearance at all (I mean particularly the change in character and the sexual failure).

(2) The headache — protracted and severe — the vertigo, tinnitus and momentary loss of speech, and the irritative optic nerve symptoms can be better explained as tumor symptoms than otherwise, although they have largely abated. Such abatement of pain is known to occur in the course of tumor, particularly on the appearance of focal signs, and it will be remembered that in this case strabismus appeared more or less coincidentally with the subsidence of the pain.

(3) There is at least one focal sign, slight in itself but extremely suggestive of tumor — the strabismus. The remarkable alteration of the left ear may also be

interpreted as the result of pressure in some obscure, indirect way.

What is the nature of the probable tumor? Nothing points to syphilitic growth or meningitis, or to tuberculosis; nerve and bone tumors and other recorded lesions are rare. There remains the possibility of a tumor of the hypophysis; such tumors are comparatively frequent.

Other arguments than that by exclusion favor the presence of such growth, to wit: gigantic persons are peculiarly liable to pituitary enlargement; the symptoms of progression of the growth are characteristically vague (as in this case), outside of the visual signs, and finally, certain prominent and early symptoms presented by this individual can be better explained by the supposition of glandular intoxication or disorder — of the hypophysis, for example — than in any other way.

It is true that the patient, a degenerate and partially ill-developed being with hereditary tendencies still further modified by former excesses, might well show, as has been already hinted, mental and sexual failure at an early age, and that he might become amblyopic and amaurotic through an optic atrophy secondary to a primary circumscribed process, of the kind already mentioned, at the chiasm (a well-recognized though rare type), and further that the remaining symptoms could be explained on neuropathic and catarrhal bases. The possibility of this course of things must certainly be borne in mind in attempting to understand the rather baffling history, for there is no proof of tumor.

A more attractive and equally admissible idea, as it seems to me, is that we are dealing with a disturbed chemico-physiologic equilibrium, resulting from modified function of the thyroid gland and the prehypophysis, a condition at present obscure and atypical but one which may pass on into definite acromegaly or myxedema. It would be obviously logical to think first of the hypophysis in this connection, since we suppose on other grounds that it is diseased. But it is hard to see why a lesion of this hypophysis, if it has existed long enough to have caused the initial deterioration and has grown large enough to cause a severe grade of optic symptoms, has not brought about a single definite sign of acromegaly. The principal grounds for supposing a change in thyroid secretion have been the conspicuously dry skin — an opposite condition to the sweating seen in acromegaly — and the fact that the gland was not discoverable on palpation. It is perhaps permissible to speculate to the effect that there occurred originally (in an individual whose characteristics imply a well-known liability to disturbances and arrest of vital function) a change in amount or quality of thyroid secretion which resulted in stimulating the pituitary gland to growth for the purpose of supplying some element lacking thenceforth in the economy. The slight fever, apparently chronic, to judge from two observations, is against the typical manifestations of thyroidism, but is doubtless a result of disturbed metabolism. I think it impossible to ascertain the influences — as to cause and effect — of the gastric symptoms, polyuria and thirst in this case. It is to be noted that they have all decreased, and that the skin is less dry. It must be said that there are other points in the case also which have not been cleared up, notably the pharyngeal symptoms and the change in the left pinna.

Medical Progress.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., AND WM. DUDLEY HALL, M.D., BOSTON.

(Concluded from No. 11, p. 344.)

THE SIGNIFICANCE OF INTRA-OCULAR HEMORRHAGES AS TO PROGNOSIS OF LIFE.

C. S. Bull⁶ claims the fundus should be examined in all diseased conditions of the blood and circulatory apparatus, as it may afford definite information regarding the blood current and vessels throughout the body. He draws the following conclusions: Subconjunctival hemorrhages are of little importance in the young, being usually the result of muscular effort. In the aged, when they occur spontaneously, they suggest a weakened condition of the vascular walls. Intra-ocular hemorrhages in old people are significant, and suggest the probable occurrence of cerebral apoplexy. Recurrent retinal and subhyaloid hemorrhages in the young are of slight significance, especially if due to syphilis whether inherited or acquired. Hemorrhages into the vitreous of the young are of grave prognostic importance, and point to the existence of general vascular degeneration. In chronic interstitial nephritis and diabetes retinal hemorrhages, irrespective of the existence of exudative retinitis, indicate a fatal termination of the disease. The mere presence of a thrombus of the central vein suggests albuminuria when associated with retinal hemorrhages, and renders the prognosis very grave.

INJECTION OF STERILE SALT SOLUTION IN COLLAPSED EYES.

H. Knapp⁷ states that the following deductions are drawn from cases treated by this method. When from lack of vitality in old age or any other cause the cornea sinks in so that the eye collapses in such a way as to prevent the wound from closing exactly, a liquid should be injected until the globe has resumed its shape and the lips of the wound apply correctly. Not only remnants of cataract but also cholesterol and other heterogeneous substances, including perhaps movable foreign bodies, may be syringed out of the eye with success. When during the extraction of cataract the fluid vitreous escapes in such quantity that the eyeball collapses, either totally or to such a degree as to prevent the closure of the wound, liquid should be injected so as to fill the globe and make the wound close. When from an operation or an injury the eye collapses, injection of a sterilized indifferent liquid may restore the shape of the globe, facilitate the closure of the wound, and ward off infection from the entrance of conjunctival secretion into the eye.

TUMOR OF THE PITUITARY BODY.

Walton, Cheney and Mallory⁸ report the case of a man, aged twenty-five, who for a long time had attacks of migraine accompanied by hemianopsia. Later there was persistent deficiency of vision, involving primarily the temporal field of one eye only, subsequently extending to the nasal field of the other eye, giving rise to homonymous hemianopsia. Still later there was loss of color field on the otherwise unaffected side of

one eye (hemiachromatopia). A time went on there was loss of sexual power, diminution of vision and optic atrophy, which with the severe headache pointed strongly to tumor. Towards the end there appeared vasomotor symptoms, somnolence, physical weakness, and apathy and lack of mental grasp. From a study of this and other recorded cases the conclusion is reached that congenital peculiarities in growth resembling those of acromegaly, but occurring in otherwise healthy individuals, may point to structural defect of the pituitary gland, a defect sometimes furnishing the starting point for new growth later in life. The occurrence of pituitary tumor without definite symptoms of acromegaly does not necessarily disprove a connection between this organ and the disease, for the persistence of even a small amount of healthy gland tissue suffices to carry on the function of the gland. The combination of general symptoms of new growth with optic atrophy and loss of temporal field makes diagnosis almost certain. Hemiachromatopia is not necessarily of central origin.

SUPRARENAL EXTRACT IN OPHTHALMOLOGY.

H. Landolt⁹ says the vessel-constricting action is confined to the superficial vessels, which may prove of use in differentiating between this and deeply-seated injections. This action suggests an application for cosmetic purposes in removing the so-called "red eye." The first sensation after an instillation is a sense of warmth, which soon gives place to a feeling of coolness. It has no effect on the accommodation or tension, or upon the vessels in the interior of the eye. In rabbits, when injected under the conjunctiva, mydriasis has been noted. The danger of causing local necrosis or actual death naturally would restrict its use in this manner until more is known regarding the dosage. It certainly is of use in rendering the field of operation bloodless, and thereby promoting the action of atropine, cocaine or eserine, and thus make it possible to dispense with ether in the acute form of inflammatory glaucoma.

ACOIN — A NEW LOCAL ANESTHETIC.

Randolph¹⁰ reports that Trolldenier, of Dresden, announced in the January number of the *Therapeutischer Monatshefte* the discovery of a new local anesthetic. By experimenting on dogs it was shown to be less toxic than cocaine, and upon rabbits, by using the powder or strong solutions, an anesthesia lasting several days could be obtained. Solutions remained sterile for eleven days. It is a white powder, quite soluble in water, is derived from guanin, which is found in almost all animal and vegetable cellular tissue, and is related to caffeine and theobromin. He concludes that in solutions of from 1-100 to 1-300 in a quiet eye the time to obtain satisfactory anesthesia is about the same as cocaine. There seemed to be no epithelial defect after its use. There was no change in the size of the pupil or the accommodation or the tension. Presence of acoin in agar prevents the growth of staphylococcus albus and kills it if already grown. The iodides and corrosive sublimate precipitate it, but it is compatible with cyanide of potash. Among the chemists acoin is recognized by the more pretentious title, namely, diparaanisylmonophenethylguanidinchlor hydrate, and should be respected accordingly.

LARGIN IN DISEASES OF THE EYE.

Largin is one of the more recent synthetic substitutes for nitrate of silver, occurs in the form of a stone-colored granular powder, and contains 11.10% of silver combined with protalbin, thereby being richer than any of the similar compounds. Its watery solution is brown in color, alkaline in reaction and fairly stable. It is not precipitated by either albumin or the chlorides. It is a somewhat astringent, non-irritating bactericide. Stephenson¹¹ found it inferior to protargol and silver nitrate in gonorrhoeal ophthalmia. In acute contagious conjunctivitis of the Koch-Weeks bacillus a rapid cure followed the use of a 10% solution daily. The results were good in acute trachoma and after trachoma operation. In chronic conjunctivitis, due to the Morax diplobacillus, although useful, it is inferior to a solution of zinc sulphate. It was satisfactory in acute blepharitis and lachrymal cases. It is little likely to cause pain, but will certainly stain the conjunctiva if used too long a time.

DIONIN IN OPHTHALMOLOGY.

This new remedy recently introduced by Wolffberg¹² and Nicolaier is the hydrochlorate of ethyl morphine, and appears as a crystalline powder, very soluble in water, and seems to act as a powerful stimulant to the lymph circulation in the conjunctiva and cornea. When applied locally there is, in addition to the anesthesia of the cornea and conjunctiva, a well-marked chemosis. Its use seems to be indicated in ulcers of the cornea of low vitality with impending perforation. It is claimed that in collapse of the cornea, as sometimes happens after the cataract operation, the folded cornea has been made to assume the desired curve with the flap in good position. It is also thought to promote the healing process, and to accomplish this end should be instilled several times daily before the operation. This use, locally, of the powder is apt to cause violent sneezing, and is therefore dangerous where there is a large wound in the globe, but the promoter thinks that if properly introduced on a vulcanite spoon and not insufflated, this *contretemps* may easily be avoided. He does not think that it favors hemorrhage or is a painful remedy. Where less rapid action is desired, as in reducing the tension, clearing the cornea and relieving pain in glaucoma, it may take the form of a 25% ointment of cacao butter.

PERONIN — A NEW LOCAL ANESTHETIC.

Bufalini and Guaita¹³ states that in the form of the hydrochlorate it is a white salt of slightly bitter taste but of no odor. It is slightly soluble in cold, up to 2% in hot, and insoluble in alcohol, ether and chloroform. Internally it has been used for the cough of phthisis and whooping cough, and as a hypnotic in the insomnia from alcohol. Instillation of a tepid 2% solution gives an instantaneous and profound anesthesia of the cornea of rabbits, which seems to last for several hours, and is unaccompanied by hyperemia or epithelial defects. Guaita, who has used a ½% solution in the human eye, finds that there is a slight sensation of smarting which almost immediately passes away, followed by a hyperemia which reaches

its maximum in four minutes, and lasts about a couple of hours or more. There is a smart lachrymation and even running at the nose and a slight watering of the other eye. The anesthesia of 1% peronin corresponds to 3% cocaine, and is attended with no loss of corneal epithelium. It has no effect upon the pupil, accommodation, visual acuteness, field of vision or tension. He suggests that it may be of use in enucleation or evisceration, as the conjunctival hyperemia matters little, and the penetration and anesthetic action is much greater than cocaine.

IODIC ACID, GALLICAN AND INDOGALLICAN IN THE TREATMENT OF TRACHOMA.

A. Schiele¹⁴ has lived where 30% of eye cases are affected with trachoma, and among 1,500 school children 53% were affected. He had been in the habit of using iodine and vaseline, but lately changed to iodic acid, which he uses in the form of crayons of different consistency, the softer being pure iodic acid, and a harder composed of gum arabic in proportion of 15 to 1. The application is painful even under cocaine, but does not last long. The mucous membrane becomes dry and brownish in color. He uses 5% solutions applied with a brush, and 3% solutions as collyria, which are sufficiently strong enough for home use. For the pannus he uses an ointment made up of iodic acid 1½% with lanoline, olive oil and cocaine. Iodide of potash may be given internally during the treatment, which usually lasts two months. He also uses gallican, which is a white powder, very soluble in hot water, by dusting it upon the affected areas once or twice daily during both the early and late stages of the disease. Indogallican is a dark-gray powder, insoluble in water, containing about 38% of bismuth and 23% of iodine, which can be dusted on with slight cauterizing effect. It is especially useful in superficial and deep corneal processes, healing the ulcers in a very short time by both a drying and an antiseptic effect. It is not indicated if there is much irritation.

THE INFLUENCE OF POISONS ON THE MOTOR APPARATUS OF THE EYES.

Guillery¹⁵ has studied the effect of different poisons upon the various movements of his own eyes. His method of measuring the rapidity of ocular movements depends on the principle that a line of certain length, illuminated from one end to the other during a short interval of time, creates an after image on the retina in the same direction when at rest. If the eye moves to the side the after image of a vertical line will be inclined, and from the angle of inclination the rapidity of motion can be calculated. If this is calculated for the most energetic effort of a person, any pathological diminution of function may be noted, and this method serves as a sort of a dynamometer. After alcohol the abduction is at first diminished without especial weakening of the power of adduction. Morphine weakens the external muscles, most of all the interni. It causes myosis without affecting the accommodation or convergence especially. Chloral, even in small doses, causes mydriasis and weakens the adduction and abduction. Only large doses of paraldehyde diminish the rapidity of contractions of the ocular muscles. Sulphonal and trional paralyze the in-

term. Cocaine causes mydriasis. Ether and chloroform diminish the associated movements and power of fusion.

EYE AFFECTIONS IN PERSONS WHO WORK WITH
HYACINTH BULBS.

Zeper¹⁶ claims a form of irritation of the skin and eyes seems to attack those who are engaged in separating the young bulb from the parent. It consists in a severe itching of the hands and face, with an irritation of the conjunctiva, amounting even to a conjunctivitis, and August and September seem to be the months during which the condition is most prevalent. Sometimes groups of minute worms are noticed on the bulbs and at other times are noticed masses of hard brittle crystals. In August and September when the dried bulbs are being separated much dust is scattered about, and in this dust are found eggs, larvæ and a full-grown mite about the size of a cheese mite. Although they have never been actually found, there is a strong suspicion that the parasite works its way under the skin and dies there.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

MEETING of April 16th, 1900, DR. J. G. BLAKE in the chair.

DR. ALFRED WORCESTER read a paper entitled

BREAST FEEDING.¹

DR. T. M. ROTCH: I have always been a strong supporter of breast feeding when possible. My experience as to the willingness of mothers to nurse has not been quite that of Dr. Worcester; in fact it is rather that they beg to be allowed to feed their infants. I have for many years spent much time in studying the question of modifying mother's milk as we would an artificial food. A great deal can be done to help the mother to nurse, undoubtedly, but it may happen that while attention to her general hygiene may make her milk suitable for the baby, yet that in many cases the milk cannot be adapted to the infant's digestion.

The milk of the modern mother is not always of the best. It may happen that in spite of this the mother wants to go on although the baby is not thriving and is in continual pain. In such cases it is generally best for the child's sake to resort to the bottle. There is, however, no question but that babies will thrive on human milks that we would reject if they were artificial mixtures. I think mothers should be encouraged to nurse if possible.

DR. C. W. TOWNSEND: In spite of many notable exceptions I think most women desire to nurse their children. Much can be done to encourage them in this feeling. I remember many cases in which mothers who failed to nurse their first child succeeded later. It is well to encourage such cases — even if they fail two times they may succeed the third time. This is a point in which much good can be done by the doctor. I think there are many cases in

which the breast milk is apparently disappearing about the fourth or fifth week and the parents are discouraged, but if they can be encouraged to persevere and if the mother is got out of doors and into a better condition of life it will be found that after a time the baby will thrive. Yet in spite of this poor breast milk is sometimes much worse than good modified milk.

DR. J. B. SWIFT: I find more mothers who are averse to nursing than the last two speakers apparently have. Babies certainly do much better on breast milk and I encourage nursing as much as I can.

DR. H. E. MARION: I feel the improper care of the nipple at the beginning of lactation is the great cause for the aversion that women have for nursing. Mothers are generally ready enough to nurse the first baby, but after an experience with a sore nipple they rebel.

DR. EDWARD REYNOLDS: While I now seldom see babies after the first few weeks of life the position that commends itself to me is a middle one. The enormous advances in the scientific modification of milk made in the last fifteen years make me think that artificial milk is better than anything but the best breast milk, but, on the other hand, the best breast milk is far better than any artificial milk. We should be guided as much as possible by the interests of the baby. In the class of breasts that are manifestly poor from the start we do best to dry up the milk at once and put the child on the bottle. On the other hand, the best breasts should never be given up for the bottle. In the great middle class I think it is well from the point of view of both the mother and the baby to allow nursing for some six weeks or for three months if the baby continues to thrive. When the breasts begin to fail it is well to resort to artificial milk at once. As regards the nipple and its care I have changed my views very materially in the last few years. In any nipple but a thoroughly bad one a great deal of harm is done by astringents. Most of the trouble comes from hard nipples. It is well to leave such nipples alone until three weeks before labor and then begin to soften them. The women can hardly be expected to keep on unguents during the night, but they can during the day. It is also well not to be too energetic about developing short nipples. I agree in what has been said about encouraging women to nurse in succeeding pregnancies. I have seen several women who could nurse only a few weeks with the first baby, a month or two with the second, and finally developed good breasts.

DR. GEORGE HAVEN: I have now under my care a woman who is nursing her sixth child very well, but who heretofore has met little success.

DR. REYNOLDS: I should like to ask Dr. Rotch how long a baby should be kept on the breast if the mother has perfect breasts and the child continues to thrive.

DR. ROTCH: They should not nurse exclusively after the eleventh to twelfth month, as by that time the amylolytic function is developed, showing that the child is ready to digest starch. It is not well to use starch previous to that time excepting in special cases, as it is not wise to tax a growing function. But a function may be weakened quite as much by not being used after it is once developed as if used too soon during the stage of its development, so I think some

¹ See page 361 of the Journal.

¹⁶ *Klin. Monats. f. Augenheilk.*, December, 1899.

starch should be given when the child is a year old. Of course the perfection of the artificial modification of food has made the question of the influence of teething, season of the year, etc., as bearing upon a change of diet, of much less importance than was formerly the case.

DR. J. P. REYNOLDS: I should like to ask the experience of the members of the society as regards teaching children from a very early age to go all night without disturbing the mother. There is nothing that makes women more ready to nurse than the certainty of an unbroken night's sleep.

DR. ROTCH: It seems to me that a baby requires to be fed pretty often during the earlier months in order to keep up its animal heat.

DR. TOWNSEND: I have had a number of very vigorous babies go from 10 P. M. to 6 A. M., from the very beginning. In the first six weeks I let them have one nursing at 2 A. M., if they insist, but I try to persuade them to sleep all night if possible.

DR. WORCESTER: I have always made this a practice and I think it was taught me by Dr. Reynolds. It is my ideal and in nine times out of ten I attain it. I find if the baby is waked up every two hours during the day and then nursed at 10 P. M., it will often go even later than 6 A. M. I have always looked on eight hours' rest as quite as necessary for the baby as for the mother.

DR. J. P. REYNOLDS: If sleep be the cornerstone of health there is no way to build up an inexperienced mother that is better than to give her rest. The root of the matter is having a good monthly nurse.

DR. E. REYNOLDS: I confess that in the earliest period this method does not seem quite ideal for the baby. On the other hand it probably is in the end, as it is the best way to make the mother a good wet nurse.

DR. SWIFT: I try to make my babies go all night without nursing.

DR. HAVEN: So do I, but I seldom succeed at first.

DR. ROTCH: I think it is a mistake to try to train young babies too precisely, and I think that is the chief direction in which the modern nurse is apt to err. As regards a point mentioned earlier in the evening—that of the modification of breast milk by various means—Dr. Swift has asked what is generally the cause of dyspepsia in breast-fed children. The general rule is that the fat is low and the proteids too high. If now in such cases, the mother being strong and healthy, with plenty of milk, we give the mother a stronger diet, the baby will have still more colic.

In such cases I find exercise—two hours walking daily, or riding—will bring down the proteids without bringing down the fats. As for breast pumps, I must say I have used them for years without trouble, but they should always be used gently and with antiseptic precautions. They are especially valuable when it is wanted to empty the breast for only a few days.

DR. BLAKE: To me the question of frequency of nursing is determined very much by the circumstances of the case. I have never advocated saying strictly that the baby *must* sleep all night. If it will sleep all night so much the better—if not, the intervals between nursing can gradually be lengthened. I cannot see how it can be right to feed a child every two hours during the day and make it go eight hours without

food at night. The child wakes up hungry and really needs food.

DR. C. W. TOWNSEND read a paper entitled

HOME MODIFICATION OF MILK.²

DR. ROTCH: The expense of laboratory milk will as time goes on become in the estimation of the public of very much less importance than it is now. New laboratories are being started all over the country, and, after all, it is not a question of what is cheapest but what is best. The laboratory, it should be remembered, merely corresponds to an apothecary shop where the directions the physician gives will be carried out. If he orders the milk sterilized he will get it sterilized, and if he orders it not sterilized it will not be sterilized. If he orders whole milk it will be whole milk that is given him, though for my part I have yet to see trouble from the milk being separated milk. The fat globule spoken of may come in one set of bottles and not in a single one of the hundreds of other bottles made up from the same separation, and there is no proof of its being due to the milk being separated. In cow's milk that has never been separated the lumps sometimes occur. As to scurvy, it has never been proved that it is due to the milk being heated to 212°. It probably is from some improper modification. Scurvy comes from bad milk, not from the fact that such milk has been cooked. As to Dr. Townsend's method, where it is not necessary to figure exactly it is a most excellent method, but as the top milk is not by any means always 10% cream it cannot be regarded as exact, and even if we are sure of obtaining a 10% cream there are certain per cents. of the proteids which cannot be obtained with this 10% cream. I cannot agree that most cases of indigestion are due to the fats and proteids together, as in my experience it is the case that the trouble is caused by any one of the various elements of the milk.

DR. WORCESTER: One of the superiorities of the old-fashioned method of breast feeding is that it requires no such knowledge of the higher mathematics as does even home modification. In many of my cases I am driven by mere force of circumstances to depend upon the simplest methods. I compliment Dr. Townsend upon his use of egg albumin. For five or six years I have followed the Dresden method of home modification. In these cases I pasteurize the milk, as I cannot be sure of the supply. It is with me a cardinal principle never to believe a milkman and in summer I never dare to give unpasteurized milk. Children often do not thrive on it and need something else, and I have been fully satisfied by compensation for the pasteurization by adding the white of an egg.

DR. T. M. ROTCH read a paper entitled

THE MODIFICATION OF MILK IN MILK LABORATORIES.³

Owing to the lateness of the hour it was voted that discussion of this paper be deferred until the next meeting.

ONE HUNDRED AND ONE YEARS OLD.—Mrs. Hulda Miner, who was a native of Oswego County, died at Fredonia, N. Y., on September 29th, in her one hundred and first year.

² See page 353 of the Journal.

³ See page 357 of the Journal.

AMERICAN GYNECOLOGICAL SOCIETY.

ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY
1, 2 AND 3, 1900.

FIRST DAY.

THE meeting was called to order by the president, DR. GEO. J. ENGLEMAN, of Boston, Mass., and the address of welcome was delivered by DR. JOSEPH TABER JOHNSON, of Washington, D. C.

DR. WILLIAM P. PRYOR, of New York, read a paper entitled

AN OPERATION FOR PRIMARY VAGINAL CARCINOMA,
APPLICABLE ALSO TO CANCER OF THE RECTUM IN
WOMEN.

Primary cancer of the vagina is a rare form of malignant disease. It is usually situated on the posterior vaginal wall and extends rapidly toward the rectum and perivaginal tissues. The cancer is prone to spread by invasion of the tissues having common sources of blood and any successful operation must seek the removal of all the organs belonging to the vascular group in which the affected organ is placed. It also recurs locally. In Lowenstein's case recurrence took place after three and a half years. In both of Pryor's cases it occurred within one year. The operation of Olshausen consisted in a blunt dissection of the vagina from the rectum, which usually resulted in failure and early recurrence. He reports 2 cases, the first cancer of the rectum and vagina ulcerated and infiltrated, involving the posterior vaginal wall $1\frac{1}{2}$ inches. The second — cancer of the vagina — occurred 1 inch below the cervix on the posterior vaginal wall. The operation employed by Dr. Pryor has the distinct advantage of removing as thoroughly as possible all the diseased area. After the usual preparation of the patient, an incision from the pubes to the umbilicus is made and the internal iliac arteries and the obturator vessels are ligated with kangaroo tendon; the bladder is dissected from the anterior uterine wall and the vagina opened anteriorly; the uterus and appendages with the entire rectum are later removed after the actual cautery has been used to char the cancerous mass. After the excision of the rectum and periproctal tissue an artificial anus is formed near the normal site. This radical operation has a surgical basis in the following principles: (1) The preliminary and preventive hemostasis renders the field of operation comparatively dry, and there is less danger of transplantation of cancer cells during the subsequent manipulation; (2) avoidance of injury to the cancerous field until hemostasis is secured and the cancer charred; (3) there is removal of all organs in which recurrence is apt to take place from above downward; (4) establishment of an artificial anus near the normal site.

DR. MUNDÉ has seen only 2 cases of primary cancer of the vagina in his long experience. These cases were practically inoperable — only curettement and cauterization were done, which relieved the symptoms temporarily. He does not consider that such a bloody and radical operation pays, as the benefit to the patient is slight and the recurrence inevitable.

DR. SUTTON, of Pittsburg, has seen but 1 case in thirty-four years' experience. He has little faith in the radical operations for malignant disease of the genitalia. He considers that the causation and pathology rather than new methods of operating should engage

our attention, as we need to find the factor producing cancer in order to combat it successfully.

DR. VAN DE WARKER, of Syracuse, feels that nothing is gained by operating for cancer. If his cases recover and the disease does not recur he concludes that the condition was not cancerous.

DR. MONTGOMERY, of Philadelphia, says that in no class of cases is the relapse so likely to recur as in cases of cancer of the vagina; the thin vaginal wall and the abundant lymphatic circulation is responsible for this rapid return of the disease. In 1892 he had operated on a case of cancer of the rectum and posterior vaginal wall by the Kraske method, after a preliminary Maydl operation, and had removed the uterus and appendages, with the posterior vaginal wall and 5 inches of the rectum. The disease soon recurred. He does not believe that operative treatment has much value in these instances. There is no method of treatment by which you can insure your patient against a recurrence, and no way of determining how extensively the glands and perimetritic structures are involved. Our present position in regard to these cases is one of experimentation.

DR. A. L. SMITH thinks that often unsuccessful operations on the cases deter other patients from being operated upon that might be relieved.

DR. BURNS has felt for years that radical hysterectomy was a useless operation in those cases and prefers high amputation of the cervix with galvano-cautery as the preferable procedure.

DR. REAMY has had more satisfactory experience, and has had his patients live many years after high amputation of the cervix for undoubted malignant disease. The prognosis depends upon the position of cancer and extent of invasion.

DR. DUDLEY, of New York, confined his remarks to primary vaginal cancer. He had operated on 2 cases, and considers the disease returns here more quickly than elsewhere in the body. He believes that Pryor's operation does the best that can be done for these deplorable cases and is heartily in favor of the method.

DR. PRYOR, in conclusion, said that very probably we would soon have positive evidence that the cancer bacillus had been demonstrated, and that he would not be deterred from operating on a given case, if he thought relief could be afforded, by the consideration of remote cases that might be prevented from subjecting themselves to necessary surgical procedure, because of the ill results ensuing.

DR. I. S. STONE, of Washington, read a paper on

FECAL FISTULÆ.

Small fistulæ in healthy bowels heal spontaneously. If persistent, are usually due to disease of the bowel or obstruction. The various operative procedures for the relief of the annoying condition were considered. Lateral anastomosis is applicable in some cases. The sigmoid flexure and rectum are frequently injured in the enucleation of tubo-ovarian abscesses, etc. Dr. Stone reported 2 cases successfully operated upon and detailed method used.

DR. CURRIER had seen but 1 case of fistulæ of small intestine. This was cured by resection of a portion of the bowel. If fistula is high up in the intestinal tract early operation is advisable. If low down it is wise to wait, as nature will frequently institute a spontaneous cure. The consensus of opinion in the diseas-

sion was that there is a constant tendency in the fistula to heal spontaneously in cases where there is no tubercular trouble and the opening is in the large bowel.

DR. MUNDÉ observed that fecal fistula may occur in cases where the surgery was clean and carefully performed. He cited 3 cases of intestinal fistula where the intestine had been opened to save life, by relieving the great distention. He employs the Murphy button in his intestinal work. It is important to differentiate between large and small intestinal fistula, as those of the large bowel usually result in a spontaneous cure.

DR. W. L. BURRAGE, of Boston, read a paper on

THE REMOTE RESULTS OF CONSERVATIVE OPERATIONS ON THE OVARIES AND TUBES.

The writer had had 137 operations which were performed on diseased uterine appendages with the object of preserving one or both ovaries with their tubes, or as much of the tubes as were reasonably normal in appearance. In 85 of these reliable information as to the present condition could be obtained at least a year after operation, and the results were included in the tables accompanying the paper, the cases being divided into the more severe and the less severe. In comparing the two it was found that gonorrhoea and syphilis were more prevalent and that the symptoms had resulted more frequently from difficult labors or abortions among the more severe and that the tubes were closed in a majority of the more severe, whereas they were open in all but 4 of the less severe. Pregnancy followed operation in 4 of the more severe and in 11 of the less severe. In none of the cases when the closed tubes had been opened and new ostia formed did pregnancy follow operation. All of the cases of subsequent pregnancy in both classes, except 2 of the less severe, had had previous pregnancies. Anatomical cure was recorded in 33 out of 57 cases who came under observation, and symptomatic cure in 60 out of 85.

The writer's conclusions were that it is advisable to do conservative operations in all cases where the ovaries and tubes are not hopelessly diseased in all parts of their structure, except on patients who are near the menopause, on patients who have pronounced gonorrhoea of long standing, and on cases of malignant disease. With the present methods of performing resection of the tubes, if both tubes are found closed subsequent pregnancy is not to be expected.

In severe grades of inflammation of the appendages, irrespective of causation, if the ostium abdominale of one tube is patent, the prospect of subsequent pregnancy after the preservation of a portion of ovary is about one in four and a quarter, or 23½%. In the less severe grades of inflammation under similar conditions of tube and ovary, the prospect of subsequent pregnancy is about one in two and a quarter, or 44%. In women who have borne children in both classes, subsequent pregnancy may be expected in 35%, whereas in previously sterile women it may be looked for in only 5%.

DR. EMMET, of New York, advocates strongly conservatism in surgery of the uterine appendages and cited an illustrative case in which pregnancy occurred when only a small fragment of ovarian tissue had been left. He urged that as much as possible of the tube be permitted to remain.

DR. DUDLEY, of New York, had performed 138 conservative operations on the appendages without a death, and reported a case of double pyosalpinx in which he had successfully transplanted a part of the ovary in the interior of the uterine wall after exsecting the tubes. He was certain that grafting had occurred, as the patient was menstruating regularly and had had a possible abortion since operation. Pregnancies had occurred in many of his patients after the conservative operations. He tries to save both the menstrual and procreative functions.

DR. HARRIS, of Paterson, N. J., thinks that in those instances where the tubes are exsected the ovary many times is not sufficiently diseased to warrant its removal. For the past two years he has scarcely removed an ovary except in cases of ovarian abscess. He tries to avoid the personal inferiority which a woman feels who has lost both ovaries and to prevent the occurrence of the premature menopause.

DR. VINEBERG has had poor results in those cases where there has been a pelvic peritonitis, even with slight lesions, as the patients suffer after the operation.

DR. GOFFE considers that conservative surgery on the appendages is one of the most important subjects the gynecologist has to consider. Most of his work has been done by the vaginal route; he uses the thermocautery to resect the ovary and burn out the cysts, preferring the equipuncture method.

DR. ROBB gave an instance where adhesions and an ovarian blood cyst followed conservative ovarian surgery.

SECOND DAY.

A paper on

A COMPARISON OF VAGINAL AND ABDOMINAL OPERATIONS.

by DR. G. RICHELOT, of Paris, was read by title.

DR. J. CLARENCE WEBSTER, of Chicago, presented a series of casts illustrating the

ANATOMY OF PREGNANCY AND LABOR; ALSO, MODELS USED IN GYNECOLOGIC TEACHING.

The older textbooks on obstetrics are full of fallacies and errors on this subject and these casts are prepared in exact reproduction of nature, made directly from frozen sections of the cadaver. The method of their preparation was described and attention called to their value scientifically and as teaching adjuncts.

DR. BUCKMASTER has employed paraffine to secure representations of the pelvic organs, and has illustrated the steps of perineal laceration operation by this method.

A paper by DR. E. E. MONTGOMERY, of Philadelphia, on

COMBINED NEPHRECTOMY AND URETEROTOMY,

was read by title.

DR. REUBEN PETERSON, of Chicago, presented a paper on

ANASTOMOSIS OF THE URETERS WITH THE INTESTINES: AN HISTORICAL AND EXPERIMENTAL RESEARCH.

The paper was illustrated by numerous drawings and microphotographs. The first part was devoted to a review of the literature on the subject; the second,

a detailed account of his experiments upon dogs; the changes in the ureter and kidney had been thoroughly studied and causes of death in many instances determined. In many cases Maydl's method of ureterotrigono-intestinal anastomosis was employed. The writer's general conclusions were as follows:

(1) The primary mortality of uretero-intestinal anastomosis, both in experimental work on animals and in man, is exceedingly high.

(2) The best technique is that requiring the least amount of suturing of the ureters themselves.

(3) All efforts to prevent ascending renal infection in animals, as in man, when the ureter has been implanted without the vesical orifice, have proved futile.

(4) It is impossible to determine in advance the extent of the infection which will result from uretero-intestinal anastomosis. The patient may die in a few days of a pyemia, or in a short time of pyelonephritis, or in rare cases may recover from the infection with resulting contracted kidneys.

(5) Hence the operation is unjustifiable, either for the purpose of making the patient more comfortable, as in exstrophy of the bladder, vesicovaginal or ureterovaginal fistula, or for malignant disease of the bladder.

(6) The results of uretero-intestinal anastomosis through the formation of vesicorectal fistulae have not been favorable up to the present time.

(7) The success of Frank's experimental work in vesicorectal anastomosis justifies the expectation that the future results of this operation will be more satisfactory.

(8) The primary mortality of ureterotrigono-intestinal anastomosis is low for an operation of this magnitude.

(9) While it cannot be denied that ascending renal infection may occur after this operation, the infection as a rule is of such a type that the chances of the individual's overcoming it are good.

(10) Hence the operation of implanting the vesical flap with its ureteral orifice into the intestine is a justifiable surgical procedure.

(11) There is no valve guarding the vesico-ureteral orifice, nor does the circular muscular layer of the ureter or the bladder muscles themselves act as a sphincter.

(12) It has been abundantly demonstrated by experimental and clinical work that the rectum tolerates the presence of urine and acts as a good substitute for the bladder, and that good control over the anal sphincter will be maintained.

A paper by DR. J. W. BOVEE, of Washington, on A CRITICAL SURVEY OF URETERAL IMPLANTATION, was read by title.

DR. HOWARD A. KELLY, of Baltimore, read a paper entitled

THE EVOLUTION OF MY TECHNIQUE IN THE TREATMENT OF FIBROID UTERINE GROWTHS.

DR. KELLY, with the aid of drawings and photographs, detailed his method, particularly in dealing with very difficult cases, such as large adherent tumors or intraligamentous fibroids. There are three ways of dealing with these tumors and meeting the complications: (1) By a median sagittal bisection of the uterus with the tumor; (2) by a coronal bisection of the uterus in its cervical portion; (3) by a bisection

of the tumor alone. The situation and anatomic relation of the tumor should be thoroughly studied after the abdomen is opened, before beginning operation. The dangers to be avoided are brought about by atypical cases. The hemorrhage may be excessive and uncontrollable, prolonged operation and injuries to the intestines and ureters may jeopardize the patient. In all these cases the principle of the operation is the same, and the best method of enucleation is to seek out first, isolate and ligate the ovarian vessels of *one* side; then to expose and tie the uterine vessels of the *same* side; then to cut across the cervix and clamp the opposite uterine artery, then the round ligament, and lastly the ovarian vessels.

DR. GEORGE J. ENGLEMAN, of Boston, read the

PRESIDENT'S ANNUAL ADDRESS.

DR. A. L. SMITH, of Montreal, read a paper entitled

AN APPRECIATION OF KELLY'S METHOD OF REMOVING FIBROIDS OF THE UTERUS.

He had formerly been strongly opposed to operative treatment for fibroids, because of the high mortality then prevailing among the best operators, but the ideal method perfected by Kelly had led him to adopt this as the method of preference. He detailed the salient features of this procedure and considers that the great advantage is that there is much less danger of injuring the ureters. He laid great stress upon the importance of feeling for each individual artery and tying it before cutting it, and then putting a second ligature on it, as the first may be loosened after the tension of the tumor has been removed. Chromicized catgut is employed. He opposes leaving the tubes and ovaries remaining after hysterectomy, as he believes that sooner or later they will cause trouble. Hysterectomy is far more preferable than myomectomy except in case of a single polypus. All fibroid uteri should be removed as soon as discovered because the woman with a fibroid is liable not only to hemorrhage, but to suffer from reflex disturbance of digestion and circulation. Besides, every day its removal is becoming more dangerous and the chances of its becoming malignant greater. The writer strongly condemned the vaginal morcellation, as the operation is carried on in the dark and the ureters frequently wounded, while complications such as adhesions of the vermiform appendix and tears of the intestine, which are easily dealt with by the abdomen and with the patient in the Trendelenburg position, are almost impossible to manage when working from the vagina.

DR. F. H. DAVENPORT, of Boston, described an

INTRA-ABDOMINAL AMPUTATION OF THE UTERUS; A MODIFICATION OF HYSTERECTOMY.

In cases of cancer of the cervix or body of the uterus he employs the vaginal hysterectomy, but in non-malignant conditions even in small growths, particularly in young married women, he prefers supravaginal hysterectomy, permitting the cervix to remain. After careful study of the technique he thinks that not only the cervix, but even part of the lower uterine segment may be left without ligating or disturbing the uterine artery, by doing a high amputation of the uterus. He first clamps the broad ligaments and divides them, then divides uterus high up, having a curved needle armed with silk introducing a

continuous suture, controlling the bleeding as he cuts; later the clamps are removed and the ovarian vessels are ligated. The organ being removed above the vesico-uterine peritoneal fold there is practically no danger of injury to the ureters or bladder.

In the discussion on methods of treating fibroid growths Dr. PLYOR described his method of treating intraligamentous fibroids by bisecting the uterus and enucleation of the intraligamentous nodules. After their removal the then symmetrical uterus can be safely removed by the ordinary method.

Dr. GORDON has for a long time employed the continuous suture in hysterectomy and is then certain that all the vessels are secured. He condemns strongly the use of chromicized catgut in abdominal surgery, as he believes it is not easily absorbed, and universally employs the ordinary catgut. Does not use silk because non-absorbable. He thinks the sutures should be permitted to remain in abdominal incision for at least two weeks, until complete union has occurred.

Dr. MANN, of Buffalo, thinks that cutting the upper part of both broad ligaments after ligation often will permit the elevation of the uterus and facilitate extirpation of growth. By Kelly's method one may get the growth out very quickly, but it will require much time to complete the operation. He leaves a part of the cervix in place and drains through the dilated cervical canal.

Dr. BALDY has had 2 cases recently in which the tumor extended over the bladder and he made the posterior incision through uterus to safely remove. He thinks that Kelly's method is of much value in the difficult and unusual cases, but is not valuable as the routine method, and is a dangerous operation for a general surgeon or untrained gynecologist. He cited 2 cases where the ureter had been injured in following the plan.

THIRD DAY.

Dr. THADDEUS A. REAMY, of Cincinnati, O., contributed a paper on

BRONCHIAL DISEASES NOT INVARIABLY A CONTRA-INDICATION FOR ETHER ANESTHESIA IN ABDOMINAL SURGERY.

His personal experience with surgical anesthesia covers 8,000 cases. For surgical work he considers ether in every way preferable as an anesthetic. He has, however, never lost a patient under either ether or chloroform. The prejudice against the use of ether in the presence of acute, subacute, or even chronic bronchitis, is largely unfounded, provided proper conditions are observed in its administration. These conditions include proper preparation of the patient, that the anesthetic be administered in the operating room, the temperature of which must be from 98° to 100°F, the chest and trunk of patient lower than the pelvis and lower extremities and the ether of pure quality. He exhibited the inhaler which he employs. He has never witnessed a case in which pneumonia was probably produced by ether inhalation. He has seen bronchitis, both acute and chronic, at once cured as a result of ether anesthesia, these results probably being due largely to its action upon the respiratory mucous membrane. In some instances he does not hesitate to administer it to patients suffering from severe bronchorrhoea, but would not employ ether in

the presence of emphysema. He would, of course, not employ ether when the patient is suffering from Bright's disease, but he has rarely seen damage to the kidney follow its administration in properly selected subjects. It is his custom in subjects for abdominal or vaginal section, to administer 4 or 5 grains of calomel four hours before the operation, and he orders that they have hypodermatically $\frac{1}{4}$ grain of morphine and $\frac{1}{120}$ grain of atropia twenty minutes before the section. The calomel he has found a good foundation for securing purgation by salines within twenty-four hours after the operation. He orders such patients to drink freely of water, and believes that all these means protect the kidneys and respiratory organs from damage from anesthesia.

Dr. McLEAN advises a warm, quiet room and believes that if no confusion or conversation is permitted one-third the quantity of ether will be required.

Dr. HARRIS prohibits conversation in the anesthetizing room and permits nothing to divert the attention of the patient from the anesthesia.

Dr. ARCHIBALD McLAREN, of St. Paul, read a paper on

THE RELATIONSHIP BETWEEN DYSMENORRHEA AND APPENDICITIS.

He spoke of the unsatisfactory results usually obtained in the treatment of dysmenorrhoea and the necessity for prolonged general treatment. Pelvic inflammation is frequently the cause of dysmenorrhoea and appendicitis causes disease of the appendages, and the appendix is frequently found adherent to the right appendage. In many cases appendiceal colic is caused by the pelvic congestion at the menstrual period—the pain is principally on the right side and the symptoms are relieved by removal of the appendix. He detailed several illustrative cases where the entire menstrual pain was relieved by removal of the appendix. In 40% of cases of inflammatory disease of the appendages he removes the appendix.

Dr. SKENE has noted many cases when the ovarian pain has disappeared after a removal of the appendix. He uses the hemostatic forceps as the best method, diminishing danger from hemorrhage and infection.

Dr. SMITH has frequently found the appendix firmly adherent to the sac of a tubal pregnancy or tubo-ovarian abscess. The combination of appendicitis and salpingitis is present in many cases. He thinks this fact an argument against the vaginal methods of dealing with intrapelvic lesions.

Dr. PHILANDER A. HARRIS, of Paterson, N. J., demonstrated the utility of a certain chart for the determination of pelvic asymmetry from a very simple method of external pelvimetry. He exhibited the instrument employed and urged the more frequent use of the pelvimeter. The best interest of the patient and physician demands this study of pelvic measurements. Dr. Harris also exhibited photographs illustrating the advantages of employing a certain background in the photography of pathologic specimens.

Dr. MALCOLM McLEAN, of New York, read a CONTRIBUTION TO THE MANAGEMENT OF FACE PRESENTATIONS, WITH REPORT OF TWO CASES.

He reviewed the methods of dealing with the head thus faultily placed. Dr. Schatz had advised the converting the face presentation into a vertex while the

head is free above the superior strait and the membranes are unruptured, but there are usually two difficulties to contend with: (1) The diagnosis of the malposition is not so easy as the textbooks indicate, and if descent is far advanced it is too late to employ Schatz's method; (2) it is difficult to secure the normal position, and relapse to the abnormal is apt to occur. Dr. McLean's method is practically a version by the vertex within the pelvis, and is performed as follows: The patient being under full anesthesia, the hand is passed carefully within the vulva, with the outside hand seizing the body of the child. In the entire absence of uterine contractions, the chest is pushed as much away from the pelvic brim as possible from the point toward which the chin is pointing in the direction of the occiput, that is, pushing obliquely from behind forward; at the same time the fingers of the vaginal hand are pushed up alongside of the head in one or other of the oblique diameters of the pelvis so that they can reach the suboccipital portion of the head. The thumb at the moment steadies the brow and with a slight lifting motion imparted to the whole of the head it is caused to rotate on its axis as described, the chin passing upwards above the sacro-sciatic notch as the occiput is drawn down below the pubes. Flexion may be considerably hastened by pressing down the occiput by the outside hand as soon as the face is dislodged from its wrong position.

Dr. A. J. JOHNSTONE read a paper on

THE INTERNAL SECRETION OF THE OVARY.

There is no proof that the ovary has any function other than the manufacture of eggs. It is in no sense a gland. It is incorrect to compare it any way with the thymus, thyroid or other glands. He considers that if the cause of nervous phenomena in a woman was the lack of an internal secretion, the girl prior to puberty or the woman with delayed menstruation would have similar phenomena. He thinks that the results produced by the administration of ovarian extract could be produced equally well by salt and soda, as hysterical patients are very easily influenced. Gouty cases have greatest trouble at the menopause. He thinks there is not an iota of proof that the disorders of the menopause are produced by the absence of an internal secretion, but they are due to faulty oxidation and deficient elimination. As a proof that the ovary has little influence on the development of the woman, he cites a case in which he removed both ovaries for cystic disease in a girl of eleven who, notwithstanding, went on to perfect physical development. He condemns the practice of preserving a part of the tubes and ovaries as simply a postponement of trouble.

Dr. HIRAM N. VINEBERG, of New York, read a paper on the

TECHNIQUE, INDICATIONS AND ULTIMATE RESULTS OF SUTURING THE ROUND LIGAMENTS TO THE VAGINAL WALL FOR RETROVERSIONS AND FLEXIONS OF THE UTERUS.

Dr. VINEBERG by an incision through anterior vaginal fornix sutures the round ligaments of the uterus to vaginal wall. He has operated on 53 cases in four years and detailed the results in these cases. The operation is indicated in the following conditions: (1) In all cases of mobile retroversions and flexions of the uterus in which a surgical procedure for one rea-

son or another may be deemed necessary; (2) in the same conditions when they are associated with prolapsus uteri of the first or second degree; (3) in all cases of adherent retroversions and flexions in which the uterus only is adherent; (4) in cases of retroversions and flexions associated with moderate disease of the adnexa, such as cystic ovaries, catarrhal salpingitis, hydrosalpinx and hematosalpinx and pyosalpinx, when the latter is of moderate size and not too firmly and extensively adherent; (5) it is the operation of choice in women with thin, lax abdominal walls, which would offer a poor support for the uterus. The same applies to the extreme opposite condition, in women with very fat abdominal walls in whom a suprapubic operation constitutes a very serious affair.

Recent Literature.

Operative Surgery. By JOSEPH D. BRYANT, M.D., Professor of Principles and Practice of Surgery, Operative and Clinical Surgery, in the University and Bellevue Hospital Medical College, etc. Third edition. Vol. I, with 587 illustrations, 50 of which are colored. New York: D. Appleton & Co. 1899.

Dr. Bryant has written an extremely satisfactory book, which treats, as its title indicates, of operative surgery. The general arrangement of the former edition has been maintained, and is an excellent one. The classification is anatomical. The first three chapters are devoted to general considerations, including anesthesia, operative, aseptic and antiseptic technique, the control of hemorrhage and the treatment of operative wounds. The remainder of the book has special subjects: The ligation of arteries, operations on veins and capillaries, the nervous system, tendons, ligaments, fascia, muscles, bursa, bone, amputations, deformities, and finally plastic surgery.

As one studies this volume the more one is impressed by its excellence. It is terse, and at the same time complete. The data are accurately presented. Few operative procedures are omitted from the list. The student sees as well as reads, so many are the graphic aids to his understanding. Many practical points relating to the detail of operative work, learned usually only by long personal experience, mark this book as unusual, and distinguish it from the routine publication on operative surgery. The plan of describing and enumerating the instruments required for special operations by means of an excellent cut, showing them in detail as arranged for an operation, is novel and time saving. The character of the illustrations in general is very satisfactory and the plan of arrangement of their descriptive references is highly to be commended. The cuts illustrating the operations on nerves are similar to those usually employed to demonstrate the anatomy required for the ligation of arteries and are one of the many features of the book which attract attention. The entire chapter, indeed, of the surgery of the nervous system is one deserving of special study.

This book will not only be popular with the student, but will also be found in the working library of many a surgeon in active practice, and its appearance will be that of a much used volume. It is of conven-

ient size, while the work of the publisher arouses only commendation and admiration.

Heissler's Embryology. A Textbook of Embryology for Students of Medicine. By JOHN CLEMENT HEISSLER, M.D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. Pp. 405. Philadelphia: W. B. Saunders & Co. 1899.

This work is a conventional compilation not without merit, being an abbreviation of the substance of the larger standard authorities. It is clearly written and shows on the part of the author a respectable mastery of the authorities, and offers few indications of a first-hand acquaintance with embryological material. As is natural with an author whose facts and nearly all of whose illustrations are taken from other handbooks, the more important topics are fairly well dealt with, while there remain numerous minor errors. These minor errors are indeed numerous: for example, page 82, the zona pellucida is called the prochorion and is said to unite with the false amnion to form the true chorion! Page 88, the placenta is said to be formed in the third month; Fig. 55, the oral plate, *rh*, is made to include mesoderm; page 134, no mention is made of the membrane separating the nasal and oral fossæ in the embryo; page 155, Hertwig's erroneous diagram of the development of the veins is reproduced; page 189, the development of the intestinal villi is incorrectly stated, since they arise from ridges and not separately. This list of errors could be almost indefinitely extended, so that the treatise is without authoritative value, since its statements often need rectification. Nevertheless the clearness of the author, his well-proportioned text and the judicious selection of illustrations will doubtless render the compendium convenient and useful. There are 26 colored illustrations and a good index.

Colpoperineorrhaphy, and the Structures Involved.

The Vagina and Perineum and How to Mend Them. By BYRON ROBINSON, B.S., M.D., Chicago, Ill., author of "Practical Intestinal Surgery," "Landmarks in Gynecology," "Life-size Chart of the Sympathetic Nerve," "The Peritoneum, its Histology and Physiology," "The Abdominal Brain and Automatic Visceral Ganglia," etc.; Professor in Chicago Post-Graduate School of Gynecology and Abdominal Surgery; Professor of Gynecology and Abdominal Surgery in the Harvey Medical College and in the Illinois Medical College; Gynecologist to St. Anthony's Hospital; Consulting Surgeon to the Mary Thompson Hospital for Women and Children. Chicago: The Clinic Publishing Co. 1899.

This most excellent monograph belongs to a class of publications of which we could wish that more were put forth. It consists of two parts. The first section consists of an extensive, exact and scholarly study of the very difficult subject of the structures which surround and support the lower end of the rectum and vagina. This is the best description of that subject which we have seen. The second portion of the book is made up of the author's conclusions from his extensive anatomical studies and an experience of about a hundred cases as to the best way of repairing the rent. The conclusion consists briefly of an enthusiastic treatment of the adaptability of Tait's flapsplitting operations, as modified by the author, to all conditions of loss of perineal support, to which is

added an acknowledgment that Emmet's latest operation is also thoroughly efficient and rational, with which conclusions one may or may not agree. But few gynecologists can help learning much from the admirable way in which the author explains the anatomical reasons for the success of both these operations, which he concedes act in much the same way. The cuts are crude, but illustrate the text satisfactorily.

Histology and Pathology. A Manual for Students and Practitioners. By JOHN BENJAMIN NICHOLS, M.D., and FRANK PALMER VALE, M.D. Lea's Series of Pocket Textbooks. Pp. 458, with 213 illustrations. Philadelphia: Lea Brothers & Co. 1899.

This work is one of intelligent and competent compilation, which has put together in clear and succinct form the main facts of the two sciences of histology and pathology. The authors have not collaborated, for Dr. Nichols claims sole responsibility for the histology, Dr. Vale for the pathology. They have, however, kept well the same scale of treatment, and have produced a volume which only a publisher could call of pocket size, for it weighs about two pounds (972 grammes). The absence of originality is the most striking characteristic of the volume, the facts being with few exceptions such only as are found in all the better textbooks, but these are accurately presented, though some mistakes could of course be pointed out. The illustrations are taken almost exclusively from other textbooks, and are all so coarsely printed that whatever delicacy or softness the originals may have had is utterly lost. It seems to us that the profession gains very little from the publication of such works as the present one, which is distinctly of the second class, and merely establishes a fresh rivalry with its superiors. Were there no good books already in the field for students of the two sciences concerned, Nichols and Vale would deserve a welcome, which under the actual circumstances is not due to their book.

Duane's Medical Dictionary. A Dictionary of Medicine and the Allied Sciences. Comprising the Pronunciation, Derivation and Full Explanation of Medical, Pharmaceutical, Dental and Veterinary Terms; together with much collateral descriptive matter, numerous tables, etc. By ALEXANDER DUANE, M.D., Assistant Surgeon to the New York Ophthalmic and Aural Institute; Reviser of Medical Terms for Webster's International Dictionary. New (third) edition. Pp. 656, with 8 full-page colored plates. Philadelphia and New York: Lea Brothers & Co. 1900.

The third edition of this dictionary will be welcomed by those who desire a combination of much information compressed into a comparatively small volume. The author has aimed to accomplish this end by omitting obsolete words, and utilizing the space thus gained by a considerable amount of descriptive matter, supplementary to the mere definitions. Another excellent feature of the book is the care bestowed on derivation of words, those from the Greek being given in ordinary type. We have found occasion to make practical use of the dictionary on several occasions and have not as yet found it wanting. The addition of a few colored plates no doubt increases the expense of the book, without proportionally adding to its value. The type is small but clear, and the binding good.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, OCTOBER 11, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,

SPECIALISM IN MEDICINE.

THIS is the subject of an address recently delivered at Ottawa, by Dr. F. C. Shattuck, of Boston, on the occasion of a meeting of the Canadian Medical Association. The subject is certainly not a new one, nevertheless its importance and interest are perennial, and demand from time to time a reconsideration at the hands of those whose experience renders them competent to speak. Dr. Shattuck has certainly brought a judicial spirit to bear upon his not too easy task, which must appeal both to those who call themselves specialists and to those whose practice leads them into broader fields. The threadbare assertions of certain writers on the subject are conspicuous by their absence. We are not told, for example, that a man must have had a term of so-called general practice before he can hope to be a success as a specialist, an assertion which our every-day experience at once controverts, nor is the narrowness of the specialist held up as a warning. There is a tacit if not a definitely expressed recognition of the fact that narrowness is due to a frame of mind and not to a variety of practice; that the man who accepts every one who comes to him for medical aid may be as narrow in his interpretation of any given case as the man who confines his attention to the disorders of any special organ or set of organs. There is also in this address a welcome and refreshing acceptance of things as they are, with no attempt at an adjustment of facts to suit some theoretical assumption. The fact seems to be that specialism has come gradually and as a perfectly inevitable consequence of the growth of knowledge. This may be good or bad, but there is not the slightest prospect that any human argument will check a tendency which is absolutely bound up with progress. The attitude of the critic of the details of this, to our mind, wholly beneficent movement may be analytical to the last degree, but it cannot be iconoclastic. The growth of specialism is coincident with the growth of education, and in medicine, as in any other field of knowledge, progress is dependent upon the degree to which

special investigation is carried. As we understand Dr. Shattuck's point of view it is essentially this: Specialism in medicine we must accept as a fact; on the whole we should be sufficiently optimistic to see in this a good rather than an evil; in the meantime we should critically analyze the details and vagaries into which an acceptance of this fact may lead us.

We are inclined to think that the reason for the discussion we are constantly hearing between the claims of the so-called general practitioners and specialists lies in the failure to distinguish the theoretical from the practical side of the question. Theoretically no one can now consistently question the utility of specialism; practically, in the every-day treatment of this or that individual patient, abuses are possible and no doubt of frequent occurrence. This is a difficulty and misconception under which medicine must always labor, inasmuch as it is on the one hand an abstract science, and on the other an applied art of the most practical sort. Much of the foregoing we have read between the lines of Dr. Shattuck's address; he is dealing rather with the practical aspect of the matter, as it applies to the rank and file of practising physicians. The first line of cleavage in the treatment of the sick appeared between medicine and surgery. Obstetrics was also early separated off as a specialty, and rightly so, whereas gynecology, as a special field of practice, is a much later growth, and one of rather unique interest. At first received with undue enthusiasm, it has gradually ceased to exist as what we may term an exclusive specialty. "If I read the signs of the times aright, what may be called pelvic tinkering, which has been so much practised in the last decades, is suffering from a rapid decline. What is really necessary can safely and best be left in the hands of the obstetrician alone or aided by the general physician; and major gynecology, the great bulk of which involves laparotomy, seems to be going where it belongs — into the hands of the general surgeon. It may all have been a necessary sequence in the evolution of knowledge, or I may be ignorant or prejudiced, but I cannot look at the groping course of gynecology as a triumph of human intelligence."

Dr. Shattuck recognized the broad bearings of neurology, and finds in the nervous system a field worthy of and demanding special study. "Neurology," he says, "deals with a system rather than with an organ; has length and breadth, touches medicine at very many points, and thus involves less risk of narrowness of view to its devotees than do some specialties." We are disposed to think that neurology is not properly termed a specialty in the usual practical acceptance of the term, because of its intimate relation with every organ of the body. Dr. Shattuck does not, however, look with unfeigned delight at the minute subdivisions of practical medicine; he doubts whether gastro-enterology should be dignified into a true specialty; he suggests that y- and z-rays may ultimately be discovered to broaden what seems to be the inevitable specialty of the x-rays; he finds also that the diseases of

childhood constitute a doubtful field for the establishment of a specialty. "Specialism divides up the organs and systems of the body, separates the sexes in a measure, and still insatiate, steps in between children and parents. Shall we see parents and grandparents similarly set apart? Why not a chair in medical schools for the diseases of old age as well as for the diseases of children? It is a conservative statement that the pathology of old age is at least as peculiar as that of childhood. Infant feeding alone affords scant material for a specialty, particularly if the profession as a whole would insist more on the use of nature's provision for young mammals, apparently sufficient for all of this class, save man. The number of women who can nurse their children is much larger than is that of those who do."

Dr. Shattuck is of the opinion that it is both more economical and more conducive to the ultimate progress of medicine to encourage subdivision of the medical branches in one large hospital, rather than add to the number of institutions by supporting minor hospitals for the sole treatment of some special form of disease. With this view we are in entire agreement. The function of a great hospital should be to give opportunity for the completest development of legitimate specialism, in conjunction with what are still recognized as the more general fields of medicine. This is the surest means of preventing what all alike fear, the unsymmetrical development of medical knowledge as a whole. The situation and our proper attitude toward it are well summarized in the closing sentences of this excellent address.

"It is all very well to say, 'Take no thought for the morrow'; if our predecessors had acted literally on this precept we should be in a bad way. Progress will march and evolution go on in spite of us, doubtless. But we can have some influence over the rapidity of evolution, and it is our business to do what we can to foster right and to discourage wrong tendencies. One fact stands out clearly—that specialism in medicine has come to stay. Its advantages infinitely outweigh its disadvantages, and we have faith that all things work for good in the long run.

"We study the past, and speculate as to the future. We all sometimes feel as did the late Dr. Hagen, the great entomologist—'I should like to be my own great-grandson.' We cannot greatly influence the amount of pity which our great-grandsons may feel for our attainment, but we can force their respect for our honest and unremitting effort."

MEDICAL NOTES.

THE "AMERICAN JOURNAL OF NURSING."—The first number of this new journal has appeared, published by Lippincott for the Associated Alumnae of Trained Nurses of the United States, under the editorship of nurses. The objects of the journal are first to provide an official organ for nurses throughout the

country, and also to bring into convenient and accessible form various matters relating to the progress of the act of nursing. The contributions in this first number are chiefly from the pens of nurses, but not wholly. We note for example, a brief paper on the "Relation of Bacteriology to Preventive Medicine," by Dr. John H. McCollom. The appearance of the journal is attractive and its contained matter for the most part excellent. We wish for it every success.

A MEMORIAL TO THE LATE J. M. DA COSTA.—The Board of Trustees of Jefferson Medical College, Philadelphia, has decided to establish a laboratory of clinical medicine, as a memorial to the late J. M. Da Costa. Dr. Da Costa had been a teacher in the college for more than thirty years. Contributions to a fund for this purpose are solicited.

A SOMEWHAT EXTREME POINT OF VIEW.—It is reported in the *Philadelphia Medical Journal* that the School Board of El Paso, Texas, requires the teachers to wear short skirts, since the long ones sweep along the walks and gather germs that may injure the health of the children.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, October 10, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 133, scarlatina 9, measles 9, typhoid fever 21.

NEW SITE FOR THE HARVARD MEDICAL SCHOOL.—The old Francis estate in Brookline has been purchased, and is now held in trust as the proposed future site of the Harvard Medical School, and the allied departments of veterinary medicine and dentistry will also be located on the recently acquired land. The school, during the comparatively short period of its residence in the present building, has outgrown its accommodation, and the land furthermore is desirable for the future uses of the Boston Public Library, which is already feeling the need for more space. An appropriation for the School of Comparative Medicine has already been made from the H. L. Pierce bequest to Harvard University. Space is furthermore provided for a possible University Hospital.

A VIGOROUS LEGAL DECISION.—The following important decision has recently been rendered by Judge Grime, of Fall River, in the case of Dr. Ezra R. Wilbur, clairvoyant physician, against a police officer, to recover for professional services. Judge Grime ruled in these words: "I am satisfied in my own mind that the services rendered were worse than valueless, and that had they been continued without change the defendant would have reaped his reward in death. Still, he employed the plaintiff and must pay the bill."

DR. J. F. LEWIS ELECTED SUPERINTENDENT OF THE DEPARTMENT OF ADULT POOR.—The State Board of Charity has unanimously elected Dr. J. F. Lewis, of Malden, Mass., to the position of superin-

tendent of the Department of Adult Poor, to succeed the late Stephen C. Wrightington. The appointment requires the approval of the governor, which, it is supposed, will certainly be forthcoming.

DR. A. J. RANNEY APPOINTED SUPERINTENDENT OF LONG ISLAND INSTITUTIONS, BOSTON.—Dr. A. J. Ranney, assistant superintendent of the State Almshouse at Tewksbury, has been appointed superintendent of the Long Island Almshouse and Hospital, Boston Harbor, in place of Mr. A. T. Hopkins, who has resigned his position to enter professional life.

NEW YORK.

FORGOTTEN IDENTITY.—There is at present under treatment at the White Plains Hospital, Westchester County, a case of unusual interest, that of a man who has forgotten his identity as the result of a stroke of lightning. Dr. H. Ernst Schmid, the head of the visiting staff of the hospital, and who is an alienist of high repute and one of the consulting physicians to the Department for the Insane of the New York Hospital, pronounces it one without a parallel. The patient was found one night in July, after a severe electrical storm, near the tracks of the Harlem Railroad, with the entire left side paralyzed. When questioned as to his identity he appeared much annoyed that he could not give an intelligible reply. During the night there was twitching of the various muscles of the body, and on the following day if any part of the body was touched the patient would, after a delay of from five to ten seconds, put his hand to that part of the body and touch it in the same manner; if stroked, would do the same; if slapped, would slap himself. If roused and questioned sharply, he would say simply, "I—I—I." After three months he was very much improved. Asked if he remembered when he became ill, he said a flash seemed to strike him in the face. From that time on he gradually gained in health and strength. The paralysis disappeared and his muscular system was built up by a course of calisthenics.

RICHES RESIGN TO THE INEVITABLE.—Charles Broadway Rouse, the millionaire merchant and philanthropist, who is suffering from blindness due to optic nerve atrophy, and who some time since announced that he would give \$1,000,000 to any one who would restore his sight, has now withdrawn that offer and resigned himself to the inevitable. Ever since the announcement was made he has been besieged by all sorts of quacks and "healers," and during the greater portion of the time he has paid a substitute who was affected in the same manner a regular salary for submitting to experiments and various forms of treatment.

DR. JACOBI ON ARTIFICIAL INFANT FEEDING.—At the first meeting of the New York Academy of Medicine after the summer recess, a resolution was passed establishing a separate section on otology, this branch having hitherto been included in the Sec-

tion on Ophthalmology. On this occasion Dr. A. Jacobi read a paper on "Artificial Infant Feeding," which was the complete report he prepared for the Pediatric Section of the Thirteenth International Medical Congress, and at the suggestion of the president, Dr. Thomson, it was decided that a special evening should be set apart for a symposium on this subject.

MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.—At the first regular meeting for the college year of the Trustees of Columbia University, held October 1st, the annual report of the Vanderbilt Clinic was presented, showing that 49,173 patients were treated during the year. The following appointments in the Medical Department were announced: Drs. Charles H. Peck, Warren S. Bickham and Alfred S. Taylor, assistants in operative surgery. Among the gifts received during the year was \$100,000, from John D. Rockefeller, for the endowment of a chair in psychology.

GOLDEN WEDDING.—On October 1st the venerable but genial Prof. R. Ogden Doremus and his wife celebrated their golden wedding. Dr. Doremus, who equipped the first laboratory in the United States for instructing medical students in analytical chemistry, was professor of chemistry in Bellevue Hospital Medical College for thirty-seven years, and still holds that office in the College of the City of New York.

A HOME FOR CONVALESCENTS.—Mr. Adrian Iselin, a wealthy resident of Westchester County, has purchased the old Hartley mansion in the outskirts of Yonkers, for a hospital for the convalescent poor of New York and its vicinity. The house is surrounded by extensive grounds, on which there are many fine trees, and from \$50,000 to \$75,000 will be spent in enlarging and equipping it.

ONE HUNDRED AND SIX YEARS OLD.—Benjamin Prine, probably New York's oldest citizen, died at Port Richmond, Staten Island, on October 4th, at the age of one hundred and six years. He was a negro and born a slave not far from the place of his death. He is noted as having driven the first stage coach on Staten Island, and he was freed by the Northern Slave Act in 1822.

INCREASED INSANITY AT ELMIRA REFORMATORY.—The past six months there has been an increase in insanity, no special reason for which has been assigned, among convicts at Elmira Reformatory. Since March sixty-five inmates have been transferred.

Correspondence.

TENDON SUTURE.

COLUMBUS BARRACKS, O., September 19, 1900.

MR. EDITOR:—The article on "Tendon Suture" in the *JOURNAL* of September 13, 1900, by Dr. Hatch, recalls a case which I treated many years ago, and which may be of interest to your readers.

In 1866 the steward of the steamer *Saratoga*, plying between New York and Richmond, Va., was brought to me with a divided tendo Achillis. He had received his injury while standing on the washstand of his stateroom, a lurch of the ship throwing his foot into the washbowl, breaking the bowl, and in withdrawing his foot the tendon was severed obliquely. The wound was carefully cleansed and the severed tendon united by silk sutures, the external wound closed with sutures and dressed dry with lint and bandages. A slipper was obtained, and a piece of flat iron, 1 x $\frac{3}{4}$ inch, riveted to the sole. The iron projected for about 4 inches beyond the heel of the slipper, and had an eye at its extremity for insertion of a bandage, which was attached to a band above the knee, thus keeping the foot fully extended and leg flexed. There was no suppuration; the wound healed by first intention, and the patient recovered in little more than a month. This seems worthy of note in that the case occurred in pre-antiseptic days and before dry dressings were in vogue. The experience of the war and the closing days of the Rebellion had convinced me that wet dressings were not free from danger, and I had removed them from a case of gunshot wound of the knee at Farmville, Va., with a most satisfactory result.

Very respectfully,
TIMOTHY E. WILCOX,

Major and Surgeon, U. S. Army; Late Lieutenant
Colonel and Chief Surgeon, U. S. Volunteers.

LETTER ABOUT PARIS AND LONDON.

REMINISCENCES OF THIS SUMMER'S TRANS-ATLANTIC TRIP.

THE ROYAL COLLEGE OF SURGEONS OF ENGLAND;
THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

MR. EDITOR:—It has occurred to us that your readers may like to have a few words about the recent celebration of the One Hundredth Anniversary of the Royal College of Surgeons of England and a few about the Thirteenth International Congress, with one or two incidents that occurred en route to and from the Continent. To relieve the *ennui* of our voyage home, we therefore undertake the recital of our adventures, at the risk of adding to the *ennui* of your readers.

Separated at the first moment of our intended voyage on the *Oceanic*, we were united again at that typical English hotel "The Burlington." The voyage of the *Oceanic* was without incident. We were not so lucky on the *Campania*, for after a remarkably favorable crossing to Queens-town we struck a thick fog in the Irish Sea. Off Holy-head at 8.30 A. M., while running at half speed, we struck and cut in two a twelve-hundred-ton steel barque, just beginning her voyage to New Zealand. Nothing was seen or heard of this vessel until it was too late to avoid her. The sharp bows of the *Campania* cut slowly through her just behind the foremast. The bow half (she was headed to the southeast with a southwestward breeze) grazed along our starboard side, but sank before it came as far aft as our foremast! The bowsprit, as the fore part sank with bursting decks, pointed straight up in the air and nothing was left but white, bubbling water. Then suddenly the foremast, detached in some way from the wreck, leaped high in the air and fell back into the sea. Later two men came up, and as they passed astern into the fog were seen clinging to the wreckage from which they were rescued by the life-boat crew. The stern half we did not see, but it sank quickly leaving a half dozen of the crew struggling in the water. The life boats were lowered and put back into the fog astern. Seven men of the crew of eighteen were saved.

It was amazing how slight the shock was. It seemed trivial. We were dressing when the blow came. From the cries of the women and the immediate launching of

the life boats it was natural to suppose that the steamer was going down at once. Had she suddenly foundered, the loss of life must have been great, though the sea was calm and we were but forty miles from land, for there were not enough boats to take the 1,700 human beings, more or less. Our escape seemed providential when we learned by talking with the saved that the barque carried 30 tons of dynamite, 600 barrels of gunpowder, and 1,000 cases of cartridges! The *Campania's* bows were stove in, and there was considerable water in the forward hold.

The meeting of the Royal College of Surgeons was interesting and impressive. The chief event was the conferring of honorary degrees. Besides the Prince of Wales, the Marquis of Salisbury, the Earl of Rosebery, and possibly other titled dignitaries, prominent surgeons from many countries were thus honored; of these there were from France, Ollier, Lannelongue, Tillaux and Pozzi; from Germany, von Bergmann; from Italy, Bassini; from Switzerland, Kocher; from the United States, Halsted, Keen, Weir and Warren; from Canada, Roddick, Cameron and Kingston.

The attendance at the celebration was large. All candidates and guests were in cap and gown of their college or university. But few foreigners were present besides those who were candidates for the honorary degree.

The dinner at Lincoln's Inn Fields was extremely interesting. In the first place the dinner itself was good—and that is saying much for a dinner for 400 men. The hall made us think of Memorial Hall on Commencement Day. Could we have had the brilliant speakers of that day, the resemblance would have been even more striking. After dinner, the president, Sir William MacCormac, introduced the chief guest of the evening, H. R. H. the Prince of Wales, who spoke well. Before the dinner we had been all delighted by his charming manner. We were reminded of a medical friend who visited London a few years ago with the Ancient and Honorable Artillery Company. He met the prince on that occasion and shook hands with him. Asked his impressions of the prince, he said very naïvely, "Well, now, you may not think it, but he's a real good fellow,—not a bit of d—d nonsense about him." This always seemed to us one of the greatest compliments he could have received, for it showed the tact which at once had put our friend at ease.

After the speech from this distinguished guest, came others by Salisbury, Rosebery, the Lord High Chancellor and other laymen. Besides the president, Sir William MacCormac, but one surgeon spoke, Mr. Bryant, who introduced one of the lay speakers. Salisbury got pretty well mixed up before he finished, but he managed to extricate himself. Though on the whole the speaking was good we all sighed, "Oh, for a word from President Eliot now!" Yet it was all admirable and interesting.

The most charming entertainments were the private dinners, of which there were many each night. We were greatly delighted with our experiences in London. We were, however, much disappointed that we were offered no opportunity to see English surgery, although most ready to avail ourselves of such courtesy.

The International Congress opened on the following week. We were not there, however, for the congress or the exposition; we may as well admit it; we were there in search of amusement—theatres, concerts, museums and good dinners! We nevertheless had our names enrolled, went to the opening session of the congress, and left cards upon our friends. To at least one of our party the congress was dull and uninteresting. The meetings in General Surgery were not attractive. The chief aim seemed to be to get through one paper and to the next. Murphy made a very favorable impression with his paper on lung surgery, which he had condensed into a few words.

The general entertainments were tremendously overcrowded. A reception was given at the Palace of the Luxembourg. We succeeded in getting within sight of the door, before which a crowd was struggling. We had the good sense to retire before we got hopelessly caught in the jam. It was like a school of fish trying to get out of a

seine. We finally got out; and as we went we met lines of carriages which extended back to the Seine. At the reception of the President of the Republic there was the same enormous crowd. One of us who had succeeded in penetrating the halls of the Luxembourg tried the President's Palace. He was discouraged and about to give up when by announcing himself to the guard at a private entrance as "délégué spécial des États Unis," he was admitted with much saluting!

We had the pleasure of meeting Tuffier and seeing his spinal cocainization. This demonstration was really remarkable. The first patient was a woman of, say, forty with a large abdominal tumor. She was seated upon the table bending forwards. After brief scrubbing of the skin over the ilio-lumbar region a needle was introduced at the right of the spinous process of the last lumbar vertebra just above the crest of the ilium. By feeling his way the operator deftly introduced the needle into the spinal canal. As soon as the canal was reached a few drops of cerebro-spinal fluid escaped. The cocaine was injected very slowly through the needle. The patient was then placed on her back. The skin of the abdomen was prepared while the surgeon was sterilizing his hands. While two large ovarian tumors were being removed the patient made no sign of pain or even of discomfort. She was very pale and her pulse was with difficulty felt. Though the pulse was so feeble, it was slow, between 60 and 70.

The next patient, after cocainization of the cord, had an enormous kidney removed. During the operation she lay perfectly quiet and without pain. She had cried out shortly after the injection of the cocaine that she was paralyzed. She talked and answered questions. She said that she had no pain whatever. Her pulse was very weak but slow. M. Tuffier said that he had had no bad effects from cocaine; that there were at times vomiting — simply *mal de mer* he called it — and invariably an increased temperature for a day or two.

Our impressions of this method of producing anesthesia were that it was a matter of scientific interest rather than of routine practicality; that from the nature of things it could not be used with safety — with the safety of ether or even of chloroform; that even if the general effect should prove not dangerous or disadvantageous, the possibilities of local damage could not but prove prohibitive. Granted that puncture of one of the nerves of the cauda equina may not always do harm, it cannot be looked upon — certainly not as yet — as a procedure of demonstrated safety. That a needle can be introduced into the spinal canal at the level of the sacrolumbar articulation without danger of wounding the cauda equina we do not believe, though we admit that such an accident may be uncommon. One of our friends who has tried the method told us that his patient had paralysis of the bladder lasting six months.

We predict that spinal anesthesia will not prove of wide general acceptance and utility, though we confess that we should like to try it. When we proposed to make use of the method on our return, however, we were solemnly warned that Boston would not be — at least at present — a good place to try any experiments in anesthetics, especially spinal, even if the crowning glory of surgery had resulted years ago from experiments there in general anesthesia. We nevertheless feel obliged to say that we shall advise spinal anesthesia the very next time we operate for lesions associated with abdominal distention and vomiting. In a recent case of amputation of the leg, a feeble patient with distended abdomen and full stomach vomited under ether and was drowned in his own vomit — spinal cocainization would have been admirable. So would it probably be in general peritonitis, in urgent operations upon patients just after a full meal, in all conditions in which it is essential that the patient retain consciousness and the power of keeping his throat clear. Under certain circumstances, therefore, spinal cocainization seems of definite and conspicuous advantage. It is quite possible that beginning with this limited field its use may with increased knowledge and experience become of wide and beneficial application.

From Tuffier's interesting work we went to Doyen's private clinic. There we saw a man of great ingenuity and dexterity. While the patient was being prepared for operation the assistant showed us several cinematographic reproductions of operations. One was an amputation of the thigh, another a thyroidectomy, a third a hysterectomy. These illustrations were extremely interesting. Of their value we would say that we have already adopted two things which these pictures alone demonstrated. How much a beginner would learn from them unexplained is doubtful, but an experienced operator would see every detail. By stopping the machine at a given period every step of the operation could be explained at leisure. We believe that the cinematograph has a great teaching value.

Doyen's first operation was a craniotomy. He had operated some time before and the wound had healed beautifully. Thinking it best to remove a little more bone, he reopened the wound and took a half-inch rim of bone about the edge of his previous bone cut. He used his electric circular saw, which made so violent a buzz and whirr that we could not but recall our terror and flight from the classroom when our colleague, Dr. M., first used years ago his electric saw and burrs. After the operation M. Doyen demonstrated his instruments on dry bone. We were very much impressed by his instruments and by his skill. The next day we went again and saw a hysterectomy which was a very brilliant and successful piece of work, our only criticism being that brilliancy and speed are incompatible with absolute safety of the ureters. In his hysterectomies, and some other operations, M. Doyen uses the angiotribe, but with this sensible admission, that the instrument is not safe when used alone. He compresses the tissues with the angiotribe and then through the compressed tissues ties his ligature. Doyen's audience was a brilliant one. Crowded together upon a raised platform and standing upon stools were many of the most eminent surgeons of the world.

Opinions as to the clinic varied between wide limits. We thought it the most brilliant thing and the best in Paris.

Pozzi's clinic drew a large and illustrious audience. There we saw asepsis carried on more thoroughly than anywhere else — in a manner possibly suggesting the thoroughness of American methods. The operation performed by Pozzi was an extremely difficult one, in which the ovaries, tubes, uterus and other structures were removed.

On Friday, the day that the congress closed, we were invited to subscribe to a dinner given by Americans to a Parisian physician. This began and ended the hospitalities we received.

On leaving Paris our party separated, some going to the Alps, some to the "Passion Play," some to England. We ourselves went to the Alps, where we caught the Alpine fever and had it so severely that we cannot but congratulate ourselves that the blisters of the first day prevented further attempts at climbing. Had our feet been able to follow our inclinations we should doubtless be now reposing at the bottom of a crevasse.

On arriving home our first visit was to the Massachusetts General Hospital, where we were profoundly impressed by way of contrast with the excessive care of American surgeons in everything relating to asepsis: the twenty-four to forty-eight hours' preparation of the patient; the efficient sterilization of the sheets, towels, gauze and instruments; the long-sleeved operating gown, rubber gloves covering hands, wrists and sleeve ends; the protection of head and beard; the general air of neatness, cleanliness; and finally the man-of-war discipline by which the chain of asepsis remains unbroken from the beginning of sterilization twenty-four hours before operation to the close of the operation itself.

We have much in surgical technique to teach and little to learn this side of the Atlantic.

Very respectfully yours.

Deaths reported 2,437; under five years of age 906; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 2,437, diarrheal diseases 252, acute lung diseases 170, consumption 164, diphtheria and croup 67, typhoid fever 46, whooping cough 23, cerebrospinal meningitis 8, scarlet fever 6, erysipelas 3, measles 8.

From whooping cough New York 7, Baltimore 4, Pittsburg 3, Boston 2, Providence, Cambridge, New Bedford, Lawrence and Fitchburg 1 each. From cerebrospinal meningitis New York 5, Providence, Worcester and Somerville 1 each. From scarlet fever New York and Baltimore 2 each, Boston and Philadelphia 1 each.

ALVARENGA PRIZE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1901, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1901.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1900 has been awarded to Dr. David De Beck, of Cincinnati, O., for his essay entitled "Malarial Diseases of the Eye."

THOMAS R. NEILSON, M.D., Secretary.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold its next regular meeting at 19 Boylston Place, Wednesday, October 17, 1900, at 8 P. M.

At 8 o'clock: Dr. R. C. Larrabee will report "A Case of Dextrocardia."

At 8.15 o'clock: Dr. C. J. Enebuske will read a paper entitled "Chronic Diffuse Interstitial Nephritis."

Business: The election of a chairman for the ensuing two years.

J. BERGEN OGDEN, M.D., Secretary, Harvard Medical School, Boston.

MEDICAL SOCIETY OF VIRGINIA. — The thirty-first annual session of the society will be held in the Auditorium, Charlottesville, Va., October 23, 24 and 25, 1900.

RECENT DEATHS.

LAWRENCE MERVIN GOULD, M.D., M.M.S.S., of Hyde Park, died in Portland, Me., October 7, 1900.

WILLIAM MUNN, M.D., fifty-three years old, of the Borough of the Bronx, New York, died in Bellevue Hospital, on September 24th. He was a graduate of the Medical Department of the University of the City of New York in the year 1868.

WILLIAM WEBB BROWNING, M.D., of Brooklyn, N. Y., died on October 4th, from cerebral apoplexy. He was born in Methuen, N. J., in 1852, and was graduated from Yale College in 1873. In 1875 he was graduated from the Columbia Law School, and, after practising law for several years, entered Bellevue Hospital Medical College, from which he was graduated in 1884. In 1895 he received the honorary degree of A.M. Dr. Browning held two professorships in the Long Island College Hospital, the chair of anatomy and the chair of clinical orthopedics.

STEPHEN E. D. HORNBECK, M.D., Secretary and Treasurer of the Building Commission of the Eastern New York Reformatory at Napanoch, Ulster County, died suddenly at his home in Ellenville, N. Y., on October 3d. He was born at Wawarsing Corners in 1844, and was graduated from the College of Physicians and Surgeons, New York, in 1865.

BOOKS AND PAMPHLETS RECEIVED.

Studies in Pancreatic Digestion made with Pancreatic Juice. By B. K. Raebford, M.D. Reprint. 1900.

SUPPURATIVE PERICARDITIS AND ITS SURGICAL TREATMENT.¹

BY CHARLES B. PORTER, M.D., BOSTON.

Your committee invited me to present the subject of suppurative pericarditis because they knew that in 1895 I had had a successful case of pericardotomy in a patient of Dr. F. C. Shattuck, who asked my surgical aid in its treatment. The case in full was reported to the American Surgical Association in 1897, together with a study of the literature of the subject up to 1895 and 1896. As all here may not be familiar with that report, I should like to read two short extracts from it, and then present the literature of the subsequent years with additional cases and some new ideas.

In my previous study of the subject I collected 24 published cases, beginning with the first case of recovery, the case of Rosenstein, operated upon in 1881. Of this number 8 recovered and 16 died, and in 1 the result was unknown.

In 1 case pericarditis developed one month after a wound. Many of the cases were complicated with left empyema, and twice the pericarditis was discovered at operation while draining the empyema. Of the fatal cases, 2 died at operation; 1 lived two days; 1 (Delorme's case) lived eight weeks after the operation.

The organisms found in the exudate were the staphylococcus aureus and streptococcus pyogenes, pneumococcus, and colon bacillus (in case of stab wound).

The amount of pus evacuated varied from 10 ounces to 2 quarts. In 1 (Dickinson's case) it was brownish and thin with arterial blood; in 2 (Korte's and Eiselberg's cases) foul and thick; in 2 (Newman's and Delorme's) thin. In the majority it was thick, creamy, without odor. In a number of cases large fibrinous masses were found, the pericardium being covered with thick layers of lymph. At autopsy in 1 fatal case (Pepper's), the whole sac was full of a thick mass of fibrin as large as the fist; the drainage had been good, and the heart probably failed from pressure of these fibrinous clots. The shortest case of healing of the sinus after drainage was nineteen days, the longest two months.

Preliminary aspiration was done in all these cases before opening the pericardium. In a number of cases paracentesis was done more than once, with and without injection of carbolic acid; and incision was finally resorted to owing to the rapidity of the reaccumulation. The immediate relief to pulse and respiration was almost always striking.

THE SURGICAL ANATOMY OF THE PERICARDIUM.

All authorities agree as to the great variations in the line of reflection of the pleura and pericardium.

Sick found that in the adult, out of 23 cases, the pleural reflection at the level of the fifth rib cartilage lay either at or within the left border of the sternum in 17; at the level of the sixth cartilage the pleural border had not gone beyond the sternal border in 10; at the level of the sternal articulation of the seventh cartilage it was in 9 cases at the sternal border, or

this cartilage was below its lower border. Twice it was less than 1 centimetre from the sternal border.

In 12 children Sick found at the level of the fifth rib cartilage the pleura was either within or just at the sternal border in 11. At the level of the sixth cartilage the pleural had not left the sternal border 8 times.

It will thus be seen that, according to Sick's careful observations, even at the fifth space the reflection of the pleura will often be behind the sternal border. Brooks (quoted by Quain) in 4 of 7 quite healthy cases found the left pleural reflection entirely behind the sternum, and in 1 at the sternal border.

According to Luschka (quoted by Quain), the pleura normally diverges from the median line at the upper border of the fifth costal cartilage, so that at the level of the fifth cartilage it is $\frac{1}{2}$ centimetre, at the sixth 2 centimetres, and at the seventh 3.5 centimetres, external to the left border of the sternum.

Delorme and Mignon found in 32 adults that in the fourth interspace the left pleural border was within the border of the sternum in 17. At the level of the fifth cartilage it lay 15 times internal to the sternal border, and 17 times outside. In 12 cases at the fifth interspace the pleural border was at, or inside, the sternal; and in the sixth space the pleural border was outside the sternum in 26 cases, and at or within it in 8.

Dr. Thomas Dwight, professor of anatomy at Harvard University, agrees in the main with Sick's observations, but states that there are many variations, and that frequently it is possible to reach the pericardium through the fifth intercostal space and frequently not. Owing to the fact that the sixth intercostal space is small and narrow, and that even here the pleural often reaches the sternal border, he concurs with the writer in advising resection of the fifth costal cartilage, and if necessary the excision of a piece of the sternum opposite this cartilage.

The internal mammary artery, according to Quain, runs parallel to the sternum at a distance from it of 1 centimetre. Delorme and Mignon, in 30 cases, found it a distance from the sternum of from $\frac{1}{2}$ to 2 centimetres, the distance averaging about the same in the first six interspaces.

In looking over the arrangement of the left pleura by Dwight, Delorme, Sick, Quain and Testut, all agree that there is a varied arrangement. Below the fourth intercostal space in the majority there is a slight interspace close to the border of the sternum which is free from pleura. In 22 operations on the cadaver by myself it was found that the removal of the fifth intercostal cartilage, and the removal of $\frac{1}{2}$ inch of the sternum opposite the sternocostal joint, gave free access to the normal pericardium near its lowest level.

Three of the methods of operation which have been proposed and practised, namely, trephining the sternum (Riolan), approach through an intercostal space, and epigastric incision (Larrey), should all be discarded, as it will be evident from the above account of the anatomy that in all of them there is danger of wounding the pleura or diaphragm.

In this earlier work I decided that operation was indicated in all cases of purulent pericarditis and perhaps in serous pericarditis in cases where aspiration once or twice repeated is followed by reaccumulation of the fluid; and the following "ideal operation" was planned after careful consideration and experiment on

¹ Read before the Massachusetts Medical Society, June 12, 1900, and recommended for publication by the society. Abstract.

the cadaver in order so far as possible to meet the following indications: (1) To avoid opening the pleural cavity. This may be made more easy by adhesions as a result of tapping or inflammation; (2) to open the pericardium opposite the point where drainage will remain good after the sac has contracted; (3) to secure permanent and free drainage.

The steps of the operation are:

An incision from the middle of the sternum outward over the fifth costal cartilage to its junction with the rib.

The soft parts are cleaned from the cartilage with periosteum elevator, care being taken not to wound the pleura on the under surface. The cartilage is divided with bone forceps from the rib and the sternum. The internal mammary artery and vein are thus exposed, ligated in two places and divided between. The triangularis sterni is separated from the sternum and pushed to the left.

A little careful dissection with the director in case fat is encountered exposes the pericardium, which is normally much thicker than the pleura. An aspirating needle should now be introduced, if this has not been previously done, in order to corroborate the diagnosis. If confirmed, the knife should follow the needle. The incision in the pericardium is best made obliquely downward and outward, beginning close to the excised border of the sternum. The edges of the pericardium should be stitched to the soft parts.

Irrigation should always be employed, with the object of removing any masses of fibrin which may lie at the bottom of the cavity; and if there are many such masses, it should be continued until the fluid returns clear. The fluid may be weak sublimate or carbolic solution, or salt solution, according to the preference of the operator. The fluid must be warm and must have free exit. With this exception no harm has resulted from irrigation, which has been practised in more than half the cases.

Drainage is best provided by two rubber tubes, one long and reaching to the bottom of the sac for the inflow, and a short tube just entering the sac for the outflow. As the discharge diminishes one tube may be removed and finally gauze drainage inserted. Gauze drainage has proved adequate from the first, but where the fluid is thick or flocculent, tubes give the only adequate facilities for the subsequent daily irrigation.

The after-treatment must, of course, be directed to two ends: (1) Systematic treatment, consisting of forced feeding and free stimulation, and (2) the care of the wound and the maintenance of drainage. The wound should be irrigated daily and the patient, if his strength is sufficient to allow it, turned on his stomach to facilitate drainage.

Roberts, of Philadelphia, also, before the meeting of the American Surgical Association in 1897, presented an elaborate and exhaustive review of this subject. In this report he advocates the method of turning up a flap consisting of portions of the fourth and fifth left costal cartilages with the attached soft parts, thus exposing the field of operation. This method he had never followed on the living subject. Roberts collected 35 cases from all literature up to June, 1897, including my own case.

The previous work of the writer and the careful paper by Roberts brought the collected knowledge of this subject up to the summer of 1897, and leaves us nothing further to do than search the work of the last

three years, and make our final conclusions and analyses.

Voinitch-Sianojensky, of St. Petersburg, in 1897, a Russian writer,² contributed a long study on the anatomical questions in pericardotomy, but added nothing new to the conclusions of Delorme and Mignon, or to the anatomical studies of the writer given above. He refers to a case of incision in the second intercostal space for suppuration in the pericardium done by Bexman, of Russia, in 1891, with recovery. This case is not mentioned, so far as known, elsewhere. He refers to a number of different methods of incision and the advocates of each as known to him:

Through the third intercostal space, Sievens; through the cartilage of the fourth rib, Eiselberg; through the fourth space, Rosenstein, Orlov, Minnie, Bronner, Parker, Klefberg; through fifth rib cartilage, Ollier, Gussenbauer and Körte; through fifth space, West and Davidson. Desault and Robinson, as well as himself, advise operation through the sixth rib and sixth space. Del Vecchio resects fourth and fifth ribs and cartilage, also Roberts. Delorme and Mignon the fifth and sixth; Riolan, Laennec, Skielderup and P. Malle propose to trephine the sternum in the median line. Velpeau, Pirogoff, Baizeau, Delorme and Mignon think it unnecessary to keep to left side of the sternum, while Desault, Romero, Karanaff, Trousseau and Tillaux advise it. Rotch, Wilson and Dickinson choose fifth space on right side for tapping.

He claims to have had the opportunity of studying post mortem 20 cases of pericardial effusion and to have done 100 pericardial operations on the dead, and on this experience he declares that incision through the sixth costal cartilage will *always* avoid the pleura (which is not an accurate statement), and his proposed method of operation is to go through the sixth cartilage, and, if necessary, cut away some of the seventh cartilage also.

He states that open incision in all cases of pericardial effusion (not only in purulent cases) should be much preferred to puncture, because of the danger of wounding the heart and pleura by any method of using a needle.

Eichel, in 1899³ gives a fairly complete résumé of the anatomy of the pericardium and pleura with several diagrams. This article is chiefly valuable as showing that the most modern anatomical work does not change the accepted views of 1897 as given by me. In his paper he makes reference to all the latest foreign anatomies.⁴

He recommends pericardotomy for all effusions as well as for all wounds. He gives several interesting cases of operation for wounds and resulting hemorrhages into the pericardium.

The use of tubes for drainage after hemo- or pyopericardium operations Eichel opposes, stating that he had a case in which he could not keep the ends of the tubes from impinging on the heart wall and causing stormy and irregular action. He says that Riedel had a case that taught him the same thing.⁵

A point which is of great importance and which

Brentano and Schaposchnikoff lay great stress upon, namely, the anterior situation of the heart in all effusions into the pericardium, is denied by Eichel. In his case, he says, there was plenty of fluid between the heart wall and the anterior wall of the pericardium.

Brentano⁶ reports 5 cases of operation for pericarditis, and discusses this question as to the situation of the heart when the pericardium is more or less full of fluid, whether it is nearer to the posterior than the anterior wall. From his clinical experience Brentano decides that in all pericardial effusions the heart is situated down and forward and most often lies right against the anterior wall of the sac even when no adhesions exist, and that in many cases there will be adhesions between the pericardium and the anterior wall of the heart. In all cases most of the pericardial fluid is behind. If this anterior situation of the heart is a fact, the danger of wounding the heart wall in all cases of paracentesis is great.

Brentano advises open incision in any effusion, with resection of the fifth costal cartilage. In fact, this seems to be the growing thought in the last few years, that incision through resection of the fifth left costal cartilage is a far safer operation than paracentesis.

Schaposchnikoff, in 1898,⁷ agrees entirely with Brentano on this question. He states that he has studied the point for twenty-seven years clinically, post mortem and experimentally, and has proved that the heart is in all cases forward against the sac wall.

Brentano recommends almost the identical procedures of my own technique, namely, stitching of the sac to the skin, and irrigation; for drainage, however, he always used iodoform gauze, not tubes.

He decides that opening the pericardium through a resection of fifth rib cartilage is very simple, and advises against puncture in any case. Local anesthesia with cocaine is all that is needed in most cases. In regard to this question Körte — speaking at the Freie Vereinigung der Chirurg. at Berlin, December 13, 1897⁸ — favored the use of cocaine in many cases, but stated that in certain cases of thick chest walls ether or chloroform must be used. Brentano mentions as one of his chief arguments against puncture in cases of serous effusion that it is impossible to remove all of the fluid by aspiration alone. Of 80 cases of paracentesis tabulated by West, in 23 the puncture had to be repeated.

Brentano reports 5 cases which are as follows: All 5 were done by resecting the fifth rib cartilage. Two were for purulent pericarditis, both of these cases following acute osteomyelitis in children seven years old. Operation was followed by temporary and marked improvement, but death occurred in twelve days from pyemia, as shown by autopsy. In both cases there were found multiple abscesses in the heart muscle itself, and in one the direct cause of death was from rupture of one of these abscesses into the left ventricle.

Two cases were for subacute serofibrinous pericarditis after rheumatic attacks and rheumatic endocarditis. Both died in three days.

The fifth case was a brilliant case of open incision for simple serous pericarditis, without preliminary puncture.

Delorme, in 1897,⁹ the same surgeon who collaborated with Mignon in 1895 in an article on the technique of pericardotomy,¹⁰ recommends resection of the fifth rib cartilage to relieve mediastinal and pericardial adhesions whether or not due to tuberculosis, and also as the route to the pericardium in all cases.

H. Allingham¹¹ brings forward an entirely new method of operation for draining the pericardium in suppurative cases, and also, with Ogle, of London, reports a case of purulent pericarditis operated on, though not by his suggested method. The case was one of purulent pericarditis originating from a chronic abscess in the pleural cavity near the pericardium. Incision after resecting the fifth cartilage was followed by death in fourteen hours.

Allingham's suggested method which he tried on 12 cadavers, but never on the living, is as follows. It is designed to give best access to the sac and best dependent drainage by opening the sac from below through the diaphragm:

(1) An incision about 3 inches long with its upper end at the costoxiphoid angle is made along the lower edge of the seventh costal cartilage; the latter is then exposed by separating the abdominal muscles from it; the cartilage can then be pulled up and back, exposing the fibres of the diaphragm together with the cellular interval between its attachments to the cartilage and to the xiphoid appendix.

(2) This cellular space is enlarged by cutting or tearing through the muscle of the diaphragm as far as necessary, when a mass of fat is usually seen just above the diaphragm in the space between the diaphragm below, the sternum in front, the pericardium above and behind. This fat, together with the diaphragm, is then pulled down when the pericardium presents, and can be opened up at its lowest point.

During the operation the peritoneum may be exposed to a slight extent as it sweeps downward from the under surface of the diaphragm. It is, of course, not injured, being pushed away as in a suprapubic cystotomy.

The advantages claimed for this method are as follows:

(1) The pleural cavity cannot be injured, as it is far away in the normal arrangement of the organs and further off in pericardial distention. It is claimed that this is the only sure method of avoiding the pleura.

(2) Drainage is through the most dependent part of the sac, through a large opening not limited by bone or cartilage.

(3) Great ease of exploration and cleaning of the sac is afforded.

In certain fat subjects it may be necessary to cut away some of the seventh cartilage to get room in the xiphoid space. (It is to be noted that Roberts has recommended this area as the point of election for puncture, though not for incision.)

Ljunggren¹² reports a case of suppurative pericarditis successfully treated by incision and drainage.

He objects to puncture as a dangerous procedure in any case, recommending incision and drainage as the rational thing in all cases. He added 6 cases to Roberts's 35, making 41 in all, but 4 cases are inaccessible

to us and doubtful. Of these, 16 recovered and 25 died. Of the 16 recoveries, 8 were complicated by other diseases; in 7 of the fatal cases death was due either to faulty methods or slowness in operating.

His eight rules for the technique of the operation do not differ from my published method. He uses rubber drainage tubes, double.

The pleura should be bluntly loosened and sutured laterally to prevent infection of the pleural cavity. He mentions the occasional necessity of cutting away some of the sixth cartilage after resecting the fifth, in order to get more room, but does not mention removing any of the sternum. General anesthesia is not necessary and in weak cases is contraindicated.

Lilienthal, of New York, in 1889,¹³ reports a case of recovery from operation in a boy convalescing from lobar pneumonia; operation under eucaïne, local anesthesia, 40 ounces pus evacuated, giving cultures of pneumococci; this organism and streptococci were also in the sputum.

C. Mansell-Moulin, in 1897,¹⁴ reports an operation for "hemopericardium" as he calls it. The case was successfully operated on about one month after a blow on the chest at foot ball, and six pints of thin, dark, bloody fluid removed, from which no cultures were made. It seems reasonable to class this with purulent cases like certain other cases of suppurative effusion after injury (note the case of Riedel, also case of West). The case is not very dissimilar from Eiselberg's at the first aspiration.

Sevestre, in 1898,¹⁵ reports a case of purulent pericarditis in the course of acute pneumonia. Cultures, pure pneumococcus. Operated on under cocaine anesthesia. Double empyema afterward with resection of ribs on each side. Death.

In Sevestre's case two aspirations were attempted before the incision was finally resorted to. At the second aspiration only bright blood was obtained (the query arises as to whether the heart itself was wounded); the operation through the fourth space seems to have been careless, and the empyema following may have been caused by the pericardial operation.

H. Bethan Robinson, who reported his first case,¹⁶ has reported a second case, in 1898.¹⁷ A case following bronchopneumonia in a child four years old. Death in three days.

Several recent elaborate papers given in my bibliography deal with the surgery of the heart itself or with the surgery of wounds of pericardium.

Loison, on wounds of the heart and pericardium, in an exhaustive paper¹⁸ gives in his table 4 cases of pericardotomy for wounds of pericardium, namely, cases of Cappelen, Eiselberg, Garber and Riedel. Two of these, Eiselberg's and Garber's cases, are cases of operation for suppuration following wounds.

A new method of opening the chest in surgery of the heart and pericardium is advanced by Wehr.¹⁹ He recommends it especially where large exposure is necessary in wounds of the heart itself. It consists of making an elliptical flap of skin, bone and cartilage, cutting across sternum at the base of fourth cartilage

and again at the xiphoid joint, and by a curving sweep taking in fourth, fifth, sixth and seventh costal cartilage, turning this flap back with the right edge of the sternum as a hinge. He does not say he has done this on the living. His method can best be shown by reproducing his cuts, two in number.

Manges, of New York, in 1900, reported on cases of pericarditis following pneumonia at the Mt. Sinai Hospital.²⁰ Of 500 cases of pneumonia, pericarditis developed in only 11, and of the 11 5 died. He thinks all cases of pericarditis as a complication of pneumonia are due to the pneumococcus, and further states that infection with this organism is probable in many cases of so-called idiopathic pericarditis. This same organism finds its way from the pulmonary passages. In the pericardium, as in the meninges, the pneumococcus is always a pus-producing organism. It is probable, he says, that many cases of pericarditis in pneumonia are overlooked because the conditions around the heart when the left lung is affected are such as to obscure the most important sign, namely, increase of heart dulness; the to-and-fro murmur of the pericardial friction may last but a few hours.

Connor and Stimson, of New York, in 1900²¹ report a case of purulent pericarditis after a severe pneumonia. Operation under local anesthesia by Dr. Stimson. The right pleura was cut accidentally; death in a few days from purulent pneumonia.

Ljunggren in his paper,²² after reporting his case, the history of which has been translated and put in my list of cases, goes on to say that he has found some new cases which are not in previous lists. Three of these cases are inaccessible, however, and are given thus by him with no details; he merely gives the references: Hirschsprung, cited by Heyde; Heyde in a Dissertation, Kiel, 1896; Perls in a Dissertation, Strassburg, 1896. The other cases are those of Brentano, which I have given.

It has been possible for the writer to add 14 cases to the former collections of my own and Roberts, without counting the 3 cases cited above by Ljunggren, the details of which are not to be had. These make a total of 51 cases. (Of this series of cases the annexed tabular view has been made.)

An analysis of the 51 cases gives the following facts: 46 were for purulent pericarditis, septic; 2 were for serofibrinous pericarditis, rheumatic; 1 was for hemorrhagic pericarditis, traumatic; 2 were for serous pericarditis.

The etiology is as follows: Pneumonia, with and without empyema, 14; bronchopneumonia (in a child), 1; osteomyelitis, 5; wounds, gunshot or stab, 4; blow on chest, 1; periostitis, 1; necrosis of nasal bones, 1; septic throat, 1; septic arthritis of knee, 1; abscess of buttock, 1; empyema without pneumonia, 5; pleurisy of doubtful origin, 2; pleurisy with typhoid fever, 1; pleurisy with bronchitis, 1; influenza, 1; tuberculosis (?), 2; unknown origin, 7; rheumatic fever and endocarditis more or less acute, 3.

Of the total 51 cases of incision for pericarditis, 20 recovered and 31 died, a mortality for all cases of 60.5%.

Of the 2 operations for simple serous pericarditis both recovered.

Of the 14 cases in which acute pneumonia, either

lobar, bronchial or septic, was the cause of the purulent pericarditis, only 4 recovered (cases of Bohm, Lilienthal, Porter and Bjorkman); in 2 of these the pneumococcus was grown from the pus. The other 2 do not report bacteriological studies.

Twenty cases were not tapped previous to operation. Local anesthesia with cocaine or eucaine was used in 6 cases.

CONCLUSIONS.

(1) Pericardotomy is indicated in all cases of suppurative pericarditis.

(2) Because of the uncertain and varying relations of the pleura and because of the anterior position of the heart, whenever the pericardial sac is distended by fluid, aspiration of the pericardium is a more dangerous procedure than open incision, when done by skilled hands.

(3) Incisions of the pericardium can be done quickly and safely by resection of the fifth costal cartilage and in many cases under local anesthesia.

(4) In many cases of serous effusion open incision without puncture will offer less risk and speedier cure than aspiration.

(5) The method and detailed technique of the writer proposed in 1897 have been followed out by the majority of recent operators.

HYDROTHERAPY IN PNEUMONIA.¹

BY SIMON BARUCH, M.D., NEW YORK.

A RETROSPECTIVE glance at the treatment of acute diseases during the past half century reveals the fact that a revolution has taken place which has culminated in the practical abolition of the treatment of these diseases. In our own country the revolution was initiated by Jacob Bigelow, a former member of this society, by his work on the "Self Limitation of Diseases," published in 1835, and by his later book on "Nature in Disease." Reinforced by the good sense and captivating eloquence of your Oliver Wendell Holmes, American medical men have slowly, too slowly, alas, changed from destructive to constructive therapy.

We realize today that, with few exceptions, the manifestations of disease are but the expression of pathological conditions which no remedial agent is capable of removing. This proposition will not be construed by any fair mind as an abandonment of the patient to his fate, but simply to emphasize the fact that we no longer attack the disease by violent medication, as was formerly done by blood letting and mercury and blisters, later by *veratrum viride*, and more recently by antipyretics. If the symptoms of disease were really the essence of disease, our complete control of the pulse by *veratrum*, of temperature by antipyrin, of sleep by chloral, of pain by morphia, of feebleness by the modern foods and stimulants, would today ensure our triumph over disease. The fact that despite the response of the most significant symptoms to these powerful agents, patients continued to succumb, has awakened the medical conscience to a realization of the truth of the doctrines taught by Bigelow, Holmes and Hooker, sixty or more years

ago — that the patient rather than the disease must be treated.

In a malady like pneumonia, blood letting and other spoliative agents relieved pain, softened the pulse, and lulled the doctor into a false security, from which he was too often rudely awakened when heart failure presaged the approach of the end. So it is now with antipyretics, the chief value of which consists in enabling the patient to die with a more nearly normal temperature.

The old spoliative practice was abandoned when practical men discovered that it robbed them of the chief ally in the campaign against disease — the *vis medicatrix nature*.

If you reflect that for two thousand years the medical profession labored under the fatal error of fighting disease while the patient, being the battleground, suffered from friend and foe alike, you will bear with me in paying a tribute of gratitude to the man who courageously blazed a pathway through the confusing mazes of spoliative medication to "nature in disease." I esteem it a high privilege to announce here, amid the very scenes of his professional activity, that like Jacob Bigelow I trust to nature in pneumonia, as in every other acute disease. Not blind as that of the Christian Scientist in prayer and faith is my reliance on nature, but ready in armed expectancy to intercede in her behalf when peculiarities of the patient or of the disease or conditions of environment point to a deviation from normal processes of restitution.

Isolation, rest, cleanliness, ventilation, food, drink, and if need be medication, should be so directed as to enhance the resisting powers of the patient — to so fortify him that his inherent powers have free play in eliminating the noxious products which threaten to overwhelm him.

Among these agencies I esteem hydrotherapy as one of the most valuable. Water is not a curative agent for pneumonia, but its judicious use has afforded me much comfort and has doubtless contributed greatly to the diminution of mortality.

A somewhat active professional life of nearly forty years, spent in country, village, city, army, family and hospital practice, has brought me to the conviction that pneumonia is an infectious disease, which tends to destroy life by enfeebling the nervous and circulatory system, and that the indications for overcoming this lethal tendency are: (1) To fortify the nervous system; (2) to sustain the heart, whose integrity is of vital import in overcoming the local lesion and in removing inflammatory products by a vigorous circulation; (3) to strive for elimination of noxious products arising from the life and death of the diplococcus; (4) to render the patient comfortable by reducing high temperature, deepening inspiration and producing sleep.

Flexibility is a notable quality of hydrotherapy. By various procedures, changing of temperature and duration, we may adapt the application of water to the most opposite conditions for the fulfilment of these indications.

In no disease is this better exemplified than in pneumonia. Although its general manifestations resemble in many respects typhoid fever, its local manifestations differ from the latter as the Eberth bacillus differs from the diplococcus of Fraenkel. While in typhoid fever the cold bath, preferably as suggested by Brand, has proved of surpassing value, such a bath is not adapted

¹ Read before the Massachusetts Medical Society, June 12, 1900, and recommended for publication by the society.

to patients suffering from pneumonia. The reason is clear at the bedside. The typhoid patient resists temperature abstraction with much tenacity; the pneumonia patient, as a rule, quickly responds to heat abstraction. This clinical fact has often enabled me to confirm a tentative diagnosis, especially in children between eight and sixteen years of age.

While the typhoid patient, as a rule, bears the disturbance involved in tub bathing fairly well, such a procedure is extremely distressing in pneumonia by reason of dyspnea, cough and pain. Although Vogl, of Munich, Folsom, of Boston, and others, have reported good results from the cold full bath, I have abandoned them in adults for these reasons. In the pneumonia of young children, who are easily lifted, I still use full baths of moderate temperature (95° to 80°), or affusions of water of lower temperature (70° to 60°) in the bronchopneumonias with obstruction, because pleurisy is usually absent, and the shallow breathing and deficient oxygenation due to bronchial obstruction are greatly relieved by the agitation, crying and coughing incident to the full bath, with friction. It is my rule in all cases to be present during the first bath, in order to note the reaction and obtain other information for future guidance, because individuals differ materially in their response to bathing.

While each case demands special study with regard to baths, I usually begin with a tub bath (given alongside of the bed) of 5° below the patient's temperature, and diminish the bath 2° or 3° at each repetition in four hours until 80° are reached. The child's head and face are bathed in water at 65° before entering the bath, and gentle friction is made over the body during the entire bath. During the interval between the baths the method pursued in adults is adopted. In the latter, I have for the reasons stated substituted the wet thoracic compress for the full bath. It is my custom to have the rectal temperature taken every hour when the patient is not asleep. So long as the thermometer registers over 100°, a compress made of three folds of old coarse linen wrung out of water at 60° F. is wrapped around the chest from the clavicle to the umbilicus. It should be long enough to lap over one inch in front, and so slit in its axillary portion that it may rise easily up to the clavicle without leaving rough folds in the axilla. This compress is smoothly wrapped around the chest and covered by one larger of thin flannel, an inch wider and longer.

The effect of such an application of cold is so readily observed that it would seem needless to dwell upon it, did not so much misapprehension exist in the average medical mind on the object of cold applications in febrile disorders that it is necessary to again and again define it, to remove these erroneous impressions. Pardon me if I advert to some familiar physiological data. We know cold and heat are thermic irritants which stimulate when mild, depress when more severe, and destroy vitality when sufficiently intense. Applied through the medium of water, and regulated with regard to temperature, duration and mechanical impact, we may so modify these thermic impressions as to produce therapeutic results for which we look in vain in other remedies.

The primary effect of cold is that of irritant to the sensory network of the skin. This has been called shock, an error which is made evident by the definition of shock. In Gould's Dictionary shock is defined as

"depression, a grave effect produced by severe injuries, operation and strong emotion." To produce a shock with cold water, it would be necessary to put the individual into a tub of water very much below the body temperature and sufficiently long to prevent reaction. If the water were near the freezing point and he could not escape, shock would ensue. The individual would become unconscious, and the vitality of the skin would be destroyed if he survived long enough to suffer from frostbite. Bear in mind that the same effect would be produced by hot water under similar conditions, and yet no one ever speaks of the shock of hot water. The truth of the matter is — and I trust you will pardon my offering so simple a proposition — that cold stimulates when mild, and shocks when it is intense. Upon this principle we stimulate the nerve centres in pneumonia. A compress containing water at 60° F. when applied around the chest of a patient having a temperature 40° higher, produces an irritation of the sensory terminals in the skin, which convey it to the central nervous system and thence reflect it upon the organs receiving impulses from the latter. This is plainly evidenced by the patient's momentary gasp, the heightened pulse tension, the deepened and prolonged inspiration and the lowering of temperature.

By changes in the preparation of the compress we may modify positively the effects aimed at. If, for instance, the body temperature is not very high, say from 100° to 102°, the compress may be more thoroughly wrung out, so as to make the impression of cold more brief, reaction more rapid and less enduring. If the temperature be high, 103° or above, the water temperature may be raised to 65°, more water may be allowed to remain in the compress, thus rendering the reaction more slow and enduring and abstracting more heat. In the first instance the application will be more stimulating, in the latter more soothing and antipyretic. If the patient is easily chilled or does not react readily, whether the body temperature be moderate or very high, the compress may be allowed to remain longer without change; its repetition may vary from half an hour to an hour, or even longer, according to the patient's condition, his reaction and other effects produced and aimed at. Such cautious adaptation will gradually improve or regulate the reactive capacity of the patient, and sooner or later will enable him to bear more frequent repetition. It must always be borne in mind in all applications of cold water that shock is to be avoided; there should be no prolonged chilliness, no chattering of teeth, no cyanosis of lips, nails or face; in fine, every manifestation which indicates a depressing effect demands a modification of the procedure or its abandonment if need be. And right here let me emphasize a much neglected point. We do not abandon quinine in malarial fever when it produces distressing effects. On the contrary, bearing in mind the importance of the remedy, we circumvent its distressing effects by changing the method or time of administration, etc. Cold water is often entirely abandoned when it produces unfavorable manifestations, which is a serious error. Treat it as you would any other remedial agent; change the method, the temperature, the duration, and you will be gratified by the result, for it is a most flexible agent, as I have shown.

Besides the general effect referred to, we observe a local stimulating effect upon the cutaneous circulation.

The arterioles contract under the cold compress, but they quickly dilate again, as is evident from absence or disappearance of chilliness and the gradual warming up of the part, so that when the compress is removed in an hour, it is quite warm. This dilatation, be it remembered, however, is not a passive one like that under a warm poultice. The skin does not wrinkle and become cyanotic, but remains smooth and becomes ruddy. Moreover, repetition again stimulates the walls of the arterioles to contraction and dilatation, propelling the blood flow through them, and thus relieving the overburdened heart of much labor. Romberg and Paessler have recently confirmed by laboratory experiments what I have several years ago and repeatedly since that time insisted upon, that in acute infectious diseases we encounter disturbances of the circulation which manifest themselves clinically as reduced tension and diminished filling of arteries and which are commonly described as heart failure. Undoubtedly this condition of the peripheral vessels bears a very large share in the production of cardiac inadequacy, as I have sought to impress when explaining the rationale of cold application in typhoid fever. Romberg has shown by experiments with injections into rabbits of Fraenkel's diplococci that the circulation is damaged by a paralysis of the vasomotors, while the heart itself remains unaffected. By restoring the lost resiliency of the cutaneous vessels, the compresses tend to relieve the heart of much labor—a labor, too, which it vainly endeavors to compensate by increased pulsations—the sum of which too often leads to heart failure.

Upon this principle we endeavor to meet the second indication in pneumonia.

The third indication—the elimination of noxious products—is signally met by the improved condition of the central nervous system and of the heart, these presiding over all the functions of the body. The urine shows by its increase in quantity and toxicity that the most important noxæ are eliminated with great activity under the external application of cold. In addition to the latter the systematic administration of ice water (45° F.), 4 ounces every two hours, acts as a cold douche to the stomach and by increasing arterial tension increases urinary excretion. Allow me here to controvert an erroneous idea, which is almost universal, namely, that it is the increased quantity of water imbibed which increases the urine. (I have observed an increase of 100 to 400%.) Glatz has shown and I have confirmed his finding, that the imbibition of very hot or very cold water acts upon the arterial tension precisely as its external application and not by reason of the quantity drunk. This is readily demonstrated by the fact that only a slight increase of urine is produced by drinking tepid water, and the quantity is always increased with decided differences between the body temperature and that of the water drunk. It is my custom therefore to alternate 4 ounces of milk or other liquid food with 4 to 6 ounces of very cold water (45°) each and every hour when the patient is awake. The result is systematic and moderate feeding and renal stimulation.

The fourth therapeutic indication is certainly fulfilled by the mild application of cold in pneumonia. The comfort of the patient is greatly enhanced by the reduction of temperature, deepening of the inspiration and general *bien aise* which are renewed at each

application. The cold compress when its temperature is equalized to that of the patient's body really becomes a poultice, soothing in its effect, relieving pain, dyspnea, shallow and rapid breathing, but not relaxing the cutaneous vessels nor increasing body temperature like the poultice. It also increases leucocytosis, as has been established by Thayer, Winternitz and Rovighi.

To sum up briefly the effect of hydrotherapy in pneumonia, I would say that its judicious application fulfils all the therapeutic indications in this disease by meeting all the depreciating conditions which lead to a fatal termination. Only one condition is unaffected by this treatment, namely, resolution. I have observed crisis only in about 25% of cases. The local course of the disease appears to be unchanged. Resolution proceeds slowly, but surely. The patient has a normal temperature, pulse and almost normal respiration from five to twenty days before all signs of consolidation have disappeared. In the meantime I permit him to go out in mild weather and endeavor to hasten convalescence by the usual measures, good food, gentle outdoor exercise, ventilation, etc. I am still unable to explain theoretically this retardation of resolution in 50% of the cases, except on the same principle as the relapses in typhoid fever after the Brand treatment may be explained, namely, there are more cases escaping death and therefore more cases to relapse. The cases which do not have crisis under hydrotherapy would probably be added to the great silent majority or pursue the same chronic course toward convalescence.

TO WHAT EXTENT DOES "RHEUMATIC AND GOUTY DIATHESIS" ENTER INTO TRAUMATIC JOINTS (SPRAINS AND BRUISES), SEPTIC AND GONORRHEAL JOINTS, ACUTE ARTICULAR RHEUMATISM, NEUROPATHIC JOINTS, ARTHRITIS DEFORMANS (OSTEOID, RHEUMATOID), AS AN ETIOLOGICAL FACTOR? WHAT IS THE SCIENTIFIC BASIS FOR SUCH A TERM?*

BY WILLIAM H. PORTER, M.D., NEW YORK.

OF the six subdivisions propounded for discussion under the common subject, "Diseases of the Joints often Diagnosed as Rheumatic or Complicated with Rheumatism," the one given above was assigned to me by your committee.

The question is composed of two distinct parts, the last of which calls for elucidation before the first can be logically considered.

Taking up first the question as to the scientific basis of the two terms "rheumatic" and "gouty diathesis," before we can decide their true position in connection with scientific medicine, we are at once forced to analyze the origin and literal meaning of these terms in the light of our present chemico-physiological and pathological knowledge.

Take, for instance, the term "diathesis." What is its true significance in relation to the chemistry of the human economy? For years the term "diathesis" has been used to indicate that something has been handed down from generation to generation, but what that something is has never been made clear to the science of medicine. Taking the literal meaning of

* Read before the Massachusetts Medical Society, June 13, 1900, and recommended for publication by the society.

the word, from its Greek origin, *diathesis*, and applying it to the chemistry of the body, it must indicate simply and only that there is a tendency on the part of the animal economy to arrange the chemical phenomena of the system in certain and definite directions. This, however, does not justify the supposition that the individual is of necessity born to finally develop those symptoms recognized as constituting the conditions so long known under the term "gout" and "rheumatism." Therefore, the term "diathesis" as it is commonly applied, has neither fact nor foundation to rest upon; for all the evidence at our disposal tends to prove that all diseased conditions, with the possible exception of syphilis, are acquired after birth. All are abnormal chemical states of the system which can be either fed into or fed out of the human race, so to speak. This, however, is assuming a very high and almost theoretically ideal position; nevertheless, it is one that can be practically accomplished, provided we can succeed in attaining the highest perfection in the hygienic and dietetic conditions influencing animal life.

Thus, we find, without going further into exhaustive details, that there is no real scientific basis for the term "diathesis" as it has been commonly used in the past. In fact, it would be better if this term were dropped entirely from medical literature.

In like manner the terms "gout" and "rheumatism," when viewed from a purely scientific basis, are almost as meaningless as is "diathesis." Naturally, with this statement before us, the first question that arises is, what is this so-called "gout" and "rheumatism" that we hear and talk so much about? Turning back to the derivation of the word "gout" we find that it comes from the Latin word *gutta*, meaning a drop. According to Dunglison's Medical Dictionary, "gout received its name from the French *goutte*, drop, because believed to be produced by a liquid which is distilled drop by drop on the diseased part. The name was first used about 1270." Hence, gout is the drop disease. This, however, gives no insight into the etiological factors entering into the production of the pathological conditions so long honored by this name. Nor does it give any suggestion as to the disturbances of the chemistry of the body, which will ultimately bring about the pathological changes and symptoms so well recognized under the name "gout." We might possibly strain a point and say, in a similar manner to what has been said in the past, that the term "gout" was coined to indicate the dropping of the uric acid radical into the protoplasmic structures of the various tissues of the body, as the result of the final and vicarious oxidation of the proteid molecule in the tissues already made pathological by the prolonged disturbances in the chemical activities of the animal economy.

Vicarious oxidation being synonymous with the term "distillation" of the ancient writers, referred to in Dunglison's definition of the disease, accepting this more modern interpretation, there might be some justification for considering the term "gout" as a word based upon our present scientific data. On the other hand, as this vicarious oxidation of the proteid molecule in the already pathological structure of the body is but a little factor in the great and complex chemical problem constituting the condition so long known by the name "gout," there is no logical reason for regarding the term as one resting upon a clearly elucidated and per-

fectly scientific basis. Furthermore, the condition known as gout, as commonly defined, is said to be one in which there is a production of uric acid in the blood; a condition, however, that never occurs, because chemistry forbids the separate presence of an active acid in a strongly alkaline solution without the formation of a salt of that acid; at least it cannot occur unless all chemical laws are suspended in connection with the blood. So far as my observation and researches have carried me, there is nothing to warrant the assumption that the well-known laws of chemistry have been suspended, so that uric acid exists as such in the blood and does not result in the formation of a salt. Furthermore, it can be asserted that uric acid does not exist in the blood, for the reason that the salts of uric acid have never been found there, as must have been the case had uric acid entered the blood stream.

The definition above mentioned further affirms that the phenomena recognized under the term "gout" are due to the non-elimination of the uric acid from the blood stream, and its subsequent discharge from the blood as uric acid into the protoplasm of the various structures of the body, by preference into the cartilage cells of certain joints. But this explanation does not tell why the acid refuses to attack the sodium and calcium compounds in the blood stream, but seizes upon them with intense activity as soon as it is discharged into the semi-solid protoplasmic structures. Thus we find that the whole theory of gout is developed largely without any reliable scientific foundation, at least so far as the name is concerned, and it also disregards, almost from beginning to end, the well-known and inflexible laws of chemistry, as we understand them today. The only indisputable fact in connection with the whole theory of "gout," as it is commonly given, is the final deposition of the insoluble salts of calcium, together with some urate of soda crystals, in the various structures of the body. Therefore, it can very justly be stated that there is no well grounded scientific basis for the term "gouty diathesis."

When we come to the term "rheumatism" or "rheumatic diathesis," the mystery, so far as the derivation of the name is concerned, is greater even than is the case with gout. There is absolutely no scientific basis for the term. Yet under the term "rheumatism" is included a very great complexity of disturbed physiological phenomena.

If we attempt to secure any information through the derivation of the word we are led still further away from any scientific basis for it. Taking its Greek origin, *rheumatismos*, from *rheum* or *rheo*, and translating it literally "rheumatism," would mean a fluxion or flow, but of what or in what direction we are in total ignorance.

The more modern definitions are almost as vague and uncertain as those based upon the old and long since discarded humoral theory of rheumatism.

If there is no scientific basis for these terms, it is difficult to see how their relation to the topics under discussion can be elucidated or explained from a scientific standpoint. On the other hand, the natural inference is that both "rheumatism" and "gout" are, in a measure at least, connected with some of these joint affections under discussion.

Before we can discuss any etiological relationship between "rheumatic" and "gouty" conditions and the joint affections enumerated, we must first have

some fixed and definite conception of the chemico-pathological phenomena that are to be included under these terms. The weight of evidence, however, both chemico-physiological and clinical, points to defective oxidation on the part of the system as the chief predisposing factor in bringing about these two dissimilar conditions.

In the majority of instances the chief cause for a suboxidation state of the system is the ingestion of more oxidizable food than there is oxygen absorbed through the lungs to completely reduce the proteid constituents to the normal end products. In other instances diminution in the food supply, together with that of a poor quality, may so deteriorate the nutritive activity of the system that a pronounced anemia is produced, thus cutting down the intaking capacity of the animal economy for oxygen to such an extent that there is not sufficient oxygen absorbed through the lungs to perfectly oxidize the little proteid that is taken in the limited supply of food. Hence, too little or too much food may act as determining factors in producing an imperfect oxidation of the proteid constituents. It matters little whether the proteid be derived from the vegetable or the animal kingdom. Its imperfect oxidation and the toxic products developed in consequence of incomplete oxidation transmutation are *the* factors which excite the symptoms.

Attributing these pathological conditions to a suboxidation state of the system does not fully explain why in the one instance the result is "rheumatism" and in the other "gout." This was at one time attempted by assuming from the general clinical history that those individuals who partook freely of starches and saccharine substances developed "rheumatism," while those who lived largely upon an animal class of foods and used alcoholic beverages freely as a rule developed the condition called "gout." This was during the period in which lactic acid was supposed to be developed from the incomplete oxidation reduction of the saccharine elements and when uric acid was supposed to be the product of an animal diet only. That both uric acid and lactic acid do result from the imperfect utilization of the proteid constituents derived from the vegetable as well as from the animal kingdom is a well established fact. With this conception of the oxidation problem it is easy to understand how both "rheumatism" and "gout" can be developed from an excessive diet of either vegetable or animal food. It does not explain fully, however, why a liberal vegetable diet is more likely to produce the condition called "rheumatism," and the liberal animal diet is more likely to produce the condition called "gout." At the same time it must be clear to every one who has observed many cases clinically that certain kinds of diet have a decided influence in determining the nature of the suboxidation processes. It should further be remembered that none of these incomplete end products found in the excreta is to be considered as constituting the disease any more than urea constitutes normal nutrition. They should be regarded only in the light of results or indicators by which the different types of suboxidation can be recognized and differentiated.

The development of the so-called rheumatic condition cannot be explained as it was at that time, by assuming that lactic acid is the chief etiological factor in producing the disease, and that this so-called

lactic acid or rheumatic condition is due to the imperfect oxidation of the starches and sugar alone, while the gouty condition is due to imperfect oxidation of the proteid constituents. Assuming that such a condition is true from a chemical standpoint, it does not explain the development of the rheumatic condition, so called, in those who live almost exclusively upon an animal diet, in which there is no excess of the starch and sugar to undergo imperfect oxidation reduction. Therefore, such a theory is absolutely untenable both from the chemico-physiological and clinical data at our command. Hence, we are forced to the assumption that in the so-called lactic or rheumatic condition, as in the so-called uric-acid or gouty state of the system, all the toxic products found within the system, and all the abnormal products found in the excreta, are due to the imperfect oxidation reduction, or faulty isomeric transformation of the proteid constituents contained in the animal economy. This fact accepted, our theories can easily be made to fit all the clinical facts met with. Now, we can readily understand how it is that overindulgence in the starches and sugars is so prone to excite imperfect oxidation of the proteid constituents. The starches, sugars and fats, all being easily and quickly oxidized into their complete end products, if taken in inordinate quantities will overtax the oxygenating capacity of the system and there will not be left sufficient oxygen to complete the more difficult task of perfectly oxidizing the proteid constituents. In this manner they act as very potent factors in bringing about the imperfect oxidation of the proteid elements. Further than this, their oxidation being differently effected than the proteid, it is easy to understand how their excessive utilization may have a different result upon the system than an excessive use of the proteid constituents; thus, in a measure, explaining why, in the one instance, we are more likely to have "rheumatism," and in the other the "gouty" condition.

As there seems to be so much confusion in the minds of many in regard to the true position and meaning of these imperfect products of proteid oxidation, and especially so in reference to the most common of all, namely, uric acid, it may not be unprofitable to enter a little more into the detail of the formation of uric acid and its significance in connection with health and diseased conditions.

Uric acid is one of the substances by which nitrogen is eliminated normally from the system. It is an almost insoluble and very stable substance. It was first separated from human urine by Scheele, in 1776. It is a dibasic acid, having two replaceable hydrogen atoms, one of which is easily substituted by sodium, forming an acid urate, or biurate, of sodium. Both of the replaceable hydrogen atoms can be substituted by sodium, but, so far as is known, only the acid salt is a product of the animal economy. This urate is relatively soluble. Uric acid is formed by the oxidation of the proteid molecule or its derivatives, and is a lower oxidation product than urea, in the same manner that urea is a lower oxidation product than ammonia and carbon dioxide and water, which are the final products of proteid oxidation, chemically speaking. Why urea is the final oxidation product in man instead of ammonia, carbon dioxide and water has never been explained, further than to state that it is according to the original plan of nature.

It has been claimed by some that uric acid is not

an oxidation product, and they base their claim on the fact that this acid and its salts are the normal and complete excrementitious products in birds, reptiles, etc., in which animals the oxidation powers are said to be exceedingly high. However, there is nothing to prove the capacity of birds, reptiles, etc., to take in oxygen, or of the blood to distribute this oxygen, and of their system to utilize it, and that is sufficient to oxidize all the assimilated hydrocarbons and proteid compounds into their final and complete products. At any rate, to draw such an inference is begging the question. The chemical fact remains that their excreta, as compared with those of the higher order of animals, are products of a lower proteid oxidation; the same as urea is lower than the final product ammonia. Why in the one species the chemiophysiological apparatus of the animal economy is so constructed that uric acid and its urates are the final excretory product, while in another it is urea, is just as mysterious and absolutely unfathomable as the phenomena of life and death. In what follows we shall endeavor to show that in man the production of uric acid in quantities above the normal is due to a condition of suboxidation.

The two most prominent theories advanced to explain the genesis of uric acid in the system are :

(1) That it is an oxidation product manufactured in the renal cells; (2) that it is made in some manner in the liver, spleen, etc., but chiefly in the liver.

Minkowski,¹ Schroder,² Horbaczewski,³ are among the more recent defenders of the latter theory, while Garrod⁴ is generally credited with the former. The latter view is the one that has been accepted generally and on the following grounds: (1) That uric acid is found in the blood; (2) that in gout it is found in the tissues; (3) that after extirpation of the kidneys uric acid continues to be formed, and (4) that at the height of digestion, when the liver and spleen are most active, uric acid is most abundant in the urine.

In this connection it may be remarked that in all the experiments which have been brought forward to sustain the theory that uric acid is formed outside the kidneys, or in the liver, there have been produced profound abnormal or pathological states of the system. Therefore they should be completely discarded from a physiological standard, as all deductions founded thereon are upon a purely pathological basis, and not normal.

The claim that is so commonly made that free uric acid is found in the blood is not tenable, as we have already seen; for, on coming into close relation with the alkali metals, salts of the same are immediately formed. Therefore, if this nitrogenous organic acid were in the blood, it would be in the form of a urate only, and, as already stated, such a salt has never been found in the blood.

The statement that uric acid does not exist in the blood is based upon Hayercraft's⁵ method for detecting uric acid, or upon others of a similar nature. As they all admit of a possibility of oxidizing the proteid elements, and thus producing uric acid in the process for detecting this compound, they cannot be relied upon as proving the existence of uric acid in the blood. Some have claimed to obtain good results from this method. On the other hand, Salkowski⁶ regards the process as of little value even in solutions known to contain uric acid, as the composi-

tion of the silver urate formed is not constant; this opinion is further supported by Gossage.⁷

On the other hand, it has been, and is still, distinctly affirmed that free uric acid and its biurate salts do exist in the blood, and the method called upon to explain the possible presence, in some form, of uric acid in the blood is by the so-called quadriurate (quadriurate) theory. The following statement made by Roberts,⁸ the author of this theory, in his description of his method for obtaining the quadriurate, tends to prove that the quadriurate—if it really has a chemical existence—is an accident rather than a constant product, for he says: "To obtain a product of uniform composition by this process requires a somewhat nice adjustment of the reaction. If the quantity of alkaline carbonate added be faint, the precipitate, on cooling, is apt to be contaminated with free uric acid. On the other hand, if the alkaline carbonate be added too freely, and the resulting alkaliescence be excessive, the precipitate is apt to be contaminated with biurate. These risks are greatly minimized by using the alkaline acetates instead of the alkaline carbonates." From this it appears that Roberts failed to obtain the quadriurate with the regular uniformity necessary to establish his theory; in fact, the nice adjustment of the reagents required for the precipitation of the quadriurate might lead one to believe that, with this test, the precipitate was a mixture of biurate and uric acid in quantities to satisfy the theoretic demands for the quadriurate.

In Watt's Dictionary of Chemistry (Vol. IV, p. 835, edition 1894) is the following: "Naha. $\frac{1}{2}$ aq. (dried at 100) crystalline powder. Occurs as an amorphous urinary deposit."⁹ This statement, together with the fact that the alleged quadriurate is an amorphous deposit and very unstable, makes it appear highly probable that the biurate is still the form of urate most commonly found in the urine. It is not necessary to find a more soluble form of urate than the acid urate, for it is well known that the disodic monohydrogen phosphate,¹⁰ which is often present in the urine in abundance, will hold large quantities of uric acid in solution. It is also known that the uric acid in the urine, and in the absence of any newly added chemical agent, steadily attacks the disodic monohydrogen phosphate, so that when the acid phosphate which will not hold the uric acid in solution has replaced the neutral phosphate, the uric acid is precipitated; all of which occurs naturally, and without adding anything to the urine as is required for the demonstration of the presence of the quadriurate according to Roberts's theory. The one occurs naturally, and the other requires very nicely adjusted reagents for its demonstration. This method, which may be called the natural one of precipitating uric acid in urine which apparently contains no excess of the acid, can be artificially quickened by a very simple procedure. This is best done by filling a test tube with urine and bringing the upper stratum to the boiling point, then add a drop or two of a 4% solution of acetic acid and set the tube aside in a cool place. At the end of a few hours, if there is an abnormal amount of uric acid contained in the sample and held in solution, as already described, the heat and the acetic acid will excite chemical action between the uric acid and the disodic monohydrogen phosphate, thus destroying the solvent power of the

urine for the uric acid. Now the uric acid will rapidly be crystallized out, and the amount so formed, when collected on a filter and weighed, will give the exact percentage of uric acid in excess of the normal amount. In this manner and in a few hours the exact quantity of uric acid can be estimated. When the amount of uric acid is normal in the urine, no precipitation of the acid can be effected by this method. It then requires the use of a considerable quantity of one of the stronger mineral acids, sufficient to decompose the normal urates, and thus set free the uric acid otherwise held in combination with the sodium, before its presence is demonstrated.

The quadriurate, as has been said, is a very unstable compound and one that is easily broken up by washing with water. This being the case, its decomposition and the subsequent demonstration of the uric acid and the biurate in the blood should be easily accomplished. No mention is made, however, of finding the so-called quadriurate in the blood, but it is introduced artificially into the blood serum and synovia, and from this it has been claimed that it can exist in the blood; but failure to demonstrate its presence directly in the normal blood stream is negative proof that it does not exist in that medium. The production of the quadriurate in the system necessitates first the production of uric acid. So far, in connection with the quadriurate theory, we are in total ignorance as to the point where the uric acid is manufactured, also as to where it attacks the sodium compounds to form the theoretical salt, and where the latter finally gains access to the blood. Until these doubtful points have been cleared up satisfactorily, the quadriurate theory is one grand speculative problem which does not explain the facts as developed by clinical observation. Unless our theories can be made of practical value in the study and management of the case at the bedside, they are of no real value.

From all the preceding, it can be justly deduced that uric acid and its urates have not yet been clearly demonstrated in the normal blood stream. That uric acid and its urates are found in the tissues in pathological conditions is true. This, however, does not necessitate the assumption that uric acid or its urates existed in the blood stream in defiance of all the known laws of chemistry. But it does demand the hypothesis that, as a result of a faulty nutrition, there is developed an imperfect oxidation, or an abnormal isomeric transmutation of the proteid compounds; that as a result, these substances are oxidized at an abnormal position, instead of in the renal cells, as normally occurs; that when this is the case there is a sudden production of uric acid and the formation of urates in the protoplasmic masses, and that when this happens all the symptoms are those which indicate a profound irritation and an increased chemical activity. Thus, by assuming a vicarious production of uric acid, a theory which holds true in many other abnormal and pathological conditions in the body, the presence of uric acid, or rather the urates, in the tissues is explained by simple chemical phenomena, and without deviating from any well-defined law of chemistry. All this can be done without predicated that uric acid or its urates are present in the blood.

The pathological condition which is produced by extirpation of the kidneys will admit of the formation of uric acid by the vicarious oxidation of the proteid substances in the protoplasm of cells other than those

of the renal gland, upon the same principle as given in the foregoing example.

Upon the theory that uric acid is due to a deficiency in the quantity of oxygen reaching the body as a whole, and the renal cells in particular, the manufacture of uric acid by the kidneys should normally be greatest during digestion and least during the interval; for during digestion the carbohydrates, fats and proteids are being introduced into the circulation in large quantities. The two former are rapidly oxidized, the one in the liver and the other in the lungs, tending to use up the oxygen supply, so that a deficient amount of oxygen reaches the kidneys and a less perfect oxidation transmutation of the proteid in the renal cells is the result, while the output of uric acid is augmented. Thus a normal physiological phenomenon, which is called upon to explain the production of uric acid in the liver instead of the renal glands, when viewed in this light makes it appear quite plain that no such deduction is justified. It rather strengthens the theory which points to the renal cells as the true source of the uric-acid production, except in pathological states of the system, when it can be made at abnormal points by the vicarious action of the protoplasmic masses.

This theory of uric-acid production by the oxidation of the proteid substances in the protoplasm of the renal cells is by far more logical, is best sustained by all the points in evidence, and fits most accurately all the known facts and conditions. This formation of uric acid is one method for the elimination of nitrogen from the system.

It is absolutely necessary to have this acid produced at this particular point, and poured into the uriniferous tubules; for by this action upon the disodic monohydrogen phosphate in the uriniferous tubules the monosodic dihydrogen phosphate is produced, and the production of this acid phosphate of sodium is absolutely necessary to hold in solution the otherwise insoluble phosphate of calcium, thus preventing the formation of this form of calculi in the urinary passages.

The theory that the uric acid is produced in the renal cells in the manner described above is further substantiated by the steady presence of this acid or the urates in urine, and by their absence from the blood.

When uric acid is herein contrasted with urea as a suboxidation product, it is not meant to intimate that uric acid is the direct antecedent of urea. On the contrary, it is one of the complete end products of proteid oxidation, so far as the animal economy is concerned, just as much as urea, carbon dioxide and water are final products. Chemically, less oxygen has been utilized to produce this particular form of compound than is required to produce urea and the other higher oxidation products. Physiologically, when produced in excess, it is a suboxidation product, for it is found that the output of uric acid is always augmented by anything that interferes with the utilization of the full amount of oxygen by the system, as compared with the quantity of food stuffs absorbed. A prolonged high tension of the arterial system under the influence of digitalis, for instance, causes the blood to be driven through the capillary blood vessels so rapidly that sufficient oxygen cannot be taken up from the blood and utilized for the complete transmutation of the proteid elements of the food. As a result, suboxidation occurs, and the manufacture and output of uric

acid by the renal cells are increased. The same is true with every condition of the system which produces a prolonged high tension of the vascular system and a rapid pulse rate. When the intaking capacity of the lungs for oxygen is diminished by mechanical defects in the heart or by pneumonia, pleurisy, emphysema, etc., the oxidation of the proteid substances falls to an abnormally low degree, the excretion of urea decreases, and that of uric acid increases, the latter often to a marked degree. When the carbohydrates or fats are taken in excessive quantities, and especially the former, the oxygenating capacity of the system is exceeded, the more difficult task of oxidizing the proteid elements is imperfectly performed, suboxidation ensues, and as a result, uric acid increases in the urine, while the urea output decreases. When an excessive amount of the proteid substance is taken either alone or in combination with the carbohydrates and fats, the oxygenating capacity of the system is exceeded in a similar manner, and the proteids are imperfectly oxidized as before.

When the uric acid rises above the normal, it is simply a symptom found in the urine, which indicates an imperfect state of proteid oxidation and a general condition of malnutrition. This suboxidation may be, in a measure, caused by many different conditions acting singly or in combination—causes which may arise either in the nervous, digestive, circulatory or in the respiratory system. In every instance there is more or less profound impairment in the glandular activity and nutritive tone throughout the whole system. In some instances one organ or tissue will suffer more than another, and thus the symptomatic manifestations are varied and irregular in their development. When the renal cells temporarily cease to act, thus failing to produce uric acid, the associated defective state of nutrition results in many instances in the various masses of protoplasm throughout the body, which are in an abnormal physiological state, assuming an abnormal or vicarious action. In this manner the proteid substances are oxidized into uric acid in the cells of the tissues with the immediate production of the urate of sodium. This abnormal oxidation may occur in any protoplasmic mass which is in this state of malnutrition, but it is most commonly met with in the cartilage cells of the metatarsophalangeal articulation of the great toe. It does, however, occur in other parts of the body and in other tissues than the cartilaginous structures. This development of uric acid in the cartilage cells, or at other points of the body, results in its immediate precipitation at such points as a urate of sodium. This abnormal deposit acts as an intense chemical irritant, and excites a local inflammatory process by which a fibroplastic exudate is thrown around this foreign body until the urates are finally incapsulated, and gradually all the local symptoms subside.

The problem has further been very much simplified by the fact, now generally recognized, that all the non-nitrogenous food products, such as starch, sugar and fats, are directly oxidized into their end products, carbon dioxide and water, and that they do not yield any toxic by products to the system. Therefore, we are left to deal chiefly with proteid constituents as the etiological factors in the production of these toxic and suboxidation conditions of the system. This much established, we still have no clear and complete explanation for the different degrees and forms of suboxida-

tion processes which constitute the various diseases, such as so-called "rheumatism," so-called "gout," etc.

Strenuous attempts have been made in this bacteriological age to associate a specific germ with all pathological problems, and in many instances this has apparently been successfully accomplished. Still, the declaration of the presence of a specific germ as the causative factor in the production of disease does not explain in full the special and characteristic features of the pathological lesions found, or the symptoms by which the different diseases are characterized. Working along these lines, a considerable number of observers profess to have found a specific germ as the causative factor in the production of so-called "rheumatic conditions" of the system. Among this number may be mentioned von Schueller,¹¹ Buss,¹² Brunner,¹³ Buday,¹⁴ Petrone,¹⁵ Hlava,¹⁶ Tizzoni,¹⁷ Goldscheider,¹⁸ Löffler,¹⁹ Bouloche,²⁰ Mantle,²¹ Guttman,²² Fleischhauer,²³ Waibel,²⁴ Bonchard,²⁵ Sahli,²⁶ Lucatells,²⁷ Leyden,²⁸ Singer,²⁹ Chvostek,³⁰ and Humphrey.³¹ All of these observers have given more or less attention to this subject. Buss states that he considers it highly probable that acute articular rheumatism, so-called, is in many, perhaps in the majority of cases caused by attenuated pyogenic micro-organisms, among which he includes the Friedländer pneumobacillus and the diplococcus of Fraenkel-Wechselbaum. Sahli cultivated streptococci from the blood and contents of affected joints in cases of so-called acute articular rheumatism. Singer made bacteriological examinations in 17 cases of so-called articular rheumatism and secured positive results in 16 instances. In 10 cases he found staphylococcus albus; in 1, staphylococcus aureus; in 3, streptococci; in 2, staphylococcus albus and streptococci. He further argued from his observations that the constancy of the occurrence of the micro-organisms in the urine, and the fact that the number of the colonies obtained diminished in number as the symptoms improved, were sufficient evidence for considering a coccus infection as the exciting cause of the disease. Chvostek, on the other hand, made repeated observations in 12 cases of so-called rheumatic affections of the joints. In 1 of these cases he found the diplococcus ureæ; in another, in which the urine was not drawn with a catheter, staphylococcus albus; and in a third, large cocci, which have not yet been described, but which, probably, according to Chvostek, are derived from the urethra. In this connection it should be remembered that Krause³² has shown that bacteria are often excreted in the urine during infectious disease, which have no connection whatever with the particular infection from which the patient is suffering, and which must not therefore be regarded as the exciting cause of the disease. Among these bacteria the staphylococcus albus plays an important part. And this is the form of micro-organism that has most frequently been described in connection with these rheumatic conditions. Krause further says that these bacteria are no longer found in the urine when all the signs of disease have vanished, simply, as he argues, because the conditions of the system necessary for their growth have been removed.

Chvostek extended his examinations and made examinations of the blood, urine and articular fluid in cases of so-called acute and chronic articular rheumatism, as well as in cases of other infectious diseases, in which an acute swelling of the joint takes place. The results which he obtained from his examination of the

articular fluids were negative in all his cases, except in the changes in the joints that arose directly in the course of a sepsis or a gonorrhoea. Chvostek sought further to discover whether the bacteria which are present in the blood entered the joints during the life of the patient; and if so, the conditions necessary for their transit through the wall of the blood vessels. In this connection it may be mentioned that his experiments on animals showed that certain alterations in the nutritive composition of the vascular wall must be produced before the passage of the micro-organism could be effected. He also demonstrated, to his own satisfaction, that the construction of the synovial membranes and that of their contained blood vessels resisted to a high degree this nutritive change that makes possible the passage of the germs, thus rendering it very difficult for the micro-organisms to pass through the walls of the blood vessels and gain access to the joints. This is not the case, however, with the vascular walls of the kidneys; hence, the bacteria, if they appear at all in the joints, will do so at a much later period than they are excreted by the kidneys.

That micro-organisms have been found in the urine, and in some instances in the blood, and in the fluid accumulations in the joints, and in various structures of the body, in connection with the varying conditions which have been described under the common term "rheumatism," cannot be denied. We may even go further and state that the prevailing organism when described at all is most frequently of the coccus type.

From the great diversity of results obtained, and from the fact that no one form of micro-organism is found with any degree of regularity in connection with these so-called "rheumatic" conditions, the consensus of opinion is that the pathological conditions and symptoms classed as rheumatic are not to be attributed to the direct and intrinsic bacterial invasion of the structures of the body, as is the case in connection with some of the well-known and undisputed microbial diseases. Nevertheless, it is reasonable to suppose that in conjunction with overfeeding, and with under-feeding, and the consequent suboxidation state of the system, the action of the micro-organism and the toxic products that are developed as a direct result of their presence in the alimentary canal are largely responsible for the different forms and degrees of suboxidation included under the terms "gout," "rheumatism," etc. The micro-organism in all these instances acts by its presence in the alimentary canal, and by its disturbing influence upon the digestive process, and not by its inherent presence within the intrinsic structures of the system.

To understand this proposition thoroughly, it must be remembered that the presence of certain kinds of bacterial life are, in all probability, absolutely essential to a perfect performance of the digestive function. In this connection it must also be remembered that only a few years ago Nuttall and Thierfelder,⁸³ in a series of experiments in which they used young guinea pigs, apparently proved that the alimentary canal could be kept free from all bacterial influences, and a perfect nutrition at the same time be maintained. In opposition to this is the fact that in almost all instances the alimentary tract at all times contains various micro-organisms. Added to this are the more recent experiments of Dr. M. Schottelius.⁸⁴ Dr. Schottelius's series of experiments was carried out in a manner similar to those of Nuttall and Thierfelder,

but instead of selecting the guinea pig, hens and their eggs were utilized for the experimental work. Two sets of eggs were taken, one in which the surface of the eggs was made absolutely free from bacteria by washing with a strong solution of bichloride of mercury, the remaining set remaining contaminated by micro-organisms. The first, so far as their exterior is concerned, will be called for convenience sterilized eggs, while the other batch will be designated as non-sterile eggs. The former were introduced into a sterile incubator, while the others were not. When the chickens were hatched, those from the sterilized incubator were carefully fed upon sterilized food, while those of the control experiment were given ordinary food. The feces were carefully examined in both instances. In the first set, or the so-called sterile chickens, the feces were found to be absolutely free from all forms of bacterial life, while the reverse was found to be the case in the control experiment. At the end of a certain period of time the non-sterile batch of chickens were found to have gained in weight much more rapidly than the sterile batch. The gain was 250% greater in those in which the bacteria gained access to the alimentary tract. Further than this, all of the so-called sterile chickens died within three weeks after they were hatched, while the control chickens lived on as usual. Thus it would seem to be clearly proved that for the most perfect working of the digestive function in the alimentary tract, and also for assimilation, the presence of certain kinds and amounts of bacterial life and their chemical products in the alimentary canal are absolutely essential.

To determine which form of bacterial life is essential for the maintenance of a perfect physiologic state will require a long series of experiments, in which the composition of the food is accurately determined before being ingested. At the same time the excreta, representing the utilization of the food stuffs and tissue waste, must be accurately studied. Then the various kinds of micro-organisms at work in the contents of the alimentary tract must be determined through a study of the bacterial life found in the feces. With this there must also be associated an isolation of the various kinds of bacteria found in the contents of the alimentary canal in connection with the condition recognized ordinarily as the normal state. Then the action of the bacteria should be carefully studied on the normal sterilized and non-sterilized food stuffs outside the body; and this must be done with the bacteria, singly and in combination. Their action should also be studied upon the food in the presence of the various digestive ferments. When all this has been accomplished, a very fair knowledge of the action of germs in the digestive process in the normal state will be secured. Then, in a similar manner, their action upon the digestive process could be studied in connection with the conditions designated as intestinal indigestion, and also in connection with all the pathological processes which appear, in a large measure at least, to take their origin in an imperfect digestion and assimilation, and in which an incomplete oxidation is a leading feature of the disease, as occurs in the so-called "gout," "rheumatism," "Bright's disease," "diabetes," etc.

While all this desirable information is not as yet at our command, there is sufficient evidence at hand to warrant the assertion that the varying degrees and

kinds of suboxidation met with, such, for instance, as the so-called gout and rheumatism and a host of other conditions, are the result of some special kind of micro-organism acting in the alimentary canal; or they may be the result of two or more varieties acting together; or may it not be that the absence of certain kinds of bacterial life is the determining factor in the production of the diseased process? In either instance it may be assumed that abnormal or toxic products are produced in the alimentary canal, which when introduced into the circulation with the food stuffs, act as the direct and determining factor in establishing the special degree or form of suboxidation that we know by these time-honored names "gout," "rheumatism," etc. By assuming the development of a variety of toxic products it easily explains the great variety in the clinical picture as witnessed under the so-called rheumatic condition.

This line of argument is sustained, so far as the symptoms are concerned, by the fact that with the introduction of certain chemical compounds into the system definite symptoms follow, as when morphine, strychnine, atropine, pilocarpine, etc., are introduced. Why morphine, strychnine, atropine, pilocarpine, etc., are always followed by a pretty uniform train of symptoms depending upon the special one used has never been absolutely explained. Yet no one attempts to deny the fact. In a similar manner it is reasonable to suppose that the symptoms of disease are the result of the introduction into or development within the system of definite chemical compounds; that these chemical products either emanate directly from the micro-organism or are produced from the proteid constituents, in which the bacteria grow, by the action of the bacteria upon the proteid molecule. This latter view appears to be the more probable, taking all things into consideration. The modification of the physiological phenomena by the introduction of the varying pathological conditions met with, just the same as the introduction of chemical compounds, can be made to modify pathological phenomena, and thereby enable the system to be brought back into a more nearly physiological condition. In all these suboxidation diseases the action of the bacteria is on the proteid constituents as they exist in the chyme rather than upon those which exist as intrinsic parts of the body.

Thus we find that the two great predisposing factors in the development of so called gout and rheumatism are the prolonged intake of a larger amount of nutritive pabulum than the system can perfectly oxidize, or conditions that so reduce the oxygenating capacity of the animal economy that the small amount of food taken cannot be perfectly oxidized. Added to this, as the exciting and determining factors in the production of the special type encountered, are the action of the bacteria on the proteid in the alimentary canal and the formation and absorption into the system of toxic products in conjunction with the food products absorbed. These two factors acting together determine the form of the suboxidation, the nature of the pathological lesions, the character of the symptoms, and the abnormal and by products that are found in the excreta. It is largely by the latter that we are enabled to accurately differentiate between the different forms of these suboxidation conditions that afflict humanity. In conjunction with the two predisposing factors and the exciting factor in the

production of these suboxidation conditions there are a few other things that must not be overlooked, as they often exert a decided influence in determining the final result. They are the varying changes in the temperature, hygienic surroundings, nervous disturbances, etc., for they are all very important factors and help to disturb the perfect working of the glandular system. Just how the *modus operandi* of this bacterial factor working in the alimentary canal can best be absolutely determined is the question that is still pressing for an answer from the physiological chemists. Until it has been fully solved, the absolute etiology of these suboxidation processes under discussion, so-called gout and rheumatism, cannot be absolutely elucidated except in theory. But even in the absence of this much desired complete verification, this explanation, as here given, adheres more closely to all the facts thus far known to modern science than any explanation previously advanced.

With this conception of the chemical conditions that are at work with the system, when affected with so-called gout and rheumatism, the etiological relation of these conditions, if any exists, can be applied to the various diseases that are under discussion. It is, nevertheless, difficult to comprehend how false feeding, the action of the micro-organism in the alimentary canal, and a toxic infection of the system therefrom, can in any manner be looked upon as a primary etiological factor in the production of a traumatism to a joint, a sprain, or a bruise. Therefore, it must be asserted in the very beginning that there is no direct primary etiological relationship between the so-called rheumatic condition of the system and traumatic lesion of the joints. On the other hand, it is equally true that the abnormal chemical condition of the system which produces that state of the animal economy classed as "rheumatism" and "gout" will assert itself, and modify the whole course of the pathological problem in connection with a traumatism. This does not warrant the supposition, however, that the so-called rheumatic state of the system in any manner acts as a primary etiological factor in producing the traumatism of the joint structures. Penetrating a little more deeply into this intricate problem, we find that the products absorbed from the alimentary canal, and which, if retained in the system, are the determining factors in producing the special type of suboxidation that excites the lesions and symptoms classed as rheumatic, will influence the pathological changes following a traumatic injury to the joint. This is assuming, however, that there have been false habits of feeding, micro-organisms at work in the alimentary canal, absorption of toxic products into the system, and that, in consequence thereof, the animal economy has been or is on the verge of the suboxidation state called rheumatism, prior to the receipt of the injury. In other words, after a mechanical or macroscopic traumatism to the joint structures, the nutrition in the injured parts, in one who is suffering from this characteristic chemical state of suboxidation of the system, which just precedes and makes possible the so-called rheumatic condition, will undergo changes different from those occurring in a more normal state of the system. When this term "toxic product" is used in connection with the diseases under discussion, it is understood that one of two conditions exists; either the system contains one or more by products which have resulted from an incomplete oxidation reduction of

the proteid elements, or the system contains proteid molecules which, instead of pursuing their normal isomeric transformation course, have been deflected therefrom. When this latter occurs, the proteid molecule is so changed, isomerically, that it becomes toxic in its character, yet it still remains an unoxidized proteid body. This irregular isomeric transformation of the proteid bodies, and their change into a toxic form, easily explain the toxicity of the system. It further shows the difficulty, if not the absolute impossibility, of detecting the presence of these toxic proteid bodies as they circulate in the blood and lymph stream. In whatever manner produced, the toxic product which, prior to the injury, was eliminated from the system without exciting any active symptoms, will often aid in intensifying the pathological changes and symptoms resulting directly from the traumatism. Lesions and symptoms which would not have developed in the absence of the traumatism are produced by virtue of the presence of the suboxidation and toxic condition of the system called "rheumatic." On the other hand, they would not have occurred in the presence of the traumatism in a system perfectly free from so-called gouty and rheumatic conditions. In instances of this character the so-called gouty and rheumatic states of the system can be looked upon as etiological factors in the production of some of the pathological changes and symptoms which follow direct traumatisms to the joint structures. They are, however, always secondary and never primary.

This relationship of the so-called gouty and rheumatic condition of the system should always be taken into consideration in connection with every traumatism that implicates the joints. If such a state of the system is found to be present, it must be given due consideration in the general management of the case; otherwise recovery will be greatly retarded.

In one instance that came under my observation a severe wrench to one of the great toes had occurred in a gentleman in his early fifties. This injury was followed by all the characteristic symptoms common to an ordinary attack of so-called subacute or chronic gout. So long as the case was treated as one of simple traumatism, which was the method pursued before he came under my care, there was no pronounced or permanent improvement. From the moment the condition was regarded as being primarily traumatic in its origin, and, in a large measure, secondarily kept in motion by the gouty suboxidation condition of the system which preceded the traumatism, and the treatment modified in accordance with this latter view, improvement was steady, and a permanent cure was speedily effected. Here the traumatism precipitated the so-called gouty attack, if I may so state it, and the only line of treatment that could be effectual was one directed toward removing the suboxidation state of the system. This is only one of many cases that could be cited in illustration of this principle. The same holds true in connection with the so-called rheumatic conditions. On the other hand, we frequently meet with instances in which slight fractures running into the joints and dislocations of the carpal and tarsal bones are diagnosed as so-called rheumatic affections. Thus we find that there may be a commingling of the two conditions, both acting as etiological factors, even in connection with simple traumatic injuries of the joints. Therefore, each and every case examined must be carefully

analyzed by itself, and due consideration given to the traumatism and to the possible influence that a previously existing suboxidation state of the system may at the time exert in the production of the lesions and symptoms. When this is systematically done, treatment will be more scientifically applied and the restoration of the involved joint to its normal functional activity more speedily effected.

With the septic and gonorrhoeal affections of the joints, all that has been said as to the relation of so-called gouty and rheumatic conditions of the system to a traumatism can similarly be applied to these two diseases. The so-called gouty and rheumatic states of the system are in no sense primary etiological factors in the production of a septic or so-called gonorrhoeal joint. Both, however, may play a secondary part in determining the nature of the lesions and the character of the symptoms as in the simple traumatic affections of the joints. But their influence will not be as well marked as it is in the former instance. This is especially true in connection with a septic joint, where the intensity of suppurative process and its symptoms mask all those of a minor character, and also because death usually occurs early in the disease. The same may be said in connection with so-called gonorrhoeal infections of the joints; for it is still an open question whether the acute joint symptoms developed during the course of the gonorrhoeal, or following as sequelae, are not due to a direct septic infection instead of a gonococcus invasion⁸⁵ of the joint. With so-called gonorrhoeal rheumatism which develops many months after the acute gonorrhoeal attack, the suboxidation state and the toxic involvement of the system through the alimentary canal are in all probability more largely responsible for the pathological changes and symptoms than is the gonorrhoeal infection. Thus the so-called rheumatic condition may play a large part in the development of the lesions and symptoms in so-called gonorrhoeal affections of the joints; but it is always a secondary and never a primary cause. Still, in the management of all these cases it must be carefully considered and the treatment directed accordingly if the best results are to be attained.

When we come to the consideration of those conditions commonly classed as acute articular rheumatism, we for the first time reach a point in which the errors in diet, the action of bacteria in the alimentary canal, and the absorption or the development of the toxic products directly traceable to their presence, act when they are introduced into the system as the direct etiological factors in determining the special type of suboxidation. In this manner we can further look upon the suboxidation and toxic invasion of the system from the alimentary canal as the direct and exciting cause of the so-called gouty and rheumatic affections. The great variety of toxic products which can be produced in this manner in the alimentary canal, and that can be developed within the system, as well as those absorbed from the alimentary tract, can be made to explain the varying degrees and types of suboxidation encountered. They can also be made to explain all the different forms and types of so-called rheumatic affections that are encountered clinically. This theory of the production of these lesions is well supported by that of Weigert⁸⁶ in his explanation of the various kinds and types of renal lesions that are known to exist. As yet, how-

ever, we are not sufficiently familiar with the micro-organisms and the toxic products to fully trace the *modus operandi* from the point of origin of the etiological factor to the final result. If, as seems quite probable, many of the toxic products are simply isomeric forms of the normal proteid molecule, it will be, as before stated, a very difficult matter to trace, isolate and identify them. At the same time, from the data at our command, it seems reasonable to assume that continued errors in diet, the action of various kinds of micro-organisms in the alimentary canal, and the production of an almost endless variety of these toxic products, can easily be made to explain the many forms and types of the so-called rheumatism, even from the slightest myalgia to the most extensive destruction of the joint structures. Even the so-called neuropathic joint affections can be elucidated upon this theory of a disturbance of the nutritive functions of the animal economy, as they can in no other way. When one kind of toxic product affects the system, it, like some of the well-known drugs already mentioned, will influence the chemistry of the body in its special manner, and a certain definite train of lesions and symptoms will follow. The introduction of still other kinds will produce their special results, and an almost endless variety of examples might be mentioned. In the one instance the abnormal and toxic condition may result in a simple congestion only of the intermuscular planes, with an undue pressure upon the nerve endings distributed to that particular part. Then we have the condition called "muscular rheumatism." In another instance the abnormal and toxic condition, by virtue of a difference in the toxic product, will implicate the central or the peripheral nervous system and give rise to that class of cases which are known as neurotic and in which there are no very pronounced joint lesions. In still others the toxic elements will cause a more profound disturbance of the peripheral nervous mechanism, and thereby the action of the so-called trophic centres will be so profoundly disturbed that actual and pronounced destructive changes in the joint structures are produced, such as are found in Charcot's disease. The most common lesion, however, that occurs as the result of this special type of suboxidation and toxic infection of the system classed as rheumatism, is one in which the vascular areas in and around the joints become congested and is followed by a pronounced edematous swelling of the soft structures in and around the joints affected. In all these cases it is the lowered nutritive activities and the action of the toxic products within the system, acting either upon the central or the peripheral nervous system, that cause the disturbance in the vascular and nutritive supply to the parts affected and thus give rise to the anatomical changes and symptoms. In the vast majority of instances the injury to the structures involved in the so-called rheumatism is not sufficiently great to excite the phenomena characteristic of a true inflammatory process. Hence, with the removal of the cause and an improvement in the general, as well as in the local, nutrition, there is a perfect restoration of the implicated joints to their normal state. In a few instances the primary injury from the toxic infection may be sufficiently great to excite a truly inflammatory process with all the changes characteristic of inflammation. In all these cases there is a tendency to more or less permanent damage to the structures in

and around the joints involved. The amount and permanency of the damage to the joint will depend entirely upon the intensity of the primary injury and the duration of the actual inflammatory process.

The most extensive damage to the joints, however, is met with in those cases which are not inflammatory, but in which there is a long-continued general suboxidation state of the system, together with its peculiar type of toxic infection. In these instances the continual augmented vascular supply to one area, with a defective supply to another adjacent zone, but in both instances of material poor in quality and also toxic in its nature, causes a very irregular distribution of the nutritive pabulum with which to carry on the functions in and around the joints. So great and varied is this abnormal distribution of the nutritive pabulum that almost all grades of new formations are met with in and around the joints. These vary from simple swellings consisting of atrophied fibrillated connective tissue infiltrated with a watery exudate into its meshes to well-defined enlargements composed of dense fibrillated connective tissue almost as firm and well developed as the normal tendon tissue. These new formations are located chiefly in the ligamentous structures and around the end of the bones at the point of the attachment of the ligaments and tendons.

This newly formed tissue in some cases is infiltrated with the insoluble salts of calcium and the urates, but it differs from the so-called gouty depositions in position rather than in kind. In the latter the salts are deposited by preference in the cells of the cartilage structures, while in the condition under consideration it is outside the joints and in the newly formed tissue.

In some rare instances there may be developed both a carious condition and new bone in and around the joint. The two latter conditions are very rare and always suggest the possibility of a syphilitic infection as an accessory etiological factor.

In all but this latter class this complex chemical suboxidation problem, with its associated toxic condition of the system which has for many years been included under the so-called rheumatic condition, can be looked upon as the direct etiological factor in producing the lesion and symptoms of so-called acute articular rheumatism in all its varied forms, also the neuropathic joints and some of the forms of arthritis deformans. This is especially so in all cases in which the joints become enlarged and distorted by an undue and irregular deposition of newly formed connective tissue.

In the osteoid types and in those cases in which a certain amount of caries occurs it is highly probable that other etiological factors must be taken into consideration in explaining the loss of bone and the development of new bone. As already mentioned, it is highly probable that syphilis plays a decided part in producing these grave changes, as it is well known that syphilis causes a decided tendency on the part of the system to bring about a carious state of the bones and a tendency to the formation of new bone.

This method of explaining the phenomena that occur in connection with conditions of the system so long known under the names "gout" and "rheumatism" places us in a much better position to prevent their development and to displace them from the system when they have developed. It further shows in which of the diseases under discussion the "gouty" and

"rheumatic" condition of the system acts as a direct etiological factor, and also where its influence is only of a secondary nature.

SEPTIC AND GONORRHEA JOINTS.¹

BY CHARLES A. PORTER, M. D., BOSTON.

THERE is probably no medical term which is made to cover so many sins and errors in diagnosis as the oft-used words "joint rheumatism." By dint of careful clinical study, and especially through the aid of bacteriology, certain types of joint disease have been gradually differentiated from this ancient chaos. Last to endure—it is to be hoped soon to go—is the rather indefinite phrase "gonorrhœal rheumatism." This paper deals with joint infections, septic and gonorrhœal, which may be confused with articular rheumatism. As this disease is probably also an infection manifesting itself chiefly in the joints, it is evident that we are dealing with more or less similar processes, which, though varying in etiology, must still have many symptoms in common.

No mention will be made of the septic infections which follow immediately upon operations or open wounds of joints, or of joint tuberculosis. There remain the infections which occur secondary to a suppurative process in other parts of the body, or following general infection through undiscoverable local lesions. The more carefully this question is investigated the more we recognize that pathogenic organisms may enter the circulation even in conditions of apparent health. These organisms either die in the blood, are eliminated by the kidneys, etc., or localize

themselves in various organs or tissues where they may be destroyed by the phagocytic cells or germicidal body fluids. If, through a general or local diminished resistance, the germs continue to grow, there results a general or local infection of varying intensity. A favorite site for such manifestations is the joints or the adjacent epiphyseal ends of bones. Where a suppurative or septic process is known to coexist, errors of diagnosis are infrequent. In the infective diseases like scarlet fever, dysentery, pneumonia, meningitis, the attendant joint complications are usually recognized. Most difficulties occur in the cases of so-called idiopathic arthritis, where the mode of entrance of the organisms is undiscoverable, through the tonsils, pharynx, intestinal tract, a boil or pustule, a small healed wound. The germs which most commonly are found in such joints are the ordinary pyogenic staphylococcus, the streptococcus, the pneumococcus. Unusual infections occur from the typhoid bacillus, glanders bacillus, etc. Cases of gonorrhœal infection and the arthritis accompanying osteomyelitis or epiphysitis, are most frequently mistaken for rheumatism. In infants or young children often no existing cause can be found. In older children or young adults exposure to wet or cold not infrequently precedes the joint inflammation, or so-called "rheumatism" sets in after an injury. There may have been a sore throat. The constitutional symptoms are in general more severe, the fever higher and less irregular, with a more rapid pulse. Sweats are uncommon, chills relatively frequent, the leucocytosis more marked. The pain is extreme and boring, limited in the earlier stages to the epiphyseal end of the adjacent bone; this sign soon giving place to general tenderness about the joint as it becomes involved. Of value for diagnosis is the definite interval by which the general symptoms and great pain precede the signs of local infection, thus differing from rheumatism. In superficial joints edema soon appears and rapidly extends; redness appears later than in acute rheumatism; the joint capsule or periosteum may be perforated, when fluctuation becomes evident. Though more than one joint may be involved, such septic processes are usually monarticular. Salicylates have little effect on the pain. As early diagnosis is all important to save the joint from disorganization, puncture, in doubtful cases, should be resorted to without hesitation. Not all septic joints have such an acute onset. For example, a boy eight years of age entered the Massachusetts General Hospital with the diagnosis of articular rheumatism of the right knee, duration five days. Salicylates had caused no improvement. Temperature 100°, pulse 80; only moderate pain and tenderness. The effusion was slight; leucocytosis 11,000. The condition remained relatively the same for days, when it was learned that he had fallen on a needle which had entered to one side of the patella. The joint was opened and found much disorganized. Cultures showed pure streptococcus infection.

Another boy of ten, without preceding illness, fell and struck his left knee. He was brought into the hospital three days afterwards with the diagnosis of acute rheumatism. There were high temperature and rapid pulse and several general symptoms. The joint was very tense and held immovably fixed. The skin was much reddened; pain and tenderness extreme. Under ether, 3 ounces of creamy, yellow pus were evacuated, which showed a pure culture of the pneu-

¹ Read before the Massachusetts Medical Society, June 13, 1900, and recommended for publication by the society.

nococcus. The subsequent course of this case illustrates the frequent burrowing of pus even after apparently thorough drainage. Several successive abscesses formed which extended between the muscle planes and fasciæ, and up and down the leg. From all of these pure cultures of the original organisms were obtained. Although in both of these cases at the time of operation it appeared as if permanent ankylosis would follow, at the end of three months the knees could be flexed to a right angle. With early operation in such cases the prognosis is probably not as bad as would be expected, especially in children and young adults. As gauze stimulates the formation of granulation tissue, protective seems to be the ideal drainage material. Under it the synovial membrane is more quickly restored, adhesions are prevented rather than excited, irrigation and changing of dressings is almost painless, and the danger of pus backing up behind gauze wicks is not present.

To illustrate a joint infection with one of the rarer organisms, a case of Dr. C. B. Porter is of interest. A man of thirty-five entered the hospital with severe general symptoms and an arthritis of the great toe and knee. Cultures from the pus were sterile on ordinary media. Inoculation into guinea pigs, however, proved that the infecting organism was the glanders bacillus. There was nothing characteristic in the joint lesions.

When once the diagnosis of a septic joint has been made, the surgical indications for drainage and disinfection are so clear that there is no need to speak of their treatment.

The pathological processes in these septic joints are well recognized and need not be alluded to.

Of late several cases of joint infection with the typhoid bacillus in pure culture have been reported, and attention has been called to these typhoid joints, especially by Keen in his monograph.

Owing to the general condition of the patient the joint lesions are often overlooked. It appears to be characteristic that an insidious disorganization occurs in the articular structures which relatively early leads to dislocation. Indeed, it is this dislocation which in several cases has first attracted attention. Later, joint lesions may occur in typhoid fever, after apparent recovery, due either to the typhoid bacillus itself, or mixed infection with the ordinary pathogenic organisms which have entered through the healing ulcers. In such cases a subacute rheumatism may be simulated.

Though any of the above septic joints may occasionally be mistaken for rheumatism, gonorrhœal arthritis is a disease which has hitherto not been sufficiently recognized as quite different from ordinary rheumatism. Although continual advance has been made of late, particularly by the Germans, I do not believe that the majority of the profession yet realize how often a careful analysis of so-called "rheumatic cases" will lead to the discovery that the real nature of the arthritis is gonorrhœal. For many reasons the relative frequency of joint complications is hard to determine. Statistics from in- or out-patient departments of hospitals and from private practice vary much, according to their source. The well-known unreliability of venereal statistics, the great difficulty in diagnosing chronic or latent gonorrhœa in men, and especially in women; the comparative rareness of thorough bacteriological examination, with the fre-

quent negative findings, even in undoubted cases,—all combine to make accurate statistics hard to obtain. One is often struck on carefully questioning gonorrhœal patients with the frequency with which mild or severe rheumatic symptoms have coexisted, and the more the physician's attention is directed to this subject, the more cases of gonorrhœal arthritis does he find. If, as seems probable, between 2 and 5% of the cases of gonorrhœa are complicated by arthritis, it is certainly not a rare disease. From another standpoint, although arthritis in connection with a gonorrhœal infection has been recognized for a long time, the causative relation of the gonococcus to it has only recently been demonstrated. The old idea, that the patient, run down by the disease, developed articular rheumatism, has been and is still advocated by some. While articular rheumatism may occur in such a patient, the nature of the arthritis, unless absolutely typical of rheumatism, should be regarded with much suspicion.

It has been demonstrated, also, that certain joint lesions occurring in connection with gonorrhœa have been due to the ordinary pyogenic organisms, though classed under the general heading "gonorrhœal rheumatism." In such cases, where the bacteria have entered the blood from the urethra or elsewhere, the pyogenic organisms dominate the symptoms, and it is essentially a septic joint disease and not gonorrhœal arthritis. The gonococcus undoubtedly forms a powerful toxin, and certain writers have put forward the view that the joint manifestations may be due to this toxin, without actual localization of the organisms. Careful examination of the contents of undoubted gonorrhœal joints have so frequently proved sterile by smear and culture that there is some plausibility in favor of this toxic origin of the milder forms of arthritis. This subject will be spoken of later under bacteriology. Until recently, gonorrhœa had been regarded as essentially a local disease, spreading by continuity. There are, however, a sufficient number of reliable reports which definitely establish that this organism may cause metastases in various distant parts of the body. Such localizations are numerous; in the joints, tendon sheaths and bursæ, pleura, peritoneum, meninges, sheaths of nerves, heart wall and valves, spleen, lungs, kidneys, periosteum, lymphatic glands, subcutaneous tissue, skin and parotid gland. From the circulating blood gonococci have been recovered several times, so that we have absolute proof that this organism may cause a general septicemia, or pyemia, and may produce pus wherever localized.

As "grippe," with rheumatic pains in various parts of the body, not infrequently complicates an acute gonorrhœa, or exacerbation of a chronic process, it is probable that mild systemic infection occurs, which never goes on to a definite arthritis. The rôle which gonotoxin absorption plays in producing these symptoms has not yet been determined.

TIME OF OCCURRENCE OF METASTASES.

Though a period of from two to six weeks usually elapses before metastasis occurs, the joint complications may first appear months or years after the original infection. Fingers's statistics seem to show that the joint lesions occur more frequently in chronic or relapsing gonorrhœa than during the acute stage; certainly in the older cases, where few or no local signs exist, far more errors are made in diagnosis. Very

rapid dissemination may occur within a few days of infection. For example, a case of Resniko's, a girl of twenty, four days after marriage, acquired an acute infection from her husband, who had purulent discharge at the time. She developed with the symptoms of general infection a severe polyarthritis. The ruptured hymen was regarded by him as the infection atrium. In chronic gonorrhoea the connection between an increase of local symptoms and a recrudescence in the joint is most striking and characteristic in many cases. The opposite may be true, and as in epididymitis, local symptoms may cease with the complication, or may show no change from the previous condition. Recent medical literature is full of articles emphasizing the long duration of gonorrhoea and demonstrating the difficulties of determining when infection has actually ceased. Particularly is this true in women, where the disease may appear to be chronic and mild from the start, and unknown to the patient. Owing to the numerous bacteria which exist in the vagina, culture methods and even staining are often most unsatisfactory. Negative findings after careful search are so commonly proved erroneous by the subsequent infection of another party that their value for exclusion is slight. In 226 cases of chronic cervical catarrh in prostitutes without symptoms, gonococci were found 117 times. In many of these cases the organisms could be found only during or after menstruation.

Kopp reports 52 cases of chronic urethritis where repeated search was made for gonococci in vain; yet without renewed infection, recidives occurred in which the organisms could be demonstrated. Therefore, in males also the latent period is often as impossible to diagnose, and is certainly far longer than is usually thought.

In a patient of mine who was positive that no new infection had occurred, gonococci were found in the seminal vesicles five years after the original disease. I dwelt on this part of the subject simply to emphasize that, apart from the mere misstatements or ignorance of patients in regard to gonorrhoeal infection, there are many cases where the physician can find no reason to suspect a connection between the present "rheumatism" and past venereal disease, and to show that the danger of gonorrhoeal metastases endures for a long time. Though there is a general belief among genito-urinary surgeons that the metastases in males occur most frequently after posterior urethritis, it would appear that the depth to which the gonococci have penetrated into the mucous membrane is of more importance than the part of the urethra involved. A few days after infection the gonococci proliferate deep in the mucous membrane and are carried about within the migrating leucocytes. The not infrequent edema of the prepuce and swelling of the inguinal glands are usually due to toxin absorption, though the presence of gonococci has been occasionally demonstrated. Though infection may thus occur through the lymphatic apparatus, it is believed that the organisms enter through the blood vessels.

Wertheim was able to show the gonococci in a thrombus of the bladder wall. The chain was thus made complete, and found to be similar to ordinary pyemic infection.

Though males are probably more frequently afflicted with joint complications than females, the disproportion is not as great as was once thought.

In babies, subsequent to gonorrhoeal ophthalmia, there is naturally no disproportion between the sexes. In childhood cases occur in young girls from vulvovaginitis more frequently than in boys of the same age. In adults, Nasse reports in one year 43 cases, 24 in males and 19 in females; Northrop, 117 in men and 76 in women. As attention has not been called sufficiently to gonorrhoeal arthritis in women — and venereal disease is by them denied or unknown more commonly than by men — more cases have undoubtedly been overlooked.

Bedouin reports 42 cases of arthritis in connection with the puerperium. While some of these were ordinary pyemic joints, many of them showed the presence of gonococci. The lacerations attendant upon childbirth were considered as the source of entrance. The well-known tendency of puerperal non-suppurative arthritis to prolonged stiffness or ankylosis is regarded by him as characteristic of a gonorrhoeal joint. One case now in hospital illustrates this disease. Coincident with her confinement she had acute swelling of the metacarpophalangeal joint, ankle and knee on the right side. There was no evidence of uterine sepsis. The baby had gonorrhoeal ophthalmia. Salicylates gave no relief to the pain; the local lesions, which will be spoken of later, were quite characteristic of gonorrhoea. The organisms were recovered from the joint contents in pure culture, as well as from the urethra.

In addition to the error of believing that women rarely suffer from gonorrhoeal arthritis is the mistaken idea that such arthritis is essentially a monarticular affection, and different in that respect from acute articular rheumatism. Recent statistics have shown that more than one joint is involved in 60% of cases; yet, though several joints are involved, it is true that *one usually* bears the brunt of the infection.

The larger joints — the knee, ankle and elbow — suffer most frequently. The small joints of the hand, foot and fingers are more commonly attacked than in acute articular rheumatism, though usually in connection with other joints. The jaw, spine and sternoclavicular articulation are affected more often than in rheumatism. The sheaths of tendons, the bursæ, especially the bursa under the Achilles tendon, are favorite seats for gonorrhoeal metastases. The tendons about a joint may be involved with it or independently. Trauma and overexertion are predisposing causes. Curetting, the passage of sounds, too vigorous local treatment, may precipitate a metastasis or make an existing joint lesion worse. Exposure to cold or wet exercises no influence.

SYMPTOMATOLOGY AND COURSE.

In a disease like this, which varies in its manifestations from a slight effusion with little pain to disorganization of a joint with formation of pus, accompanied by severe general and local symptoms, it is naturally difficult to classify the various forms and hard to describe any definite type.

Though at any given time the joint lesion may closely simulate acute or subacute articular rheumatism, it is, I think, possible in a great majority of cases to make a clinical diagnosis of gonorrhoeal arthritis. In cases of acute joint disease, not conforming typically to articular rheumatism, a careful history will often make the physician at least suspicious of a past gonorrhoeal infection. Thorough local examina-

tion may show the presence of an old urethritis or signs of an old gonorrhoea in women. Bacteriological examination of urethral shreds, discharges from the cervix, urethra, Bartholin's ducts or adjacent crypts, may show the presence of gonococci. When such evidence is wanting the course of the disease and the general local symptoms can alone be relied upon. The mode of onset varies. The majority of joint lesions are mild; particularly in connection with chronic gonorrhoea an acute or subacute synovitis develops most frequently in the knee. There is little pain, moderate stiffness, a varying amount of effusion, which may rapidly disappear, or may persist with thickening of the capsule as a painless chronic relapsing synovitis. In such cases there is nothing characteristic, and unless in the acute stage the gonococcus can be demonstrated by puncture, diagnosis is extremely difficult. If one or more times this synovitis recurs with increase in the urethral signs, the diagnosis is probable. The cases which are most frequently confounded with articular rheumatism are more severe, beginning usually in the morning without preceding exposure to wet and cold, or tonsillitis. One of the larger joints begins to swell, with fleeting pain in several others. The amount of pain is so variable that from it little help can be obtained in diagnosis. It may be extreme, but is generally less than in articular rheumatism. The pain is usually worse at night. Several joints may be involved, or one joint may follow another in fairly rapid succession; but the tendency to improve in one as another becomes involved, so characteristic of articular rheumatism, rarely occurs in gonorrhoeal arthritis. The joint most affected shows little tendency to improve, and remains swollen and tender for a long time, entirely out of proportion to the general symptoms. The amount of fever varies; rarely absent at the onset, it may disappear at the end of a few days, though the joint symptoms remain active. In severer cases it may last for a number of weeks, and soon assume the suppurative type with morning remissions. This is true in cases which have been proved to be uncontaminated by ordinary pyogenic organisms. Almost never does the fever curve show the markedly irregular remissions characteristic of real rheumatism. The acid sweats are wanting; endocarditis is very rare. The amount of effusion varies. On the whole it is rather slight, and the chief changes occur in the synovial membranes and periarticular tissues. In some cases the joint capsule becomes rapidly thickened without much edema, but as a rule the subcutaneous infiltration is well marked, extending above and below the joint, and giving a doughy, boggy feeling. The skin is not reddened, the papillae are apparent, and the glossy, mottled blush characteristic of articular rheumatism is absent. The local heat and superficial sensitiveness are slight. In short, except for the tenderness and the acute onset, the gonorrhoeal joint strongly suggests a tumor albus. For weeks the local signs are out of proportion to the general symptoms. Often the pain disappears within two weeks; yet for a long time tender points on deep pressure are found over the sides of the joint at the insertion of the ligaments or tendons. In acute cases, the joint is fixed. In the knee flexion occurs relatively early. The great sensitiveness to deep pressure, the early tendency to stiffness and ankylosis, are most characteristic. In the wrist, more than in any other joint, softened tender areas appear among

the tendons, which suggest the formation of an abscess. Pus, however, is infrequent, and one finds only softened hemorrhagic granulation tissue. The contents of the joint may perforate the capsule, or infection by continuity occur. Residual abscesses, often unaccompanied by fever, may extend along the tendon sheaths or into the subcutaneous tissue.

The edema and exudate about the joints and tendon sheaths persist longer than the serous infiltration of acute articular rheumatism, and after their disappearance the boggy thickening of the capsule and sub-synovial tissue, with little effusion, is apparent; whereas, in rheumatism the joints usually recover in six weeks, gonorrhoeal joints often remain stiff and swollen for two to six months. A non-traumatic arthritis which persists for weeks in one joint should always arouse suspicion.

In several cases I have seen at the hospital, especially in the wrist, acute tuberculosis was closely simulated. In such cases tuberculin may aid in the differential diagnosis.

Periarthritis of the shoulder, not infrequent in young adults, without the history of trauma, may be due to gonorrhoeal infection.

BACTERIOLOGY AND PATHOLOGY.

A great deal of work has been done on gonorrhoeal joints in the past two years, especially by the Germans, as a result of which the behavior of the gonococcus in the joint and the resulting lesions are fairly well understood. Rindfleisch has published the results in 30 cases very carefully investigated by him. In 19, gonococci were demonstrated. In 2, the staphylococcus aureus alone; in 1, mixed with gonococci was found. In 1, the staphylococcus albus alone, in another with the gonococcus. In 9 cases no organisms could be found. Weiss has collected 121 cases of undoubted gonorrhoeal arthritis, from 92 of which the gonococcus was isolated. Young, of Johns Hopkins Hospital, recently reports 13 cases of joint and tendon sheath infection, in which the gonococcus alone was present. The gonococcus apparently first localizes itself in the subendothelial tissue, there proliferates, and is carried into the joint cavity by the migrating leucocytes, or the desquamated endothelium. In the first few days the organisms are infrequent in the joint fluid. At the end of three days the leucocytes and endothelial cells appear in about equal numbers, and the gonococci are most abundant, yet are conspicuous for their relative scarcity, occurring in twos and fours within and without the cells. The joint fluid is not a favorable medium for their growth. Degenerate forms soon appear, shown by their refusal to grow on culture, and the crowding of the leucocytes with more organisms. Subsequent proliferation occurs not in the joint fluid, but in the synovial membrane, as Rindfleisch and others have demonstrated. In 1 case, numerous organisms were present in the fluid on the third day, had disappeared by the thirteenth, yet could be demonstrated by culture and smears, in curettings from the synovial membranes.

In reviewing the cases reported of positive findings, it is striking that in all of them the joint infection was relatively fresh, or a recurrence had taken place. I can discover no mention of gonococci found in chronic synovitis. When we consider this early disappearance from the joint cavity, the relative scarcity of the organisms, and the well-known difficulties in

their successful cultivation, we can understand why so many aspirations may be sterile, and the necessity for early puncture of the joint for diagnostic purposes is evident. Both culture and staining methods should be used, for in many instances cultures have proved positive where no organisms could be found by staining, and vice versa. Though exudation, and even suppuration, has been produced by injection into joints of sterile products, gonotoxins, in view of the above-mentioned facts it seems more likely that the gonococci have early disappeared from the joint, or failed of demonstration than that local joint disease is caused by toxins absorbed from the urethra. In the effusion there is nothing characteristic. It is more apt to be blood stained and purulent than in acute articular rheumatism. König regards a reddish, gummy, seropurulent fluid as insignificant.

The gonorrhoeal process in joints is characterized chiefly by proliferative rather than destructive changes. The synovial membrane and periarticular tissues are much thickened and infiltrated, even at a distance from the joint; the granulation tissue formed is very richly vascularized. The capillary walls are thin, areas of hemorrhage are frequent, and blood usually escaped into the joint. In more chronic processes in the joint and about the tendon sheaths, the dark red, easily bleeding granulation tissue, giving to the joint or sheath a velvety appearance, is suggestive of a gonorrhoeal process. It is the rapid organization of this granulation tissue and surrounding exudate which causes the early tendency to stiffness and ankylosis.

CASES.

A few cases which I have seen at the hospital will illustrate typical gonorrhoeal joints.

A girl of thirty, who denied venereal history, entered the hospital suffering from debility. Three days after entrance she suddenly developed, with moderate fever, an acute swelling of the right metacarpophalangeal joint and right knee. The thumb was swollen, tender, not red; moderate effusion in the joint. In the knee the synovitis was slight. The capsule was evidently thickened; periarticular edema lacking. Pain severe, worse at night; leg moderately flexed. The inflammation in the thumb quickly subsided, but the local tenderness in the knee steadily increased. Three weeks after the onset the joint was tapped, and a small amount of seropurulent fluid obtained, tinged with blood. This relieved the pain. Cultures were sterile on ordinary media. No organisms could be found by the microscope. As the fever continued, varying from 99° to $101\frac{1}{2}^{\circ}$, and the joint had not improved, operation was decided upon. The knee was held moderately flexed, very tender on deep pressure over the external lateral ligaments, and presented the appearance of a chronic white swelling. At operation a small amount of turbid blood-tinged seropus escaped. The cavity of the joint was small, limited by the greatly swollen synovial membrane, which in places was an inch thick. Fibrin was small in amount. Already adhesions had formed between the patella, femur, and several parts of the capsule; the alar ligaments were greatly thickened. Cultures and smears were again negative. No organisms could be found in the sections from the synovial membrane. At operation a purulent vaginitis was found, but no gonococci could be demonstrated. A history of cystitis was finally obtained four months before the

present illness. The fever gradually subsided, but the joint swelling and tenderness persisted for several weeks with great stiffness, and ultimately ankylosis was absolute. Large doses of mercury and iodide had no effect.

Another case previously alluded to showed, coincident with confinement, a swelling of the thumb, ankle and knee. The symptoms in the hand and foot rapidly subsided, but in spite of salicylates the knee joint remained very painful, flexed to a right angle, not red, very tender at several points, with moderate effusion and moderate thickening of the capsule. This joint was opened by Dr. Harrington. The fluid was turbid, blood stained, seropurulent. Examined under the microscope, the leucocytes were numerous. In a few of them diplococci which decolorized by Gram's stain were found; in two days pure cultures of the gonococcus were obtained by Dr. Wright.

A man of forty-two, who had contracted a gonorrhoea eight weeks before, entered the Out-Patient Department with the following history: Two weeks ago, with moderate fever and much pain, he had swelling of the ankle, shoulder and wrist. In a few days the inflammation in the other joints subsided, but the wrist continued swollen. The hand and forearm were much swollen, the exudation firm and boggy; there was no redness, little heat. Motion at the wrist was impossible without great pain. In the anatomical snuff box and over the extensor tendons at the wrist, two apparently fluctuating areas existed. Gonococci were demonstrated in the urethra. On incision, the subcutaneous tissue was porky, the sheaths of the tendons were filled with a gummy, slightly hemorrhagic exudate. Communication with the joint could be made out. Gonococci were recovered from the pus and granulation tissue by Dr. Wright in smear and culture. The temperature was 100° , the leucocytosis 26,000. Recovery followed very slowly, with marked tendency to ankylosis.

Another case represented the appearance of an ordinary palmar abscess over the head of the fifth metacarpal bone. Duration six days, with superficial redness of the skin and great tenderness at operation. No pus was found, but the adjacent joint was filled with seropurulent material in which were diplococci decolorizing by Gram's stain. No growth on ordinary media. The girl had contracted gonorrhoea four months before, and the organisms were still present in the urethra.

TREATMENT.

Of the many drugs which have been advocated as beneficial in gonorrhoeal arthritis, none in my experience has exerted much influence on the joint lesion. The pain is rarely relieved by the salicyl or coal-tar products, thus giving some aid in discriminating between a gonococcus infection and articular rheumatism. Morphia is often required in the acute stages. The treatment of the urethra should be begun at once, with mild, hot permanganate, or citrate of silver irrigation. No sounds should be passed during the acute joint disease. Laudanum fomentations, turpentine stupes, guaiacol, or ichthyol ointment, so often used, have appeared to me to be of little benefit. Most relief has been obtained from the continual use of ice bags, or dry heat, preferably with a hot oven, at a temperature of 250° to 400° . The circulation is stimulated, pain relieved, and absorption of the exudate

favored. It was hoped at one time that the temperature of the joint could be raised sufficiently to inhibit the growth of the gonococcus, which is very susceptible to heat. This seems not to be the case. Flaming with the actual cautery is the best counterirritant and often relieves the pain.

Absolute immobilization by appropriate splints is the best treatment in the acute stage. As in other forms of arthritis, flexion of the knee may occur early. If gradual extension is too painful, an anesthetic should be given at once, and the joint straightened and immobilized, for if ankylosis results adhesions can be more safely broken by flexion than by extension. In the elbow the opposite is true, and this joint should be flexed to a right angle.

While the acute process usually subsides within two or three weeks, in many cases great pain follows attempts at motion, probably due to the rapid formation of adhesions within and about the joint. Here the physician is at a loss to decide upon the proper treatment. The joint grows stiffer day by day, yet movement is bitterly complained of by the patient. In such cases, advantage should be taken of the period of diminished sensitiveness to pain which usually follows the hot-air bath. Massage should precede movement. Unless the signs in the joint become worse, treatment should be firmly persisted in. At intervals, under an anesthetic, the joint may be *once* fully flexed and extended, allowed to rest for a couple of days, when active and passive movements should be continued. In the acute stages, when the capsule is much distended, aspiration should be done for the purposes of diagnosis, and irrigation of the joint. In the subacute period the usually small amount of fluid is probably beneficial, separates the inflamed joint surfaces and prevents their adhesion. Pressure with immobilization should not be used at this time. The question of operation in gonorrheal arthritis is coming more and more to the fore, and is advocated even in relatively mild cases by good surgeons, who report numerous cases where the fever, general symptoms and pain have been quickly relieved by operation, and earlier use of the joint followed.

By operation the toxins and gonococci in the joint fluid may be rapidly evacuated, and such treatment is indicated in all severe gonorrheal joints, as in any septic arthritis. With proper precautions the danger from sepsis is probably slight in comparison with the advantage to be gained; good temporary results may follow operation in the knee, where the surfaces can be seen, thoroughly cleaned, and superficially disinfected; but, as the gonococci will continue to proliferate in the synovial membrane beyond reach, the process, though checked, will often continue. As relatively few pure gonorrheal infections lead to suppuration, the treatment by immobilization and early passive motion is safer for general adoption. Particularly is this true in the more complicated joints, as the elbow, ankle or wrist, where thorough irrigation and drainage are usually impossible, and where incisions among the adjacent tendons would not infrequently lead to the ankylosis which operation is intended to prevent. When pus can be demonstrated by fluctuation, edema and redness, or aspiration of the joint or tendon sheaths, then only should operation be resorted to. Incision, irrigation, immediate suture, without drainage, should be attempted.

The passive hyperemia method, advocated by Behr,

in the treatment of joint tuberculosis, has been used with good results in gonorrheal arthritis. The limb is bandaged up to the joint; above it a flat tourniquet is applied, sufficiently tight to impede the venous circulation. The joint swells, the pain is relieved, and earlier motion is reported. This was true in 2 of my cases. In 3 others no benefit followed.

SUMMARY.

In this paper I have endeavored to show: (1) That the gonococcus alone can cause arthritis, which, without the presence of other organisms, may be purulent.

(2) Gonorrheal arthritis occurs not only in acute gonorrhea, but in the chronic or latent stages, which persist much longer than is commonly believed.

(3) The signs of such chronic infection in the male and female are often slight, and disregarded or overlooked by the patient and physician.

(4) In consequence, not a small proportion of cases are diagnosed as articular rheumatism which are really of gonorrheal origin.

NEUROPATHIC JOINTS.*

BY SIDNEY A. LORD, M.D., BOSTON.

It is obvious that the term "neuropathic joint" might reasonably be of very wide or extremely limited application, according to whether we had most in mind the fundamental rôle played by the nervous system in all vital processes on the one hand, or on the other the smallness of the number of joint affections generally regarded as essentially trophic in nature.

I shall apply the term in this paper to all those affections which seem, from the evidence at present available, to owe their characteristics to the direct influence of the nervous system, whether strictly trophic or not. The limitations of time will prevent any more than passing mention of the neuromimetic and so-called hysterical joints, which indeed do not fall within my province, for they depend upon disorder of ideas, are psychopathic in origin, not resulting from physical lesion. They have moreover but slight bearing on the differential diagnosis of the profoundly altered joints with which this paper principally deals.

Taking up first the classic examples of true nervous arthropathies as they are called—those of tabes dorsalis and syringomyelia—we find that the anatomical characters are almost identical in the joints, notwithstanding the great and essential differences shown by the diseases as a whole, so that much of what can be said of one applies to both.

It is of primary importance to recognize the facts that the joint lesions of these two cord diseases are in typical form almost absolutely limited to them, that they occur with frequency, 5% to 10% of all tabetics and about 10% of syringomyelics being thus affected, and that conspicuous among the symptoms in both troubles are extensive losses of sensation. The course of these arthropathies need not be here described in great detail.

The following mode of onset is not at all uncommon. Entirely without warning, entirely without pain, entirely without evident cause, during some mild

* Read before The Massachusetts Medical Society, June 13, 1900, and recommended for publication by the society.

muscular action, absolutely without effort, often quite before any development of ataxia, the leg gives way or the arm drops, and the joint—knee or shoulder, for example—becomes at once useless; or if not at once, in a few minutes or hours. For there quickly ensues an enormous, tense, fluctuant swelling, utterly destroying action of the joint. In its suddenness and extent, this swelling is quite out of the domain of all other conditions besides tabes or syringomyelia, except that following the great crushing violence of accident cases. The swelling extends usually beyond the joint limits—this is very characteristic; in fact it is not uncommon for the whole limb, or one segment, to increase enormously in size with astonishing rapidity. The cause of this is a remarkable subcutaneous and muscular infiltration, hard, non-pitting, often visibly hemorrhagic. There is no pain, and signs of inflammation are absent.

The further course of these arthropathies is the reverse of the onset: absorption is slow and rarely complete, there remaining permanently moderate hydrops, with eventual (sometimes extremely rapid) development of flail joint or *Schlotter-gelenk*, a unique condition of painless, fully mobile luxation. This state of abnormal mobility does not necessarily require a long time for its production—it may often be detected to slight degree in the course of a very few weeks, or as soon as the swelling has considerably receded. During the stage of active distention, it is not usually present. The extreme grades of it, resulting in those fantastic shapes which, as Marie¹ says, “shame the double-jointed man” and result even in perforation, are only found in chronic cases. After this stage there sometimes occurs complete *restitutio ad integrum*, not without tendency to relapse, however. There commonly remains grating on movement, and the neighborhood of the joint slowly enlarges. Termination in ankylosis is rare. (Schlesinger² reports 2 cases in syringomyelia.) Other than this, cure is not to be expected.

The pathologic anatomy of these lesions is most interesting. It resembles much that in arthritis deformans, and consists in rarefaction and hypertrophy of bone, cartilage, ligament, and synovial membrane. Combinations of these changes are most diverse, and explain the clinical variations in large degree. Bony fragility and weakness of ligaments are of especial importance.

There are two principal types of change—atrophy and hypertrophy. In the atrophic form there is sometimes immense absorption of bone, which may include a considerable part of the shaft,—of the humerus or femur, for example,—the heads of the bones having completely disappeared. The opposing bony joint surface is likely to become somewhat hypertrophied under the influence of abnormal attrition. The hip and shoulder usually show the atrophic form.

The hypertrophic form is more common; there are irregular bony projections, perhaps free pieces of bone, large and small, in the joint, the cavity of which looks shrunken, through the great development of connective tissue. In the middle of the joint the cartilage has disappeared. The fluid in the joint is thick, yellow, sometimes hemorrhagic, occasionally almost pure blood. The ligaments are destroyed and ossified in varying degrees. The synovial membrane is often luxuriantly fringed. Fracture into the joint is com-

mon. This last statement indicates that there is an extreme degree of bony fragility; in arthritis deformans such fracture, at least of the whole head of the bone, as is here seen is absent or extremely rare. Anatomically still other distinctions between the two conditions have been described.

What is the immediate cause of these arthropathies? In discussing this it will be important to mention the chief clinical variations. It is vital to point out that, in its etiology, it is impossible to separate fracture from the arthropathies themselves. There can be no doubt of very frequent coincidence of fracture with arthropathy; and in the joints above discussed, with large swellings, the relation is probably nearly constant. I believe it highly probable that in such cases the fluid is, much more commonly than at present supposed, purely the result of active hemorrhage. Brissaud's³ interesting case illustrates this. Tapping is unfortunately rarely done, so that we cannot be sure.

It seems to me that this factor of hemorrhage is necessary to complete the theories of Paget, Volkmann, Kolisko⁴ and others who believed that the whole cause of arthropathy lay in violent ataxic movements, sufficient to fracture bones and to rupture the joint structures. The great force of these unfelt inco-ordinated movements, the inco-ordination being augmented sometimes by irregular muscular atrophy, must be acknowledged, and the potency of this cause admitted, in view of the occurrence of so-called spontaneous fracture of even thick and sclerotic tabetic bones (Kolisko). It is easily seen that joint hemorrhage would be highly apt to result from such violence, would be rendered even more likely by the erosion of soft structures, and would explain particularly well the rapidity of swelling. There is, further, special ground to suspect hemorrhage when, as very rarely happens, much pain exists (Brissaud).

But ataxia, if a factor in producing these arthropathies, is not their exclusive cause. For, how would it account for their appearance in syringomyelia, in which there is no ataxia, or in tabes before the development of ataxia, or for their following exceedingly slight direct blows? Or, how would it explain the enormously diffused serous infiltration (not explainable mechanically), or the progression of symptoms during quietude, and the continuance of bone atrophy when the articular surfaces are no longer in contact?

It is evident that the final cause of these arthropathies is other than the immediate mechanical influence of ataxia, and that a more subtle pathology is demanded.

Arthritis deformans, gout and syphilis, all of which have been widely believed in, and strenuously put forward as exclusive causes, will, it is obvious, not begin to account for the extraordinary phenomena just described, nor will they account for the milder forms of arthropathy which their manifestations much more resemble, for those milder forms pass finally into severe ones. (Strümpell,⁵ formerly skeptical, now admits that it is hard to avoid the assumption of trophic disturbance.)

The association of these arthropathies with tabes and syringomyelia in some perfectly definite way is quite evident—their rarity in other cord diseases points to this—likewise the large number of other

phenomena of undoubted trophic origin in tabes and syringomyelia; it seems in fact quite necessary to assume a special trophic disturbance, to account for the joint disease in question.

Is this trophic disorder due to neuritis? There is much evidence in favor of this, but not enough to warrant the assumption that neuritis is the only cause. Its presence is not constant, though very frequent, as Pitres and Carrière⁶ have shown. We do not know whether it is secondary to the joint trouble, or whether it is due to the cord lesion. It is most intense in the neighborhood of the affected joint, and this points to the first possibility as the true one.

The following may be regarded as a conservative view: Several factors undoubtedly can and do exist in the etiology of both high and low grades of the arthropathies; but the only absolutely constant element is the nervous system, which acts directly by influencing nutrition, and indirectly by causing ataxia. These factors are, in the order of their probable importance, central and neuritic trophic disorder; anesthesia of the joints; traumatism, direct and (through ataxia) indirect; muscular hypotonia; arthritic tendency and syphilis. They act probably in this way. The nervous trouble predisposes the joints to disease through alteration of the sensory neurons. That the sensory nerves, while furnishing sensibility to the bones and joints, in some way take care of their nutrition may be regarded as proved. Now there is equal reason to suppose that normal synergetic muscle actions depend on continuous afflux of stimuli from the periphery. Therefore, any interruption of function of the centripetal joint nerves will result in inco-ordination, with consequent loss of normal support to the joint. This loss entails uneven and violent stretchings and pressures on the ligamentous structures and articular surfaces. The disorder increases in a vicious circle on account of the relation between muscle and ligament. Osseous hyperplasia or atrophy occurs, this being determined probably by increase or loss of blood supply from vasomotor change. Irritation from rubbing is part of the cause of the exostoses. Latent arthritic tendencies, which, of course, must often be present, are hastened into activity, and pursue a more extended course than they would otherwise take. Continued use of the joint, on account of the absence of all pain, after the lesion has begun, is a most important element in causing further damage. It must be added that the early inco-ordination which occurs on the development of joint anesthesia probably begins at once to damage the joint even before ataxia has been manifest. This helps to explain the excessively early appearance of some of these lesions. The rôle of hypotonia etiologically is likewise constant, if less important. That of syphilis may be deemed comparatively unimportant on account of the fact that there is nothing to show that the disease is frequently present.

In concluding this matter of etiology, the close and interesting correspondence of the arthropathies to the seat of the chief cord lesion must be mentioned—localization in upper limb in syringomyelia, in the lower in tabes. On the contrary, when the gliosis is of the lumbar type the arthropathies affect the lower limbs. Cervical tabes in like manner has been associated with upper limb arthropathy. It is to be presumed that shoulder affections of tabes are always to be explained on the anatomical basis of cervical

involvement, and that, in general, leg arthropathies occur the earlier in tabes.

The other joints affected in tabes are, beside the vertebræ, nearly all the articulations, knee, hip, shoulder and elbow being the most frequently involved.

The "tabetic foot" is of rather different type, showing constant tendency to hypertrophy of bone, including even tibia and fibula, and ending in ankylosis. Its sudden and painless beginning results from rarefaction and crumbling of tarsal and metatarsal bones. The shape is unlike anything else; the foot looks shortened, thickened and rounded, and the vault has disappeared. The appearance known as Chinese foot is largely due to muscular atrophy (Senator⁷), and occurs in various other diseases. It must be distinguished from true tabetic foot.

In syringomyelia, the arthropathies of the small hand joints and the severe grades of kyphoscoliosis, all ascribed to trophic disorder, are worth mention. The purity of the type in the hand is obscured by infection and suppuration (Schlesinger).

There are certain unusual events in the course of classic arthropathies, notably the very rare occurrence of pain, sometimes severe, ascribed by Brissaud wholly to stretching from effusion. It is, however, not wholly understood. It is possible that the usual rupture of the capsule, allowing escape of fluid and permeation of the periarticular tissues, here fails to occur. It is not clear why pain appears unless we assume analgesia of the joints but not of the skin. Investigation of possible association with neuritis would be of interest. The presence of pain has been adduced without justification, in my opinion, as an argument against the causative influence of analgesia. Suppuration and inflammation are most uncommon and certainly obscure the type of tabetic joint when present. The pathology is obviously different from usual. Suppuration is almost invariably secondary to trauma, occurs in the late cases, and should not confuse. Its course is remarkably mild, and in general the reaction of these joints to infection is slight.

The diagnosis of these joint lesions is rarely difficult except in certain early cases not long under observation. Mistakes would almost never occur if the possibility of cord lesion were in mind. Enough has been said to show the distinctions from simple fracture and luxation. There is, however, a condition of habitual luxation of the shoulder joint in syringomyelia, often preceded by direct trauma, which is of great practical and medico-legal importance. This may occur before obviously extensive change in the joint, and the patients have usually come to the surgeon unaware of central trouble. Schrader⁸ reports 15 cases. Some of these had had previously no cord symptoms.

Occasionally an early case with slow, chiefly hypertrophic changes, especially if tending towards ankylosis, will be confused with osteo-arthritis. The resemblance may be close clinically, but these cases are uncommon and rarely long unassociated with symptoms of the central lesion. There may be a history of undue mobility. Characteristic involvement of small joints is lacking. There is also likely to be much more extensive periarticular and subcutaneous ossification than occurs in arthritis deformans, and a greater liability in the presence of large, free, bony masses in the joint.

In those cases in which, like that of Dereum and

Spiller⁹ (syr.), grating in the joint precedes by years the development of typical arthropathy, the diagnosis may at first be impossible.

The extreme atrophic cases with luxations are unmistakable.

There have been reported anomalous combinations of symptoms resembling both syringomyelia and tabes; the greater tendency in the former to diffuse ossification in the limb and to necrosis of bone would assist in the diagnosis of any joint trouble.

The complex of Morvan's disease, so called, is common to both leprosy and syringomyelia, and need not be further considered as such. Leprosy occasions difficulty only in hand affections and only in atypical instances.

One case of central cord tuberculosis produced typical tabiform arthropathy and was not diagnosed *intra vitam* (Schlesinger).

Hematomyelia, a condition of hemorrhage into the cord in which the distribution of the blood is much like that of the gliosis process, appearing generally after accidents, may be in question. One doubtful case of this kind, that of Goldthwait,¹⁰ has come to my notice.

Syphilis must always be considered as a remote possibility, simulating perhaps more the foot affection than those of the other joints. Practically speaking, antispecific treatment never benefits these troubles. When it does do so it might be expected that other luetic symptoms would be present; but this is not true, otherwise a suspicion would be warrantable that not tabes but spinal lues was the central lesion.

Londe¹¹ calls attention to one case of true arthropathy in progressive muscular atrophy of the spinal type, and to one in chorea. He draws a fundamental distinction between the genuine lesions occurring in those diseases and gliosis and tabes, on the one hand, and all other nervous joint disorders on the other; asserting that, in the latter, one of two factors — infection or auto-intoxication — is always necessary for the production of the arthropathy, plus the nervous element. The nervous system is supposed to determine principally the location of the joint trouble in such cases, and Londe is right on the whole in thus assigning to it a subordinate part. I think, however, that two additions may be made to his list of diseases in which genuine arthropathies occur, to wit, central tuberculosis of the cord and certain instances of the trophic variety of intermittent hydrops, and perhaps hematomyelia.

Those non-genuine arthropathies emphasized by Londe are seen most frequently and typically in myelitis, neuritis and hemiplegia, also have been reported in Friedreich's disease, ataxic paraplegia, bulbar paralysis, and tuberculosis of the spinal column. They are all rare, and occur with significant inconstancy compared to the regularity of joint involvement in tabes and gliosis. And it is to be observed that they are not associated so definitely with extreme sensory losses as are tabes and gliosis.

The false arthropathies, as they may be called, are of quite different type from the genuine — they are distinctly inflammatory in nature, accompanied constantly by pain, redness, and often by suppuration.

In regard to those in hemiplegia, Weir Mitchell¹² has recently renewed attention to the intense irritative — not paralytic — sensory symptoms, and deprecates the superficial reasoning which assumes a mere

coincidence with rheumatism. These hemiplegic joint lesions are in most remarkable manner preceded, sometimes for years, by lively pains which are limited to the side afterwards paralyzed.

There are several other joint affections which may be spoken of as neuropathic. Among them the most interesting is *hydrops articulorum intermittens*. About 35 examples have been reported; they represent several different pathological states, but after eliminating those cases in which some such obtrusive condition as acute osteomyelitis gives at least an anatomical basis for the disease, if it does not afford an explanation of the periodicity, there remains a group in which the regularly or irregularly recurring hydrops, of apparently spontaneous beginning, is susceptible of no other explanation than that of vasomotor disturbance. Some of these are certainly hysterical. The location is far more commonly in the knee than elsewhere, but the other joints have been affected. It is usually unilateral, sometimes alternating right and left, seldom very painful, and often quite irregular in its manifestations. The more striking cases are, however, almost uniform in recurrence, and in duration of attack and in location. The intervals vary from hours to months, but most frequently last from ten days to two weeks. The disease sometimes persists for many years, finally to cease spontaneously or seemingly through the influence of treatment. This trouble is rarely mentioned in the books. Among others, Senator¹³ has recently written upon it and points out that the question of the presence of slight degrees of real inflammation cannot be decided as long as we do not know the absolute distinction between exudate and transudate. An exceptionally well-marked case which I have lately seen will be made the subject of further report.

Another type of great interest is the acro-arthritis of Hutchinson, recently described further by MacMahon,¹⁴ regarded by the former as induced by gout in cases showing marked tendency to Reynaud's disease; that is, to conspicuous circulatory disturbance in the fingers. In this trouble the terminal finger articulations become typically wobble-jointed, with effusion, in tabetic fashion. The anatomicopathological appearances correspond to those in tabes, which, it must be remembered, may itself produce arthropathies in this location. Tabes, however, is not present in Hutchinson's group.

The disease described by Marie as osteo-arthropathy of pulmonic origin is not an arthropathy to any essential extent, and is better described as ossifying osteo-periostitis with hypertrophy of neighboring soft parts. It is usually of toxic origin, and occurs in many other than lung diseases; although in those it develops the most acutely and to the highest degree.

Its essential lesion occurs in syringomyelia at times. Clinically, it begins with clubbing of the fingers, but the ordinary form of finger characteristic of lung disease is accentuated into a marked drumstick type with enormous nails, which attain the full width of the phalax, leaving no marginal flesh. Decided or even cauliflower-like tufting of the bone shows constantly, in radiographs. When fully developed, this disease induces pronounced enlargement of wrists, ankles and adjacent parts of the long bones. It is uncommon. The photographs which I show you indicate the freedom of the joints from the affection.

In regard to the treatment of the trophic joint

lesions, unfortunately only too little can be said. But it is certainly true that it has been unduly neglected. The outlook when the affection occurs in tabes or gliosis is undeniably bad; but can we not do a little more in prophylaxis? In all severe nervous troubles, particularly when extensive paralyses of sensation accompany them, every precaution should be taken to prevent violence to the joints. There should be constant watchfulness for grating or undue mobility; and with the first definite indication of approaching trouble in a joint, this watchfulness must be redoubled, and temporary rest in bed enjoined, with measures for immobilization. Relief of pressure from effusion must be secured in the event of tense swelling, by tapping. If done early in hemorrhagic cases the bleeding might be stopped by hemostatics, and the weakened joint structures saved from the destructive effects of great distention. Antispasmodic drugs should be given their slim chance in the beginning. The deleterious influences of ataxia should be guarded against by the early employment of Fraenkel's invaluable method of training.

The extreme forms of joint disorganization with dislocations must have orthopedic treatment; leather splints, properly applied, are very efficacious. Amputation is sometimes advisable, and I see in the peculiar state of trophic function no contraindication. As a matter of fact, these joints and limbs heal readily. Indeed, it is often affirmed that the union of fractured bones takes place with unusual speed, the large callus being held to corroborate this view. This is wrong. The repair of bone occupies generally as much time as usual, indeed sometimes obstinate non-union is seen. The great callus often observed is the result of continued attrition in the ataxic, analgesic member.

The inflammatory type of arthropathy is more amenable to treatment. Suppuration demands surgical measures. As has been pointed out, there is not here the menace to life associated with other forms of acute suppurative arthritis.

For intermittent hydrops, besides removal of obvious cause of inflammation, the use of arsenic in long continued moderate doses has seemed to be of much service. But in the purely idiopathic variety our present crude methods achieve little result.

AMBIDEXTERITY TO BE TAUGHT IN PHILADELPHIA SCHOOLS. — It is said that the Board of Education in Philadelphia is about to undertake to train school children to be ambidextrous through a regular course of exercises to be carried out at the schools. The success of the experiment will be watched with interest.

THE BOSTON Medical and Surgical Journal.

THURSDAY, OCTOBER 18, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS

PLAGUE.

WITH the development of improved and more rapid means of communication, it is a self-evident fact that distant parts of the world are being brought into closer and closer relation, and the danger of the spread of disease thereby very greatly increased. Thirty years ago we had small fear of the introduction of tropical diseases into our large cities; now we must be constantly on our guard lest through some carelessness an infected vessel gain access to our ports and its crew be the possible source of the dissemination of disease. No more striking evidence of the acknowledgment of this new responsibility could be furnished than the success of the recently organized London School of Tropical Medicine, which is already crowded with students in preparation for the intelligent study and treatment of diseases of the tropics. During the past months the danger of the introduction of disease from regions where it is endemic has been strikingly shown in the appearance of plague at various distant points in almost every part of the world. The fact that it has gained no headway is an equally strong proof of our increasing ability to cope with the large question of prophylaxis. The experience through which Glasgow has gone with regard to plague, and its gratifying outcome, is an object lesson which we should do well to ponder. In the October number of the *Scottish Medical and Surgical Journal*, Dr. W. Leslie Mackenzie, medical officer of health, narrates certain matters of interest with regard to the situation in that city. However stringent a quarantine may be, he feels that the spread of the disease is usually brought about by the mild, unrecognized ambulant case, which means vigilance far greater than is necessary to comply with ordinary quarantine requirements. Furthermore, the rats and fleas must be exterminated, a task apparently of no small magnitude. So far no really successful method has been found. Dr. Mackenzie concludes his very vigorous paper as follows: "The public confidence in Glasgow vigilance and energy

should not be allowed to mislead. The plague is everywhere, because the ports infected with it are in daily converse with every important place in the Eastern and the Western World. Europe is continually under a menace. Glasgow will solve its own problems; but every local authority in Britain had better be putting its house in order. The profusion of arrivals from South Africa is no small danger. The army will come home and bring with it much typhoid and dysentery. It may bring the plague too. The stupid creatures that deprecate 'alarmist' views are just those that run from the real danger. Our towns are none too clean, our rats are none too few, our streets are none too little strewn with foul dust, ashes and paper, that we should give any quarter to the arm-chair sanitarian, who is 'not as other men are.' The price of freedom from plague is vigilance against dirt—and rats."

ANNUAL REPORT OF THE BOSTON CITY HOSPITAL.

WE have before us the thirty-sixth annual report of the Boston City Hospital, a volume this year comprising two hundred and twelve pages. The changes and improvements at this hospital during the last few years have been so numerous that it is with a sense of surprise that we take up the report each succeeding year to find that still others are in progress. Apart from certain minor changes in the heating and power plants, necessitated by the rapid growth of the hospital, and the proper equipment of the laundry, completed in 1898, the administrative portion of the institution has not been enlarged. The most notable new building is the Ann White Vose House for nurses, to which attention has already been called in these columns. This building provides a permanent and wholly adequate home for the nurses.

The continued success and growing usefulness of the South Department, devoted to the care of contagious disease, should be a source of satisfaction to every one, whether or not he belong to the medical profession. The following statistics are of interest, showing an increase in the amount of work over the corresponding period of the preceding year, and a marked increase in the winter months: At the beginning of the year there were 258 patients, against 155 the previous year. The number of patients admitted was 2,787, against 1,620 for the previous year. The largest number at any one time was 323, against 260 for the previous year. The daily average number of patients was 250, an increase of 106 over the preceding year. The average days' stay was 30. The total number of weeks' board was 13,053. Of the total number of patients admitted, 324 have died, including 107 who died within forty-eight hours after admission, or 33 per cent. of all deaths. The death rate from diphtheria during the year was 9.9 per cent. as compared with 12.8 per cent. for the preceding year; omitting patients admitted in a moribund condition, the mortality would

be reduced still further, to 6.3 per cent. During 1899, of all cases of diphtheria occurring in Boston 55 per cent. were treated at the South Department. A problem soon to be met is increased room for this class of cases; already the hospital is frequently in danger of overcrowding. Another fact, which we note with satisfaction, is the final establishment of a relief and ambulance station on Haymarket Square, in accordance with a recommendation made by the Board of Trustees two years ago.

The hospital at present requires much larger accommodations for both the Medical and Surgical Out-Patient Departments, owing to the very rapid increase in the number of patients. Two years ago the number of visits to the surgical department was 48,482 as against 62,131 during the past year, and within the last five years the total number of surgical cases has doubled. The out-patient buildings now are the same as those in use ten years ago, although the number of patients treated is nearly three times as great. We have always felt that the work of the out-patient department of a large hospital is one of its most important services to the community, and its medical administration one of the most arduous duties a physician is called upon to perform. It is unfortunate, therefore, that a more active interest should not be shown in this department of a hospital's work, to the end that adequate accommodations be provided. There is too great a tendency to regard out-patient departments as appendages of a hospital, rather than as one of its integral parts.

A considerable portion of the report is taken up with hospital statistics, which we are glad to observe are prepared with much greater care than usual, as regards classification. The volume has several illustrations, chiefly of the new Nurses' Home, and two large diagrams of the hospital grounds and buildings.

MEDICAL NOTES.

YELLOW FEVER IN HAVANA.—It is reported that yellow fever prevails in Havana to a greater extent than at any time since 1897. For the week ended September 15th there were 9 deaths. The week ended September 22d also showed 9 deaths, while there were 19 during the week ended September 29th. The Marine Hospital reports show a total of 49 deaths for August. In August, 1898, there were 16 deaths from yellow fever in Havana; in August, 1899, there were 13. Statistics of other years are: August, 1893, 100 deaths; 1894, 73; 1895, 120; 1896, 262, and 1897, 102. The excess of mortality during the present year over the two preceding years is supposed to be due to the fact that there are many more unacclimated persons in Havana now than at any time since 1897. The filthiness of Havana harbor is regarded as one of the essential causes of the continuance of the disease, in spite of active sanitary measures within the city.

RÖNTGEN SOCIETY OF THE UNITED STATES.—The first regular meeting of this newly organized society will be held in the Academy of Medicine, New York City, December 13 and 14, 1900. The object of the society is the advancement of the knowledge of x-ray work and allied arts and sciences. Membership is open to physicians and to others interested in the general subject. The president of the society is Dr. Heber Roberts, of St. Louis, Mo.

GLASGOW PLAGUE CHECKED.—An official bulletin reports that the outbreak of plague in Glasgow has been completely checked. Twenty-one days have elapsed since the last case. The reception houses were closed October 11th.

MEDICAL CLUB OF PHILADELPHIA.—The Medical Club of Philadelphia will hold a reception for Dr. Maurice H. Richardson, of Boston, at the Hotel Bellevue, Friday evening, October 26th.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, October 17, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 124, scarlatina 26, measles 23, typhoid fever 20.

SMALLPOX IN NEW BEDFORD, MASS.—Another case of smallpox has been discovered in New Bedford in a child of thirteen. Although she is said to have been sick three weeks, the attention of the Board of Health has just been called to her. This added case is the more disappointing since the epidemic was supposed to be well in hand. Twenty-one patients were discharged as cured from the Clark's Point Hospital Saturday, leaving but 23 patients in the hospital.

TYPHOID FEVER AT NEWPORT.—A number of cases of typhoid, generally mild in character, have appeared in a small section of Newport. An examination of the surroundings and of the water and milk supply of the affected region has been instituted by the Board of Health. The Newport Hospital has been taxed to its utmost limit by these cases. Patients under treatment October 16th numbered 59. There have been 15 deaths.

NEW YORK.

TENEMENT HOUSE BUILDING.—The Tenement House Commission, appointed by Governor Roosevelt, in response to a list of forty-seven questions sent out by them on June 15th last, to one hundred prominent persons representing various professions and branches of business having relation to the subject, have received some 4,700 answers in regard to tenement house building. The writers for the most part agree that not more than 65% of an inside lot and not more than 85% of an outside lot or corner should be built over; that all airshafts should open on the outside air; that five stories should be the limit for a non-fireproof and seven stories for a fireproof tenement, except where elevators are provided; that owners should be forced to provide bathing facilities for the

tenants, mainly in the shape of shower or needle baths in the basements; and that bathrooms and closets as a rule be provided for every family. The last question on the list was the following: "In general, what suggestions have you to make to the commission with regard to its work?" To this Dr. Roger Tracy, chief of the Department of Vital Statistics of the Board of Health, replied: "It seems to me that matters relating to construction have been pretty well thrashed out, as shown by the practical agreement among the builders of new model tenements that privacy, safety and ventilation can be best secured by the fireproof structures, by outside stairways, and floors entirely separated. Although a good deal is done now, more ought to be done toward teaching the poor how to make the best of what they have, the vast importance of cleanliness, good food (and the cheapest is often the most wholesome), and right living. I think the municipality might do something towards this, and that is where an appeal to the legislature would be necessary."

SCARCITY OF WATER.—The scarcity of water still continues in the Boroughs of Brooklyn and the Bronx. In Brooklyn on September 25th, the situation in brief, according to a statement made by Chief Engineer Birdsall, was that there were on storage 100,000,000 gallons, the daily flow of water was 80,000,000, and the consumption, 90,000,000 gallons. On September 27th the East New York Avenue main was closed, with the result of reducing the pressure of water throughout the borough. On the 28th the Kings County Grand Jury for September made a presentment in which they declared that the relief needed by Brooklyn could be obtained by the construction of the Milburn conduit, a bond issue for which was recently authorized by the Municipal Council. They advocated that in the revision of the city charter the Borough of Brooklyn be given entire charge of its water supply through a commissioner, and not through a deputy commissioner, as at present, and, in conclusion, suggested that, in view of the fact that, owing to the pressure of other matters, they had found it impossible to fully inquire into a matter of such magnitude, the water supply of Brooklyn should be taken up by the October grand jury. On September 28th Commissioner Dalton, of the Water Department, signed a contract for the laying of a temporary pipe line, which it is believed will relieve the water famine in the Marble Hill and Kingsbridge sections of Bronx Borough, and the work of carting the 12-inch pipes was begun during the day. By this means it will be possible to pump water from the old Croton aqueduct in the region referred to, and the expense is provided for by an emergency fund voted by the Municipal Council on September 25th.

MORTALITY STATISTICS.—The mortality in the city in the month of September represented an annual death rate of 18.46, against 19.02 for August. This rate is slightly higher than that for September, 1899,

namely, 17.89; and the increased mortality is, no doubt, attributable to the higher temperature prevailing this year. It is noteworthy, however, that in the month of September the mortality from several of the prominent zymotic diseases was lower than at any time since the formation of the Greater City of New York. Thus, the weekly average of deaths was only 19.25 from diphtheria, 2.25 from scarlet fever, and 3.5 from measles. The weekly average of deaths from diarrheal diseases declined from 200 in August to 149.75 in September; from diarrheal diseases in children under five years, from 176.5 to 135.5; from pulmonary tuberculosis, from 143.75 to 129.75; and from whooping cough, from 10.5 to 7.75. On the other hand, the weekly average of deaths from typhoid fever increased from 14 to 24.25, and from pneumonia, from 78.25 to 82.75. There were 15 deaths from sunstroke in September, 10 of these occurring in the first week in the month.

THE LOST IDENTITY PATIENT AN IMPOSTOR.— Even the most experienced observers sometimes make mistakes, and Dr. Schmid has had to acknowledge that his unique case at the White Plains Hospital, where the patient's identity was supposed to have been lost through a stroke of lightning, is not genuine. From letters received by Dr. Schmid after the case was reported by him from Dr. Henry Hun, of Albany, and others, it appeared that the man was William Smith, of Fall River, Mass., who for a number of years has been a cunning impostor and hospital beat. At various times since 1887 he has been an inmate of hospitals in Albany, Fall River, North Adams and Stonington, and of the insane asylums at Northampton and on Ward's Island, N. Y., as well as other institutions in various places.

NEW YORK OBSTETRICAL SOCIETY.— At the annual meeting of the New York Obstetrical Society, held on Tuesday, October 9, 1900, the following officers were elected for the ensuing year: President, H. J. Boldt, M.D.; First Vice President, Ralph Waldo, M.D.; Second Vice President, H. W. Vineberg, M.D.; Recording Secretary, G. L. Brodhead, M.D.; Assistant Recording Secretary, G. G. Ward, Jr., M.D.; Corresponding Secretary, E. E. Tull, M.D.; Treasurer, J. Lee Morrill, M.D.; Pathologist, W. S. Stone, M.D.

OPERATION FOR HYPOSPADIAS AT FIVE MONTHS.— At the October meeting of the Medical Association of the Greater City of New York, Dr. Carl Beck presented an infant on whom he had operated, with perfect result, for hypospadias. At the time, the child was only five months old, and Dr. Beck stated that this was the earliest age at which such an operation had ever been performed.

A CASE OF YELLOW FEVER.— After the Ward Line steamer *Havana* arrived at quarantine on October 9th, one of the saloon passengers was taken ill with yellow fever, and was removed to the hospital on Swinburne Island. Health Officer Doty states that

this is the first case of the disease that has developed in the saloon cabin of any vessel this year.

THE PEQUANNOCK WATER SUPPLY.— The contract between the city of Newark, N. J., and the East Jersey Water Company for the Pequannock water supply terminated on September 24th, and by agreement of the legal counsel for both parties the city has taken possession of the reservoirs and pipe line.

THE LOOMIS SANITARIUM.— At a meeting of the Trustees of the Hospital Saturday and Sunday Association, held October 10th, the city branch of the Loomis Sanitarium for Consumptives was admitted to membership in the association, and the institution will hereafter participate in its annual collection.

Miscellany.

ARSENIC IN MANUFACTURES.

WE publish the following circular as sent to us by the State Board of Health:

The Massachusetts Legislature of 1900 enacted a law relating to the manufacture and sale of articles containing arsenic, and directed the State Board of Health to make the necessary investigations relative to the existence of arsenic in the materials mentioned in the act, and to adopt such measures as may be deemed necessary to carry out its provisions and to facilitate its enforcement.

The act is as follows:

CHAPTER 325, ACTS OF 1900.

AN ACT RELATIVE TO THE MANUFACTURE AND SALE OF TEXTILE FABRICS AND PAPERS CONTAINING ARSENIC.

SECTION 1. Any corporation, person, firm or agent who directly or by an agent manufactures, sells, exchanges, or has in his custody or possession with intent to sell or exchange, any woven fabric or paper containing arsenic in any form, or any article of dress or of household use composed wholly or in part of such woven fabric or paper, shall on conviction thereof be punished by fine of not less than fifty nor more than two hundred dollars; *provided, however,* that this section shall not apply to dress goods or articles of dress containing not more than one one-hundredth grain, or to other materials or articles containing not more than one-tenth grain of arsenic per square yard of the material.

SECT. 2. The State Board of Health shall make all necessary investigations as to the existence of arsenic in the materials and articles mentioned in section one of this act, may employ inspectors and chemists for that purpose, and shall adopt such measures as it may deem necessary to carry out the provisions and to facilitate the enforcement of this act.

SECT. 3. This act shall take effect on the first day of January in the year nineteen hundred and one. (Approved May 18, 1900)

Inasmuch as it will become the duty of the State Board of Health, after January 1, 1901, to enforce the provisions of the foregoing act, this circular is published and distributed by the board for the information and guidance of such corporations, persons, firms or agents as are mentioned in the act.

METEOROLOGICAL RECORD

For the week ending October 6th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,141; under five years of age 842; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 617, consumption 253, diarrheal diseases 223, acute lung diseases 202, diphtheria and croup 57, typhoid fever 49, whooping cough 10, cerebrospinal meningitis 10, scarlet fever 7, measles 4, erysipelas 4.

From whooping cough New York 5, Washington 3, Pittsburg and Providence 1 each. From cerebrospinal meningitis New York 6, Worcester 2, Somerville and Marlboro 1 each. From scarlet fever New York and Worcester 2 each, Boston, New

Bedford and Everett 1 each. From measles New York 4. From erysipelas New York 2, Boston and Washington 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending September 22d, the death rate was 18.1. Deaths reported 4,041: acute diseases of the respiratory organs (London) 203, diarrhea 497, whooping cough 105, diphtheria 72, fever 50, measles 26, scarlet fever 21.

The death rates ranged from 11.5 in Croydon to 25.5 in Blackburn; Birmingham 17.9, Bradford 12.3, Cardiff 13.2, Gateshead 17.6, Huddersfield 15.5, Hull 23.8, Leeds 19.2, Leicester 15.9, Liverpool 23.1, London 16.5, Manchester 23.2, Newcastle-on-Tyne 17.6, Nottingham 19.3, Plymouth 21.9, Salford 24.3, Swansea 19.3, West Ham 16.4, Wolverhampton 17.5.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending September 29th, the death rate was 18.5. Deaths reported 4,110; diarrhea 495, acute diseases of the respiratory organs (London) 187, diphtheria 79, fever 76, whooping cough 70, measles 30, scarlet fever 26.

The death rates ranged from 11.1 in Bradford to 27.6 in Salford; Birmingham 20.2, Cardiff 15.3, Derby 21.2, Gateshead 19.5, Hull 20.5, Leeds 18.0, Liverpool 23.0, London 16.7, Manchester 26.6, Newcastle-on-Tyne 21.6, Nottingham 18.3, Plymouth 14.8, Portsmouth 14.7, Sheffield 22.4, Sunderland 27.6, Swansea 19.3, West Ham 14.9.

VACANCIES, CARNEY HOSPITAL.

There are two vacancies in the staff of surgeons to out patients; one in the staff of physicians to out patients and one in the staff of assistant ophthalmic surgeons. Applicants for these positions will send their names to the secretary, Dr. James J. Minot, 188 Marlborough Street, Boston, before November 10, 1900.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for Obstetrics and Diseases of Women will meet at 19 Boylston Place, Wednesday, October 24, 1900, at 8 P. M.

Papers: Dr. Sarah E. Palmer, "Report of a Cesarean Section."

Dr. Frank A. Higgins, "Some Cases of Placenta Previa." Dr. Francis D. Donoghue, "Treatment of Placenta Previa by Cesarean Section, with Report of a Successful Case." Discussion by Drs. Edward Reynolds, C. M. Green, F. W. Johnson, M. F. Gavin, F. A. Higgins and Alfred Worcester.

Business: Election of chairman for the ensuing two years.
R. A. KINGMAN, M.D., Chairman.
C. H. HARE, M.D., Secretary,
285 Marlborough Street.

SUFFOLK DISTRICT MEDICAL SOCIETY.—There will be a stated meeting at the Massachusetts Institute of Technology, Walker Building (corner of Boylston and Clarendon Streets), Room 22, Saturday, October 27, 1900, at 8 P. M.

Papers: "Recent Investigations on the Origin of Cancer," Dr. J. C. Warren.

"Statistics of Cancer," Dr. W. F. Whitney. "First Annual Report to the Surgical Department of Work Done on the Etiology of Cancer," Dr. E. H. Nichols.

Business: Election of a committee of five to prepare a list of candidates for officers of the society.

Supper after the meeting at the Hotel Brunswick.
HERBERT L. BURRELL, M.D., President.
HOWARD A. LOTHROP, M.D., Secretary,
10 Marlborough Street.

SUFFOLK DISTRICT MEDICAL SOCIETY, CENSORS' EXAMINATION.—The censors of the society, officiating for the society at large, will meet to examine candidates for admission to the Massachusetts Medical Society, at 19 Boylston Place, on Thursday, November 8, 1900, at 2 P. M.

Candidates should make personal application to the secretary and present their medical diploma, or its equivalent, at least three days before the examination.

For further particulars apply from 2 to 3 P. M., to
HOWARD A. LOTHROP, M.D., Secretary,
10 Marlborough Street.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.—The next meeting of the association will be held in Minneapolis, Minn., December 27-28, 1900

GEORGE H. SIMMONS, Secretary and Treasurer.

RECENT DEATH.

FRANKLIN SMITH, M.D., of New York City, died on October 9th, at the age of seventy-six. He was born in the State of New York and was graduated from the Medical Department of the University of the City of New York in 1865. His son, Dr. Charles Smith, was associated with him in practice.

CONGENITAL DISLOCATION OF THE HIP JOINT.

BY E. H. BRADFORD, M.D., BOSTON.

THE collected experience of the operative treatment of congenital dislocation of the hip joint has demonstrated the following facts:

In many cases successful reduction of the dislocation has been performed. Frequently, however, relapse has occurred after apparently successful reduction. Relapse is more frequent after operation without incision than after operation with incision. Operative treatment, with or without incision, lacks precision.

Among others it will be seen that an important obstacle is encountered by the surgeon in a fold of the capsule attached to the lower part of the acetabulum, which may be termed an acetabular or capsular hymen, and is often pressed in front of the entering head of the femur allowing apparent reduction, but preventing complete reduction, and favoring relapse

DIAGRAM 1. Congenital hip; F, femur; C, capsule; A, acetabular pouch; a, a, adhesions of stretched capsule to acetabulum; ff, attachments of capsule to femur.

as the limb is placed in certain positions. An anatomical knowledge of the contracted tissues has been acquired, and means have been devised for stretching, tearing, or dividing, by force or incision, the contracted tissue. Where this has been done, the head can be placed under the upper edge of the acetabulum, but frequently an elastic resistance is encountered which prevents a complete reduction well in the acetabulum, without which relapse occurs.¹

Where the opening is sufficiently large to admit the entering head into the acetabular pouch through the constricted portion of the capsule, without pushing the acetabular hymen between the head of the femur and the bottom of the acetabulum, complete reduction can be effected (Diagrams 1 and 2).

It does not, however, follow that the reduced head will remain permanently in place after the remaining bandages have been removed, for the reason that a relaxed capsule and the lengthened pelvic trochanteric muscles may be inefficient in holding the head in its normal place. The influence of the capsule in retaining the head in the socket is well illustrated on exam-

ining a case of infantile paralysis in a child of two, affecting all the muscles of the hip, so that the arc of motion was abnormally large. It was found possible under an anesthetic to move the hip in the socket, but not to the extent that could be done in a congenital dislocation with or often without an anesthetic. Furthermore, the neck of the femur is often so twisted that to retain the axis in its proper direction in relation to the acetabulum, it is necessary that the femur be twisted inwards, a position incompatible with locomotion, and an anterior dislocation often follows.

The way in which it is planned that these conditions be overcome in the treatment without incision is as follows: First, by retaining the introduced head into the acetabulum under such pressure that if a fold of the capsule is interposed between the head and acetabulum, it will in time be absorbed by pressure; also by the supposition that the loose capsule, lengthened muscles and twisted neck be gradually changed

DIAGRAM 2. Head inserted under acetabular rim encounters the obstructing acetabular hymen or fold of capsule.

by adaptive alteration if the limb is retained a sufficient time in a normal position. It is unnecessary to state that under these conditions it is not strange that relapses are frequent. It is as true with this as with other procedures in surgery that if the essential indications are met, a cure is effected; if not, relapse occurs.

It is manifest that for the best result as little injury as possible be done to the tissues. Little is inflicted if the following procedure be carried out:

An incision is made along the outer and anterior edge of the femur, reaching from above the greater trochanter to two inches below the lesser trochanter. The upper portion should be curved slightly upward so as to uncover the head and neck of the dislocated femur. The tensor vaginae and glutens medius muscles are separated. When the femur is reached the femoral insertion of the rectus is pushed aside, and the attachments of the psoas and iliacus are pushed away by a periosteum elevator, the lesser trochanter being well bared.

The capsule is then opened and cut across, first on the head in the line of the axis of the neck, and then from the neck downward towards the acetabulum, in

¹ Kermisson: Rev. d'orth., March, 1899, p. 153; also Halfa, Arch. f. klin. Chir., Bd. lxx, II, 2, S. 525.

front and behind. The finger is then inserted and the acetabulum exposed and the size of the capsular neck estimated. The capsular insertion on the femur is

DIAGRAM 3. Head freed from capsule.

then entirely cut away, as well as the ligamentum teres if present, and the head of the femur pulled aside (Diagram 3).

If the capsular neck is sufficiently large the head of the femur can be passed through it readily into the acetabulum and the capsule stretched over this; but if not, the lower portion of the capsule is to be held upon the stretch by hooks or by two inserted stitches. A blunt-pointed bistoury is inserted into the acetabulum, and the acetabular hymen is divided from within out (Diagram 4).

The head of the femur should be placed in the

DIAGRAM 4. C C', capsule; H, portion of capsule in front of and attached to acetabulum, filling it and causing an obstruction to reduction.

acetabulum and the incised capsule stretched around the neck and secured by catgut sutures to the cut tissues around the neck or to the opposing parts of the cut

capsules. To accomplish this it is necessary first that all contracted tissues which prevent pulling the head to the level of the acetabulum be lengthened. This can be done in suitable cases, as has already been shown by clinical experience. It will be found advisable in some of the more resistant cases to supplement stretching the contracted tissues by division of the intermuscular fascia through an open skin incision. In the few cases in which this has been done it has seemed more surgical than the use of extreme force. An oblique incision is made along the middle of the thigh across to the bellies of the hamstrings and the adductors, and the intermuscular fasciæ are divided and the limbs pulled into place (Diagram 5).

In certain cases the stretching is accomplished with

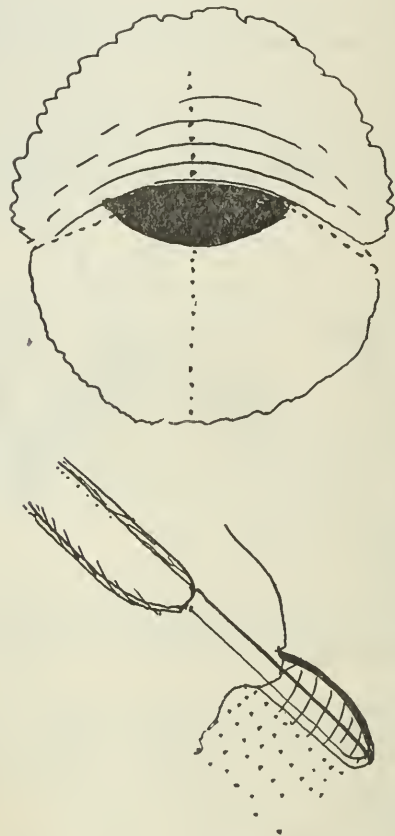

DIAGRAM 5. Lines of division of capsule.

but little difficulty in manipulation, especially by forcible abduction carried to an extreme, stretching the abductors and hamstring of the straightened leg, but in some cases this is not easy, and in these here reported it has seemed better to forcibly stretch with myotomy, if necessary, in a preliminary operation, the dislocation being practically reduced by the bloodless method and the limb properly secured by plaster bandages. If, at the end of a month, it seems that the head is not sufficiently firm in its normal position, preparations for operation are made and the head securely placed in the acetabulum, according to the method of operation already described (Diagram 6).

In certain cases after operation it will be found, owing to a twist of the neck of the femur, or an anterior obliquity of the plane of the acetabulum, that un-

less the limb is forcibly turned inward, the head of the femur (although well in the acetabulum when inverted) is in a position of forward dislocation when the foot points forward. Under these circumstances, an osteotomy of the femur is necessary. This can be performed at the middle or lower end of the femur, in the latter case by an osteotome, in the former by a Wyeth's fragment saw, or by a Gigli wire saw (Diagram 7).

It is believed that an osteotomy is of advantage as high up in the femur as is compatible with safety. This weakens the dislocating force of the abductor and hamstring muscles and can be utilized in correcting or diminishing the deformity of coxa vara often found in a congenitally dislocated femur. Attempts have been made to secure, until healing is well established, the reduced head in place by passing a silver wire through the trochanter and the skin, and another through the tuberosity and skin and tying firmly the free ends of the silver wire together, protecting the underlying skin by felt or rubber. In the 2 cases this has worked satisfactorily, but where the head is

children ranging from fourteen to one year, but most satisfactorily in ages of two and over, and under seven. It is believed that as improvements in skill increase, the range of suitable ages for operation will be extended. It is not claimed that the operation by incision can be permanently successful in all cases; it is claimed that it is successful in many cases, and where the details here mentioned are carried out precisely it can be expected that it can be performed without danger to the patient, with precision, and with a reasonable chance of success, with practically no serious injury to the tissues.

The 34 cases, single and double, 44 hips, operated upon by the writer may be grouped as follows: The cases operated upon between 1890 and 1895 were not benefited by the operation; in 8 cases, 11 hips; no death followed the operation (2 deaths occurred, 1 from scarlet fever and 1 from cholera infantum some months after operation). Those cases, 19 to 23 hips, between 1895 and 1898, show a small percentage of successful reduction, with 1 death from shock on a double operation, radical, on too young a child, one year old (an unjustifiable procedure and a preventable

DIAGRAM 6. Divided capsule.

well placed in the acetabulum, this procedure seems unnecessary if the limb is well secured by a plaster-of-Paris spica. The wound, though a deep one, will be found healed after from two to three weeks, if strict aseptic precautions are used.

Strict aseptic precautions will be found necessary for the reason that a joint cavity, rudimentary in character, and not subjected to the absorption of retained blood, is opened by the operation and stopped by an introduced femoral head. An elevation of temperature for a day or two immediately following the operation is sometimes seen even in wounds which heal rapidly, thoroughly and permanently, without suppuration and without any evidence of sepsis. It has not been found necessary to retain the limb in any abnormally peculiar position during the healing process. A plaster-of-Paris spica is worn for two months with the limb slightly abducted; after this a stiffened leather spica is worn. The patient is allowed to stand and walk with this, using it from two to three months.

These conclusions are based upon the past ten years' experience in this operation with improving results each year. The operations have been done on

DIAGRAM 7. Divided capsule stitched around the inserted head.

death). In 18 cases, 15 single and 3 double, 3 hips were firmly replaced by operative reduction (as proved by the x-ray); 1 was not heard from after leaving the hospital. In 4 hips, 3 cases, there was improvement; in 8 cases, 9 hips, there was improvement, but the head was not firmly in place. In all these, bloodless reduction was first performed with a relapse. In 4 hips bloodless reduction was tried with a relapse in 3 cases; in 1 the reduction has seemed permanent. In 1 of the above-mentioned cases death took place from whooping cough a month after successful radical operation on one hip, but before the radical operation on the second hip, both having been reduced by the bloodless method with relapse. The pathological specimen shows firm reduction in the operated side.

Cases operated upon in the last year, 1899 to 1900, with improved technical experience: Seven cases, 10 hips, all reduced, first with bloodless operation, and all relapsed; of these, 9 operated upon again by radical reduction with incision. Four hips were firmly replaced, as shown by x-ray; 2 hips firmly replaced, but no x-ray as yet secured; 1 apparently reduced, by

x-ray photograph; 2 relapsed after radical operation; 1 relapsed after bloodless reduction, without attempt at radical reduction.

THE CORONER SYSTEM IN THE UNITED STATES AT THE CLOSE OF THE NINETEENTH CENTURY.¹

BY S. W. ABBOTT, M.D., BOSTON.

IN the following paper I propose to show as concisely as possible the present status of the coroner system in the United States, as derived from an examination of the latest compilation of the statutes of each of these States. A very good and complete digest of such laws as they existed twenty years ago may be found in Lee's "Handbook for Coroners," published in 1881, in which the laws are quoted in full as they then existed.

The office of coroner has probably existed for a thousand years, possibly for a longer period. The system appears to have been well established at the time of Edward I of England (thirteenth century), since, in the Statute 3 of Edward I, 10, the methods employed at the coroner's inquest appear to have been quite fully described, and the rules of action definitely laid down.

Connected with the coroner system in early times were many singular customs which appear to us today quite as absurd and useless as some of the remaining adjuncts of the system as it now exists among most English-speaking people. I shall allude to only two of these.

Any personal chattel, animal or thing, forfeited to the king for pious uses, on account of its having caused the death of a human being, was termed a *deodand* (*deo dandum*). Blackstone traces the custom back to Greek and Jewish laws, which required the destruction of anything which caused a man's death, the notion of the punishment of the animal or thing being implied. Certain peculiar distinctions existed in relation to *deodands*, as, for instance, between objects in motion and objects standing still. If a horse or any other animal in motion killed any one, either infant or adult, or if a cart ran over him, it was forfeited as a *deodand*. If death was caused by falling from a cart or a horse at rest, the law made the chattel or animal a *deodand* if the person killed were an adult, but not if he were a child. If death was caused by a thing not in motion, that part only which was the immediate cause of death was forfeited. If one were climbing upon the wheel of a cart, and were killed by falling off, the wheel only was a *deodand*. If the cart were in motion and ran over some one, the whole cart and its burden were also forfeited. Similar distinctions prevailed with reference to vessels at anchor and under sail.

The finding of a jury was necessary, not only to determine the facts, but also the value of the chattel which was thus decided to be a *deodand*. The nature and value of the weapon or chattel must be distinctly stated. This singular custom became deservedly unpopular, and juries interfered with the action of so unjust a measure, until the act of 1846² provided that there should be "no forfeiture of any chattel for or in respect of the same having caused the death of a man,

and no coroner's jury sworn to inquire, upon the sight of any dead body, how the deceased came to his death shall find any forfeiture of any chattel which may have moved to or caused the death of the deceased, or any *deodand* whatever; and it shall not be necessary, in any indictment or inquisition for homicide, to allege the value of the instrument which caused the death of the deceased, or to allege that the same was of no value." With the numerous accidents constantly occurring at the present day, on sea and on land, on railways, street cars, steamers and other conveyances, such a law would be productive of great inconvenience and obstruction to public travel.

The term *felo de se* is nearly synonymous with suicide. It has, however, occasionally a more restricted significance when applied to "any one who commits an unlawful malicious act, the consequence of which was his own death, as if, attempting to kill another, he runs upon his antagonist's sword, or shooting at another, the gun bursts and kills himself." For many centuries it was the custom in England to bury each *felo de se* on the highway with a stake driven through his body. This ignominious form of burial was abolished in the reign of George IV, by an act of Parliament which ordered the burial of the body of a *felo de se* within twenty-four hours after the inquest, between the hours of nine and twelve at night, and without the rites of Christian burial.

The following is a condensed statement of the coroner system as it now exists throughout the United States: The laws in all the States without exception bear the marks of English origin, and afford the strongest evidence that English laws and English customs, once implanted in a new soil, are only uprooted by the most vigorous efforts, and the presentation of convincing evidence of a necessary change. English laws and customs are almost coeval with the marvelous spread of the English language and its hold upon nations. Habitual inertia toward the acceptance of new and improved methods and a tenacity in retaining old and established usages and ways of action, even in the face of evidence showing the need of better methods, is a peculiarity of our race. The marvelous discoveries of recent years, which have emanated from the schools and laboratories of Berlin and Paris, and other Continental cities, have usually been accepted at London only after mature deliberation, and even then with tardy acknowledgment.

This habitual slowness undoubtedly accounts for the fact that English-speaking communities are extremely slow to adopt better and more rational methods for dealing with deaths from violent and sudden causes.

Laws relating to coroners' inquests may be found in the early statutes of all the States as part of the legal machinery under which those States were established, and, going still further back, this is true of the colonies which existed in the seventeenth and eighteenth centuries, down to the Revolutionary period.

One of the best statements of the coroner laws of the Massachusetts Colony is that which appears in the statutes of the year 1700, chapter 3, enacted June 10th of that year. Eighteen jurors were summoned, of which number fourteen were sworn in sets of three or four. Two oaths were administered to them. The fee of the coroner was then ten shillings per day, and that of the jurors two shillings each. As new colonies were planted, and, still later, as new States and Ter-

¹ Read before the Massachusetts Medico-Legal Society, June 5, 1900.

² 9 and 10 Victoria, c. 62.

ritories were established, the same ancient method was invariably adopted with slight variations, for want of due care in searching for a more rational model, and it was not until the last quarter of the present century that our own State broke away from the established usage and adopted the excellent system under which medico-legal inquiries are now conducted.

The coroner, the inquest and the jury exist in nearly all the States in practically the same form. Rhode Island and Connecticut have imitated the example of Massachusetts, but not in so radical a manner.

There are, however, certain minor points of difference among the States, to which I will now refer. These relate chiefly to the functions of the coroner's office, the mode of his election or appointment, his fees, the number of the jury, and the employment of medical officers. The vicarious duties of the coroner, whereby he was occasionally required to perform the duties of sheriff, were also copied from the English statutes, and certain still more incongruous duties have been added in some of the Western and Southern States.

In some of the States an inquest may be held in the case of a person who is seriously wounded, and in imminent danger of death. In Indiana the jury was abolished by an act of 1879. In Texas also an inquest is held without a jury. In Alabama the coroner must be keeper of the jail, if the sheriff is imprisoned. In Kentucky the coroner may hold an inquest in cases of house breaking. In several of the States the coroner is a conservator of the peace, and must suppress riots and disturbances and may apprehend and commit felons and traitors. In Mississippi the coroner is also the county ranger, and it is his duty to take charge of stray horses, mules, jacks, cattle, sheep and hogs.

The modes of election are quite diverse. In Alabama, Arkansas, Colorado, Georgia, Idaho, Iowa, Kansas, Kentucky, Louisiana, Michigan, Minnesota, Nebraska, New Jersey, Nevada, New York, North Carolina, Ohio, Oklahoma, Pennsylvania, South Carolina, South Dakota, Washington, Wisconsin and Wyoming the coroner is elected by the inhabitants of the county. In Tennessee he is appointed by the county court. In Virginia also the county court appoints a coroner for two years and can appoint more if necessary. In Illinois, Indiana, Maine and New Hampshire the governor appoints the coroner.

In Texas, Vermont and Utah the office of coroner (under that name) is unknown, a justice of the peace acting in all cases where the presence of such an official is required.

The fees of coroners are also quite varied. In New Hampshire the fee for holding an inquest is \$1.50, in some States it is \$5.00 and in others \$10. The fees for recording, for mileage and other items also present a considerable range of variation. In some States, by recent statutes, stenographers may be employed at inquests, payable either by monthly salary, as in Kentucky, or by fixed prices for the amount of work performed.

In several States physicians receive regular appointments for aiding the coroner in his official work. In others the coroner selects any one whom he prefers for the time being. The compensation of such physicians ranges from \$6.00 in Minnesota to \$50 in some States for an autopsy, and \$100 in Mississippi in cases where the body is exhumed. In Missouri the fee for

an autopsy is \$10, but if the coroner makes it, it is \$25. In New Jersey the coroner may provide grave clothes for nude bodies at an expense of \$1.00 each.

In several cities of the United States the coroner is a salaried officer, this being the case in New York, Philadelphia, Detroit, St. Louis, Cincinnati, Cleveland, Washington, Charleston and other cities, a plan which has obvious advantages.

The requisite number of jurors is usually either six or twelve. In New Hampshire three only are required, in Louisiana five and in Tennessee seven. In several States the number of jurors summoned is larger than the number sworn for the inquest, the number thus summoned ranging from nine to twenty-three.

The amount of bond required of a coroner varies from as low as \$250 in Colorado, to \$50,000 in the large cities of Ohio.

The jury is usually selected from the inhabitants of the town or county. In Iowa, North and South Dakota, from the "electors." In Kentucky they must be "housekeepers." In Utah they must be "qualified residents." In Washington a juror must be a "male inhabitant over twenty-one years old and of sound mind." In West Virginia he must be "a suitable resident." In Washington a jury is thus defined: "A jury of inquest is a body of men, six in number, summoned from the qualified inhabitants of a particular district, before the coroner or other ministerial officer to inquire of particular facts."

In Wisconsin the coroner is *ex officio* a deputy fish and game warden, and must assist the State warden upon due notice. He must resign to the sheriff, who transmits his resignation to the governor. The coroner must also make complaint as to violation of the statutes relative to the sale of liquors to Indians. In Colorado the coroner may be held for bribery and assault. He cannot practise as an attorney. He must investigate mining accidents and must also seize gambling implements, take snares, traps, nets, etc., and is liable to very many penalties.

Whenever a reform is proposed in any department of the government, every species of argument is employed for the purpose of convincing the law-making authorities. Arguments from the moral standpoint, from the sanitary standpoint, from the patriotic standpoint, all have weight, but experience has shown that the economic argument has usually proved the most successful in the end. An appeal to the public purse is usually the appeal which wins. It was shown after three years' experience in Massachusetts that the abolition of the jury, and the introduction of a system requiring investigations by skilled practitioners of medicine in every case of violent death, had not only wrought a marked improvement in the method of work, but had resulted in a material financial saving to the State. In the city of New York in 1898 the coroners estimated the expense of conducting their work for one year at \$239,050, or about seven cents per capita for the city of Greater New York. In Massachusetts in the same year the cost was only one and one-third cents per capita, or less than one-fifth as great, and this too over a territory of 8,000 square miles.

There are in the United States about 3,000 counties, in the majority of which a coroner exists by law. There are also at least 100 cities of sufficient size to require the continuous services of at least one medical

man for medico-legal work of this character. There is no valid reason to prevent the medical profession from taking the initiative in this much needed reform. The old time coroner is a foe to medical progress, and it is time to "move on his works."

AUTOPSIES AND PHYSICAL EXAMINATIONS.¹

BY DISTRICT ATTORNEY R. O. HARRIS, EAST BRIDGEWATER, MASS.

MR. PRESIDENT AND MEMBERS OF THE MASSACHUSETTS MEDICO-LEGAL SOCIETY:—Since I, somewhat rashly, agreed to read you a paper on the subject of "Autopsies and Physical Examinations," I have been afraid that you might feel that I had undertaken to invade your province and deal with a subject better understood by you than by me.

The two professions of medicine and law should go hand in hand in search of truth. Medicine, in capital cases, must often go first, and upon her judgments must the law base its proceedings. I find, in discussing the matter with physicians, that there are two opinions as to the purpose of the autopsy.

One school, if I may so term it, holds that the duty of the post-mortem operator is only to ascertain the proximate cause of death, and that the manner in which death came is of no concern to him. That is to say, if a man is found dead, with skull split or crushed, and a bloody axe or club is found near by, the operator can report the proximate cause of death as wounds upon the head, and that the axe or club would be an instrument adequate to give such wounds.

The other school holds that the operator is also an examiner, and that every detail should be noted, both of appearances upon the body, and of surrounding objects, and furthermore that nothing should be assumed or taken for granted. The latter opinion is the better one, and the reason is not far to seek. The very purpose of the autopsy is to obtain information, evidence. The examiner should therefore approach his case with mind open, unbiased and unwarped by theories or opinions. He should note *every* abnormal appearance. He should also note carefully the appearances following upon his own operations. The contents of stomach, bowels, bladder, and other organs should be accurately observed. Surrounding objects ought not to go unnoticed.

Very many of these things may be noticed and not reported. Above all, in a case when, by any possibility, a charge of unlawful killing may be made, judgment as to the *manner* of the killing ought to be suspended. The medical examiner is not a prosecutor; he has no power to commit or examine parties. His duty is to ascertain facts within a certain field, and instruct the officers of the law in regard to them. He cannot anticipate explanations or defences. If careful and thorough in his work, however, he can pass upon them when offered, and tell whether they are good.

This, I fear, may seem trite and uninteresting to you, and you may say that of course we should do all these things.

The experienced medical examiner, who has been in many trials, will do these things, because the importance of what I say has probably been borne in upon him at some time, and with great force. Let

¹ Read before the Massachusetts Medico-Legal Society, June 5, 1900.

me cite a few instances out of my own limited experience.

Several years ago a woman, of some seventy years of age, was found dead in her house. The body was found doubled up like a jackknife, in a closet, the door of which was closed. After the door was opened they could not close it again, owing to the rigidity of the body. The medical examiner, a skilful and intelligent man, called in another to assist him in performing the autopsy. Marks, as of fingers, were found around the throat. Evidences of death by strangulation were abundant, and vomitus was found in the windpipe and air passages. Death by violence was clearly established, and the *proximate* cause of death was clear. The physicians were not content to stop there, and examined the body minutely. A very slight abrasion or bruise upon the genitals led to examination of the vagina, and rape was clearly shown. The subject, both in age and personal appearance, had passed the time when one would have expected her to be the object of either solicitations or sexual attack. The choking might well have had robbery as its motive, and an examiner would be tempted to stop with that. The rape, however, once demonstrated, care required examination of the contents of the stomach and all the organs. The stomach assisted to fix the time of day when she died, as the remains of the last meal were found upon the table. No such food as the defendant told about was found either upon the table or in the stomach. The examiners were thus able to stamp his story as a lie. The rigor mortis also helped to establish the time. No one could possibly have anticipated what the story of the defence would be, but the complete *examination*, as well as autopsy, enabled the prosecution to hear down the defence completely.

In another case, again of an old woman, upon opening the head, the brain was found to be edematous, and the heart affected, and the proximate cause of death was apparent. Again a bruise upon the genitals, slight and easy to be overlooked, led to examination for rape. That once demonstrated, other bruises on the hands, arm, and legs, all slight, and none of fatal character, told a story much more important than that told by heart and brain. A bullet hole in the back of the head tempted one examiner to form his conclusion, and stop his examination. Upon being urged to go further, another hole was found, and the discovery changed the whole theory of the *case*. The word *case* I use advisedly, as the examinations are made with a view to gaining exact knowledge of facts, for use in further proceedings, not medical, and in the course of which the physician's may be a small, although very important, part.

It is impossible to anticipate the theories that may have their origin in the necessities of a defendant who has the assistance of ingenious and intelligent counsel. Unimportant bruises upon the body of a man that shows apparently clear evidence of foul and wilful murder may be the foundation for a theory of killing in self-defence, or at most of manslaughter.

The autopsy, at least the exact and careful autopsy, can be made but once. Only by thorough observation will you be able to successfully meet all theories, to fully answer all questions. Any one of you may be called in to assist at an autopsy at any time, and I am, unduly, perhaps, but earnestly, trying to impress upon you all the need of care. There are two par-

ties who have a right to demand it, the commonwealth and the accused. The commonwealth, while prosecuting all cases, never intends to convict the innocent, or to ask more than is due. The accused, when his time comes to speak, may state a case which some apparently trifling mark or condition, in its relation to something else, may substantiate. He is entitled to the benefit of your knowledge and of your testimony. Failure to observe, and consequent inability to testify to the existence of such mark or condition, will carry the presumption that it did not exist, and may deprive an honest defendant of his life or his liberty. I have spoken of care in observing the results of your own work. Recently one of the most skillful operators in the State had to face the proposition that the appearances in the vagina that were claimed to be evidence of rape were caused by him in the course of post-mortem operation. Absurd as it seems, it was yet seriously urged that the lower blade and end of the entrotome scissors, in the hands of a skilled examiner, caused the tears that are characteristic of rape. The experts for the defence finally took the ground that it "was possible, but not probable." Could the theory have been anticipated, the positive answer would have been ready. As it was, the surgeon could only say that he did not cause the wounds. Probably no one believed that he did, and yet it was a suggestion of a possibility, and such suggestions, in capital cases, are sometimes as good as proof. The operator who has to admit that he did not observe any abnormal appearance, or the results of his own work, may sometimes find himself in the uncomfortable position where he knows, but yet cannot testify as of his own knowledge.

Passing from the autopsy, and coming to physical examinations of the living, I am aware that I come upon dangerous ground. Let me preface what I shall say by the remark that my own profession is open to much criticism in the matter of expert testimony. I am aware that it is, by some, looked upon as legitimate to construct a theory, and go from expert to expert until one is found who will testify to suit. Still, the average practitioner goes to his expert for an unbiased opinion, seeking only to know how much of a case he has got from the medical side. It is a trifle disturbing and dazing to have a man whose skill as a specialist in certain sorts of cases is well established, and to whose care you would gladly give yourself for treatment, tell you that a client who has been in a railroad smashup isn't hurt, but is "faking."

When one has known a person in health and vigor, has seen him emerge from a wreck, bruised, shaken, lame, and in such condition that he has to be put to bed; when in the train of the accident come positive symptoms, noticed by physicians, nurse and family, symptoms that never before existed, it is disheartening to have your specialist say that they have nothing to do with the accident, but are merely "coincident." I have known of a physician's refusing to see an injured person, and saying that such an accident or injury could not possibly account for the conditions that followed, and that the patient must be lying. Even when a skillful and reputable local physician has observed and treated positive troubles, which the nurse has had to give attention to, troubles which followed immediately upon the receipt of a heavy blow, I have had the expert calmly declare that physician and nurse must be telling untruths, or the symptoms must be concurrent without being conse-

quential, because in his opinion no such trouble could result from such an injury.

We who are not physicians believe that the swelling that follows when we bump our heads is caused by the blow; that if we are well and sound one minute, and the next are a mass of bruises and lameness as the result of a railway or other accident, the lameness and subsequent disturbances are attributable to the collision. The tendency is to divide men who are supposed to be, and who are in fact, learned and skilled men in surgery into two camps, plaintiff's experts and defendant's experts, the members of one ready to agree that almost any result may come from any injury, the others poolpoohing at everything and saying, "impossible, impossible," to everything. The result is that the expert has become a partisan. He cannot treat his case as he does his patients, disinterestedly. He is bound to one side of the case, and is always a plaintiff's or defendant's expert. This has become so marked that some men will say to us when we seek their opinions, "Go to So-and-so, he is more sympathetic than I am; I can't testify for a plaintiff," or else, "I am not the man you want; So-and-so is a good defendant's expert." These things have been said to me when I have gone to good men, whom I have met in cases and found to be skilful.

This may seem to you like mere scolding, but you must remember that it comes from a member of another profession. I try on both sides; I have to consult your profession; and I can see no reason why, if it chanced that, when trying for the plaintiff, I meet a physician whose opinion seems to me to be entitled to weight, I should not consult him when I need a man for the defence to instruct me as to medical facts or probabilities. All I want is his best knowledge; when I get that, I can shape my own course. As in the case of the autopsy, the physical examination is for the purpose of gaining information, evidence; of establishing that a condition does or does not exist and testifying accordingly. It is not intended for the purpose of enabling you to ascertain conditions, and then raise theories to account for them that have no foundations except in theory.

You come to us for opinions in law, based on facts stated, and you do not want us to suppose some other facts and give opinions based on them, and you do not want us to tell you that your facts are mere imagination.

Pardon me for being so long, but believe me that I am moved to say what I have only by my desire that our two great professions may be held in the esteem to which they are entitled.

THE MORTALITY OF FOREIGN CITIES. — The following statistics are, according to the *Medical Press and Circular*, the latest official returns of the mortality in 26 cities in widely separated parts of the world, and represent the last weekly death rate per 1,000 of several of the populations: Calcutta 36, Bombay 75, Madras 75, Paris 16, Brussels 13, Amsterdam 12, Rotterdam 15, The Hague 13, Copenhagen 16, Stockholm 13, Christiania 13, St. Petersburg 25, Berlin 21, Hamburg 17, Dresden 29, Breslau 22, Munich 29, Vienna 16, Prague 18, Buda Pesth 15, Rome 16, Turin (ten days) 16, Cairo 42, Alexandria 37, New York (including Brooklyn) 19, Philadelphia 15.

Clinical Department.

A CASE OF CONTRACTING SCAR OF THE PALM OF THE HAND REMEDIED BY A FLAP FROM THE ABDOMEN.¹

BY F. M. BRIGGS, M.D., BOSTON,

Professor of Clinical Surgery, Tufts College Medical School; Surgeon to the Boston Dispensary.

THE patient, a woman aged twenty-four, while working in a steam laundry had her left hand caught and carried in between two rollers. The upper of these rollers was covered with heavy felt- ing, and was not hot; the lower one was of polished metal, and was very hot. Upon withdrawing the hand it was found that its back, which had come in contact with the felt (not heated) roller, was badly lacerated but not burned. The palm, which had come in contact with the heated roller, was both badly burned and badly lacerated. This accident occurred in January, 1898, and she was treated at the Boston City Hospital, where she stayed for two months.

When she left the hospital both front and back of the hand were covered with a thin, delicate cicatrix, which slowly contracted on the palmar surface. This contraction gradually flexed the fingers and the thumb until, at the end of one year, the ring and little fingers were drawn down on the palm and could not be extended. The thumb, also, was strongly flexed and held in this position by a rigid band of cicatricial tissue. The index and second fingers were but slightly affected.

The usefulness of the hand was greatly impaired by these contractions, as the only motion it possessed was between the flexed thumb and the second finger, and this was extremely limited. The hand was practically useless, and the patient depended for her needs almost wholly upon the uninjured right hand. In addition to this loss of function, the cicatricial tissue, which had replaced normal skin, was extremely delicate, and was the cause of much pain and discomfort, for upon exposure to cold it fissured and slight injuries caused abrasions. The result of the injury was, therefore, twofold, as it caused both loss of function and a painful cicatrix.

The patient consulted me in February, 1900, or about two years after the injury, and stated that there had been no noticeable contraction for nearly one year, thus indicating that the progressive contraction had reached its limit. She was a strong, healthy individual, with a clear skin and good capillary circulation. I decided to operate by removing the cicatrix entirely and making a new palm from an abdominal flap, thinking that, even if I failed to restore the functions of the hand, I stood a good chance of replacing the delicate, painful, cicatricial tissue with normal skin. If the operation proved unsuccessful she would be no worse off than before.

Operation, February 7, 1900. — Assistants: Drs. N. T. McLean and S. McLeod. The double field of operation (the hand and the abdomen) was carefully cleansed and made aseptic. Patient etherized, and circulation to the hand cut off with a rubber bandage and tourniquet. It is to be noted that the

entire palmar surface of the hand was composed of cicatrix. There was no normal skin at any portion of its surface. This palmar cicatrix was wholly dissected off, cutting away the superficial fascia and freeing the ring and little fingers. The thumb was found to be bound down by deeper adhesions than were the fingers, the adhesions spreading out in a fan shape. These were all dissected off, allowing full extension of the thumb. The palmar tendons were found nowhere adherent. The rubber tourniquet was then removed and a large, firm compress laid over and bandaged to the denuded surface. There was very little bleeding. An outline of the surface left bare by this denudation was carefully marked out on a piece of paper before applying the compress, this outline being made a trifle larger all around to allow for shrinking of the flap. This pattern was laid over the left side of the abdomen, just below the sternum and with its base on the median line. In this way the outlines of the flap were indicated, marked out with the scalpel and dissected up, leaving for its pedicle the broad base line running vertically along the median line. The flap was then turned over, just as a book is opened, or, a better illustration, just as a leaf of a book is turned, thus having its cut surface upwards. Five long sutures were inserted at regular intervals along the edges of the flap and were not unthreaded. Bleeding was quickly checked by compression.

The hand, its compresses having been removed, was then brought over from the side and its denuded palm laid directly over the upturned cut surface of the flap. The two surfaces fitted nicely, and the sutures were tightened and knotted after being passed through the edges of the wound on the palm. This fastened the hand to the abdomen. A corrosive dressing was placed between the forearm and the open wound left by the removal of the flap, a second dressing was placed under the fingers and the whole combined seat of operation was then covered with a large sterilized dressing. The hand was held in position by long strips of adhesive plaster carried around the elbow and the body, the whole being encased in a Velpeau bandage. In this way the hand was kept fixed and quiet. The patient was kept closely confined to the bed, and the course of the case was uneventful.

Fourteen days later the patient was again etherized and the pedicle cut free from the abdomen. This was not easy, as it proved difficult getting under the forearm and dissecting away the abdominal attachment of the flap. However, it was done successfully, and the free edge of the flap then stitched to the corresponding edge of the palmar wound. The hand was confined in a spoon splint. The abdominal wound was left to heal by granulation, no attempt being made to replace the lost skin.

The new palm united rapidly and firmly, but the skin was much thicker than that of the other hand, and had a most unsightly appearance on that account. This thickness of the flap prevented closure of the hand, and attempts to flex the fingers on the new palm made the skin rise up in the centre, somewhat resembling a rubber ball. This tendency persisted for some time, but finally, as the flap grew more and more firmly attached to its base, it began to disappear. With the disappearance of the tenderness necessarily present after such an operation, the patient began to

¹ Read before the Boston Society for Medical Improvement, May 7, 1900.

use the hand, and, with continuous efforts to close the hand over firm objects, the thickness of the flap began to wear away. It disappeared first from that portion of the palm where pressure was most constant, or along the line of junction of the fingers with the palm. Slight thickness of the portion near the base of the hand has persisted, and there is one spot which is tender to the touch. Slight sensation was present from the first, but it was greatly impaired. It gradually returned until finally full normal sensation was regained.

It was interesting to note the development of the lines, or "creases," of the new palm. When the skin was first laid in its new position it was wholly smooth, like the normal skin of the abdomen, and could not be made to crease. But with more and more closure of the hand lines began to be visible. These at first varied from the normal lines of the palm, but with the progressive thinning of the skin, the regular "creases" of the palm are to be noted in their proper positions and running in the usual directions.

The result of the operation is wholly satisfactory.

The skin of the new palm is very soft and pliable and is fully doing its work. The operation would have been a success if it had accomplished nothing beyond this substitution of good skin for weak cicatrix. But it has done more than this. It has restored the functions of the useless hand. The case is of more than ordinary interest, in that it demonstrates what it is possible to accomplish towards correcting some of these old deformities, and it is for this reason that it is reported in full detail. Taking such a flap from the abdominal wall ensures good nutrition, provided a long base line is left for the pedicle, and the skin grafted in the manner described makes an excellent substitute for the original skin. In this case there were no adhesions between the cicatrix and the tendons, nor were any of the finger joints ankylosed. This, of course, made the operation more promising than would be the case where contraction is due to old inflammatory processes with resultant adhesions, or in cases where long-standing flexion has resulted in fixation of the joints by bony ankylosis. Still, the operation seems to me to be well worth trying in any case of palmar contraction involving the skin, for it is

devoid of danger, offers a possible remedy, and, in any event, leaves the patient no worse off than before.

So far as I can learn, this is the first case where this particular method of plastic work has ever been attempted in the treatment of these cases. The accompanying illustration gives a good idea of the appearance of this hand as it now is.

PHYSIOLOGICAL DILATATION AND THE MITRAL SPHINCTER AS FACTORS IN FUNCTIONAL AND ORGANIC DISTURBANCES OF THE HEART.¹

BY MORTON PRINCE, M.D., BOSTON.

This subject is of great practical importance, not only in examinations for civil service, life insurance, etc., but for a clear understanding of diseased conditions. I used to reject many men whom I now would not think of rejecting because of this evidence of regurgitation. Sir William Broadbent has lately called attention to the great number of murmurs heard over the various cardiac orifices in candidates for civil service examination, and this, I am pleased to think, has corroborated the accuracy of my own observations, although he has not undertaken to give an explanation of the mechanism of the murmurs. He calls attention to the unnecessary rejection of candidates for civil service because of murmurs of this kind. The recognition of this principle of physiological dilatation whenever the heart is called upon to do an increased amount of work, no matter from what cause, is of the utmost importance. Whenever the heart is obliged to do an increased amount of work, whether this be due to increased stimulation of the heart or to increase of the resistance against which the blood is thrown, the heart physiologically dilates. This dilatation within normal limits may be so great that the volume of the blood thrown out at each contraction may be trebled or quadrupled. At the end of systole the heart may be larger than it was before at the end of diastole. The sphincters may be so dilated that the valves cannot close the auriculoventricular orifices and thus physiological regurgitation may result. Normally this is observed under nervous excitement and severe physical exercise. The same law of necessity applies as much to diseased hearts as to healthy hearts and, for example, the dilatation observed in aortic stenosis may be physiological rather than pathological. In general systemic conditions, such as the febrile diseases, anemia, Bright's disease, etc., the dilatation and regurgitation are of the same sort, due either to an absolute increase of resistance or a relative increase: in the latter case because of a weakened heart working against normal resistance. Unless this is recognized there is great danger of confusing this purely physiological condition, which probably exists in a great many such cases with serious cardiac disease and in consequence giving an unfavorable prognosis.

As to the absence, notwithstanding the dilatation, of murmurs in the contestants of the last Marathon race, I agree with Dr. Williams in his explanation. To this I would add the fact that the heart was not beating with the force which I think is necessary to produce murmurs. It did not seem to me the heart was beating very strongly in any of them. They were examined so long after the race that the heart

¹ Abstract of a paper read before the Boston Society for Medical Improvement, May 7, 1900.

had quieted down besides being weakened by fatigue. The heart's action did not compare with the action in the men who were under the nervous stress of the civil service examination. Besides that the absence of murmur does not so frequently denote the absence of regurgitation, as is frequently assumed. Every one admits, in principle, that you can have regurgitation without murmur, but, in practice in the consulting room the tendency is to say: "No murmur, no regurgitation." It is well recognized that even in organic disease, where there is mitral regurgitation, when the heart becomes weakened the murmur ceases, but when the heart recovers strength the murmur appears. In these cases of the Marathon runners I think the weakened force of the heart is a perfectly satisfactory explanation of the absence of murmurs. As a matter of fact, and this Drs. Williams and Arnold showed last year, they are fugitive, and only appear when the hearts are beating strongly. This was my experience. In most of the cases they are very fugitive and have got to be caught "on the fly." I feel fairly confident there was regurgitation in the Marathon runners, even in the absence of murmurs. I base this on the cyanosis present, the feeble circulation and the condition of the kidneys showing passive congestion as well as on the dilatation of the heart.

REMOVAL OF THE GREATER PART OF STOMACH FOR CARCINOMA; CLOSURE OF THE PYLORIC END; ANASTOMOSIS BETWEEN JEJUNUM AND CARDIAC END; RECOVERY.

BY W. A. BROOKS, JR., M.D., BOSTON.

On May 24, 1900, A. L., a resident of Dorchester, was admitted to the Massachusetts General Hospital. For a little over a month previous he had been under the care of Dr. F. Pfaff, who had made the diagnosis of carcinoma of the stomach and had advised operation. The patient was a man a little over forty-four years of age, and up to two or three years previously had always enjoyed good health. His father died of "ulcers," but his mother and five sisters are alive and well. The patient gave the history of his trouble as beginning about two years ago, before he saw Dr. Pfaff. His first symptom was pain in the epigastric region, and for a time this symptom was relieved by drinking hot water. About a year ago he commenced to be troubled with a great deal of gas in the stomach and within the last four months he has had frequent attacks of vomiting, has lost weight, and has been in constant pain. On account of the pain, distress and vomiting, he was compelled to give up his work as a cigar maker three months ago.

Dr. Pfaff stated that there was no retention of food in the stomach, that HCl was absent, and that the stomach contents did not contain blood or shreds of tissue.

When the patient was examined in the ward, it was found that he was much emaciated and in very poor general condition. His heart, lungs and kidneys were apparently normal, although the urine was of low specific gravity. In the epigastric region, a little to the left of the median line, there could be felt a hard lump, the anterior surface of which seemed nodular. This lump or tumor moved up and down with respiration. It was about as large as a medium-sized closed fist and was not tender to the touch.

The patient was operated upon May 29, 1900. For the twenty-four hours previous he had been given nothing by mouth, but had been fed by rectal enemata. On the morning of the operation the stomach was washed out with hot water and a boracic-acid solution and a cleansing enema was given. The rectum was cleared by an S and G enema. He took his ether very well, and when etherized was placed in almost a sitting position.

With the assistance of Dr. Graves and Dr. Simmons the following operation was performed: A long median incision was made extending from the ensiform cartilage to the umbilicus. Edges of the wound retracted and the anterior surface of the stomach was brought into view. There was some omentum adherent to the anterior wall, and it was this that gave the nodular feel through the abdominal parietes. The wall of the stomach itself felt hard and very much thickened.

At first it was thought that the growth only involved the anterior wall and some valuable time was wasted in placing the line of sutures external to the mass in preparation for excision of tumor. When, however, the stomach was lifted forward it was found that the growth had extended completely around it, close up to the pyloric end, and for a considerable distance towards the fundus. The original plan of the operation was then changed. A loop of the jejunum was brought up and a lateral anastomosis was established between it and the top of the fundus. (The loop and anastomosis were about 18 inches from the beginning of the jejunum. In making the anastomosis, Lembert's sutures were used.) Two ligatures were now passed around the pyloric end of the stomach, and the stomach walls severed between them. The edges of the pyloric end of the stump were turned in and the peritoneum stitched over it. The removal of that part of the stomach containing the new growth was then begun.

The greater and lesser omenta were sutured and cut away from edges of stomach. The arteries remaining along the greater and lesser curvature were ligated. The stomach walls were then cut through as close up to the place where the anastomosis had been made as possible. The free edges of the stomach were then brought together and tied with a series of Lembert's sutures. Before this procedure was completed the pulse became very weak and the patient had to be infused with a salt solution. The wound was swabbed out with peroxide, a wicking-off wick was left towards the intestine, and another was passed to the pyloric stump of the duodenum. A third was passed to where the stomach edges had been sutured together.

The patient made a good recovery from the ether. His pulse came up quickly. He felt comfortable the evening of the operation and passed a comfortable night with very little pain. He was given $\frac{1}{6}$ grain of morphia. Occasionally during the night he would vomit a little, but suffered no great distress.

May 31st. He was in good condition. He was fed by nutrient enemata every six hours.

June 1st. There was no vomiting. Patient felt comfortable. There was no distention of the stomach, but the gauze wick had become infected. Cultures from the wicks showed streptococci, diplococci and some unknown bacilli.

June 3d. For the first time the wicks became

stained with bile. He was given sips of water every half hour.

June 4th. Was given ice cream.

June 7th. Great many silk stitches were removed from the wound.

June 9th. Sleeps well. Is perfectly comfortable, and was given sugar and water by mouth.

June 11th. Was fed on liquid food.

June 16th. Sat up in bed with a bed rest.

June 24th. Was fed on soft solids.

July 1st. Was given six meals daily, consisting of meat, soft solids and milk.

July 9th. Went out of doors for the first time in a chair.

July 30th. Has gained nine or ten pounds since he was able to get out.

September 1st. Has been up and about the hospital since July 20th. He takes short walks through the grounds, and is out nearly all day. There are two sinuses, and unless they are tightly plugged with gauze allow the escape of bile and fluid. He eats six meals daily and has gained about fifteen pounds since he first came out after the operation.

September 15. Patient is not so well. He has been suffering from an attack of phlebitis and has lost some weight and strength.

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY F. S. WATSON, M.D., AND PAUL THORNDIKE, M.D., BOSTON.

IMPLANTATION OF THE URETER INTO THE BLADDER.

DR. ACHILLE BOARI,¹ Pascia, Italy, accomplishes this operation by means of a small button similar to that used by Murphy in performing intestinal anastomosis. It has been recently used in 4 cases in women with favorable result in all. The button is small and may be removed, in women, through the ureter; in men it can be extracted only by a suprapubic cystotomy. The operation consists, first, in isolating the ureter by means of a small incision through the peritoneum covering it, dividing it across at the point that may be desired, inserting the one side of the button, securing the dividing end of the ureter around it by a suture. A purse-string suture is then inserted in the bladder at the point selected for implantation; the incision of the bladder is then made in this area, the larger end of the button is pushed through, the purse-string suture is drawn tight, and the two halves of the button are pushed together. Rapidity and ease of performance are the advantages claimed for the method.

TUBERCULOUS DISEASE OF THE KIDNEY.

This article, by David Newman,² appears in this and the two following numbers of the *Lancet*, and is a full and interesting exposition of this very important subject. The remarkable power of the healthy kidney to destroy organisms or to eliminate them is noted, and the frequently observed passage of tubercle bacilli through the kidney without producing any pathological change in the organ is cited as an ex-

ample. Their presence, therefore, in the urine is not pathognomonic of tuberculous disease of the urinary tract necessarily.

The author goes on to consider the methods of invasion of the kidney by the bacilli as follows: (1) By the blood stream, (a) the tuberculous particles being so small as to be arrested only by the terminal capillaries, where they give rise to miliary deposits; (b) from infective emboli passing through a branch of the renal artery, and giving rise to a definite area of local infection corresponding to the distribution of that branch; (2) by invasion along the lymphatics of the kidney from foci in the lower urinary tract; (3) by contagion along the lumina of the excretory ducts; (4) by direct extension to the kidney through neighboring organs. In the majority of instances the renal infection probably occurs by means of the blood current, which has become infected when passing through the lungs, alimentary canal, or mucous and cutaneous surfaces.

In the form originating in tuberculous embolism the renal lesion appears as a wedge-shaped area, and while they often break down and are disseminated, they sometimes, on the other hand, become encysted, in which case the disease is generally unilateral and involves but a portion—occasionally more than one distinct area—of the kidney substance, and usually remains limited to the parenchyma. This is the form of the disease which offers the best chance for recovery if treated surgically, when not too far advanced.

The manner of invasion of the kidney from the lower part of the tract is carefully considered, the ascending form of the disease being by no means uncommon in the author's opinion.

The much greater frequency of renal tuberculosis is referred to and illustrated by pathological statistics.

Symptomatology.—The following are pointed out as amongst the most important evidences of the condition; pyuria especially, when associated with evening rise of temperature, loss of strength, and anemia, is highly suggestive of renal tuberculosis. The local and constitutional symptoms vary, however, greatly, and depend largely upon the extent and position of the lesion in the kidney.

When the lesion is limited to the parenchyma, fever is rarely marked, pain is slight and sometimes absent, the urine is acid, and the quantity of pus is very small. Occasionally it happens that there is an absence of local symptoms even when the pelvis and ureter are involved; the kidney may be wholly destroyed, even without having caused sufficiently marked symptoms to attract attention; ordinarily, however, pain, bladder irritability, and marked evening pyrexia become conspicuous with the pelvis and ureter. Vesical irritability is very characteristic even when the bladder is not involved. Renal swelling sometimes attains considerable dimensions. In about one-fifth of the cases collected by the author tuberculous pyonephrosis was discovered by palpation during life. One of the earliest symptoms to which attention should be drawn is polyuria. Hematuria is seldom profuse; it may precede, as in pulmonary tuberculosis, the development of other recognizable symptoms.

Diagnosis.—The diseases with which tuberculous lesions are most likely to be confounded are tumors, septic pyelitis or pyonephrosis, and renal calculus. The author makes the point in this connection that

¹ Ann. des mal. des organes genito-urinaires, November, 1899.

² London Lancet, February 24th, p. 526.

the pain attendant upon tuberculosis does not radiate, as does that of calculus; blood is not apt to be increased by exercise.

With regard to treatment the writer dwells upon the fact of the increasing recognition of the possibility of spontaneous cure, but does not conclude because of this that hygienic treatment is to be preferred to the operative under all circumstances. The statistics and conclusions of Dr. L. Bolton Bangs, of New York, are quoted to the effect that from the study of the former he is led to state that upon the whole operation affords better remote results than hygiene, and that the undoubted fact is that the immediate results of operation in suitable cases of renal tuberculosis are brilliant.

TREATMENT OF RENAL RETENTIONS.

Gosset,³ in the course of an investigating communication, notes amongst other observations the following:

If a ureteral catheter be passed, the kidney being in a normal condition, there is, at first, no flow of urine through it; then, after a few seconds, an intermittent flow begins and continues as long as the catheter remains in place. In certain pathological states, on the other hand, the flow of urine, which is continuous, takes place as soon as the tip of the catheter has entered the renal pelvis, until more or less has been passed, when it suddenly ceases. Whenever a continuous flow like this of even a moderate quantity of urine (25 grammes) takes place it is a sure indication of renal retention. The quantity of the liquid passed is the measure of the degree of retention.

Suppuration of the renal pelvis (pyelitis) does not imply the existence of renal retention.

In some of the cases of renal retention noted by the writer the quantity of the retained urine amounted to 300 grammes.

It is not necessary to resort to the ureteral catheter to establish the presence of the retention, since the condition is always accompanied by a pathognomonic symptom, which is intermittence. In many cases of intermittent hydronephrosis this phenomenon is a conspicuous feature, the emptying of the renal pelvis being also preceded by an attack of pain which is coincident with a marked diminution of the quantity of the urine, and which is relieved with the re-establishment of the flow. This intermittence is equally characteristic of pyonephrosis.

The necessity for surgical intervention is considered by the writer to be imperative and to rest on the following grounds: (1) That the progressive character of the condition is practically invariable, and eventually results in the total destruction of the kidney; (2) the liability of infection of the affected kidney, and (3) the probability of the other kidney being involved.

These factors are reviewed in an instructive manner and numerous reasons in support of the writer's contention are clearly set forth.

In the course of the discussion of these data it is pointed out that there is no tendency whatever toward a spontaneous restoration of the affected kidney to the normal condition. The most important factor in the perpetuation of the pathological change is the formation of a pocket or pockets in the renal pelvis or the renal substance itself, or both, and once established such pockets are never abolished by any natural effort of the organ, nor, it is asserted, is a restoration

ever wholly brought about by lumbar drainage of the kidney, although a decided improvement does take place after a lumbar nephrotomy, no matter how long continued. What is accomplished by drainage, however, is to prevent further progress of the renal destruction which was being produced by the distention of the urinary retention, and also to avert the painful crises dependent upon the periodic recurrence of that condition.

With regard to the destruction of renal tissue, the writer calls attention to the fact that it is far greater in the complete than in the incomplete retentions, though the pocket formation and thinning of the renal cortex is more extensive in the latter, and that even in the cases in which but very little of the renal cortex remains, it may — in that class — retain a surprising secretory power. But while this is true, the need of relief for the retention at as early a date as possible is not the less manifest; it is more imperatively demanded in the suppurative, but is also essential in the non-infected retentions as well. The great ease with which an aseptic renal retention becomes septic is the writer's ground for urging early surgical intervention in these cases.

In the treatment of all renal retentions there are two indications to be fulfilled: (1) To evacuate the retained contents; (2) to prevent its recurrence, that is to say, to re-establish the normal and entire emptying of the secretion by the ureter. The first of these is met by nephrotomy, the second by various plastic operations upon the kidney or ureter. It is no longer a question of nephrectomy and nephrotomy, for the proper sphere of the former has become limited, practically speaking, to tuberculous and new growths, and today nephrotomy should be practised systematically as the first step, at any rate, in all renal retentions. This is, according to the writer, the first imperative indication in these cases. It is absolutely unimportant whether there is suppuration or not; relief of the renal retention is the first indication to be met, and there is no need to determine the condition of the other kidney previous to doing this by establishing drainage through the lumbar operation of the one known to be the seat of the primary retention. The article is summarized as follows: The treatment of all renal retentions should be by two successive operations: First, lumbar nephrotomy for drainage, which permits in many cases a partial restoration at any rate of the diseased portion of the organ and the possibility of determining by urinary analysis of the liquid coming from the fistula, and to what degree the restoration has proceeded, and the value of the kidney which is being drained. In infected renal retentions the drainage permits disinfection of the affected tissues and places the organ in the most favorable condition possible under the circumstances for the success of the secondary operation, the nature of which will be determined by the conditions found at the time or determined beforehand by aid of the primary one.

NEW OPERATION — RENAL PAPILLECTOMY.

This article, by E. Hurry Fenwick,⁴ is "a contribution to the study of painless unilateral renal hematuria in the young adult." It is based upon 2 carefully studied cases of renal hemorrhage, in each of which the affected kidney was determined by the use

³ Rev. de chir., March 10, 1900, p. 335.

⁴ British Medical Journal, February 3, 1900.

of the cystoscope, and then operation through a loin incision was performed. In each case the pelvis of the kidney was incised and a varicose condition of one papilla was found. The removal of the papilla by curette cured the hemorrhage in both instances. This short article is a really valuable addition to our knowledge of renal hematuria.

VALUABLE SUMMARIES OF CASES.

Dr. Assendelft⁵ has made a study of 630 cases of stone occurring during a period of twenty years. Of these cases 616 were in men or boys and 600 were operated. Of the 600, 460 were operated by the suprapubic route and only 12 by litholapaxy. His mortality was 3.6%. The author says that in skilled hands litholapaxy is the operation of choice, but that in his country (Russia) with its enormous distances and its comparatively small number of surgeons, it cannot be expected at present that many have the skill requisite for the proper performance of this operation.

PRIMARY MALIGNANT DISEASE OF THE PROSTATE.

E. Hurry Fenwick⁶ has made a study of 50 cases. Forty-four cases were of hard scirrhus growth, and 6 cases were of soft, rapidly growing disease. In the scirrhus cases three years is given as the average duration of life, and in the latter group of 6 cases, progress of the disease was rapid, and death from sepsis came quickly.

VESICO-INTESTINAL FISTULE.⁷

A. Pascal⁸ has made a study of 300 cases representing all that he could collect. The article is of value as a résumé of all cases to date.

INTERESTING AND UNUSUAL CASES.

Calculi Impacted in the Ureters.

David Newman⁹ presents a most valuable article in which is embodied the report of 4 unusual cases of impacted ureteral stone.

CASE I. Three attacks. Stone located in ureter at brim of pelvis. Expelled after nine days' massage over ureter.

CASE II. Ureteral catheter detached calculus, which was removed by a suprapubic cystotomy after ureteral orifice was dilated to allow it to drop into bladder.

CASE III. Cystoscope showed swelling at ureteral orifice. Thought to be a tumor. Operation revealed stone impacted in orifice of ureter.

CASE IV. Suprapubic cystotomy for hypertrophy of prostate with stone in bladder. Second stone (un-suspected) found impacted in ureteral orifice.

Excision of a Seminal Vesicle for Tubercular Disease.

Mansell-Moulin¹⁰ reported at the meeting of the Medical Society of London (January 8, 1900) 2 cases of excision of a seminal vesicle for tubercular disease, which had extended upward from the epididymis. In each case the vesicle was removed through the perineum by a modification of the Zuckerkaudl in-

cision. Little bleeding. One case healed promptly. The other maintained a small urinary fistula for a few months. The author advocates complete removal of the vesicle where it can be felt enlarged per rectum in cases of tubercular epididymitis.

A Case of Ruptured Ureter or Renal Pelvis.

E. Percy Paton¹¹ points out that the ideal treatment of immediate suture can rarely be carried out, as in the majority of cases diagnosis cannot be established until some time has elapsed after the injury.

NEW INSTRUMENTS.

Wossidlo,¹² of Berlin, reports a new cystoscope which he calls *Incisions Kystoscop*, and which he expects to use in performing the Bottini operation for hypertrophy of the prostate under the control of the eye. The author operated with the instrument, which consists of a cystoscope in which slides the Bottini knife, on January 24, 1900.

Dr. Franklin H. Martin¹³ has recently demon-

FIG. 1.

strated a new clamp for ureterorectal anastomosis. The object of the instrument is to facilitate the operation by shortening the time of the procedure, to guard against leakage at the mucous membrane of the bowel without, at the same time, getting constriction of the ureter, to provide for a free flow of urine, to guard against the possibility of occluding the ureter

FIG. 2.

by thoroughness of suturing, otherwise necessary, and to provide for adequate burying of the ureter. The application of the instrument is easily understood, but rather difficult to explain. The bowel is prepared, as I have described heretofore, for ureterorectal anastomosis by denuding it of the serous and a portion of the muscular coats (see illustrations). A small opening

is then made through this oval-shaped denudation, which denudation is about 2 inches in length on the lateral wall of the rectum, sufficiently large to admit one of the blades of the clamp. This blade is passed through the anus into the bowel and passed through the opening in the mucous membrane until it projects for the distance of an inch or an inch and a half. The ureter, which has been prepared, is placed over this blade. The blade, by the way, is hollow, having an opening through its centre large enough to allow the free passage of urine, the opening passing off to the side of the blade lower down. After the ureter is put upon the blade, a small piece of catgut is tied around it to secure it at a point where there is a slight notch in the blade. This secures the ureter to the blade; the blade is then partly withdrawn so as to draw the ureter through the bowel opening into the interior of the gut. Only about one-half inch of the

FIG. 3.

blade is outside of the denuded surface, and at this point the forceps are closed and locked, and the ureter secured to the mucous membrane and the denuded portion of the bowel. The blade remains clamped until it comes away as the Murphy button does by pressure atrophy. The opening in the bowel is now closed around the ureter. As the ureter contains the hollow blade of the forceps there is no danger of constricting it. One suture, properly placed, will accomplish that; so that but one catgut suture is really necessary to fix the ureter to the mucous membrane and to the muscular coat of the bowel. Then, with the application of two rows of catgut sutures, the ureter is buried, and the operation is finished.

There should be different sizes of the instrument, as the ureters vary markedly in size. The opening at the side of the blade has a small olive tip, over which a rubber tube is slipped, which will conduct the urine out of the bowel.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting Monday, May 7, 1900, Dr. E. H. BRADFORD in the chair.

Dr. F. M. BRIGGS showed a case of

CONTRACTING SCAR OF THE HAND REMEDIED BY A FLAP FROM THE ABDOMEN.¹

Dr. MORTON PRINCE read a paper entitled

¹ See page 422 of the Journal.

PHYSIOLOGICAL DILATATION AND THE MITRAL SPHINCTERS AS FACTORS IN FUNCTIONAL AND ORGANIC DISTURBANCES OF THE HEART.²

DR. ARNOLD: It seems to me that this matter has a decidedly practical bearing in its clinical aspect. As a rule I think one is apt to look upon the mitral valve in the same way that we do upon the arterial valves, and to consider chiefly the question of disease of the valve itself. From this point of view we are a little surprised to find that so many of the mitral murmurs are clinically of little importance. Our old distinction between organic murmurs and functional murmurs is not entirely satisfactory and is not as sharply defined as we are apt to think. With regard to mitral murmurs I think the explanation is to be found in the part taken by the muscle of the ventricular wall in the closure of this valve. Whether Dr. Prince's description of it as a sphincter helps our ideas is a little questionable in my mind. There is not an absolute muscular sphincter, for on the inner side the mitral valve is contiguous with the aortic valve. The essential point is that it is the contraction of the circular muscular fibres of the heart which narrows the mitral valve and thus enables the valve curtains to completely close the opening. We may call it sphincter if we understand it in that light. Again, in valvular disease its importance, as we know, depends not entirely on the disease of the valve itself, but on the condition of the cardiac muscle. As long as we have a good condition of that muscle, or good compensation, as we call it, as long as the mitral valve closes muscularly, the valvular lesion is of comparatively little importance. When the muscle diminishes in its force and yields to a certain extent, when it does not aid by contracting in the closure of the valve, we get broken compensation and leakage which is of practical importance. It seems to me that is the practical bearing of the question, and if we keep in mind this action of the heart muscle about the mitral valve we shall better understand the various conditions in which the mitral murmur is heard. It is, of course, understood that we may have a lesion of the mitral valve itself so extensive that the muscular contraction will not enable the valve to close tightly, however strong that contraction may be.

DR. HAROLD WILLIAMS: Dr. Prince's paper is so complete that it does not seem to me one can say very much in addition to it. Anything further would be simply what Dr. Prince has omitted to read. What Dr. Arnold has said is very important, and for my part I think it probable, not only that the other muscular fibres of the ventricle participate in this contraction, but also that the papillary muscles play a more or less important part, as pointed out in our article of last year. In connection with this subject I should like to emphasize one thing, namely, the importance of judging of these muscular exercises according to their individual merits and the characteristics of the individual participating. It seems to me we are apt to generalize too much on the effects of muscular exercise without considering what the exercise is and the conditions under which it is taken. There are many factors which enter into these cases. Each case should be considered on its own special merits.

DR. J. B. BLAKE: The point which Dr. Williams

² See page 423 of the Journal.

made that each form of exercise must be judged for itself and under its own conditions, I should think was illustrated both by the temperature and the fugitive heart murmurs. I will refer to the temperatures found at the finish of the race which differed considerably from those found last year. Last year it was run on a cold day (temperature about 44° F.), against a wet, stiff east wind, and some extreme subnormal temperatures were discovered, in some cases 5° below normal. This year there were 1 or 2 cases of increased temperatures before the race, but after the race in 23 cases we found mouth temperatures were either a little above the normal or very slightly below the normal in 7 cases, the lowest mouth temperature after the race being 97°, highest mouth temperature in the race 102°.

DR. HAROLD WILLIAMS: In regard to the absence of murmurs in this last examination I should like to say a word. I think it can be accounted for in two ways. Certainly for 26 men to run twenty-five miles each and for none of them to have heart murmurs would be an unusual occurrence, and one that ought to be accounted for. In this instance I think it is to be explained in two ways: In the first place it must be remembered that these murmurs are very ephemeral in character, and as a rule are only to be heard at the time of the exercise. We examined the hearts of the men as soon as they came into the building. They were carried to the examining room in the elevator, laid on the table and the hearts were examined instantly. During our examination the murmurs disappeared in a large number of cases. In only one case was the murmur persistent. In that case it lasted one-half hour and then disappeared. In the others the murmurs lasted only a few minutes, in some of them seconds only; so that if the examination of the heart had been deferred, as in the recent examination, the murmurs would have disappeared before auscultation was practised. The other reason is the degree of exhaustion. The participants in the recent race were not so exhausted as the men in our race. The freshness of the men at the close of the recent race as compared to the condition of exhaustion of the competitors of last year's race was very marked, and was a matter of comment among the spectators. I consider the extreme exhaustion in our race to have been largely due to the cold. The men ran in ordinary running costume, and to expose the body thus lightly clothed to external air at 44° F. and a high head wind for three hours would probably call for a very great loss of heat and very great lowering of the vital forces, so that probably exhaustion in that case was very much greater than in the recent race, when the conditions were much more favorable.

DR. MEYLAN showed

SPHYGMOGRAPHIC TRACINGS.

The general result shows a very great dilatation of the vascular system, and in the number of the men, especially those most exhausted at the end of the race, there is almost complete loss of the regular normal curve. In the case of the men who finished strong, the sphygmograph showed the heart to be in better condition.

NUMBER OF STUDENTS AT JOHNS HOPKINS MEDICAL SCHOOL. — Johns Hopkins Medical School has opened this year with 215 students.

AMERICAN PEDIATRIC SOCIETY.

TWELFTH ANNUAL MEETING, HELD IN ST. JOHN'S PARISH HALL, WASHINGTON, TUESDAY, MAY 1, 1900.

FIRST DAY.

THE chairman, DR. HENRY KOPLIK, of New York, presented his paper, entitled

THE AMBULATORY AND HOSPITAL MANAGEMENT OF THE GASTRO-INTESTINAL DERANGEMENTS OF INFANCY IN THE SUMMER MONTHS AMONG THE POOR OF LARGE CITIES.

He said that the breast-fed infant is not as much exposed to infection as the infant who is artificially fed. Cow's milk in the latter case is the substitute for the breast in the opinion of every practical man. But before the milk reaches the infant it passes through so many channels and is open to so many sources of infection that it is surprising the mortality is not greater. Milk, of all the foods, attracts infection, even if the milk is not directly infected. The animals from which the milk is obtained first introduce infection; reference was not made to tuberculosis but to filth. The udder of the animal may be the means of introducing into the milk streptococci, which are capable of causing virulent forms of diarrhea. Dirt, while milking, is likewise introduced. Further, in going from receptacle to receptacle in commerce, milk is exposed to many sources of infection. All practical persons will agree that cleanliness is the light that has penetrated the dark and baffling problem of infant feeding. The basis of artificial feeding is necessarily breast feeding, although by this natural process the greatest diversity is found in the quantity and quality of the food, giving equally brilliant results. In a limited number of studies upon breast-fed infants it is shown that there is much variety in quantities; where one infant will take only 89 caloric equivalents daily, another will take 126. Both infants at the same time will be equally well nourished. Another feature, fat varies in the milk of different breasts, yet children of each breast thrive. The problem is a more difficult one in the case of milk from the cow. The milk must not only be diluted, but the waste is large, even in thriving infants, of the proteid constituents of the milk. An indication of this is phosphoric increase in the excreta. Both mild and severe forms of gastro-intestinal diseases are therefore infectious.

DR. IRVING M. SNOW, of Buffalo, N. Y., read a paper on

INTESTINAL OBSTRUCTION THROUGH A LOOP FORMED BY MECKEL'S DIVERTICULUM WITH LIGAMENTOUS ATTACHMENT.

with specimen showing a Meckel's diverticulum of 12 inches; the constricted portion was the last foot of the ileum. A three-year-old boy was the patient, and up to the present illness he was in good health. The history of the case is, that falling some little distance from some steps he struck on the abdomen to the right of the navel. He suffered no bad effects from the accident and in an hour's time there was complete relief. He ate freely of grapes a day or so later, and it was believed that this dietetic indiscretion, by producing intestinal irritation and increased peristalsis, was the exciting cause of the obstruction. He had a normal fecal passage three days after the accident, but for four days he vomited persistently, and laxatives

and enemata failed to move the bowels, which for five days were obstinately constipated. Agonizing and almost continuous abdominal pain was present and opiates were required. There was no tenderness, induration or abdominal tumor to be felt. There was a slight distention of the belly, with a little gurgling and rumbling on palpation. The temperature was only a little above normal and there was no fever during the entire course of the illness. The patient died inside of twelve days. The cause of death, as shown by the post-mortem, was due to exhaustion and inanition from pain, vomiting and interruption of assimilation from an unrecognized abdominal obstruction. As the condition was not recognized as intestinal obstruction, it was not relieved by operative treatment, hence, it ended in death.

A case was reported by DR. AUGUSTUS CAILLE in which the symptoms of obstruction were present, although the obstruction was not complete. Exploratory laparotomy should be made in such instances on the first occasion of fecal vomiting. The patient might have been saved by prompt surgical interference.

A case that was not operated upon until the symptoms became alarming was reported by DR. SAMUEL S. ADAMS. There was a free movement of the bowels while the patient was being placed under anesthetics. The invagination was not found to be disturbed.

In a case reported by DR. W. S. CHRISTOPHER, where air was injected into the intestines after the abdomen was opened, he said that sufficient pressure could have been exerted to burst the intestines without loosening the intussusception. As this was the second time intussusception had occurred in the same patient, the case was of more than usual interest and Dr. Christopher noted that the patient recovered from the second attack.

DR. IRVING M. SNOW said it was very difficult to make a diagnosis in cases where the symptoms are obscure. An exploratory incision should be made even if there be a doubt as to the diagnosis.

DR. B. K. RACHFORD, of Cincinnati, O., presented a paper entitled

PANCREATIC DIGESTION OF CASEIN.

In his experiments he used rabbits' pancreatic juice. This was collected in a common receptacle and then equally divided between digestion tubes by an experiment giving to each tube an equal quantity of pancreatic juice of like digestive capacity. The bile, which was also obtained from the rabbit, was filtered before using. Ordinary dairy milk, boiled and neutralized, was employed. Free fat or butter, he ascertained at the close of such experiments, floated on the surface of digestive mixtures in which the milk had been subjected to the action of both bile and pancreatic juice.

DR. AUGUSTUS CAILLE thought hydrochloric acid a proper agent to assist digestion in a child from one to two years of age.

DR. L. E. HOLT was opposed to giving hydrochloric acid to infants. He approved of diet exclusively.

Farinaceous matter, DR. T. M. ROTCH said, did not assist the digestion as much as lime water, and on that account he rather objected to the former.

DR. RACHFORD said his object was to determine how a baby should be treated, and the manner of these investigations could be determined afterwards. To his mind there were two things to consider, (1) whether hydrochloric acid caused a larger amount of casein

to be digested by the pancreatic juice, and (2) whether hydrochloric acid was found upon examination to be deficient.

DR. AUGUSTUS CAILLE read a paper entitled

CLINICAL OBSERVATIONS UPON THE OPERATIVE TREATMENT OF TUBERCULOUS PERITONITIS,

and stated a case in which a diagnosis of tuberculous peritonitis was made by exclusion. In this case tuberculosis of the hernia sac developed, the Bassini operation for the cure of the hernia at the same time effecting a cure of the tuberculous peritonitis. He stated, however, that the abdomen was not encroached upon. Other cases referred to by him presented solid tubercular tumors of the peritoneum and mesentery. He had observed these cases himself and the variety was distinct from the other well-known forms of tuberculous peritonitis. In another case the diagnosis was made very early, but operative interference refused. For nearly two years every well-known method of medication, both internal and external, was persisted in, but without any apparent benefit. His conclusion was that medication was useless so far as cure is concerned. He stated that diagnosis is made by exclusion except where the tuberculosis bacillus is found in the puncture fluids, when a diagnosis is positive. Exploratory laparotomy, in all doubtful cases, is imperatively indicated because surgical interference can effect a cure only in cases that are recognized early and when they are not complicated by tuberculosis of other parts. He stated that in every case observed by him there was a low, irregular tumor. The main diagnostic features are the abdominal symptoms—pain, distention, disturbed bowel action, affusion.

DR. T. M. ROTCH referred to more than 200 autopsies in fatal cases of diphtheria in infants and young children, there being 17 or 18 cases of tuberculosis in some part of the body. He dwelt on the importance of diagnosis between primary and secondary peritonitis. In the secondary condition, the treatment of tuberculous peritonitis is nearly useless. In the primary instance, however, good results are obtained from laparotomy. A case was reported by him in which an enlarged mesenteric gland was removed, and the importance of the early removal of such glands when tuberculous was strongly emphasized, as in this way a further spread of the infection is prevented. He considered the use of tuberculin in diagnosis very important, especially where there is a low range of temperature.

DR. J. HENRY FRUITNIGHT reported obtaining good results in a number of cases of tuberculous peritonitis following an operation in the Children's Hospital, New York, but, in his opinion, recovery could not be considered permanent.

In the absence of positive clinical evidence, DR. A. C. COTTON stated that he was turned to bacteriological findings to decide the diagnosis in suspicious cases of tuberculous peritonitis. He drew attention to the indications for exploratory laparotomy in such cases.

This brought a reply from DR. ROTCH that he did not see why exploratory laparotomy should not be made in all cases.

DR. JACKSON emphasized the advisability of examination of the blood for leucocytosis, but questioned whether such examination would separate the disease from typhoid fever.

DR. CAULLE did not consider medicinal treatment of any avail in these cases. He did not think it worth while to waste any time on guaiacol and creosote. He considered it the absolute duty of the operator to open the abdomen if the disease is suspected. Fluid in the abdomen may be due to a chronic muscular infection, a large spleen, sarcois, anemia, nephritis, or to valvular disease of the heart. The opening of the abdomen, if the diagnosis could not be made otherwise, was harmless, as the patient, being anesthetized, suffers no pain. So far as the examination of the blood was concerned, he did not lay much stress upon it, as such an examination, he thought, would not differentiate cases of tuberculous peritonitis and every case of affection caused by chronic malaria or anemia. He admitted, however, such an examination might occasionally be useful in diagnosis.

SECOND DAY.

DR. EDWARD P. DAVIS, of Philadelphia, presented his paper, entitled

THE TREATMENT OF HYDROCEPHALUS BY CRANIECTOMY.

He cited a case of an infant six months old, the mother of whom had two other children, and was in excellent health before the birth of the present child. The birth was spontaneous, and the mother nursed the child for three weeks, at which time she was taken with what was called a "bilious attack." The secretion of milk failed and the child was fed upon starchy food. At the time of its birth, the child weighed $5\frac{1}{2}$ pounds, and 9 pounds at six months of age. The child was restless and had a poor appetite, and it was brought for treatment. It was stupid and apparently suffered from intracranial pressure. It was seen by Dr. W. W. Keen, in consultation at the Jefferson Hospital, where it was transferred, and an effort made to secure continuous drainage. The fluid was difficult to withdraw from the ventricles. The child was then anesthetized, and the cranium was trephined at one side of a sagittal suture, and in the parietal bone on the right side, antiseptic precautions having first been taken. The child finally collapsed and died.

So far as the operation was concerned, DR. ROTCH said it appeared to be quite simple. No bad results had taken place from the operation. He referred to a case in the Infants' Hospital at Boston in this connection, and said that the cases were either treated with one tapping, or there was frequent drainage with tubes introduced into the ventricle, the fluid being withdrawn every day. He did not think that the operation was curative, but thought perhaps it might be palliative, the child being more comfortable for the time being.

A case was reported by DR. DORNING where 2 ounces of fluid were withdrawn. The child was quiet after puncture and seemed to improve for some three weeks. Unfortunately, he lost track of the child, so that definite results could not be reported.

Three interesting cases were reported by DR. KORLIK, which came under his observation. One of them was a baby seven months old which developed symptoms similar to those in tuberculous syphilis. It was tapped in the lumbar space, and from 10 to 20 centimetres taken, which varied according to the indi-

cations. There was a visible improvement after each tapping.

DR. ROTCH recited his experiences in the Infants' Hospital, where great care had been taken to tabulate the amount of pressure under which the fluid was withdrawn, and the amount up to the time the child died. His opinion was that it was a palliative treatment.

DR. DAVIS said that the danger of immediate death appeared to depend largely in this case upon the amount of fluid which was drawn. He laid stress upon the care to be exercised in withdrawing the fluid so that very little should escape. Hence the effort to maintain pressure while the drainage was being inserted.

DR. ROLAND G. FREEMAN, of New York, presented his paper, entitled

NEPHRITIS OF INFLUENZA IN CHILDREN.

He cited the case of a four-year-old boy, who, for three years past, has suffered from influenza. The ordinary symptoms of cold, prostration, fever and moderate earache accompanied the present attack in January, 1899. There was no discharge from the ear. His temperature on January 31st was 102.5° . On February 5th it reached 105° , then gradually diminished. On February 9th it varied between 100° and 101° . Some very red urine was passed on this date containing a large amount of blood, about 5% by bulk. The doctor thought that, although albumin is fairly frequent, the influenza nephritis is a rare complication. The nephritis complicated in influenza is usually clinical of an acute hemorrhagic type, and morphologically shows toxin lesions. The attacks occur more frequently apparently in children than in adults. He added that any disturbance may appear some days after the acute symptoms of influenza and sometimes a month later.

DR. FRUITNIGHT stated that he had found but 1 case of albumin in 57 cases, and this had disappeared in a few days.

More care should be exercised in examining the children, DR. DORNING said, in his report of 3 cases of complicated nephritis; he cited the fact that one child nine years of age had shown some adenia of the face. Upon examination of the urine, 30% of albumin and a large number of blood casts appeared. It was three weeks later before the casts and the albumin disappeared. In another child of four years, which showed adenia on the face, pathological and blood casts were found which cleared up and are now entirely well. The third case reported was that of a four-year-old child, in which it appeared that influenza affected every member of the family. A very pronounced form of nephritis was shown. An examination of the urine showed blood casts and 50% of albumin.

One case of nephritis was reported by DR. JENNINGS, following a double infection. The nephritis followed an attack of influenza and was of a mild character. The urinary findings amounted to 16 ounces and its specific gravity 1.015. The urine cleared up in a very short time and on the third day the blood casts disappeared. For a week later the granular casts persisted in a few numbers. The urine increased to 20 ounces on the third day and 28 on the

fifth day. The child was practically convalescent after that period.

It would be very interesting, said DR. ROTCH, to see a case following nephritis. He thought that these cases of nephritis and influenza are of an acute interstitial type, following the general rule of an infectious disease. A diagnosis of any special form of renal disease in young children should be made by means of an examination of the urine, and he laid stress on this point.

A case was reported by DR. CARR, which to him bore a very striking feature, namely, that the child suddenly developed a taste for sugar. The case was interesting to him by reason of a sudden increase in the specific gravity, the child's fondness for sugar and the absence of albumin.

A question was raised by DR. CHURCHILL whether in these cases of influenza, as well as other infectious diseases, they are not often the beginning of inward trouble which developed later on in life, particularly at puberty or later. He wanted to know whether we find manifestations of inward trouble by careful and thorough examination of the urine. A case was cited by him of a young man, nineteen years of age, who was suffering from an attack of appendicitis. While examining the urine, simply as routine practice, he found chronic nephritis.

DR. FREEMAN stated that more than a year ago the examination of this child's kidneys had been made, and that during all this time the kidneys remained perfectly right, and there had never been any deviation from the normal. There was no otitis at any time, and it did not figure as a factor in the matter. The child had complained during the months of January and December of pain in the ear at times, but it would pass off in a short time and would not recur for a week perhaps. The cases reported by him, he said, were the result of an exhaustive search through the literature of ten years past, and by calling attention to the matter he hoped it might be of interest to others.

DR. AUGUSTUS CAILLE presented a paper on

SUDDEN DEATH FROM PERFORATION OF TRACHEA AND BURSTING OF CASEOUS GLAND.

He showed a specimen which, he said, had been taken from a body of a girl with a diagnosis of bronchitis. A cold basis about the size of a walnut was revealed by the autopsy. This was a little above the bifurcation of the trachea. It had ruptured into the trachea, the contents being a cheesy matter, which had completely flooded above the trachea. This child, it was stated, had been sent in by some doctor with a diagnosis of bronchitis. In going over the child, however, the house physician had heard a few râles underneath the sternum. There was no fever and no pain, and but little cough.

DR. BLACKADER referred to the bronchial nose and thought that a large nose interfered to some extent with the entrance of air, especially if it has been associated with bronchitis.

Post-mortems, DR. FRUITNIGHT said, had, in several cases, revealed enlarged bronchial noses. In this case, auscultation had not revealed the presence of bronchial nose, and it did not possess any symptoms to indicate the presence of this condition.

A case was reported by DR. WEST where the symptoms disappeared and then reappeared. It was due,

he thought, to an enlargement of the glands. In one case the child had a cough that resembled whooping cough and there was a resemblance to whooping cough in another case he had in mind.

DR. A. C. COTTON, of Chicago, presented a paper on

CONGENITAL CARDIAC MALFORMATION WITH ENDOCARDITIS AND ANURIA.

The family history in this case was negative, and there was no history of syphilis obtainable. The baby was born March 19, 1900. It weighed at birth 7 pounds and 4 ounces, and was 22½ inches in length. It was well developed and presented no external malformations. There was a marked pallor which changed to a greenish hue, actual cyanosis supervening gradually as a light symptom. There was a loud, harsh diastolic murmur upon examination of the heart, which was heard all over the chest, and it was difficult to locate the exact position of this murmur. The child died of progressive asthenia on the fifth day, there having been no urine secreted.

(To be continued.)

Recent Literature.

Ear Records. A Method of Recording Ear Cases.

By JOHN C. LESTER, M.D., and VINCENT GOMEZ, M.D. Pp. 175. New York: J. W. & George H. Hahn. 1899.

The method of recording ear cases provided for in the record book of Drs. Lester and Gomez has evidently been very carefully considered with a view to including all items likely to be demanded in the running record of the personal history, functional examination, physical examination and treatment of the majority of cases of aural disease. The book is provided with a lettered name index, and has on each page a schematic figure of the sound-transmitting apparatus of the middle ear, and in addition sufficient space for notes. Based upon the method of Dr. Rohrer, of Zürich, this book, for practitioners who use this form of case record, will be found to be practical, suggestive and time saving.

Manual of the Diseases of the Eye. For Students and General Practitioners. By CHARLES H. MAY, M.D. Pp. 406, with 243 original illustrations, including 12 colored figures. New York: William Wood & Co. 1900.

The author in preparing this handy little volume has kept well in mind the desire on the part of the medical student and the general practitioner to possess a manual which shall contain the essential facts of ophthalmology and at the same time not be overburdened with theory and irrelevant detail. Although it is very elementary in character and not likely to be of especial interest to those who are familiar with the more pretentious treatises on this subject, it will nevertheless serve as an easy introduction to an already extensive special literature. An unusually full index facilitates a ready reference.

PHYSICIANS AS SPEAKERS.

THE matter of public speaking is becoming one of greater and greater importance to physicians. It certainly rarely happens nowadays that a man goes through his professional life without being called upon to express his thoughts at some time before an assemblage of his associates. That some men, and we are disposed to think a growing number, do this well is undoubted; that others, and we fear this is the larger proportion, fail lamentably in expressing their ideas in an interesting and convincing manner is equally self-evident. The demands of medicine as a profession do not particularly call for the cultivation of oratorical gifts, as law, for example, is supposed to do; nevertheless attention to the principles of public speaking should be developed far more than is ordinarily done.

An interesting criticism and analysis of the shortcomings of physicians in this regard has recently been given by William Whitford, official stenographer of the American Medical Association, in a paper entitled "Physicians as Speakers," recently published in the *Journal of the Association*. Mr. Whitford unquestionably speaks from a dearly-won experience, and his suggestions are worth more than a passing notice. One can hardly imagine a more trying position than that of a stenographer who is called upon to report with exactness the remarks of a body of medical men. He is in a position to recognize faults which a less responsible person might easily overlook, and to place the blame for the often criticised reports exactly where it belongs. Mr. Whitford gives much good advice, which we have no doubt will be read by physicians with no feelings of resentment and we hope with some sense of personal application. We are told that the first duty of a physician in addressing an audience is to make himself heard, a warning which is frequently unheeded in spite of the best intentions. The following paragraph, which we quote in part, admirably expresses the real point at issue: "The real secret of effective delivery lies in the ability of a speaker

to impress himself with his subject. He for the time becomes the standard by which all thought and feeling and sentiment of a whole assembly are measured; nor can he hope to produce in his hearers an interest greater than his own. A good speaker, as his mind becomes inflamed with unwonted activity, rises to a plane of thought and feeling of which he himself is altogether incapable in his calmer moments. His conception is sharpened and his thoughts come with a clearness and precision that leave no time for hesitation. The mind, as it were, becomes intoxicated with its own ideas. The perception of the hearer is correspondingly quickened, and the audience, catching the inspiration of the speaker, unconsciously rises with him if animated by the same spirit."

Our experience has been that if a man is really deeply interested in his subject and has the enthusiasm which always goes with such interest, he can hardly fail to impress himself upon his audience, however lacking in oratorical finish his remarks may be. Self-consciousness must be laid aside, as a prerequisite to success in speaking before an audience; if that can be done the subject is given an opportunity. Again, we are warned against over-diffuseness and are told that this is an error most common among young physicians, although their elders are not always exempt. Diffuseness is certainly one of the most glaring faults to which young and old are alike exposed, and which does more to deaden interest even than poor delivery. We are, however, by no means sure that Mr. Whitford is right in attributing this error especially to the young. In fact we have a vague impression that men of the older generation are at times likewise prone to verbosity. We should rather say that over-detail is a weakness of youth and diffuseness a fault of riper years. The indefinite wandering into fields of experience is one of the labyrinths into which the relative inexperience of the younger man is not likely to lead.

As in all other classes of public speakers, Mr. Whitford finds that physicians vary greatly in the rate of utterance, from a hundred and ten to a hundred and sixty or more words a minute, from which it is clear that the difficulties of the stenographer are in certain cases greatly increased. Here comes in a defence of the reporter, of which we are glad to make mention. It is common enough to hear complaints on the part of individuals who have spoken at medical gatherings that their remarks have been miserably reported, that they never could have said what they have been credited with, and so on. Mr. Whitford gives fourteen reasons why reports may at times be inaccurate, through no fault of the stenographer, all of which, no doubt, are important. One, however, he omits, which certainly should have a place, and that is the carelessness of the speaker. Comparatively few men realize exactly what they say when speaking extemporaneously; repetitions are unnoticed; extraordinarily inappropriate words are used, and sentences mangled in various ways, all of which is

attributed to the inefficiency of the reporter. If speakers knew exactly what they had said, there would be far less criticism of the stenographic reports which they look at with dismay perhaps a week or two after the occasion of their remarks.

This really entertaining discussion closes with a classification of speakers, of which Mr. Whitford finds thirty-eight varieties. A few of these we give: The moderately slow speaker; the exuberant and tempestuous speaker; the musical, flowery speaker; the loud, husky speaker, whose voice is somewhat indistinct; the grandiloquent speaker; the rapid and spasmodic speaker; the one who hurls disconnected sentences at the reporter; the clear, distinct, unassuming speaker, who talks with absolute precision, with perfect grammar; he is a *rara avis*; the physician who commences his speech in a deliberate, measured, distinct, far-reaching tone of voice, and who, when he becomes influenced by the magnetism of his audience and their rapt attention, gives vent to rare flights of oratory; the man who does not realize that his first duty is to make himself heard; the physician who never completes his sentences, but is utterly oblivious of that fact when he criticises the report of his speech; the foreigner who imagines that he speaks like a native; the man with a strange and unfamiliar style, whose sentences are portentously long; the rapid and monotonous speaker who becomes tangled in his own sentences and mispronounces words; the physician who is known for his elegant diction, his scholarly references, and the ornateness of his phraseology; the physician who stutters, speaks indistinctly, and yet is extremely technical; the pompous speaker; the physician who begins a sentence, but is not satisfied with its construction; he therefore draws up, makes a plunge in another direction, wanders about in a maze, and finally lands in a region of impenetrable obscurity; the physician who is afflicted with that terrible malady — *cacoethes loquendi*.

We trust none of our readers are in any of these classes; if such be not the case, however, possibly the pinching of the shoe may have a salutary effect.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE ARMY.

SURGEON-GENERAL STERNBERG'S report for the fiscal year ending June 30, 1900, of which we have before us an advance summary, is of more than usual interest because of the added duties and responsibilities of the medical arm of the service incident to our recently acquired possessions. In spite of the increased demands being made upon the medical department it appears that there are at present but 192 officers, a number hardly sufficient before the outbreak of war with Spain, and wholly insufficient when the strain of that campaign was well inaugurated. Since the close of the war the medical department has been undermanned, rendering necessary professional assistance

from civil life. The surgeon-general acknowledges the excellent service received from this source, but insists that much experience is needed to fit these civilians for the sanitary work required, and to render them familiar with army methods. On the 30th of June there were 462 acting assistant surgeons under contract, all of whom have been examined by properly constituted boards relative to their physical and professional fitness for the discharge of their duties. Two boards of specially qualified physicians have been appointed for the study of tropical diseases, one for duty in and about Manila and the other in Cuba. The army nurse corps appears to be in a very satisfactory condition. There were 210 female nurses in the service June 30th. There are now 122 nurses in the Philippines as against 33 the beginning of the year. Women are serving in increasing numbers on the army transports in the Pacific; the service of these nurses is highly appreciated, and they are in demand at almost all hospitals of importance. As time goes on the organization of the army nurse corps has improved, and its adjustment to the conditions in the army made more satisfactory in details.

A number of new hospitals have been opened during the past year, among them one at Fort Bayard, New Mexico, for the treatment of army officers and men suffering from pulmonary tuberculosis.

The following comparative statistics are of interest regarding the health of the army in 1899 as compared with 1898. During the calendar year 1899 there were 229,885 admissions to sick report recorded in a mean strength of 105,546 regulars and volunteers. This is equivalent to a rate of 2,178.06 per thousand of strength as compared with 2,146.18 per thousand during the year 1898, and with 1,237.24, the mean annual rate for the decade 1888-1897. Of the admission rate for the year, 714.99 was constituted by malarial diseases, 380.69 by diarrheal diseases and 192.48 by injury, of which 21.56 admissions per thousand men resulted from gunshot; typhoid fever contributed only 20.69 cases per thousand of strength. Of the admission rate for 1898, malarial fevers constituted 611.78, diarrheal diseases 388.62, injuries 140.38, of which only 13.92 resulted from gunshot; typhoid fever contributed 141.59 cases per thousand of strength.

The report from the Philippines shows a considerable number of sick and a relatively large death rate among the troops, due, no doubt, to the exposures and fatigues of a long campaign. The opinion is said to be prevalent among medical officers that in time of peace and while doing only garrison duty, the sick rate of the army in the Philippines would be no higher than it ordinarily is in the Southern United States. Malarial fever, diarrhea and dysentery head the list in point of numbers. A relatively small number of cases of typhoid fever is reported, and but 238 cases of wounds and injuries out of a total of 2,807. The cases of malarial fever, on the other hand, constitute approximately one-fifth of the whole number.

The whole report is worth a careful reading, as

demonstrating both what has been accomplished in the way of prophylaxis and treatment, and also as showing how much remains to be done before the medical department may look with entire complacency at its work. To accomplish the best results it is clear that the medical corps must be materially increased in numbers.

MEDICAL NOTES.

YELLOW FEVER IN CUBA.—The situation in Havana regarding yellow fever is not encouraging. Every part of the city has contributed cases, and it is thought that many of the inhabitants will leave unless an improvement in the conditions takes place soon. The south side of Cuba, on the other hand, of which Santiago is an important city, is practically exempt from the disease, owing to the precautions taken by General Wood, and the fact that few Spanish immigrants, who are apparently particularly susceptible to the disease, come to that part of the island. General Wood is reported to have said that the large amount of yellow fever in Havana is due to the constant arrival of these immigrants, and also, from a later reported interview, that the relative number of cases this year as contrasted with previous years is really about the same, though apparently greater, because of insufficient returns heretofore.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, October 24, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 122, scarlatina 31, measles 23, typhoid fever 25.

LIABILITY OF PHYSICIANS IN THE COMMITMENT OF INSANE AND INEBRIATES.—The full Bench of the Supreme Court of Boston, in a recent decision, sustains the judgment of the Superior Court relative to the liability of physicians in committing insane and inebriates to institutions. The court holds that physicians, acting under our statutes relating to the commitment of dipsomaniacs and insane persons, are not liable for mere negligence in making a false certificate that a person was a dipsomaniac or inebriate, as a result of which the person was committed to the hospital at Foxboro for inebriates, provided they act in good faith and without malice. The decision is put upon two grounds: (1) Because assuming the defendants' examination was a careless one and their certificates false, their conduct was not the proximate cause of the commitment of the person, as a judge must, under the statutes, determine that, and (2) public policy, because they should be protected against liability by being made privileged, like parties and witnesses in other cases, as long as they act in good faith and without malice.

BOSTON SOCIETY OF MEDICAL SCIENCES.—A meeting of the Boston Society of Medical Sciences was held October 23d, the general subject of the evening being the first annual report of the Cancer

Investigation Committee to the Surgical Department of the Harvard Medical School. Dr. J. C. Warren spoke of the conditions under which the investigation is being undertaken, and showed, as did Dr. W. F. Whitney in remarks which followed, charts illustrating the increase of cancer during recent years. Dr. E. H. Nichols read a paper on "The Etiology of Cancer," in which he discussed the existing evidence for and against the parasitic theory of the disease, and gave the results of his own investigations, which are, as yet, inconclusive. Dr. R. B. Greenough presented a communication representing his work on the histology of mammary cancer. Mr. E. E. Tyzzer spoke on "Tumors and Sporozoa of Fishes." Mr. E. M. Locke showed a wax reconstruction of a nodule of cancer, and described the technique. Dr. Oscar Richardson gave the results of attempts to cultivate the parasites of cancer, which were unavailing.

DIPHTHERIA IN BROOKLINE AND WALTHAM, MASS.—A number of cases of mild diphtheria have been brought to the notice of the Board of Health of Brookline. It is at present confined chiefly to school children. A second circular to parents has been issued and distributed, warning them to take all possible precautions against the spread of the disease. Waltham is also suffering from a mild epidemic, confined to no special portion of the city. The contagious hospital is already very much overcrowded, so that it has become necessary to care for a number of patients at their homes.

INCREASE OF TYPHOID FEVER IN CONNECTICUT.—During September, while most of the infectious diseases decreased in Connecticut, there was a striking increase in the number of cases of typhoid fever. It is reported in fifty-four towns, and the cases number 228, as compared with 190 in August, making a total in two months of 418, which is 51 in excess of the same months in 1899. The increase is to be attributed largely to the low state of the wells. There is reason to expect an increase of typhoid in October.

ENFORCEMENT OF BOSTON MILK REGULATIONS.—Eleven dealers, charged with violation of the milk law, have recently been tried in a Roxbury, Mass., court. The court imposed a number of fines, one of the offences being the use of formaldehyde as a preservative, a violation of the law which forbids the use of foreign substances in milk.

NEW YORK.

VERDICTS OF \$37,000 AND \$7,500 FOR DAMAGES.—On October 17th in the Supreme Court Mrs. Elizabeth Rhoades obtained a verdict for \$37,000 damages against the Metropolitan Street Railway Company for the death of her husband, Captain George B. Rhoades, of the Seventh Regiment, in July last. This is the largest amount ever rendered against a surface railroad in New York in a suit growing out of personal injuries or death, due to the alleged negligence of the railway company. Two days later in Part V of the Supreme Court a jury

rendered a verdict of \$7,500 damages against the same company. This was the second trial of a case in which at the first trial, in June, 1899, a verdict was given awarding six cents damages for the life of a child who was killed by a trolley car, the smallest sum ever awarded in a similar case in the history of the State. The foreman of the jury explained after the trial that this insignificant amount was decided upon because the father of the child was rich. An appeal was promptly taken to the Appellate Division of the Supreme Court, where the six-cent verdict was set aside, and a new trial ordered.

NEWARK'S WATER SUPPLY. — In the last issue of the *JOURNAL* brief mention was made of the acquisition of the Pequannock water supply. Newark has now become the absolute owner of a water supply ample for all the needs of the city for fifty years to come, and capable of still further enlargement at comparatively small cost. With an outlay of \$6,000,000 there have been acquired the water rights of the Pequannock Valley and a plant capable of delivering by gravity to the distributing reservoirs a daily supply of not less than 50,000,000 gallons of clear, unpolluted water. With the construction of three distributing reservoirs, the necessary pumping stations, and a large storage reservoir at Cedar Grove, and with the cost of the connecting mains and 250 miles of street mains, the total expenditure will amount to \$10,700,000. Incident to the establishment of the water plant Newark has enforced economy in the use of water by compelling the use of meters by consumers who are likely to waste water. Thus far 9,000 meters have been installed, and since May 1st, 1899, the consumption of water has thereby been reduced 6,000,000 gallons a day.

CONTRACT WITH A LUNATIC. — Another case of medico-legal interest has just been decided in the Appellate Term. One Louis Fiegenbaum, who was of unsound mind, but had not been judicially so declared, applied to a well-known firm of lawyers to institute an action for divorce against his wife, paying them \$110 on account, in advance. One of Fiegenbaum's delusions, it seems, was with respect to the fidelity of his wife, though the lawyers were entirely ignorant of his mental condition and undertook the case in good faith. A summons and complaint was made by them, but was never served. In a suit by Mrs. Fiegenbaum, as committee, in the Fifth Municipal Court, to recover the sum advanced by her husband, the case was decided against her. In the Appellate Division of the Supreme Court this judgment has now been reversed, the court holding that the mere drawing of the summons was not a bringing of the suit, but only a preliminary step, and of no use or advantage to the plaintiff, and that, therefore, a cause of action had been made out against the lawyers, as for money had and received.

MIDWIFE HELD FOR CAUSING AN INFANT'S BLINDNESS. — Mrs. Barbara Harpreicht, a midwife, has been

held in \$600 bail for trial, charged with causing, by her negligence, the blindness of an infant at whose birth she officiated last spring. This is said to be the first case of the kind in recent years in which the Health Department has been able to get the evidence in such a shape as to enable it to proceed against the responsible person, although it is well known that a large part of the blindness existing at present has been caused by neglect and improper treatment during early infancy. The section of the Penal Code under which the woman will be tried provides that when the eyes of a young child whose birth has been attended by a midwife become affected, the midwife is forbidden to treat or prescribe for the condition, but must either notify the board of health or secure the services of a physician. Violation of the statute is punishable by a fine of \$250 or six months' imprisonment, or both.

THE EFFECT OF TWO BULLETS IN THE HEAD. — At the autopsy of a male patient, sixty-five years old, who died recently in the insane pavilion of Bellevue Hospital, where he had been confined for one month, it was found that there were two bullets, from a .22-calibre revolver, in the head, one being lodged in the structures of the internal ear and the other in the substance of the brain. Nothing was known of the man's history, but later Dr. John A. Beurman called at the coroners' office and stated that he had been acquainted with the deceased, and that several months ago the man had informed him that he had fired two shots into his brain with suicidal intent. He had, however, discredited his story at the time.

LAPAROTOMY UNDER SPINAL ANESTHESIA. — In a laparotomy performed at Bellevue Hospital last week, for the removal of a malignant abdominal growth, Dr. Henry C. Coe employed with entire success Dr. J. Leonard Corning's method of anesthetization by the injection of cocaine within the sheath of the spinal cord in the lumbar region.

A CASE OF YELLOW FEVER IN NEW YORK CITY. — A mild case of yellow fever is reported to have developed among the passengers of the Ward Line steamer *Mexico*, which arrived from Havana on Tuesday. The passengers and patient are under observation.

REQUESTS OF \$5,000 TO FOUR HOSPITALS. — By the will of Ignatz Hoff, who died recently in New York, a bequest of \$5,000 each is left to the German Hospital and Dispensary, St. Francis's Hospital, the Columbus Hospital, and St. Joseph's Hospital.

Miscellanp.

THE ENDOWMENT OF PROFESSIONAL SCHOOLS.

We quote the following from a recent article by Rev. James H. Ross, of Cambridge, Mass., relative to the question of the endowment of professional schools:

The question of the medical school and the law school receiving only those who have given themselves the advantage of a liberal education is a question of profound significance to American life. It is also, in particular, a question of gravity for every member of the professional faculty and for every member of the board of trust which manages a school of law or a school of medicine. For if the student is to give so large a share of his life's time to the preparation for his life's service, if he come up to the law school or to the school of medicine with powers well trained, with the capacity of appreciation large, with his character matured, he has a right to demand of the professional school that it shall give to him advantages adequate to the ripeness, richness and maturity of his character. It is simply absurd for a medical school or a law school, such as can be found in many of our States, to demand that candidates for admission shall have a college training; for the schools cannot offer adequate opportunities to men of these advanced attainments. For medical schools, such as can be found in many of the great cities of this country, to ask that students who are admitted shall be liberally educated is quite as absurd as for a high school in New York or Boston to require that candidates for its junior class shall have already taken a college course. The medical college which demands a liberal education from candidates for admission should offer as good teaching in the fundamental branches of anatomy, physiology, bacteriology, chemistry, histology, materia medica, therapeutics, and in special branches, as these candidates themselves have received in Latin, mathematics, philosophy, German, and history in the undergraduate colleges. These schools, furthermore, should offer the student a fitting scholastic environment. The medical college should offer to him hospitals and clinics having many cases and unique, and the law school should put into his hands a properly equipped library.

For schools of medicine and of law to offer the student such opportunities requires, primarily, money — and money, too, in large amounts. Professional education in this country has not yet received, with the exception of theological education, a fitting endowment. The theological schools of this country are now possessed of about \$20,000,000 of endowment, and the value of their buildings and grounds is about \$12,000,000. Be it said, also, that one-half of this amount is found vested in the theological seminaries of the North Atlantic States. Of the seminaries of the various churches the Presbyterian are the best endowed. About one-fifth of the entire amount of endowment funds of churches in America are found belonging to the Presbyterian Church. This endowment allows each professorship in these seminaries to have about \$40,000 in case there were an equal division of these funds. In the Congregational and Episcopal Churches the endowment would be about \$35,000 for each chair. But the endowment of the medical and law schools is so slight that one hesitates to give any figures at all. In fact, the endowment is so slight that some schools of law and of medicine are unwilling to reveal their poverty. The largest endowment in this country belongs to the medical school of Johns Hopkins University; the next largest is that of Harvard Medical School, and the next largest, so far as reported, is that of Western Reserve University Medical College. In a recent year \$1,500,000 was given to endow professional education in this country, and of this sum 63% was given to schools of theology, 17% to schools of medicine, 14% to schools of technology, and about 1% to schools of law. For the improvement of professional education in medicine and law the American people must give of their wealth with a generosity akin to that with which they have poured out their millions each year to the undergraduate colleges. The great need of American life at the present time is better trained doctors and better trained lawyers. This need can be met only by the rich endowment of schools for the training of doctors and lawyers; for it is only such schools, well endowed and well equipped, that can worthily and fittingly ask men of a liberal education to become their students. The next

movement in the endowment of American education should be directed toward the schools of law and the schools of medicine.

With these statements we are in essential agreement and are particularly glad to note that they come from a representative of the clerical profession; we think, however, that Mr. Ross loses sight of two important points in the development of his argument. In the first place, so far as we are aware, only those institutions which can offer to the student adequate clinical and laboratory facilities are demanding a preliminary training equivalent to a bachelor's degree. In the second place, it is no longer reasonable to class the schools of law and medicine as equally in need of endowment. Law is a study which requires relatively small provision for its students, whereas medicine, on account of the increasing demand for laboratory space and laboratory instruction and the necessarily greater length of the course, is each year becoming more expensive, and is by all means the most costly form of professional education.

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, OCTOBER 13, 1900.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diarrheal diseases.	Typhoid fever.	Diphtheria and croup.

Melrose . . .	15,411	5	3	—	—	—	—	—
Newburyport . . .	15,157	3	—	33.33	33.33	—	—	—

Deaths reported 2,369; under five years of age 889; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 626; consumption 262; acute lung diseases 246; diarrheal diseases 195; typhoid fever 71; diphtheria and croup 61; whooping cough 12; scarlet fever 10; cerebrospinal meningitis 8; erysipelas 4; measles 3.

From whooping cough New York 4, Philadelphia and Pittsburg 2 each, Baltimore, Boston, Lynn and Clinton 1 each. From erysipelas New York 3, Philadelphia 1. From scarlet fever New York 4, Philadelphia, Pittsburg, Providence, Worcester, New

Bedford and Haverhill 1 each. From cerebrospinal meningitis New York 3, Lynn 2, Worcester, Somerville and Gloucester 1 each. From measles New York 2, Boston 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending October 6th, the death rate was 17.8. Deaths reported 3,964: diarrhoea 406, acute diseases of the respiratory organs (London) 164, diphtheria 92, fever 66, whooping cough 49, scarlet fever 32, measles 28.

The death rates ranged from 8.7 in Croydon to 26.0 in Manchester: Birmingham 19.5, Bradford 14.7, Cardiff 14.2, Gateshead 23.4, Hull 16.2, Leeds 18.5, Liverpool 22.8, London 15.8, Newcastle-on-Tyne 22.7, Nottingham 13.8, Plymouth 16.3, Sheffield 21.4, Sunderland 25.1, West Ham 14.6.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 20, 1900.

E. G. DORR, medical inspector, detached from the Navy Yard, Portsmouth, N. H., on reporting of relief, and ordered home to wait orders.

B. F. STEPHENSON, surgeon, ordered to the Navy Yard, Portsmouth, N. H., October 25th.

H. E. ODELL, assistant surgeon, order to the Asiatic Station modified; to take passage on the "Solace."

B. F. STEPHENSON, commissioned medical inspector from May 31, 1900.

H. A. DUNN, assistant surgeon, detached from the "Dorothea" and ordered to the "Frolic."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING OCTOBER 18, 1900.

GASSAWAY, J. A., surgeon. Leave of absence for four days from October 15, 1900, under provisions of paragraph 179, Regulations, M. H. S.

STONER, G. W., surgeon. Granted three days' extension of leave of absence. October 16, 1900.

STONER, J. B., passed assistant surgeon. Granted leave of absence for twenty-two days from October 30th. October 12, 1900.

YOUNG, G. B., passed assistant surgeon. Granted leave of absence for one day. October 12, 1900.

CURRIE, D. H., assistant surgeon. To proceed to Indianapolis, Ind., in charge of the laboratory exhibit of the service, to be shown at the meeting of the American Public Health Association. October 12, 1900.

SCOTT, E. B., hospital steward. Granted leave of absence for twenty days from October 22d. October 13, 1900.

BOARD CONVENED.

Board convened to meet at the Purveying Depot, New York, N. Y., on Wednesday, October 24, 1900, for the purpose of revising the official supply table of the service. Detail for the board: Surgeon G. W. STONER, chairman, and Surgeon C. E. BANKS.

APPOINTMENTS.

ALBERT M. ROEHRIG, appointed temporary hospital steward and assistant chemist for duty at Immigration Depot, New York, N. Y. October 13, 1900.

W. F. SCHLAAR, reappointed senior hospital steward. October 13, 1900.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The first regular meeting of the society for the year 1900-1901 will be held at the Medical Library, 19 Boylston Place, on Monday, October 29th, at 8 o'clock.

Papers: Dr. H. F. Hewes will read a paper entitled "Observations upon the Symptoms and Treatment of Hyperacidity of the Stomach."

Dr. R. C. Cabot will present the subject of "Irritable Breasts, or Chronic Mastitis."

Dr. Fred'k J. Cotton will read a short paper on "Subperiosteal Fractures."

This is the last date for the nomination of new members for the December election.

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

NEW YORK STATE ASSOCIATION OF RAILWAY SURGEONS.—The annual meeting of the association will be held at the Academy of Medicine, New York City, on Thursday, November 15, 1900, under the presidency of Dr. J. L. Eddy, of Olean.

C. B. HERRICK, *Secretary*, Troy.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.—The thirteenth annual meeting of this association will be held in Atlanta, Ga., on November 13, 14 and 15, 1900.

EXAMINATION FOR LICENSES TO PRACTISE MEDICINE IN NEW HAMPSHIRE.

The next examination for licenses to practise medicine in the State of New Hampshire will be held at the State House, Concord, on Tuesday and Wednesday, December 11th and 12th, beginning at 8 o'clock A. M.

All unlicensed physicians who were not in practice in this State on and before March 16, 1897, must pass the examinations in order to receive a license to practise legally their profession.

All information regarding the examination will be cheerfully given by the Department of Public Instruction, State Library, Concord.

CHANNING FOLSOM, *Regent*.

RESIGNATION OF SAMUEL O. L. POTTER, M.D.

Dr. Samuel O. L. Potter has resigned from the Board of Trustees and from the chair of theory and practice of medicine and clinical medicine in the College of Physicians and Surgeons of San Francisco, and has severed his connection with that institution, of which he was one of the incorporators.

RESOLUTIONS ON THE DEATH OF JOHN M. BROWN, M.D.

At a meeting of the Medical Board of the New York Metropolitan Dispensary and Hospital, the following resolution was passed:

"Inasmuch as by the death of Dr. John M. Brown the Metropolitan Dispensary and Hospital has sustained a loss which is poignantly felt and with difficulty retrieved, and since, individually, we miss the rugged honesty, the incorruptible friendship which was constantly evidenced to us who knew him intimately, be it *resolved*, That this feeble expression of our esteem for his character and our appreciation of our loss be spread on the minutes and a copy of this resolution be sent to his family and to the medical press."

GEORGE MCAULIFFE, New York City.

RECENT DEATHS.

WM. R. LARKIN, M.D., a prominent Harlem physician, died of cerebral apoplexy on October 15th, at the age of forty-two. He was born in New York City and educated in Manhattan College. He was graduated from Bellevue Hospital Medical College in 1883, and afterwards served on the house staff of St. Vincent's Hospital. He was one of the founders of the Manhattan Hospital, now known as the J. Hood Wright Memorial Hospital, and for several years was one of the surgeons to the New York Fire Department.

JOSEPH L. CUTLER, M.D., for fifty years one of the leading surgeons of Alleghany County, died on October 14th, at his home in Bolivar, N. Y., at the age of seventy-one years. He was born in Moravia, N. Y., and was graduated from the Medical Department of the University of the City of New York in 1850. He served as assistant surgeon of the 134th Regiment, New York Volunteers, during the Civil War.

BOOKS AND PAMPHLETS RECEIVED.

Typhoid Fever and Our Water Supply. Anatomy of Hauging. Medical Education. By Edmund W. Holmes, A.B., M.D., Philadelphia, Pa. Reprints. 1900.

A Contribution to the Study of Anastomosis of the Hollow Viscera: A Modified Murphy Button. By John S. Miller, A.M., M.D., Philadelphia. Reprint. 1897.

A Short Practice of Gynecology. By Henry Jellett, B.A., M.D., B.Ch., B.A.O. (Dublin University), F.R.C.P.L., L.M. Illustrated. London: J. & A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1900.

Anleitung zur Diagnose und Therapie der Kehlkopf, Nasen und Ohrenkrankheiten. Vorlesungen gehalten in Fortbildungscursus für practische Ärzte. Von Dr. Richard Kayser, Breslau. Illustrated. Berlin: Verlag von S. Karger. 1901.

A Manual of Otology. By Gorham Bacon, A.B., M.D., Professor of Otology in Cornell University, New York. With an introductory chapter by Clarence John Blake, M.D., Professor of Otology, Harvard University. Second edition, revised and enlarged. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1900.

Progressive Medicine: A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., assisted by Charles Adams Holder, M.D. Volume III, September, 1900. GUNSHOT INJURIES BY THE RIFLES OF REDUCED CALIBRE.¹

BY LOUIS A. LA GARDE, M.D.,

Major and Surgeon, U. S. Army; Delegate from the United States Army.

A CONSIDERATION of the effects of the rifles of reduced calibre is properly divided into (1) the theoretical, (2) the experimental, and (3) the observations in war.

(1) *Theoretical.*—The theoretical considerations deal with the advantages claimed by Hebler and they relate to certain ballistic values which have been generally admitted, and to humane effects.

(2) *Experimental.*—To an audience composed of distinguished military surgeons, many of whom have been among the foremost experimenters to determine the difference in destructive effects between the rifles of large calibre and lower velocities as compared with those of reduced calibre and high velocities, it is needless to dwell upon the conclusions that are based upon this experimental evidence. Suffice it to say that these conclusions were generally unanimous, and that they sustained the advantages claimed by Hebler to a marked degree, especially as to humane effects.

(3) *Observations in war.*—The effects of reduced-calibre weapons in war now are becoming thoroughly understood, so that the material already accumulated, when properly worked out, will give us a definite idea of the real value of the new arm as a military weapon.

I come before you in this instance to add some observations upon the effects of the 7-millimetre Mauser rifle among 1,400 wounded in the Spanish-American War, a consideration of which may be discussed as follows:

(1) *Shock.*—Shock on impact, as you know, increases with the velocity and sectional area of the projectile. If you will remember the experimental evidence showed that the shock from the reduced-calibre bullet was always less than that of the larger calibre leaden bullet. Many surgeons have entertained the opinion that the small jacketed bullet would not possess sufficient stopping power to arrest a man when hit, and that this would be a strong argument against its use in war. Upon inquiry among the line officers in the Santiago campaign I find that as a rule, to which there were but exceptions, men when hit fell back at once. The universal impression therefore was that the Mauser possessed sufficient stopping power for the purposes of war.

(2) *Explosive effects.*—The terrific explosive effects so universally observed by the experimenters with the reduced-calibre bullets on animate and inanimate objects were seldom witnessed in the campaign. This seemed to be a contradiction of the established notion of the experimenters who had witnessed explosive effects by the new bullet upon impact with resistant structures up to a distance of 400 metres. If one stops to consider the nature of the terrain over which the various engagements were fought, the infrequency of explosive effects will not be so strange. The ground was broken, rocky and covered with trees and thick grass. It is fair to presume that the remaining velocity of the Mauser bullet was often very much

reduced. This was substantiated by the large percentage of lodged balls, in 10% of all wounded; and to their deformed appearance, showing evidence of ricochet. In an open field, on even ground, I dare say the explosive effects of the experimenters would have been realized upon resistant structures, at close range.

(3) *Flesh wounds.*—The smaller frontage of the jacketed Mauser bullet caused it to inflict flesh wounds of a corresponding diameter. The wounds of entrance and exit and the narrow track of the missile favored rapid healing. Infection was but seldom noticed, and when present it was almost invariably about the wound of exit, consisting of a slight slough, or a drop or two of pus under a scab.

(4) *Hemorrhage.*—Johann Habart, Surgeon-General, Austrian Army, who among the experimenters referred to paid special attention to the injury to the blood vessels, states that "blood vessels are seldom torn by the small jacketed bullet and that when wounded they are not closed so easily by coagulation as those severed by leaden projectiles." Writers have deduced from this statement that alarming or fatal primary hemorrhage would be more frequent in future wars. The experience in the Santiago campaign does not confirm these apprehensions. Of the 1,400 wounded none died of external hemorrhage, nor was it necessary to ligate a vessel for alarming hemorrhage on the field. The femoral, the external iliac and the ulnar were each tied once for diffuse aneurism; whilst the radial and subclavian were each tied twice for the same cause. There were 5 cases of gangrene from injury to blood vessels which required amputation.

(5) *Diaphyses.*—The gunshot injuries of the diaphyses were as a rule attended with but little comminution. A number of instances of complete perforation and guttering without fracture came under our notice. It was rarely necessary to open up wounds to take out loose fragments of bone. The infrequency of fractures attended with marked fragmentation was attributed to long range and to interference with the remaining velocity of the bullet from the nature of the field, as already mentioned.

(6) *Joints.*—In gunshot wounds of the principal joints, including the epiphyses, clean-cut perforations without fracture were the rule. As an illustration of the humane feature of the joint wounds by the reduced-calibre bullet it may be stated that out of 17 gunshot wounds of the knee joint, recorded in the "Annual Report of the Surgeon-General for 1899," 14 were restored to duty and 3 were invalided. No amputation, no death.

(7) *Head.*—Of 31 cases of gunshot injury of the head, 58.1% ended fatally. Some of the injuries were marked by extensive fracture and laceration of brain substance, doubtless from shots at close range; others were marked by clean-cut perforation at point of entrance and exit in calvarium, with surprisingly few brain symptoms. These were undoubtedly from shots in the mid and remote ranges. Guttered fractures were apt to show extensive comminution of the inner table.

A remarkable case of lodged ball is that of Private J. G., First Nebraska Volunteers, in which a Mauser bullet entered above the left eye, and remains lodged as shown in the skiagraph fifteen months after the injury, with no symptoms of paralysis.

(8) *Thorax.*—Fifty-three penetrating wounds of

¹ Read before the Thirteenth International Congress of Medicine and Surgery, at Paris, August 6, 1900.

the thorax were observed, with a mortality of 24.5%. This mortality is less than half that observed in the Civil War. This happy outcome is largely due to the diminished frontage of the jacketed bullet, and to the fact that it here usually traverses the lung, a tissue offering very little resistance and therefore but little opportunity for the exhibition of destructive effects. Although more than half the cases of penetrating chest wounds were restored to duty, quite a number suffered complications worthy of mention. Greenleaf, who followed up 24 of the 53 cases in the Spanish-American War, found that 37% of them developed complications like hemothorax, pyothorax, etc. He therefore calls attention to the fact that perforating chest wounds are not so trivial as they might seem.

(9) *Abdomen.* — Penetrating gunshot wounds of the abdomen were very fatal. Of 41 recorded cases, 29 died. Three laparotomies were performed at the First Division Hospital with fatal results. The fatal cases very likely died of shock and hemorrhage, fac-

ognized by Surgeon-General Sternberg, who caused a machine to be placed upon the hospital ship *Relief*, and one at the United States General Hospital at Key West, under men of recognized ability in photographic work.

No attempt was made to locate projectiles except with the x-ray. The orders in the Reserve Divisional Hospital were *not to remove lodged projectiles except for urgent reasons*, because of the extra time and labor which such an operation imposed upon the already overworked surgeons. The value of skiagraphy and the use of the fluoroscope were exhibited, (a) in locating missiles; (b) in determining the extent of bone lesion, so often desirable in proximity to the main joints; (c) in detecting supposed cases of guttering or perforation of the long bones without fracture; (d) and in probable lesion to nerves and tendons by loose spiculae of bone. The use of the x-ray in the latter has done much to interpret remote effects, such as paralysis, neuritis, loss of function, etc. Cases such as these occur especially in the forearm, foot and

NUMBER, REGIONAL DISTRIBUTION AND MORTALITY OF GUNSHOT WOUNDS IN THE WOUNDED WHO CAME UNDER TREATMENT IN THE AMERICAN CIVIL WAR AND THE SPANISH-AMERICAN WAR.

	Fractures	130	23	8.91					

tors which usually attend gunshot wounds in the explosive zone. The surgeons reported that the cases were apparently hopeless from the beginning. On the other hand, the 12 cases that ended in recovery very likely resulted from long range shots, or from projectiles whose remaining velocity had been lessened by traversing objects in their path. The edges of the small intestinal wounds were very likely closed by coming together, thus favoring healing without extravasation. In this connection I should state that our army had subsisted on a scant ration for three days before the battle.

Clothing or other infectious substances were not carried into wounds to cause inflammatory disturbances; and to this extent the work of the experimenters has been sustained. Indeed the small sectional area of the jacketed bullet of reduced calibre, its polished exterior, that affords little opportunity for the lodgment of dirt, and, again, the fact that it seldom deforms, add very much to the absence of infection in the wounds which it inflicts.

The value of the x-ray in diagnosis was early rec-

ognized by Surgeon-General Sternberg, who caused a machine to be placed upon the hospital ship *Relief*, and one at the United States General Hospital at Key West, under men of recognized ability in photographic work.

No attempt was made to locate projectiles except with the x-ray. The orders in the Reserve Divisional Hospital were *not to remove lodged projectiles except for urgent reasons*, because of the extra time and labor which such an operation imposed upon the already overworked surgeons. The value of skiagraphy and the use of the fluoroscope were exhibited, (a) in locating missiles; (b) in determining the extent of bone lesion, so often desirable in proximity to the main joints; (c) in detecting supposed cases of guttering or perforation of the long bones without fracture; (d) and in probable lesion to nerves and tendons by loose spiculae of bone. The use of the x-ray in the latter has done much to interpret remote effects, such as paralysis, neuritis, loss of function, etc. Cases such as these occur especially in the forearm, foot and

hand, from cicatrization of the wound channel, which often exhibits injury in the surrounding soft parts, due to secondary projectiles such as bone sand, fragments of softer tissues, like pieces of tendon set free by the energy of superior velocities. In all instances of gunshot injury in these parts the fluoroscope should be brought into use at the earliest moment to determine what should be done in the way of treatment to prevent distressing conditions that are difficult to relieve later. The skiagraphs exhibited revealed in a striking way the lesions wrought by the projectiles of reduced calibre.

The killed. — The regional distribution of the wounds among those killed in action was reported in 64 instances as follows: Head, 26; penetrating wounds of abdomen, 19; penetrating wounds of chest, 17; thigh, 1; leg, 1.

Captain W.C. Borden, assistant surgeon, U. S. Army, in a study of the regional distribution of wounds treated in the Santiago campaign as compared with the Civil War, finds some interesting results, especially in the wounds of the lungs and extremities. Antisepsis and

the humane effects of the new projectile have doubtless been the controlling factors.

The following tables illustrate the effects of the new armament on the target areas of the human body as compared to the conclusions based upon the results of many battles with the old arm. The Santiago campaign, as far as it goes, shows that wounds of the lower extremities are not nearly so frequent as they were observed in former times. The battle tactics which cause a man to lie down to fire, and to advance by rushes have doubtless added much to these results :

TARGET AREAS OF THE BODY.

Region of Body.	Percentage of the whole Area of Body.
Head, face and neck	8.51
Trunk	28.91
Upper extremities	21.14
Lower extremities	41.44

PURPURA HEMORRHAGICA, OR MORBUS MACULOSUS OF WERLHOF.

BY STEPHEN SMITH BURT, A.M., M.D.,

Professor of Physical Diagnosis and Clinical Medicine, New York Post-Graduate Medical School and Hospital.

THE hemorrhages in the skin which are associated with a variety of conditions, and are essentially symptomatic, will not be considered under the heading of this monograph. So also the less serious form of the disease in question, termed "purpura simplex," even though a mild expression of the more serious affection, will be excluded from present consideration. Reference here is made more especially to the grave malady, in which the cutaneous hemorrhages are often of minor importance, known as Werlhof's disease, or purpura hemorrhagica. We are indebted to Paul Gottfried Werlhof,¹ who was born in 1699, and who died in 1767, for its first comprehensive description, and for the name of "morbus maculosus of Werlhof" in consequence.

This disease is characterized by the occurrence of ecchymoses in the skin, the mucous membranes, the viscera, and the serous membranes, while, at the same time, there is more or less profuse hemorrhage from all the mucous surfaces. Much bleeding is quickly followed by a profound anemia, in which the red blood corpuscles and the fibrin-forming elements are rapidly decreased, the white corpuscles increased, and the percentage of hemoglobin is diminished. After several days of general weakness, or suddenly without previous indisposition, a purpuric eruption appears upon the trunk and limbs, but preferably upon the lower extremities. This is fol-

lowed, or accompanied, or sometimes preceded, by bleeding from the gums and other mucous surfaces. Usually the blood lost is non-coagulable. The spots upon the skin, which may appear in successive crops, vary in size from 1 to 4 millimetres in diameter; the smaller being termed petechie, and the larger ones ecchymoses. In color they shade from a bright to a dark red, according to the depth of the extravasation, and they gradually fade to a brownish hue during their absorption. Unlike inflammatory congestions, they do not disappear upon pressure. Vierordt suggests the following test, namely, "through a piece of thin glass pressed upon the spot in question, a hemorrhage becomes more distinct, whereas an inflammatory congestion is obliterated temporarily." While the disease may exist without fever, there is usually a moderate elevation of temperature, and sometimes there is hyperpyrexia. The pulse soon becomes weak and rapid; the mind remains clear in some cases to the end, whereas in others there is delirium which lapses into coma towards an approaching fatal termination. Another group of symptoms, wherein multiple arthritis together with urticaria, as well as purpura, are dominant features, is called peliosis rheumatica. There is another group in which nervous symptoms, and still another in which gastro-intestinal and renal symptoms, are uppermost. These are thought by some authorities to be too closely allied to Werlhof's disease to admit of a separate classification.

"Scurvy," says Lockwood,² "if proved an infectious disease, may be really Werlhof's disease modified by the surroundings and poor condition of the patient, and also by the possibility of the infection being more chronic." Purpura hemorrhagica at present is differentiated from scurvy by the presence of fever and by the absence of swelling of the gums, notwithstanding the bleeding, by the fact that a mixed diet has been previously maintained, and by its failure to respond to an antiscorbutic regimen.

That Werlhof's disease is infectious seems to be well established. Adults as a rule are less likely to succumb to the infection than young children. The latter are very prone to die of the disease, and likewise women attacked during pregnancy. Four of the 5 cases complicating the pregnant state, cited by Lockwood,³ had a rapid and fatal termination. "In children the affection nearly always proves fatal," says Dr. Holder,⁴ who had seen a good many cases on Randall's Island. Of the 30 examples of various ages and different sexes included in Lockwood's⁵ paper there was a fatality of 25.

It is a disease of early life ordinarily, and is somewhat less frequent in the male than the female. It is also a treacherous disease, for it may begin with apparently mildness and rapidly become grave and exceedingly dangerous. There are some evidences which point to its communicability, yet this same proof might serve for an argument in favor of a common source of infection. Dr. Holder,⁶ in discussing a paper by Dr. Bremner on the subject, says, "The disease seemed to have a tendency to recur in groups and to affect especially a single ward at a time, so that there was little doubt of its contagiousness." The latter agreed with his colleague, and expressed similar sentiments as a result of a like experience. Moreover, Grüning⁷ has reported 3 cases of purpura simplex in children, three, four and sixteen years old

respectively, 2 of whom occupied the same room, and all of whom lived in the same house and came into frequent contact with one another. All presented high fever and profound constitutional phenomena. Furthermore, in an instance of my own, to be related, the mother of the child stated that 2 other children in her family had previously developed purpuric eruptions upon the lower extremities.

The grave forms of purpura hemorrhagica, at least in this country, fortunately are not of very frequent occurrence. During one year, stated Dr. Lewis,⁸ there were only 3 cases of this form of the disease out of 20,000 general medical cases in nineteen of the hospitals of New York. Among 63,834 medical cases, in sixteen and a half years at the London Hospital, cited by Mackenzie,⁹ there were but 200 examples of purpura of all descriptions. Of these 61 were associated with rheumatism, and 68 were unexplained, and hence Werlhof's disease, inferentially.

The *New York Medical Record*, during the past ten years, has published an number of papers upon this subject, and notably one by Lockwood, already quoted, who gathered 30 cases, 19 of which were from German, 4 from English, 3 from American, 2 from French, and 2 from Spanish sources; also one by Lewis,¹⁰ who reported 3 cases, 2 of which proved fatal. In the *Transactions of the Association of American Physicians*, during this same period, is a paper by Musser,¹¹ who described 5 cases, including 2 deaths. The *New York Medical Journal*, in 1897, published a paper by Weber,¹² who reported 3 cases that recovered, but which were manifestly mild in character. They were of interest in illustration of infection, probably through bacteria, which gained entrance into the system from gangrenous foci in the mouth and the intestines.

The following is a history of a patient who came under my care and observation during my service at the New York Post-Graduate Hospital.

William S., age eleven, admitted to the wards of the hospital December 29, 1898.

Family history.—Father and mother living and in good health. Upon the maternal side two uncles died of consumption. No other record of tuberculosis. A sister and two brothers alive and well, except that two of the children recently had a mild purpuric eruption upon the lower extremities.

Previous history.—The patient has had the usual diseases of childhood. One year ago he was operated upon for enlarged glands in the neck said to be tubercular. Last Tuesday morning (December 27th) he, being apparently in his usual health, began to bleed from the gums, and shortly afterwards the mother noticed a number of small hemorrhagic spots scattered over his body, but more especially upon the lower extremities.

Present condition.—Patient anemic; pulse weak and rapid; temperature 101°; blood oozing from the gums, which are not swollen; a purpuric eruption, moderate in extent and amount, chiefly upon the legs and thighs, the spots varying in size from a mere point to a quarter of an inch in diameter, and in color from a bright red to a faded brownish tinge. These ecchymoses do not disappear upon pressure. Both heart and lungs are normal, no swelling or tenderness of the joints, no edema, no pain, no soreness of the throat and no gastro-intestinal disturbances.

Examination of the urine.—Specific gravity, 1.012;

reaction, acid; color, yellow; transparency, clear; sediment, slight in amount and nebulous. Chemical analysis: Albumin, a trace; no sugar.

Microscopical examination.—Abundant hyaline and finely granular casts; moderate amount of cellular and coarsely granular casts. Blood, few red and white cells. Bacteria present.

During the first four days the patient continued to bleed more or less from the gums, especially at night, and finally from the nose, despite temporary relief from plugging the nostrils and the application of astringents. His mind remained clear, and his strength and appetite fairly good. The temperature varied between 99½° F. and 101¼° F., and the pulse between 110 and 132 per minute. On the fifth day he bled freely from the nose, and vomited considerable blood, and, what is more, passed blood from the bowels, at first in the form of black stools, and then in clots of pure blood. His mind was still clear. He had an exsanguinated appearance; his temperature fell to 97° F. and his pulse rose to 160 per minute. Of course he was in bed. His condition becoming alarming from sheer loss of blood, transfusion of a normal saline solution was performed in his left arm, and stimulants were administered. By midnight he was delirious. The following day his temperature ranged between 99° F. and 100° F., and his pulse between 120 and 140. He had two small black stools. On the seventh day he had six bloody stools, and vomited blood. He was in a stupor with intervals of delirium. His temperature was from 100° F. to 101° F., and his pulse from 138 to 160 in the course of the twenty-four hours. On the eighth day he had a small stool of blood and mucus; his pulse was weak, rapid and irregular; he was delirious. On the ninth day his temperature ranged from 99¼° F. to 102° F., his pulse from 140 to 150, and his respirations from 34 to 40 per minute. Finally, upon the tenth day, which was the 7th of January, with temperature 101½° F., respiration 42 and pulse 156 per minute, he died towards evening.

These comprise the essential facts which have been abstracted from the daily records. Besides plugging of the nostrils and transfusion, numerous remedies, including ergot, digitalis, hemostatics and stimulants, without avail were employed. In view of the mortality of the disease, and the contradictory statements in regard to the efficacy of remedies, one is inclined to be sceptical about the value of all medication, certainly in the virulent forms of purpura hemorrhagica. Dawson¹³ reported a case, which, however, was evidently not of a grave nature, where one deep injection of 5 minims of ergot worked a cure immediately. On the other hand, Mackenzie¹⁴ states that ergot may be tried, but that it has not in his hands proved very efficacious. Arsenic, turpentine, ergot, benzoate of sodium, nitrate of silver, iron preparations, all have their advocates. Meanwhile, like several other diseases, the mild cases are likely to get well under a diversity of treatment, and the severe cases are very prone to die, drugs to the contrary notwithstanding. This, at all events, is certainly true in regard to young children. Dr. Holder¹⁵ states that, "therapeutic experience on Randall's Island had rather fostered the idea that there is no specific medication for these hemorrhagic conditions in children." Blood serum, it is said, in doses of 250 cubic centimetres has been employed successfully. It is not impossible that the se-

rum of some naturally immune animal, which has been inoculated with a sterilized culture of the bacillus described by Tizzoni and Giovannini, may eventually find useful therapeutic application. Meantime, the discovery of the cause of this not infrequently malignant infection should exert a direct influence upon the prevention as well as the treatment.

Mackenzie¹⁶ remarks that "bacteria or their products must play an important part in the production of the cutaneous hemorrhages," and also that "it is certain the cutaneous hemorrhages are sometimes determined and in all probability primarily caused by nervous influences." Stengel¹⁷ says in connection with the subject under consideration that "organisms have been found in the blood by a number of observers. No definite and specific bacteria have, however, been isolated, and it is doubtful whether the infection in all cases is the same." Letzerich,¹⁸ in 1889, described a long bacillus having sharp angles and edges which he considered peculiar to this affection. These bacilli can be cultivated "from the blood of the petechia, and pure cultures in gelatine injected into rabbits give rise to hemorrhages spontaneously. A hyaline thrombus full of bacteria and spores was always found at the site of the bleeding."

Lapin¹⁹ mentions 2 cases of purpura hemorrhagica, 1 of which ended fatally, and in both of which micrococci were found in the blood. In the fatal case streptococci were present. In his opinion the infecting principle enters the body by the mouth and the pharynx. The proximate cause of purpura hemorrhagica is believed to be a hyaline and amyloid degeneration of the walls, both intima and adventitia, of the blood vessels, with ultimate hemorrhage, and by rupture of the vessels rather than by diapedesis. It seems probable that any unusual pressure of the circulation against the vessels, previously weakened by degenerative changes, would be sufficient to precipitate the extravasation. What is known regarding the part taken by bacteria or their products in the causation of these degenerations will be shown in the following extracts from Flüge's²⁰ "Die Mikroorganismen."

The hemorrhagic infections of man have not as yet been wholly elucidated, at least they have no uniform etiology. In many cases the process is dependent upon the especial malignant character of an infection otherwise progressing without hemorrhagic diathesis, or upon an abnormal disposition of the affected individual; in others upon specific microorganisms causing fragility of the vessel walls. Cornil and Ranvier* and Babes,† giving examples, distinguish three groups of causes: (1) Infection exciters, which are to be classed along with bacteria or hemorrhagic septicemia in animals; (2) such bacteria as gain access from gangrenous foci in the mouth and intestinal canal (*Bacillus proteus septicus et letalis* of Babes, *Bacillus capsulatus septicus* of Foa and Bonome, Bardoni-Uffreduzzi, and pyogenic cocci); (3) violently acting streptococci. Compare Claisse.‡

Bacillus hemorrhagicus septicus. — Cultivated by Babes§ from 3 fatal cases of hemorrhagic sepsis accompanied by stomatitis, angina, bronchitis, purpura, hematuria and fever. In the hemorrhagic pulmonary foci and mesenteric glands there were found dense masses of bacilli. From the spleen and lungs the following bacilli were obtained in pure culture: Non-motile short rods (3-4 millimetres thick), surrounded by a capsule. Stain faintly with aniline dyes, still fainter with Gram's method. No

spore formation. Facultative anaerobic. Slight growth on surface of gelatine; along the stab a granular stripe; no liquefaction. Upon agar agar minute transparent droplets; later, whitish-yellow, indistinctly defined spots. On potato, whitish drops. Bouillon is clouded.

Mice die within a few days, often with manifestations of septic changes (spleen tumor), with hemorrhages upon the serous membranes. Rabbits die in three to eight days with hemorrhages in all the organs, especially in the liver and lungs, and with swelling of the spleen. In those animals which die late the bacilli are often no longer microscopically demonstrable. Sterilized cultures (filtered or heated to 60° C.) also produce multiple hemorrhages. For guinea pigs and dogs it is slightly pathogenic. The cultures rapidly lose their virulence.

Bacillus hemorrhagicus (Kolb). — Isolated in pure culture from the cadavers of three persons who died in three or four days with fever, hemorrhages in the skin and mucous membranes.* Besides pin-head to twenty-five-cent piece sized hemorrhages in all the organs, the early autopsies show no other changes. The bacilli lie in all sections, especially numerous in the spleen, partially in clumps, partially isolated. Non-motile rods, .8 : 1-2 μ , also in long threads with slight capsule, which, however, is inconstant. They are in great part decolorized by Gram's method. No spore formation. Facultative anaerobic. Superficial colonies in gelatine show serrated periphery; no liquefaction. Upon agar-agar smooth, non-serrated layers. On blood serum thin, moist stripe; the same on potato. Bouillon is first clouded, then (on sixth day) simply a sediment. Slight reduction power. Exact biological description is wanting, as in the preceding bacilli.

A drop of bouillon kills mice in two or three days with numerous multiplication of the bacilli, which are found in especially large numbers in the organs; quite numerous small hemorrhages, and spleen tumor. Guinea pigs are susceptible to infection only on administration of large doses. Rabbits frequently die within one to three days after intraperitoneal injection of $\frac{1}{2}$ to 1 cubic centimetre, with production of extensive hemorrhages. Bacilli everywhere. Doves are not susceptible. In dogs hemorrhages are also noted, even after twenty days, if they do not die too quickly, as do rabbits. Sterilized cultures in doses of .3 to 3 cubic centimetres produce in experiment animals phenomena similar to those caused by the living bacilli.

Bacillus hemorrhagicus velenosus. — A non-motile bacillus, isolated by Tizzoni and Giovannini in a case of purpura hemorrhagica, secondary to an impetigo contagiosa, which came to autopsy. The bacillus occurred, associated with staphylococcus pyogenes aureus, in the hemorrhagic foci of the skin occupied by impetigo pustules, also in the liver, and venous blood, but not in the spleen and kidneys. The staphylococcus was found in the pure hemorrhagic foci of the skin and also in the kidneys.

The bacillus is pathogenic for dogs, rabbits and guinea pigs, but not for doves and mice. The bacilli multiply locally only (edema); they cause fever, hemorrhagic nephritis, vomiting, bloody stools, and cutaneous hemorrhages. Spleen normal; coagulation necrosis of the liver and renal epithelia; non-coagulability of the blood. Cultures sterilized at 70° C. produce albuminuria; repeated injections of the same immunize against subsequent infection.

In spite of admixture with staphylococci, this bacillus, as its behavior toward animals proves, is said to be worthy of consideration as the excitant of purpura.†

EYE STRAIN AS A CAUSE OF GASTRO-INTESTINAL NEUROSES.¹

BY M. P. SMITHWICK, M.D., BOSTON.

"A GASTRIC neurosis is the local expression of some constitutional state or nervous irritation arising outside of the stomach." If this definition taken from the "American System of Practical Medicine" is made to include both stomach and intestines, it describes accurately the class of cases on which my remarks are based.

In searching for the cause of a gastro-intestinal neurosis one should avoid "snap" diagnosis. It isn't sufficient to discover astigmatism, deafness, inharmoonious environment, exhausting occupation, or other single cause of nervous fatigue. It is my custom to learn the temperaments of my patient's parents, brothers and sisters; to get a clear mental picture of the early home life, and review carefully the patient's life, endeavoring to see his environment from his point of view. By ascertaining when health commenced to fail it is possible frequently to determine the cause. All this requires time and patience, but often reveals a suitable background for the picture as we see it. Every means of diagnosis that can contribute to an accurate knowledge of the whole organism should be employed. Of course this includes a careful study of the gastric and intestinal functions. The eyes should be examined by an oculist.

One can attempt the removal of all possible causes or commence with the most probable. The latter allows the more intelligent study and is my preference. If, for example, the oculist reports defects to be corrected, and the eyes are probably responsible for the nervous exhaustion, the patient is allowed to wear glasses for a time, only dietetic errors being corrected.

After all possible causes have been considered it might seem easy to determine the real one. A little experience, however, teaches one that digestive neuroses tend to disappear spontaneously for considerable periods, improve temporarily under almost any treatment, and often persist for a long time under treatment that finally effects a cure. It may be impossible to state which of several possible causes was the real cause where all have been removed and the neurosis cured.

Treatment of the digestive tract is frequently necessary, but when once the diagnosis of digestive neuro-

sis is established, our chief aim should be to discover and remove the cause.

The first case which particularly directed my attention to this subject was a barber, thirty years of age, who consulted me in July, 1898, for so-called bilious attacks, from which he had suffered every two or three weeks since he began that work, at sixteen years of age. Previous to that time he was well, and excepting these attacks has always been well. His appetite has always been good, and the only digestive symptoms are moderate constipation and occasionally "sour" stomach. Between attacks headache is present only when he rides on cars, or occasionally when the electric lights are turned on in the shop. An attack may be preceded a day or so by the sensation of a "lump" in the throat, and commences with vertigo, partial loss of sight, nausea, vomiting and, for three or four hours, frontal headache. Symptoms of hyperacidity are more likely to annoy him before an attack.

Physical examination negative, except for exaggerated reflexes. Nothing uniform about gastric analyses. At times delayed motility and hyperchlorhydria.

From July until late in October I dieted and treated him in every way that occurred to me, and then stopped trying; told the patient that I had not helped him at all, and did not know the cause of his attacks. I sent him to an oculist and glasses were ordered for .75 D hypermetropia. The oculist suggested that the attacks might be scintillating scotoma and was not sanguine; I was not, and the patient wore glasses because asked to do so. Some months later he made me a social call, and asked why the attacks had ceased. Apparently he could not believe me when I insisted that glasses and not medicine had done it. Later he broke the glasses and was uncomfortable, but unfortunately for the cause of eye strain the optician repaired them in two days. Since October, 1898, he has had one slight attack and one severe one, the latter in December, 1898.

Early in November, 1898, I was consulted by a man, thirty-two years of age, clerk in a railway office. His work made severe demands on his eyes, and great accuracy was necessary. He was well until June, 1897, when he had an attack of vomiting which he attributed to strawberries and ice-cream soda, eaten after a long bicycle ride. In December, 1897, he was working on dividends, and the coupons were on green paper and caused headache. For a short time he wore glasses fitted by an optician. The attacks were usually worst when his work was most trying, and might be preceded an hour or so by sour taste. Then suddenly would come nausea and intense vomiting. This might last a day or several days. In the first attacks observed by me, there seemed to be no pain, except that at times after vomiting he complained of pain apparently caused by the exertion. Later he seemed to be in great distress. No headache. He was inclined to constipation, and worried much over this symptom, but usually had a dejection every day except Sunday. He was very neurasthenic. There was an indefinite specific history.

Physical examination was negative except for diminished pupillary light reflex, diminished knee jerks, and rather prominent abdomen. No inco-ordination. Several times fecal masses in the ascending and descending colon were palpated. In February, 1899, I referred him to two specialists for an opinion as to

¹ Abstract of a paper read before the Clinical Section of the Suffolk District Medical Society, May 16, 1900.

the attacks being crises of tabes. One thought it probably tabes, but neither felt justified in making an absolute diagnosis of tabes or excluding it. Several gastric analyses failed to explain the attacks. The most constant defect was atony. Feces suggested intestinal atony. He could eat plenty of everything without symptoms between attacks. We all agreed that he should have a vacation, and he arranged to go to Europe for two months.

Before he started it occurred to me that an oculist might cast some light on the case and the report was in part: Right eye $\frac{1}{2}$ D of hyperopic astigmatism; left eye 1 D of hyperopic astigmatism. Some muscular trouble — about 6° esophoria. Pupils react slowly to light.

He received glasses and wore them while in Europe. He travelled almost constantly while there and had several mild attacks. The last week was spent under the care of Dr. Magensdorf, at Kissengen. The treatment, according to the patient, consisted in absolute rest, massage, poulticing of epigastrium and systematic stuffing with boiled rice and beef steak. He gained 8 pounds in seven days. The attacks continued on his return and cost him his position. The excitement of receiving a very desirable position in a New York banking house brought on an attack. He worked three days and then spent a week in the Presbyterian Hospital.

This case is presented as an interesting study, but not as one of this series of gastro-intestinal neuroses. With the exception of being less painful his attacks resemble the gastric crises of 3 cases of locomotor ataxia which I have studied. A year ago this patient announced to me his engagement and asked for a prognosis. I was obliged to tell him that he should not marry, as I feared that the attacks were gastric crises of tabes, but then and since have allowed him to hope that his eyes are responsible. Employment that would not tax the eyes was advised — preferably out of doors. Antisyphilitic treatment was commenced a year ago but patient continued it only during a brief period. Regulation of diet and of bowels and correction of refractive errors have not influenced the attacks.

Following is an analysis of 20 cases representing various types of digestive neuroses. In all the general neurasthenic condition was overshadowed by prominent gastro-intestinal symptoms.

Eye symptoms other than headache were present in 7 of the 20 cases, and 1 of these had normal eyes. Headache was a symptom in 14 cases — all having eye defects. Eye defects were found in 18 of the 20 cases, and glasses given. Fifteen cases had astigmatism, 13 hyperopic and 2 compound. Of these 15 cases 5 had also hypermetropia, 3 muscular trouble, 1 axis "against the rule," 1 opacity of a lens, 2 diminished vision. Two cases had only hypermetropia and 1 myopia.

In most of these cases there were several careful analyses of the gastric contents after Ewald test meals. In certain cases heavy mixed meals were used in testing gastric motor power. The stomach was normal in size in all and in position in 15 of the 18 cases having eye defects. Three had gastropnoxis. The stomach emptied itself with normal rapidity in 3 of the 18 cases, too soon in 7, too slowly in 7, and too soon or too slowly in 1. HCl was normal in 4, increased in 7, and decreased in 7.

Of the hypochlorhydria cases 1 showed free HCl but once in several analyses during a year's observation, but gained 25 pounds in weight. His eyes were normal. All other hypochlorhydria cases had some free HCl most of the time. There was no case of achylia gastrica. (Phloroglucin vanillin was the final test for free HCl.) One cannot be too cautious in making a diagnosis of neurosis in achylia gastrica, in hypochlorhydria showing persistent absence of free HCl, and in cases with obstinate constipation or such constipation alternating with diarrhea, especially when there is increasing debility. Otherwise he may have to regret allowing a gastric or intestinal new growth to pass the operable stage. It is conservative to explore doubtful cases that are losing ground, and imperative if they show pyloric or intestinal stenosis.

Of the specimens of feces examined none showed a notable amount of undigested food. Of the 18 cases with eye defects 8 had normally acting bowels, 6 constipation, 3 a tendency to diarrhea, and 1 either constipation or diarrhea.

That eye strain was the sole cause of symptoms in any of these 18 cases has not thus far been demonstrated. One is not justified in taking away glasses that are apparently curative in order to demonstrate a cure. Presumably eye strain was the cause in the first case. In several other cases it may be a factor of greater or less importance.

In the article on Gastric Neuroses in the "American System of Practical Medicine," Stockton and Jones consider eye strain one of the most prolific causes of functional gastric disturbances.² They consider it the most important factor in causing achylia gastrica.³ They give hyperopic astigmatism as the eye defect most commonly causing nervous affections of the stomach.⁴

Reference to reports of the Massachusetts Charitable Eye and Ear Infirmary shows hyperopic astigmatism and hypermetropia to be the most common refractive errors treated.

While this preliminary report of cases does not make out a brilliant showing for eye strain, I am convinced that it can cause these neuroses. Several of my cases have been almost or quite free from symptoms since they received glasses months ago, but further observation will probably prove this to have been merely a coincidence.

There may be interesting combinations of causes. One patient fifty-seven years of age has been troubled two years with gastric acidity and several years with prostatic hypertrophy. The urine was ammoniacal. To remove the residuum and wash the bladder the catheter had been passed one or more times daily for two years, recently only once a day. A testicle was swollen and had been several times previously. He had taken urotropin almost constantly for two years until a few days previous to consulting me in regard to his stomach. On inquiry I learned that the gastric and bladder symptoms improved and grew worse coincidentally. The gastric analysis showed hyperchlorhydria. He had a small amount of hyperopic astigmatism and slight opacity of one lens. He was unable to recognize people across the street, or small objects near, and his work rendered the latter necessary. His glasses, used only for reading, were correct. He

² American System of Practical Medicine, vol. iii, p. 111.

³ Loc. cit., vol. iii, p. 117.

⁴ Loc. cit., vol. iii, p. 134.

received glasses for constant use enabling him to see clearly. He was allowed to eat what he liked and to use soda mints as he had done for two years. I prescribed "Tritipalm," a combination of triticum repens and saw palmetto with improvement in the force of the stream and diminution of bladder irritability. Soon benzoate of soda was added and the urine became acid. There was still residual urine, but on the seventh day after commencing treatment he voluntarily gave up the catheter and since the nineteenth day there have been no gastric symptoms—two and a half months. Permanent cure in such a case is hardly to be expected.

The object of this paper is to call attention to eye strain as one factor to be considered in searching for the cause of a gastric or intestinal neurosis. The cause or causes can be discovered and must be removed to effect a cure. Treatment, even when based on accurate conception of the kind of neurosis, is from the nature of the case only palliative.

To guard against the injurious effects of eye strain we should recommend the routine examination of children's eyes by oculists at the earliest practicable age.

A NOTE ON RECTAL FEEDING IN PEPTIC ULCER.¹

BY GEORGE G. SEARS, M. D., BOSTON.

THE two following cases have been selected as a text because they are interesting in themselves, beside illustrating a point in the treatment of peptic ulcer of which I wish to speak very briefly:

CASE I. Margaret H., age eighteen, a domestic, admitted to the City Hospital, July 19, 1898. Although never strong, she had had no special symptoms, and was in her usual health until her catamenia began three days ago. Since then she has several times vomited a dark, bloody material, which once "amounted to a pailful." She was in fair flesh, but anemic, the red cells, a few days after entrance, numbering 2,600,000 and containing but 25% of the normal hemoglobin. There was general tenderness over the upper abdomen, especially on the right of the median line. She was given nutrient enemata containing one egg in a pint of peptonized milk every six hours, and for the first week received nothing by the mouth; she was then allowed small quantities of water, although she complained but little of thirst or discomfort. After ten days the rectum became somewhat restive, and five minims of laudanum were added to each enema, but they were omitted two days later as no longer necessary. Her color improved and her weight apparently increased. On the fourteenth day small quantities of peptonized milk were given by the mouth, and from that time the diet was gradually increased without discomfort. On August 7th, twenty days after entrance, the red cells numbered 4,000,000. She was discharged at her own request on August 26th. Her temperature throughout her stay at the hospital was somewhat irregular, but it rarely exceeded 100° F.

She was readmitted on the surgical side on January 20, 1900. Since her discharge a year and a half ago she has complained at times of dyspeptic symptoms

with pain and nausea, but she has never vomited blood. During the last three months she has twice been confined to bed with a sharp attack of abdominal pain accompanied by vomiting. On the day before her entrance, without apparent cause, she had acute pain in the epigastrium, the left side of the abdomen and the left shoulder, which lasted about five hours. There was no vomiting and no blood in the stools. She was restless and feverish during the night, but in the morning she felt much better. Her color was good and she did not look ill. The temperature was 102° and the pulse 112. There was no abdominal distention, but there were spasm and tenderness of the left rectus muscle and the whole left side of the abdomen, with extreme tenderness over the epigastrium. Operation by Dr. Munro by median incision in the epigastrium showed a perforation about one-quarter of an inch in diameter through which some curds could be pressed, situated at the pyloric end of the stomach close to the lesser curvature. There was evidence of an old peritonitis in the neighborhood which may have accounted for her irregular temperature during her first visit to the hospital. A few flakes of lymph were found in adjacent coils, but no pus. The perforation was closed and the patient was discharged on March 2d.

CASE II. Moses P., age 66, a shopkeeper, of excellent habits, was admitted January 15, 1900. Since he was twenty-five years old he has been subject to attacks of indigestion resembling the present one in many details. They have recurred about every six months, and have been growing worse with increasing years. The prominent feature has always been pain which is relieved only after vomiting. The vomitus has never contained blood, but during an attack ten years ago, he noticed that the movements were tarry. He always becomes very pale and has a slightly yellowish tinge to the skin. On two occasions he has been so weakened that he has been confined to the house for three months. He has been losing flesh for the last three or four months, but the acute symptoms did not begin until three days before entrance, when he lost his appetite and began to have sharp pain in the epigastrium, which was relieved rather than increased by eating. After an injection he passed a small tarry movement. Two days later while sitting in a chair he suddenly felt faint and lost consciousness. On coming to he vomited considerable brownish-red blood.

The patient was very anemic and had evidently lost considerable flesh. The heart was not enlarged, but systolic murmurs were heard at both apex and base, the latter disappearing during his stay in the hospital. The peripheral arteries were in good condition for a man of his age, and the liver was of normal size. Pressure over the epigastrium was not painful, but there was slight spasm of the right rectus muscle. The feet were slightly edematous. The urine was negative. The red cells numbered 2,536,000. All food by the mouth was stopped, and he was given an enema containing one egg, two ounces of beef juice, one ounce of brandy, and enough peptonized milk to make a pint, every six hours. These were continued until February 3d, but he began to receive small quantities of peptonized milk on January 23d, as he was growing restive and complained of thirst. On the former date the red cells numbered 2,400,000, with 30% of hemoglobin. He steadily improved, and was

¹ Read before the Clinical Section of the Suffolk District Medical Society, May 16, 1900.

discharged at his own request on February 26th, when a blood count showed 3,756,000 red cells, with 35% of hemoglobin.

Apart from the interest which attaches to the first case from the success which followed Dr. Munro's prompt resort to surgical measures, and to the second from the length of time, apparently over forty years, during which the process was active, both cases illustrate the tolerance of the rectum to much larger enemata than are usually prescribed. Theoretically, the best treatment of peptic ulcer is by rest of the stomach, the more complete the better and for the longest possible time, but this cannot be obtained in every case, owing either to the patient's objections to the incidental discomforts, of which the chief is thirst, or to the intolerance of the rectum which may soon come on; yet, in an experience with a considerable number of cases requiring rectal feeding, during the past three years, intolerance has not seemed to be acquired sooner with the larger than with the smaller amounts, while the comfort of the patient is certainly enhanced and thirst alleviated by the larger quantity of fluid. The routine method has been to give a high enema of plain water, early in the morning. This is retained by the patient, if possible, for an hour, at the end of which time, if it has not come away, an enema of soapsuds is given to cleanse the rectum for the work of the day. The nutrient injection of peptonized food is then given through a half-inch soft-rubber tube. The patient's buttocks are raised and an attempt is made to get the fluid beyond the sigmoid flexure, but whether ever successfully or not I must leave to the anatomist to decide. At all events, it is possible to insert a tube of this calibre, which is almost too stiff to bend up on itself within the narrow limits of the rectum, from 8 to 12 inches. The fluid is injected slowly, the tube being gradually withdrawn. Efforts at expulsion are restrained by a pad in the usual way. The enemata are repeated every six hours.

It is not claimed that all the necessary nourishment can be given in this way, yet in the first case the improvement in the anemia and the apparent gain in weight are encouraging signs, and show that it is possible to prevent the patient at least from losing ground.

ACHLORHYDRIA; ITS EFFECTS AND THEIR TREATMENT.¹

BY H. F. HEWES, M.D., BOSTON.

OF 250 cases of disorder of the stomach which I have treated during the last few years, the condition of achlorhydria was present as a constant condition investigated by several analyses at considerable periods of time in 15. Of these cases 6 were cases of simple chronic gastritis, 4 cases of gastritis with carcinoma of the stomach, 1 achylia gastrica, 3 cases in which the achlorhydria was the only abnormal objective sign.

The importance of the recognition of this condition arises from the fact that it may itself, regardless of the nature of the organic lesion of the body with which it may be associated, be a cause of special definite disturbances in the process of digestion, and thus a special treatment directed to remedying its effects is necessary in cases where it exists. The results of this absence of hydrochloric acid in the

stomach are (1) an absence of peptic digestion, (2) an increase of bacterial fermentation in the stomach and intestine.

Where the motility of the stomach is undisturbed, as is not infrequently the case with achlorhydria, the absence of peptic digestion is of little or no effect upon the organism, since the intestine can perform this function of proteid digestion. Our first aim in the treatment of this condition is, therefore, the preservation or adjustment of the motor function of the stomach. The proteid diet must be in such a form and given in such a manner that it can be easily passed through the stomach, the starches with the cellulose envelope broken so that salivary digestion may occur freely in the stomach.

In some of my cases the achlorhydria has existed for years and it is only when the motility of the stomach becomes affected that the patients have symptoms of stomach trouble and come for treatment. A proper regulation of the diet, with a regimen of rest after meals, and regular out-of-door exercise and exercise of the abdominal muscles, with strychnia or hydrochloric acid and strychnia given internally, soon causes in these, as well as in the more numerous cases of hypochlorhydria, a relief of symptoms, and presumably a readjustment of function.

The device of supplying the hydrochloric acid for peptic digestion by administration of the artificial acid, often useful in cases of hypochlorhydria where the deficiency of acid is slight, cannot be utilized with success in achlorhydria, as it would be necessary to use excessive amounts of the acid—a quart of dilute hydrochloric acid, for instance, with a meal.

That an abnormal fermentation occurs when the stomach contents lack their normal antiseptic, the hydrochloric acid, has been definitely proven by Dubarry, Bunge, Simon and others. This causes little or no effect in the stomach or intestine where the motility is normal, although the quantity of bacteria or fermentative products which are passed into the intestine and the fermentation which occurs there are increased over normal even in these cases. (*Vide* Simon's "Researches upon the Conjugate Sulphates of the Urine in Cases of Hypochlorhydria.")

In cases where motility is affected a considerable amount of fermentative products is formed, causing frequently disturbance of both stomach and intestine. In these cases marked symptoms of intoxication and of intestinal sepsis, as drowsiness, urticaria (?), intestinal flatulency, diarrhea, may occur. The treatment of this second result is, therefore, like that of the first, primarily the adjustment of the motility of the stomach. Where this function is intact antiseptics destined to act in the stomach (salicylic acid, resorcin, or large quantities of HCl given frequently throughout digestion) or in the intestine (salol) may be useful in limiting fermentation. In cases where intestinal sepsis is suggested by symptoms the antiseptic treatment must be applied and foods which do not easily undergo fermentation must be given.

The presence of achlorhydria can be determined by a simple method of analysis of the contents. A qualitative test for free HCl determines whether or not we are dealing with a marked condition of hypochlorhydria. A further qualitative test of the contents for the presence of combined HCl² determines whether

¹ Abstract of a paper read before the Clinical Section of the Suffolk District Medical Society, May 16, 1900.

² Hewes: Analysis of Gastric Contents (Ewald-Sjoqvist Test). Journal, January 4, 1900.

we are dealing with a simple diminution of HCl (hypochlorhydria) or a total absence (achlorhydria). As I have demonstrated by an extended study of cases of stomach disorders, the subjective symptoms are no index of the nature of the chemical abnormality present in three-fourths of our cases, cases of hypoacidity and hyperacidity frequently having similar symptomatology.

The diagnosis of achlorhydria can be made therefore only by analyses of the gastric contents. And these analyses should be made at various periods of digestion and upon several occasions extending over a considerable period of time. Once diagnosed, the treatment of the results of the condition is very satisfactory.

PHTHISIS; SOME CAUSES OF FAILURE IN ITS CLIMATIC TREATMENT.

BY WILL HOWARD SWAN, M.D., COLORADO SPRINGS, COL.

DURING a short residence in Colorado the writer has been so many times impressed with the unsatisfactory results in the cases of some pulmonary invalids sent here, either from the far advanced stage of their disease, or because they were landed here with little or no means of support, unable to work and among strangers, or because of an erroneous idea of the sort of life they should live, that he thinks a few words of caution not inappropriate.

We consider that the cardinal means of treatment of pulmonary tuberculosis are: (1) The maximum of pure, fresh, dry air and sunshine; (2) abundance of nourishing food; (3) rest physically, and freedom from nervous care and worry.

All these factors are very happily met here. An altitude of 5,000 to 8,000 feet above the sea level gives pure, dry, cool and bracing air; the soil is largely sandy and porous; the winter months, during which more invalids come here than at any time of the year, give a possible nine hours daily of sunshine, and the statistics of ten years show an average of three hundred and fourteen clear or partly clear days a year.

The total yearly rainfall averages 14.46 inches, and of this the normal precipitation is 11.18 inches during the five months from April to August, inclusive, leaving 3.28 inches to fall during the remaining seven months, from September to March, inclusive.¹

The annual mean *relative* humidity for two years, 1893 and 1894, at Colorado Springs was 47%, and the annual mean *absolute* humidity for the same period was 1.48 grains.²

The climatic conditions are such that the invalid can live out of doors nearly all of the winter days, and may sleep out on protected balconies with advantage all winter.

Proper and abundant nourishment is as well provided here as elsewhere. Rest, physical and nervous, and recreation are as easily possible and rendered very agreeable to most sojourners.

But the three classes of invalids spoken of, unfortunately, unless the conditions named are changed, would be much better and be much happier, were they to remain at home, among their home friends and associates.

It is true that many cases with far advanced disease have done well here and have been for years living active, useful lives. But the outlook for such cases is much less favorable, and they require much more prolonged rest and careful feeding, than those in earlier stages of the disease. If such an invalid is financially able to live a *prolonged time* in this country, with an abundance of proper food and the necessary rest and freedom from worry, there is no reason why he should not do it, and with the feeling that he is giving himself the best chance of improvement. But for *any* person suffering from pulmonary tuberculosis to be sent to this climate with no means of support, or so little that he must work when he should be resting — perhaps in a vocation in itself harmful — and with poor and insufficient food and the worry attending such circumstances, is to impose more on the kindness of a favorable climate than a rational view of matters will justify. Such a person would have a better chance of recovery were he to remain in a less favorable climate, if he could there have the other measures of treatment with the freedom from care and worry so necessary if he would make a winning fight against a fatal disease.

People here are very philanthropic and are constantly helping such invalids, but the sad fact remains that many cases come here with bright prospects for recovery, but have to go home before any permanent good is accomplished, or have to go to work when rest is a necessity to them. There are good hospitals and sanatoria scattered throughout this region, but most of them have to make some charge to all patients. Moreover many come with the expectation of radical cure in a few weeks of a disease which should require many months.

Other invalids fail to do well simply from an erroneous idea that simply *living* in this climate will cure, without regard to the *manner* of living. It is not an unusual occurrence to see a patient, after three or four months' residence here, in a materially worse condition than on his arrival; and to find that he came with the belief (too often from instruction from his home physician) that if he will "live out of doors," exercise, ride horseback, play golf, tennis, — do anything to keep him in the open air, — he will get well. Very likely he may have climbed Pike's Peak, or have done some equally foolhardy thing within a few days of his arrival. The same person may have been kept very quiet while at home. Now it is a definite fact that a person coming here from a lower altitude, till he is adjusted to the change, fatigues much more easily than at home. At the same time the bracing, exhilarating air often acts as a constant nervous stimulant which spurs one on to exercise without his feeling fatigue, till at length his physical limit is exceeded, his powers of resistance depressed to such a degree that the tubercle bacilli or other germs within him seize their opportunity, a fresh or extended infection occurs, and a partially quiescent process is fanned into activity, which may require weeks of absolute rest and more careful nursing and attention before the patient can safely go about again.

The writer would urge, then, three points: (1) Do not send patients with far advanced phthisis to Colorado, unless they are able to make the change without serious fatigue, and unless they can live here in the manner they should and for a *prolonged period*. (2) Do not send *early* cases, unless there are assured

¹ Handbook of Medical Climatology, by S. E. Solley, p. 254.

² Loc. cit., p. 253.

means for proper hygienic living for a period sufficiently long to get the patient well enough to earn, in part at least, his living, and to find employment. How long will depend upon the individual case and his progress, but, roughly speaking, three or four months at least. There are many openings for employment, but more people looking for the desirable ones. (3) Most important of all, instruct the invalid to rest and *keep* quiet after his arrival until some one competent to advise him considers it safe to begin to exercise; and then have his manner of life and hygiene directed from time to time, according to his progress and condition.

Medical Progress.

REPORT ON THE DISEASES OF CHILDREN.

BY T. M. ROTCH, M.D., BOSTON.

FUNCTIONAL CARDIAC MURMURS.

IN an article on this subject, Dr. Jacobi¹ states that changes in the shape of the chest wall, such as irritate the heart, alter the character of the cardiac sounds. In 3 cases of rachitic infraction of the ribs Hochsinger observed distinct cardiac murmurs; Steffen the same in the common forms of rachitic deformities of the chest. Jacobi then says that "during the past forty years I have had many opportunities of publicly demonstrating, with or without apparent hypertrophies of the heart, more or less marked cardiac murmurs attributable to the triangular or quadrangular shape of the rachitic thorax, the walls of which, being no longer elliptical, touch a larger surface of the heart. These murmurs are not always the same. Within a few minutes the well-marked cardiac murmur of a baby sitting erect or bent forward may change into a muffled sound when the patient lies down, which is significant of the mechanical irritation caused by the chest wall. Indeed, this muffled sound and the murmur differ only in degree. The former may often be produced by the pressure of the stethoscope on the flexible ribs of the young. Such observations as noticed by Henoeh, and also by Hochsinger, who, however, speaks only of a coarse heart sound, may readily be verified, provided the age of the patient is taken into account. They will be the more positive the younger the baby and the more flexible the ribs. Now and then the cardiac sound may be changed by pressure over the pulmonary artery.

All those murmurs which cannot be explained by any anatomical alteration of a valve, or of the myocardium, should be called functional. The causes, however, which are held responsible for functional murmurs are altogether too numerous. To say that any single theory explains their etiology is not doing justice to the case. Indeed there are but few conditions of the heart and blood vessels to which "functional murmurs" are not traced back. Thus the imagination or the diagnostic skill — or its absence — of the writer has always a great deal to do with their alleged nosogeny. Protracted diseases and convalescences, losses and abnormal conditions of the blood, all forms of anemia, chorea, poisoning by alkalies or by

acids, acute intoxications and long continued eruptive fevers, septic processes, irregular contractions of the myocardium, degeneration of the papillary muscles, minute disturbances of the valves or of the blood vessels, chronic myocarditis, and fatty degeneration, are all charged with causing "functional murmurs." Nervous influences also come in for their share. Undoubtedly, strong emotions and excitement, mainly in the young and those very impressionable, influence the heart in the most varied ways, from temporary palpitation to change of structure.

As far as the heart is concerned, its muscular labor varies according to the amount of support it finds in neighboring organs. The inability of lying on the left side, which is experienced by most healthy people, is caused in this manner. In that position the heart is more flaccid and requires more exertion to overcome resistance, a fact which is best shown by the increase in the number of the respirations.

Functional murmurs are described as soft and low, short or long, not always blowing, and are frequently combined with, or are the termination of, a more or less normal heart sound. In almost every instance they are systolic; in the adult they are mostly aortic, and are audible in the carotid; in the child they are more frequently found over the pulmonary or over the pulmonary and mitral regions. In regard to the locality and extent of their audibility there have been many differences of opinion; still there appears to be unanimity in regard to their inaudibility posteriorly in almost every case. A functional murmur may persist weeks and even months, but it has not the uniform quality of an organic murmur. It is more or less soft, or loud, or prolonged. Many disappear quite rapidly, or, having vanished, return. In this respect they differ widely from organic murmurs, which are more persistent as far as time and character are concerned. It should, however, not be forgotten that organic valvular murmurs may disappear either through recovery from endocarditis or through the establishment of compensation, but in these cases they diminish in loudness and duration only very gradually. Nor should it be overlooked that an increased frequency of the pulse, with the frequent and insufficient contraction of the heart muscle, thin blood vessels, and shortened valve excursion, may conceal a murmur which was present when the pulse was slow, or which may return when a cardiac stimulant reduces the number of heart beats.

Duplicated sounds should almost never be taken to be accidental or functional. They are nearly always organic and are of more value than Leube appears willing to assume, both the splitting of the second sound (gallop rhythm) and that of the first (*rappel* of the French). The former is often observed in aortic stenosis, chronic nephritis, sometimes also in conditions of utter exhaustion, and in very bad cases of chlorosis; the latter in mitral stenosis, sometimes with oliguria, followed by polyuria. Both of them are rare in infants and in the very old. A fine specimen of the last anomaly has been under my observation in a boy ten years old with the diagnosis of mitral stenosis and chronic myocarditis in my division at Roosevelt Hospital.

Vascular murmurs should not easily be mistaken for cardiac; as a rule they are transmitted. They are very rarely confined to the arteries of the neck, either in the adult or in the young. The relatively

¹American Medical Quarterly, September, 1899; Pediatrics, February, 1900.

large size of the carotid in the young, mainly in the rhachitic young, with its lowered blood pressure, may give rise to an occasional soft murmur. This infantile condition of the carotid (and basilar) artery accounts for the murmur which is often audible over the open fontanelle and was (rather erroneously) attributed by Fisher (Boston, 1835) to rhachitis only. It is quite possible that the irregular shape of the rhachitic carotid canal contributes to the murmur which has always been mentioned among the "functional." If, however, the large size of the artery, with its consecutive diminution of blood pressure, or an anatomical change in the carotid canal, or both, cause the murmur, to what extent are we justified in calling functional the murmur which is due to tangible anatomical causes?

Venous murmurs should never be mistaken for those originating in the heart. They are frequent, mostly about the chest and neck, and are generally found in anemic adults, less so in anemic children, but still less in infants, and never, it appears, in babies suffering from atrophy. The jugular vein is a frequent seat of murmur, particularly when the *bulbus venæ jugularis* is large compared with the size of the vein; in these cases the murmur is explained by the formation of a vortex. The *venæ anonymæ* also exhibit murmurs, which are combined with those of the jugular, are heard on both sides of the sternum, and are not isochronous with the sounds of the heart. The number of very young children who develop other than organic murmurs is small. That is why, while venous murmurs are frequent in the pernicious anemia, leucocythemia, scorbutus and hemophilia of the adult, even when cardiac murmurs are still absent or not marked, they are often missed in those of the young child. In 50 cases of infantile scorbutus I do not remember to have ever seen them.

The heart of the young is comparatively large, heavy and healthy. Its weight in the newly born is .89% of the body-weight; in the adult, .52%. In the newly born the cavity, however, is small, 23 cubic centimetres, compared with 100 cubic centimetres at the seventh, and 140 cubic centimetres at the fifteenth year. Its muscle is massive, equally thick on the right and left sides, its contractions rhythmical and energetic and quite frequent. That is why the valves, which are small and elastic, vibrate easily and quickly. During the first five years there is an increase of the heart in bulk and weight, but none in circumference. That is why the area of dulness in early age is extensive and the impetus quite marked. The cavities dilate rapidly only after the fifth year, and the large arteries, mainly the carotid and subclavian, lose their disproportionately large size only after the seventh year.

This condition of things prevents a predisposition on the part of the infant heart to murmurs of any kind. Indeed they are very rare in the first four years. This was clearly stated by me in the *Brooklyn Medical Journal*, March, 1888, where, after remarking that authorities do not agree on this subject, I said, "the heart exhibits functional murmurs seldom. Whenever there are murmurs present in the infant, it is safe to attribute them to organic disease rather than to mere functional disorder." Fifty years ago Charles West expressed the opinion that they were frequent, but it is very probable he mistook or meant vascular murmurs. Gerhardt thinks that they are rare; Biedert and Steffen, how-

ever, frequent. Bouchut believed them to be very frequent, under the impression that what he described as a proliferating endocarditis (*endocardite végétante*) in the newly born must necessarily cause murmurs. What he so denominated was, however, nothing but Albini's valvular nodes, or the "blood cysts" of Luschka and of Parrot, recently again described by Giovanni Berti ("*Noduli Lematici delle Valvule Cardiache*," 1898), that is, small elevations on the lower side of the valves containing or depending on minute hemorrhages. They are very frequent and liable to disappear, but do not always do so. They are apt to be on the mitral valve; are found in the newly born, and persist, and suggest the diagnosis of intra-uterine heart disease; but are found in the left cardiac cavity, contrary to the rule according to which fetal inflammation or arrest of development occurs in the right side, and do not result in either dilatation or hypertrophy. Such cases, which I have had an opportunity to demonstrate in my clinic perhaps once a year, must surely have been observed by Hochsinger when he absolutely and positively denied the occurrence of functional murmurs within the first few years of life. Surely these murmurs when found cannot be called functional; they are organic.

THE USE OF INCUBATORS.

At the stated meeting of the Section on Pediatrics at the New York Academy of Medicine, November 9, 1899, several very important reasons were offered for the high mortality among premature infants. Among the causes particularly noted were an insufficient supply of fresh air, lack of development of the lungs and chest walls, atelectasis, improperly cleansed incubators leading to various forms of infection, and lastly improper feeding.

The opinion was given that when modified milk was used a very low percentage of fats and proteids should be insisted upon. In the *Revue mensuelle des maladies de l'enfance* for December, 1899, is an article by Prof. V. Hutinel detailing the results of his experience in the use of incubators at the *Hospice des Enfants Assistés*. The high mortality among incubator babies he attributes to the following causes:

(1) Some infants are not viable; their organs being incompletely formed cannot perform the functions necessary for the maintenance of life.

(2) Others present malformations inconsistent with life, or are affected with an hereditary taint, such as syphilis, which has already done irreparable damage at the time of birth.

In these two cases the incubator is useless; if it protects against cold, which is all it can do, it cannot perfect undeveloped organs or cure hereditary blemishes.

(3) Some babies which seem well at birth fall ill soon after; they are put into an incubator and die there. In these cases the incubator is not to blame.

(4) This class includes premature infants who are apparently well developed and comparatively healthy when placed in the incubator. It seems if they ought to develop but they die after a few days. The author considers that they die from various infections. These are not simple surface infections, for the actual presence of the pus-producing organisms in the blood has been frequently demonstrated. The infections are due to the lack of resisting power on the part of the infantile mucous membranes which cannot oppose

the entrance of germs if the surrounding atmosphere is contaminated. That the air comes from outside is not sufficient to eliminate contagion, as the incubator must be opened from time to time and the patients are attended by those who may readily infect them. The author insists most strongly upon a well-ventilated and sunny room for incubators, and holds that in hospitals there should be at least three apartments devoted to the rearing of premature infants, one for the healthy, one for the ailing, and one for the ill ones. Germs undoubtedly flourish in an incubator, with its constantly elevated temperature, so that an infant should be removed just as soon as it is able to maintain its temperature at 98.4° F. for thirty-six or forty-eight hours. It should then be enveloped in cotton and surrounded with hot bottles. Plenty of fresh air and sunshine is required. If one of these babies falls ill it must be separated at once from the others. In regard to putting it back into the incubator, infection when it occurs is more likely to be begun outside. Incubators should be so constructed that they can be readily cleansed. The temperature changes involved in doing this are of little importance provided they are not too prolonged. By following these principles the author has lost but 3 out of 21 cases, averaging less than four and a half pounds.

THE SPLEEN IN RHACHITIS.

The investigations made by Dr. Sasuchin² have shown that the spleen in rhachitis is invariably enlarged, with the exception of the cases of clearly pronounced general atrophy in which the spleen is of normal size and weight, or below normal. A second marked characteristic is more or less thickening of the capsule and the increase in the consistency of the organ. The third peculiarity of the rhachitic spleen is the significant anemia of the organ and the diminution in the number of Malpighian bodies, which in children are otherwise well developed, but in these conditions are smooth and hardly perceptible. On section the spleen is of a blood-red color and the trabeculae clearly marked by interlacing threads, and on drawing the knife over the cut surface there remains upon the edge blood and pulp tissue. The characteristics described hold true in all cases of rhachitis, and in general indicate approximately the intensity of the changes in the bones. Only in occasional cases was the spleen markedly enlarged, or did it show all the characteristic markings where there were unimportant alterations of the bones.

In 66 cases of rhachitis the spleen was enlarged in 12, that is, 15%; in 2 cases its weight was approximately normal, and in 2 cases below the average weight of the corresponding age. In both of these cases the whole body was, however, very much atrophied.

The author presents the accompanying table of the spleen in rhachitic cases.

Only those cases were taken into consideration in which the rhachitis was not complicated by any disease which could exercise an influence upon the size of the spleen, and the author made use only of the bodies of children dying of intestinal disorders and catarrhal pneumonia. In all the cases the alterations in the bones were clearly indicated. In the 15 cases studied the microscopic changes were very

marked in 10, and in the remainder important pathological changes of lesser degree were found. From the 11 cases in which the microscopic and macroscopic appearances of the spleen are described in detail the writer draws the following inferences:

He considers the process to be an interstitial splenitis. The fibrillary connective tissue in considerable quantity divides the spleen into island-like areas, which consist of a small number of lymphatic cells embedded in a thick reticulum of ground substance. Moreover, in all the preparations the walls of the great vessels were found to be thickened and the lumina narrowed. New formation of connective tissue occurs with the above processes and presents the appearance of a peri-arteritis. The veins are in sharp contrast, their lumina being widened. In the cases in which the changes were sharply marked there was also a perceptible alteration of the intima, which appeared thickened; there was endothelial swelling, and the lumina were still more narrowed. The inflammatory appearances showed themselves by the appearance of epithelioid cells of irregular form with turbid, very colorless protoplasm, and an indistinctly circumscribed nucleus which stained poorly, like the

nucleus of a round mononuclear lymphocyte. The nucleus had a round or oval shape. Epithelioid cells occupied for the most part the centre of the follicle, which at times consisted exclusively of these cells. One by one these cells lose their nuclei and contour, and finally they are transformed into a homogeneous mass. The writer is disposed to consider this process as a chronic productive inflammation, which is accompanied by an increase of the epithelioid cells with a subsequent fatty and albuminous degeneration of the same in the centre of the follicle. Moreover, the anatomical pathological changes described were accompanied in certain cases by an infiltration of the pulp and follicle with red blood corpuscles which were converted in some instances into masses of pigment. Similar inflammatory appearances in many preparations of the spleen in children who were not rhachitic, but who had died of diphtheria, catarrhal pneumonia and enteritis, were found, but in these cases the changes were considerably less marked. Whether the higher degree of inflammatory appearance bears any relation to rhachitis, or whether it is present to the same extent in other conditions in which the spleen appears to be more severely involved

² Jahrb. f. Kinderheilk., 51, der dritten Folge, Bd. 1, II. 3, March 13, 1900, von Dr. Med. P. N. Sasuchin.

than in the control cases, the writer is not able to determine definitely from the cases under his observation. Stilling² who investigated the spleen in catarrhal pneumonia and diphtheria found that large cells appeared in the centre of the Malpighian bodies and exceeded in size by three times that of the lymphocytes, and which showed a faintly colored granular protoplasm with round or oval nuclei. These cells were found in groups or singly. In the first case they occupied the whole central space of the follicles, which appeared less intensely stained than the periphery. Similar alterations were also found in cases of rachitis. Moreover, he observed that almost all around the follicles were spaces bounded on either side by endothelial cells (venous sinuses, according to Recklinhausen) and which furnished the source of the increase of the cells.

The question as to how long the rachitic poison takes to bring about the characteristic alterations in the spleen can only be answered in the following way: The youngest case in which rachitic changes were found in the spleen was two months. Whether these changes had to do with congenital rachitis could not be decided for lack of known data. The oldest child with rachitic changes showing a thickening of the trabeculae and reticulae, but without inflammatory appearances, was a girl of four years who died of an injury to the skull and whose spleen was macroscopically quite normal.

If one holds to the opinion that the appearance of the spleen in rachitis is dependent on the complicating diseases, it is not at all clear why one and the same picture prevails when the complications differ, why the appearances described were present in all the cases described, why in many cases the degree of interstitial inflammation corresponded in degree to the intensity of affection of the bony system, and why in the control cases of catarrhal pneumonia and enteritis without rachitis they were not present, or if present were of much less degree. As the changes in the spleen which have been described suggest the appearances which occur in syphilis and tuberculosis, these diseases were carefully excluded in the cases investigated. As a result of these alterations in the spleen the writer concludes that the spleen as a blood-manufacturing organ may be considerably impaired, and he suggests the careful examination of all the blood-manufacturing organs in the early stages of rachitis, as perhaps by this means some light might be thrown upon the etiology of the subject.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

J. BERGEN OGDEN, M.D., SECRETARY.

REGULAR meeting, Wednesday, May 16, 1900, Dr. H. F. VICKERY in the chair.

Dr. G. G. SEARS presented a short communication entitled

A NOTE ON RECTAL FEEDING IN PEPTIC ULCER.¹

¹ See page 446 of the Journal.

² Fragmente zur Pathologie der Milz. Virchow's Archiv, Bd. ciii.

Dr. SMITHWICK: It seems to me if nutrient enemata can be given successfully in such large quantities that one of the chief objections to depending on nutrient enemata in these cases is removed, and that is, that the patients lose strength. The idea is wholly new to me and I think it is a very valuable one.

Dr. BOLAND: In a practice of twenty years I cannot say that I have ever fed a patient satisfactorily by the rectum even temporarily. I have used a soft-rubber tube and have only succeeded in distending the rectum the first four or five inches. Dr. Sears uses a stiffer tube and possibly gets past the sigmoid flexure. Probably there has been something wrong in my technique. I am glad to hear the doctor's encouraging results and shall try again.

Dr. VICKERY: I should like to ask Dr. Sears if he will tell the society in what proportion of cases he is successful in giving a pint at a time.

Dr. SEARS: I asked my house officer today that question in order to get another opinion. We have used this method in all cases which required rectal feeding during the last eight months, so that he has had quite a little experience. He replied that he did not think that any more discomfort was caused by the larger amounts. Personally I should say that I cannot remember a case where I have not been as successful in this way as in the other and intolerance has come on no sooner. Many of the patients have continued to take them for two weeks. I do not remember having kept them up longer than that, although they were not stopped on account of the condition of the rectum. One of the most remarkable things occurred in the first case, where the patient seemed to gain weight. Of course, the enemata should be given to stay and it does make considerable difference how they are given. They should be injected very slowly, and if expulsive efforts on the part of the patient occur it is better to wait until they have stopped before continuing. I have found that some nurses are more successful than others, but they have been given in all my wards. The first injection is as large as the succeeding ones.

Dr. VICKERY: Certainly it would be a great improvement in rectal feeding if a pint could be given at a time.

Dr. H. F. HEWES read a paper on

ACHLORHYDRIA; ITS EFFECTS AND THEIR TREATMENT.²

Dr. SMITHWICK: I should like to ask if Dr. Hewes has ever seen the secretion of HCl re-established in any of these cases?

Dr. HEWES: I have never seen the secretion re-established in a case in which I had found the absence of free or combined HCl a constant feature during a period of one or two months. It is not uncommon to find absence of secreted HCl upon single examinations followed by presence of HCl upon examination a few days or weeks later. The cases which I have classed as achlorhydria have shown a constant absence for periods of three months or more.

Dr. SMITHWICK: My experience is confined to a few cases I have seen in the clinics of some of my friends; simply had them under observation. My experience is the same. I have watched some of them for months and never seen HCl re-established.

² See page 447 of the Journal.

DR. M. P. SMITHWICK read a paper entitled

EYE STRAIN AS A CAUSE OF GASTRO-INTESTINAL DISTURBANCES.*

DR. FAXON: I can give a case in point of a little boy of eleven who was suffering extremely with headache, eyeache and pain in the epigastrium. Any study or persistent use of his eyes would bring the same tendency to headache, eyeache and blurring and pain in the epigastrium. On examination the little fellow had eye strain and astigmatism. I do not think the errors have been corrected yet and I cannot speak of the results.

DR. COGGESHALL: I am very glad to see that some one has taken the trouble to call the attention of the society to this subject of eye strain in connection with indigestion and I think it is a thing that has been altogether too much overlooked by the general practitioner. We all know that headaches come from eye strain, and if the patient has any kind of headache many a doctor will send him to the oculist, and some of us can differentiate an eye headache and predict that glasses will cure the headaches, but I think very few of us realize how often, according to my experience, you can have persistent chronic indigestion which is apparently due entirely to the eyes. I think I can quote at least 9 cases in the past seven years where I have had complete cure of the indigestion, after every attempt at dieting and administration of all sorts of drugs for the indigestion itself had failed, on sending the patient to the oculist. In my experience they have been to great extent cases that did not have any headache accompanying indigestion, no attacks of sick headache, bilious headache, so commonly recognized as due to the eyes, but most of them simply persistent recurrence of eructations of gas, distress, nausea, feeling of weight in the stomach coming on anywhere from a few minutes to two or three hours after eating. These cases I speak of without affirming positively they were cures due to the glasses were cases where I was unable to make out anything in the habits of eating or the diet which would possibly account for the trouble. I think 7 out of the 9 cases were in women, and I have seen a few where the eye also seemed to complicate other cases, — at least the patient got partial relief from wearing glasses, though they did not cure the indigestion entirely, — but the majority of them were cases complicated by uterine trouble of more or less mild types with eye strain superadded, and where I do not know that one could say positively that the eyes were the only cause. If we all could adopt the practice Dr. Smithwick has adopted of investigating the eyes in every case of indigestion, I think we would find a larger number than we realize of cases where the eyes had at least aggravated the trouble, so that it is now my practice with any indigestion that does not yield promptly to treatment, or I do not get an obvious explanation in the use of eating or the character of the food, bad teeth or some other more immediate cause, to send them to the oculist and I very rarely indeed find obstinate cases which do not have at least a certain amount of eye trouble complicating the other causes, and in the majority of cases I have seen the last three or four years, I am sure they have nearly all got some relief to the stomach symptoms from wearing carefully fitted glasses.

In this connection I should like to say, what may seem absurd to some of the members of the society, that I believe we also ought to look for eye strain as a possible cause of some cases of obstinate constipation. If eye strain can cause gastric symptoms I don't know why it is any more impossible to suppose that eye strain can also affect the intestines, and I have the records of at least one case of constipation of twenty years' standing that was sufficiently bad, so that the patient, who was a nurse, had to take laxatives all the time, — she never let a day pass without taking laxatives. I tried her on very carefully regulated doses of cascara sagrada three times a day and aloin, belladonna and strychnine pills, and the common forms of laxatives I had found frequently would stand gradual reduction of the dose instead of becoming more and more inert, and in every case she had to take larger instead of smaller doses, until on account of other trouble, headaches which did point to the eyes, she was sent for the fifth or sixth time to an oculist and the last doctor she consulted succeeded in discovering slight degrees of astigmatism in both eyes, and after the last glasses her headaches not only disappeared, but her constipation diminished within six months so that instead of a drachm to a drachm and a half of cascara sagrada three times a day to get a moderate movement, she was taking but five minims at a time, and when I last heard of her she never had to take any laxative except when particularly tired from hard work. I have seen a number of other less striking cases where it seemed to me that the complete correction of some very slight eye difficulty produced a most marked effect on persistent constipation and on persistent intestinal indigestion, as well as on cases of ordinary indigestion.

DR. SMITHWICK: I would say that the point one of the gentlemen brought out about marked errors without headache has struck me in observing my cases. I asked an oculist today if he commonly saw the same thing and he said he did. He also told me that the small degrees of astigmatism are more likely to cause symptoms than the large ones. He explained it in this way: the eye will endeavor to rectify a defect and it succeeds in doing it if the defect is small, and, as it were, carries the load. If it is too great it gives up the battle after a certain length of time.

NEW YORK STATE MEDICAL ASSOCIATION.

SEVENTEENTH ANNUAL MEETING, HELD IN THE ACADEMY OF MEDICINE, NEW YORK, ON OCTOBER 15, 16, 17 AND 18, 1900.

FIRST DAY.

THE session was entirely devoted to executive business.

SECOND DAY — MORNING SESSION.

Upon calling the association to order the president took the occasion to state that it was their good fortune to be visited by Sir James Grant, of Ottawa, Canada, and that it was an honor to introduce so distinguished a practitioner from over the border.

SIR JAMES GRANT was received with hearty applause. He accounted for his presence in a way that at the outset seemed political. "I have come to New York," he said, "in the interests of annexation. In fact my son is about to annex in marriage one of the

* See page 444 of the Journal.

fairest of the daughters of your city, and this will be but one more tie added to the many strong ones which already knit me to the United States." In a brief address he spoke of his investigations, recently reported in Canadian and English medical journals, into the nature of muscular rheumatism. This, he had proved to his own satisfaction, is no more than the manifestation of abnormal electricity in the body. If this fact is recognized and treatment followed in conformity therewith, the muscular rheumatism can be got rid of in five or six minutes instead of as many months. He has found that the use of ten or a dozen fine No. 8 needles piercing the muscle tissue will serve to discharge the surplus electricity, the muscle becomes soft and pliable, and the pain vanishes.

DR. F. H. WIGGIN, for the Committee of Arrangements, of which he was chairman, reported in detail the plans which had been formulated for the entertainment of the members.

Owing to the enforced absence of DR. ALVIN A. HUBBELL, of Erie County, his paper on

THE RELATION OF MIGRAINE TO EPILEPSY

was read by title.

DR. A. D. ROCKWELL, of New York City, read a paper entitled

ON THE ANALOGY BETWEEN NERVOUS CONDUCTIBILITY AND ELECTRIC CONDUCTIBILITY AND THEIR RELATION TO FUNCTIONAL NEUROSES.

To compare nerve current and electric current it is necessary to become familiar with the coherer used in wireless telegraphy. When the neurons are studied in the light of this analogy, the most striking resemblances are discovered and a new explanation of many of the neuroses is seen.

SIR JAMES GRANT discussed this paper, which he characterized in the most complimentary terms. As a healthy neuron differs from a diseased neuron, it is found that electricity to be of value must be applied before the stage of paralysis is reached.

COCAINISM.

DR. THOMAS D. CROTHERS, of Hartford, read this paper. After commenting upon its prevalence and rapid increase, he remarked of the addiction to cocaine that it is characterized in its habitués by mental exaltation, great volubility of words without point or purpose and without logical conclusion, style smooth and continuous—this may be recognized in fiction, poetry, and even in medical journal articles; there is frequently a mania for the writing of many letters. The conclusion of the paper was a warning against the use of cocaine under circumstances which might lead to the formation of the habit.

DR. JAMES J. WALSH, of New York City, finding the end of the session close at hand, gave a rapid recapitulation of the more salient points of his paper on

HEART COMPLICATIONS IN RHEUMATISM.

In the course of his remarks he presented a digest of the more important conclusions on the subject, which were presented at the International Medical Congress in Paris.

AFTERNOON SESSION.

The session was devoted to a

SYMPOSIUM ON OBSTETRICS.

It was opened by PROF. EDWARD P. DAVIS, of Philadelphia, who read a paper on the

TREATMENT OF THE PATIENT DURING THE WEEKS PRECEDING THE EXPECTED CONFINEMENT.

He emphasized the importance of examining the different organs and also the urine and solid excreta. The diet should also be carefully attended to. It should be largely a milk diet. Tea and coffee should be avoided. Alcohol was not indicated, but on the contrary was apt to be injurious. Fruit should be stewed or baked. The body should be regularly sponged, the residence kept well aired, and gentle exercise taken in the open air. In cases of insomnia it was a mistake to give bromides; chloral or some derivative from it gave the best results. It was well to catheterize the patient under some circumstances under an anesthetic. In looking for sepsis, the possibility of syphilis should not be overlooked, and the same remark applied to gonorrhœal affections; when traces of either of these diseases were discovered they should be treated locally as well as constitutionally.

DR. AUSTIN FLINT, JR., of New York, followed with a paper in which he discussed the

MANAGEMENT OF LABOR, INCLUDING THE USE OF FORCEPS.

The proper management of these cases, he remarked, was more far reaching in its importance than the mismanagement of a few abnormal cases. Statistics showed a gratifying improvement in the success with which these cases were treated, and it was found that the less interference of any kind that was practised the less was the percentage of accidents. He advocated the careful examination of the patient at the end of the eighth month with the view of avoiding septic conditions. It was better to make one long and complete examination than a series of short ones. Undue delay in completing the delivery was almost as dangerous as undue haste. It was better in many cases to use forceps than to wait too long.

The third paper was by DR. GEORGE W. JARMAN, of New York, and dealt with the

AFTER TREATMENT OF THE MOTHER IN NORMAL CASES.

The fourth paper, by DR. BERNARD COHEN, of Erie County, referred to the

TREATMENT OF THE CHILD.

DR. JOHN E. WEEKS, of New York, described the

PATHOLOGY, PROPHYLAXIS AND TREATMENT OF OPHTHALMIA NEONATORUM,

quoting statistics to show the large percentage of children whose eyes were affected by the gonococcus of Neisser or other bacteria, for the treatment of which it was usual to use a solution of nitrate of silver.

DR. EDWARD REYNOLDS, of Boston, discussed the MAJOR OBSTETRICAL OPERATIONS FROM THE STAND-POINT OF A GENERAL PRACTITIONER,

calling attention to the great advances that had been made in this branch of surgery, and maintaining that general practitioners must either get into the way of

performing them themselves, or be prepared to call in an expert when a major operation appeared to be desirable.

PURPERAL SEPSIS, ITS PATHOLOGY AND TREATMENT.

DR. WM. B. R. PRYOR, of New York, brought the symposium to a close by reading this paper.

EVENING SESSION.

A SYMPOSIUM ON THE BLOOD

engaged the attention of the association at this session, DR. EDWARD K. DUNHAM, of New York, dealing with the technique of blood examination; PROF. JOSEPH C. BLOODGOOD, of Johns Hopkins University, with leucocytosis; PROF. ALFRED STENGEL, of the University of Pennsylvania, with pernicious anemia; PROF. C. Y. WHITE, of Philadelphia, with leukemia; DR. T. LEWALD, of New York, with parasites in the blood, and DR. H. C. GORDINIER, of Rensselaer County, with the value of blood examination in the diagnosis of trichinosis.

THIRD DAY. — MORNING SESSION.

NECESSITY FOR FURTHER ORGANIZATION ON THE PART OF MEDICAL MEN.

DR. C. A. L. READ, President of the American Medical Association, being introduced by the chairman, was received with applause. He said he accepted the cordial greeting as a mark of fealty to their great national association. He had peculiar pleasure in meeting the members of the New York State Medical Association because he discovered in their charter a proclamation of principles which appealed to him with particular force. These principles were the cultivation of their humane science, and the promotion of *esprit de corps* among its members, the maintenance of the honor and character of the profession. Were not these sufficient to commend the organization to the enthusiastic regard of every practitioner in that great Empire State? They had also provisions of a beneficiary character which he understood they were holding under consideration, and which must appeal to every man who had a sympathetic bosom and understood the mutability of fortune. It was the irony of experience that he who needed succor was often the Samaritan himself. This feature of their organization might well be imitated by every State organization in the country. On the present occasion, however, it was the fourth plank in their platform that particularly interested him. He referred to that plank which announced as one of their fundamental principles the promotion of harmony, or as the charter had it, "the establishment and furtherance of cordial professional relations and fellowship between the medical profession of the State of New York and the medical profession of other States of the United States and of foreign countries through the medical associations and societies of such States and countries." Criticism of this clause must exhaust itself in commendation. It breathed the spirit of harmony. That spirit of harmony was abroad in the profession, not alone in the State of New York, but the country over. This clause, if it meant anything, as it assuredly did, meant the union of their local profession. This clause meant that every member of their State organization should become a member of the American Medical

Association, and he was delighted to know that already many bore that relation. If it meant anything, it meant, as it should mean, that they stood consecrated to the idea, over and above all other ideas, of the unity and solidarity of their great national profession. He knew of no object more worthy of their zealous devotion. It simply meant that this movement was one on their part that would command the cordial co-operation of the great national body of the profession, not as represented by the American Medical Association, but of the great independent portion of the profession as well, and if they stopped to think of what that independent body consisted, they would appreciate its magnitude. With their splendid success as a State organization, unparalleled as it was among such organizations, notwithstanding the existence of another State organization in the same field, the fact remained that out of a total of about 10,000 regular practitioners there were only some 2,000 within the fold of organization, while in the United States, out of a regularly qualified profession of nearly 100,000, only 10,000 were enrolled in the ranks of the American Medical Association. There was therefore a large work before them if they were to aim at the real consolidation of the profession. Still, as he had said, the spirit was abroad in the land. It would brook no opposition, and it must work in the direction of union and harmony. The sentiment was deeply graven on the minds of the general profession that to make its influence effective at the State capitals and in Washington the profession must stand together, man to man and shoulder to shoulder. It ought to take but little effort to accomplish a change which was already accomplished in the sentiment of those most concerned. There was not much occasion for the rescinding of resolutions or for the modification of by-laws or constitutions. Some memories of past differences might well be effaced, and some resolutions which had served their purpose might with advantage be modified or revoked. These were subsidiary matters, and could be left to take care of themselves. What was important to remember was that he who interposed authority, prerogative or prejudice to delay the movement for unity and harmony would be regarded as the enemy of progress. He looked with confidence to that great and efficient organization to help on the good work, and he assured them that from the remotest districts of the country they would find coming back to them words of true encouragement and co-operation. He believed — and he had reason for the faith that was in him — that the medical profession the country over was ready to take any necessary and advisable step in this direction with the end that it might present a united front to the dawning century.

DIPHTHERIA AND MILK SUPPLIES.

In a paper on this subject DR. CHAUNCEY P. BIGGS, of Tompkins County, said strong circumstantial evidence had frequently been brought against milk supplies as being the source of infection in epidemics of diphtheria. There was, however, usually one missing link in the chain, but it had been supplied in an outbreak which had taken place at Ithaca in the beginning of the year. The milk supply of all the families affected was traced directly or indirectly to one dealer. On his farm being inspected no unsanitary conditions were found, nor was there any trace of

the disease in the household. It was elicited, however, that he bought some of his milk from another farmer, and on the latter's homestead being visited it was found that several of the family, including those who attended to the cows, were suffering from sore throats, some of the cultures from which were examined and found to be diphtheritic. The wholesale milkman was prohibited from selling milk for a time, and no other cases developed except such as could be traced to primary infection.

PROF. VERANUS A. MOORE, of Cornell University, read a paper on the

MANAGEMENT OF DIPHTHERIA IN SMALL CITIES FROM A BACTERIOLOGICAL POINT OF VIEW.

In the Ithaca case the previous freedom of the city from the disease made laymen and physicians alike sceptical as to the new methods adopted. Several members of the profession had no faith in antitoxin, the fact being that they had never had occasion to test it. The Board of Health, nevertheless, took drastic measures, making early cultures from suspicious cases, establishing a rigid quarantine and not removing it until a negative diagnosis was made, and then carrying out a thorough system of disinfection. The result was that the epidemic was promptly stamped out.

THE TONSILS AS PORTALS OF INFECTION.

DR. JOSEPH ULLMAN, of Erie County, read this paper. He especially referred to septic disease as malignant endocarditis, and said he regarded rheumatism as a mild form of pyemia, in which the staphylococci and their organisms became much attenuated. He also spoke of the relation to chorea and tuberculosis borne by affections of the tonsils.

DR. MARCEL HARTWIG, of Buffalo, presented a communication on the

PRESENT STATUS OF JONNESCO'S OPERATION.

He contended that neurectomy of the cervical sympathetic ought to be called by Jonnesco's name.

DR. CLARENCE G. CAMPBELL, of New York, read a paper on the

TREATMENT OF PULMONARY TUBERCULOSIS.

It had special reference to the climate of Arizona.

AFTERNOON SESSION.

This session was devoted to a

SYMPOSIUM ON TUBERCULOSIS.

It was opened by PROF. VICTOR C. VAUGHAN, of the University of Michigan, who dealt with the

GENERAL ETIOLOGY, PATHOLOGY, AND PROPHYLAXIS.

Starting with the assumption that the bacillus of Koch was the sole exciting cause of tuberculosis, he proceeded to show that, much as had been done in recent years, much more still remained to be attempted. He discussed the question whether the bacteria of the disease could exist and multiply outside of the animal body, and came to the conclusion that they could not, except when removed for experimental purposes, and then they only lived for a limited period. There was a pseudotuberculous bacillus, but there was no evidence to support the theory that it could change into

the bacillus which caused disease in the human body.

He contended that no dairyman should sell milk without a license, and all milk cows should be tested with tuberculin. Tuberculosis, so long as it did not become a mixed infection, was not likely to become malignant. It always began as a local disease, but it had a predilection for the lungs, where it was more likely to become mixed than elsewhere. He advocated the establishment of hospitals and other measures, and said that if this was done there was no reason why the present generation should not eradicate tuberculosis as their ancestors had succeeded in eradicating leprosy. If it was correct, as some supposed, that the germs differed greatly in virulence, it was important that those already affected should be protected from those who had more malignant germs. He also showed the importance of improving the condition of the poor, among whom the rate of mortality from tuberculosis was far above that among the better-off classes.

DR. JONATHAN WRIGHT, of Brooklyn, presented the next paper, which was on the

PATHOLOGY, DIAGNOSIS, SPECIAL PROPHYLAXIS AND TREATMENT OF TUBERCULOSIS OF THE NOSE AND THROAT.

It was important, he said, to distinguish between syphilis of the larynx and laryngeal tuberculosis, and he disclaimed the ability to do this without making a thorough examination. In making a diagnosis they should always think of syphilis, and keep on thinking of it. The ideal method of dealing with laryngeal tuberculosis was local and constitutional treatment under climatic change. It is doubtful if a radical cure was ever effected, but much could be done in palliating the dreadful symptoms, and prolonging life. He favored intratracheal injections.

TUBERCULOSIS OF THE EYE; ITS DIFFERENTIAL DIAGNOSIS, PATHOLOGY AND TREATMENT.

DR. CHARLES STEADMAN BULL, of New York, discussed this subject.

DR. SEYMOUR OPPENHEIMER, of New York, spoke on

TUBERCULOSIS OF THE EAR.

He laid stress on the fact that change of climate, diet and general constitutional treatment were as essential in tuberculosis of the ear as in ordinary tuberculosis. Surgical measures were contraindicated except in rare cases.

PROF. MAURICE H. RICHARDSON, of Harvard, read a paper on

TUBERCULOSIS OF THE LYMPHATIC GLANDS OF THE PERITONEUM.

He said the propriety of having recourse to surgery in many cases of this kind seemed unquestionable.

THE SURGICAL TREATMENT OF URINARY AND UROGENITAL TUBERCULOSIS.

This was the specialty treated of in the paper of DR. SAMUEL ALEXANDER, of New York. This form of the disease, he observed, did not differ materially from other tuberculosis, except in this respect, that it was more often complicated by pus infections. There were both primary and secondary infections, and it

was strange how little positive knowledge they had in regard to the former. He urged the importance of co-operation between clinical observers and pathological experimenters with the view of discovering more about the etiology of the disease. The usual remedy was to remove the whole focus of the infection. He believed that generally the epididymis was the original seat of the disease.

Dr. E. H. NICHOLS, of Boston, discussed

TUBERCULOSIS OF THE BONES AND JOINTS.

Dr. JOHN A. FORDYCE, of New York, considered

TUBERCULOSIS OF THE SKIN AND SUPERFICIAL FASCIA.

FOURTH DAY.

Dr. HIRAM H. VINEBERG, of New York, read a paper on the

DIFFERENTIAL DIAGNOSIS OF ECTOPIC GESTATION, with special reference to early abortion. He commented on the frequency with which extra-uterine gestation was mistaken for ordinary abortion, and maintained that every case of apparent abortion should be looked upon with suspicion, and the patient should be anesthetized so that a thorough examination could be made with a view to possible surgical interference.

In the course of a short discussion which followed, the PRESIDENT said an examination should never be made without the surgeon being prepared for an abdominal section.

THE RESOURCES OF MODERN MINOR GYNECOLOGY.

Dr. A. H. GOELET, of New York, discussed this subject. He protested against the growing tendency to regard gynecology as a purely surgical field. The resources of minor gynecology were much greater than they were fifteen years ago, and yet even before then many cures were effected without surgical interference. Among the modern resources which were of great value in this species of work he mentioned the vaginal speculum, the uteroscope and the cystoscope, sponge tents, etc., besides various anesthetics, electricity and numerous therapeutic agencies.

Dr. JULIUS H. WOODWARD, of New York, read a paper on

STRABISMUS AND ITS MANAGEMENT.

He described the pathology and symptoms of paralytic and non-paralytic strabismus, gave a recapitulation of the differential diagnosis, and pointed out the psychological and sociological significance and their relation to eye strain.

Investigations upon

SPECIFIC CORPOREAL GRAVITY AND THE VALUE OF THIS FACTOR IN PHYSICAL DIAGNOSIS

were reported upon by Dr. HEINRICH STERN, of New York.

Dr. DOUGLAS AYRES, Montgomery County, read a paper on

ASEPTIC MINOR SURGERY,

wherein he indulged in a retrospect of the pre-aseptic period, reviewed the instruments of olden times, and traced the thoughts and provings which gradually led up to the present greatly improved technique. The

importance of cleanliness in every detail in preparing for all operations was strongly dwelt upon, and a sketch given of an ideal office.

AMPUTATION AT THE HIP JOINT.

Dr. JOHN A. WYETH read a paper descriptive of this operation, and giving a report of 217 cases in which the author's method of hemostasis was employed. It had, he remarked, been always considered one of the greatest and most difficult of surgical operations, and it was only within a recent period that it had been recognized as justifiable. He then proceeded to show the simplicity and safety with which it could be performed under his methods, and adduced statistics to show that it had reduced the death rate from such operations to a very large extent, the percentage of those who died in the 247 cases reported being 21, of whom the larger number died from other causes, while under older operations the percentage was 40 and 50 and even higher. Several speakers bore testimony to the success which had attended operations in which the method referred to had been adopted.

Dr. JOHN F. ERDMANN, New York, submitted a report on 3 cases of

INTESTINAL OBSTRUCTION DUE TO MECKEL'S DIVERTICULA.

He called attention to the similarity in the symptoms of all 3 cases to the symptoms of appendicitis, and also to the difficulty of making an early diagnosis between these two conditions.

INTRASPINAL COCAINIZATION FOR THE PRODUCTION OF SURGICAL ANESTHESIA

was discussed in a paper by Dr. S. ORMAND COLDAN, of New York, who gave a sketch of the history of the operation from the time it was first performed by Corning, and described its technique as now practised by Tuffier in Paris. He showed the great advantages that would result from the operation, but admitted that it was not likely to become popular because of the difficulties and dangers that attended it. He reported a number of cases in which he had performed the operation with success.

In the course of the discussion which followed, Dr. J. RIDDLE GOFFE said he had had the good fortune while in Paris recently to accompany Tuffier to the hospital and see him operate. Tuffier was very enthusiastic about the method, which he had been using for about two years. He had followed it in about 200 cases, and was perfectly satisfied as to its safety.

Several of the other speakers dwelt on the danger of infection and of the cocaine reaching the brain, etc., the consensus of opinion evidently being that it was necessary to await further investigations before adopting the method.

Papers on the

TECHNIQUE OF BLOODLESS WORK

by Dr. ROBERT H. M. DAWBARN, of New York, and

OPERATIVE TREATMENT OF SYMBLEPHARON BY THE USE OF THEIRSCH GRAFTS.

by Dr. WILBUR B. MARPLE, of New York, were afterwards read, and the programme brought to an end by the reading by title of a paper by Dr. EDWARD

H. SQUIBB, JR., of Brooklyn, containing brief comments on the materia medica, pharmacy and therapeutics of the past year.

The following officers were elected: President, Dr. John A. Wyeth, New York; Vice President, Dr. Alvin A. Hubbell, Erie County; Secretary, Dr. F. H. Wiggin, New York; Treasurer, Dr. Edward H. Squibb, Brooklyn.

AMERICAN PEDIATRIC SOCIETY.

TWELFTH ANNUAL MEETING, HELD IN ST. JOHN'S PARISH HALL, WASHINGTON, TUESDAY, MAY 1, 1900.

(Concluded from No. 17, p. 432.)

DR. SAMUEL McC. HAMILL, of Philadelphia, presented a paper, being a report of

A CASE OF ANTENATAL HEMORRHAGE INTO THE SUPRARENAL CAPSULE AND PERIRENAL TISSUE.

This paper was read by title and showed that death ensued three days after birth from rupture of the hemorrhagic sac into the peritoneal cavity.

DR. A. D. BLACKADER presented a paper on

ENTERIC FEVER IN CHILDHOOD.

This paper was based on notes taken of cases, which were very numerous, of typhoid-fever patients both in Montreal and in his own practice. He went exhaustively into all the characteristics of the disease as manifested in these cases, with the relative frequency of the various symptoms and the results obtained by treatment. He emphasized the efficiency of cold baths, and the Brandt method in the treatment of typhoid fever in children; the regular and systematic employment of the cool or cold bath in the treatment was, in his opinion, of great value. He thought it might be employed regularly without too rigid adherence to the rule of Brandt, of only using it when the fever reached 102.2°. The bath was not to be employed for its effect on the temperature so much as for its effect on the nervous system and, through it, on the heart, respiration and secretion, especially secretion from the kidneys. This paper was very thoroughly discussed, there being a difference of opinion as to the propriety of using cold baths, and whether or not infants are attacked with typhoid fever.

DR. SAMUEL S. ADAMS used the rectal temperature, and considered it the only safe temperature in all children under twelve years of age.

It was the opinion of DR. W. P. NORTHRUP that children under two years of age are little susceptible to the invasion of typhoid fever.

Typhoid fever, said DR. GRIFFITH, is of frequent occurrence in infancy under the age of one or two years. The symptoms, however, are difficult to recognize on account of the tender age of the patient.

There is room for discernment, DR. DORNING thought, in the use of water. He was impressed with the value and also with the potency for harm of hydrotherapy. He did not believe that babies stood tubing very well.

In 2,000 autopsies, conducted on children under two years of age, DR. NORTHRUP said he had seen typhoid fever in none. It was not his opinion that an infant under two years of age was susceptible to typhoid fever.

DR. BLACKADER said that he had tried to empha-

size in his paper the necessity for care in each individual case.

THIRD DAY.

DR. T. M. ROTCH, of Boston, read a paper on

A CASE OF RHACHISCHISIS.

Rhachischisis was characterized by a deficiency of the vertebral arches either complete or partial, and it was one of the principal forms of congenital defects of the spine. The condition is of more interest pathologically than clinically. He reported the case of a girl three years of age who was admitted to the Infants' Hospital February 14, 1900. The head was of normal size, the face was flattened, the chin retracted, and held in forced position with the occiput on the principal dorsal sign. The skull was apparently well over, and the foramen magnum was as large as a silver dollar. The section of the brain passed almost through the median portion of the brain, which was poorly hardened. One could not find in the cranial cavity either the cerebellum or the pons.

DR. J. HENRY FRUITNIGHT, of New York, in his paper on

A FATAL POST-OTITIC CEREBRAL ABSCESS, WITH AMNESIC APLIASIA,

reported a case of a twelve-year-old girl of New York City, who, in January, 1898, had suffered very severely from an acute otalgia of the left ear. A physician who was consulted diagnosed otitis with an abscess. A paracentesis of the drum of the left ear was made and a large amount of pus let out. It appeared that the mother neglected or failed to carry out the instructions, and when Dr. Fruitnight first saw the patient her temperature was about 100° and pulse 98. She complained of frontal headache. She had occasional chilly sensations and nausea, and there was some prostration, and a scanty discharge from the left ear. The clinical diagnosis was a deep mastoid caries, possibly cerebral abscess and beginning meningitis. Violent convulsions took place December 17th and continued six hours, being finally controlled by the use of a rectal injection of chloral hydrate, inhalations of chloroform and hypodermic injections of morphine.

DR. HERMAN KNAPP, of New York, who had made a clinical observation of the child, stated that the location of the abscess would be higher up than where it was found, if it was assumed from the symptoms. An operation was performed which discovered conclusively the presence of an abscess. There was some congestion, but not sufficient to indicate the disease.

It is well to note, said DR. HENRY CHAPMAN, of New York, that where a mastoid disease does not affect the brain, but burrows in front, it is always best to look in that region. He laid stress on the mastoid trouble in children in which the brain is not affected, and in reporting a case of a boy, five years of age, he said there was tenderness back of both ears but no swelling. In this case the temperature fell from 103° to 101½°, and remained there for several days.

DR. FRUITNIGHT referred to the absence of low pulse and high temperature.

A very interesting and instructive paper was presented by DR. W. S. CHRISTOPHER, of Chicago, on the

MEASUREMENTS OF CHICAGO SCHOOL CHILDREN.

The doctor used thirteen charts in illustrating the paper, and showed instruments used in taking the measurements of these school children. In addition to the results of the ergograph, the observations represented ordinary anthropometry measurements. The amount of energy exerted by each pupil tested was expressed by the ergographic work in centimetres and kilogrammes in place of pounds. The test consisted in lifting at each alternate second with the middle finger of the right hand a weight equal to 7% of the gross weight of the individual, and permitting them, at the next second, to return. Ninety seconds was the limit of the test, during which time this weight was lifted forty-five times, a metronome being used to beat the seconds. The ergogram indicated the degree of fatigue exhibited by the child during the ninety seconds. The work of the boys was better than that of the girls; the endurance of the girls up to fourteen years of age showed a greater percentage than that of the boys. The girls practically reached the maximum at fourteen, and from there on up to twenty years of age the limit of the examination did not increase. The boys, however, continued to increase continuously up to twenty and the ratio of increase was greater than it had been previously. The amount of energy displayed by the girls at twenty amounted to very little more than half of that exhibited by the boys at the same age, so marked was the differentiation in the sexes at this time.

Another interesting feature of the ergographic work was in the range of ergographic possibility of the different grades. The range of ergographic endurance of children in the lower grades was comparatively slight, but increased continuously as the upper grades were reached, until, in the higher grades, the endurance of the boy pupils amounted to nearly six times that of the poorest pupils. Various tracings of ergograms were shown illustrating the peculiarities of the tracings in different individuals. A very interesting ergogram shown was that of a sprinter who said that he could run 300 yards, but could not go 330 yards. The ergogram showed that he maintained a high degree of strength for a short time, and then suddenly dropped to complete exhaustion in less time than a normal child would break. In an ergogram of a choreic child, the child showed a wonderful amount of energy, working on the ergogram considerably longer than the average child could do.

The work of Dr. W. Thompson Porter in the examination of school children in St. Louis, in 1892, was confirmed by Dr. Christopher.

Dr. PORTER thought that physical superiority in the school children was associated with intellectual precocity, and the same way with physical inferiority.

Interesting charts were shown describing physical peculiarities in children of twelve years in the different grades of the Chicago schools. It was shown, by taking the average physical measurements in each grade, that the weight of a child in the second grade was less than that of a child in the third grade. In the twelve-year-old child the highest physical measurements were noted, while a child of same age in a lower grade showed a lower average in the physical measurements. The averages were distributed fairly in the intermediate grades.

Dr. McDONALD, of Washington, thought that Dr. Christopher's paper contained the most important investigations on children extant. Those who under-

take the work in these lines only know the amount of time required to accomplish it. Representing the Board of Education, he had an opportunity of measuring some 20,000 children. Expeditions could be fitted out to the North Pole for scientific research, but objection was raised at once in the acquirement of facts about the children in such cases. This might be attributed to the lack of practicality in the results obtained. Boys at fourteen years of age matured and were in the advance of girls. Children born in summer are stronger, healthier and brighter than those born in winter.

Dr. FRUITNIGHT proposed that medical men should give more attention to this line of study. He thought the school child was kept at his desk when he should be at play, enjoying the sunshine and fresh air; that the time had come for reformation along this line. From ten or eleven o'clock, he suggested, until two, were appropriate periods for recreation.

Dr. COTTON felt the importance of close attention to this subject. He believed that benefits of great value would accrue to the children. He desired some light as to the period of greatest fatigue.

Dr. CHRISTOPHER said there was a period of diminished endurance from the fourth to the eighth grade.

Dr. CURCHILL asked whether children who show the greatest amount of endurance on the ergogram stand highest in the class, to which Dr. CHRISTOPHER replied that individually this had not been noted, but that he would answer the question affirmatively.

Dr. CHAPIN said that in the New York Juvenile Asylum 1,000 children were measured with results that were somewhat peculiar; they had developed mental vices.

Dr. RACHFORD thought that Dr. CHRISTOPHER had carried on his work under better conditions than any class with which he was familiar. He believed that the ergogram meant muscle fatigue as well as nerve fatigue. He thought that if the ergogram could show nervous exhaustion in the child it would be of great value. There seemed to be a trend toward precocity, that in children of a common age the child having the best physical development is farther advanced in school life than other children.

Dr. CHRISTOPHER said that no attempt had been made to solve problems. At the Aleut School the average weight of a six, eight or nine-year-old child was not found to be greater or less after vacation. He stated that color blindness had been found in the schools, although the teachers had asserted there was no defect, because the children were able to paint, etc. The actual test, however, showed distinct color blindness.

Dr. HENRY D. CHAPIN, of New York, presented a paper on

EPIDEMIC PARALYSIS IN CHILDREN.

He referred to the epidemic which had occurred in Poughkeepsie and New York, and stated that in a number of children the paralysis was due to poliomyelitis. He thought that some infectious agent had been at work there.

Dr. NORTHROP, in a paper on

ATRESIA OF THE LARYNX DUE TO FAULTY INTUBATION.

stated that in this case the fault was that of the operator. The latter was a beginner, he thought. The child had pulled it out several times, twice with a string, and in that way acquired relaceration up to the number of five in all, and at last was not able to lift it. The larynx had been wounded by some accident and dyspnea set in and tracheotomy was required. That allowed the laceration surface to grow together. A subsequent operation was performed, but he was not able to remove the obstruction. The child died in November.

DR. COTTON inquired whether the malformation of the larynx was either natural or due to inflammation or disease.

DR. NORTHROP, in closing, said that it was distinctly the fault of the operator, and yet he seemed to be properly instructed. The operator made the hole in which the intubation tube was to go naturally, small, bringing the submembranous tissue to the surface. He said that everybody could not do intubation without detriment to the patient.

DR. J. MILTON MILLER read a paper on

THREE CASES OF HEAD NODDING AND HEAD ROTATION.

He stated that 3 cases had come under his observation in the past ten years.

Recent Literature.

The Clinical Examination of Urine, with an Atlas of Urinary Deposits. By LINDLEY SCOTT, A.M., M.D. Philadelphia: P. Blakiston's Son & Co. 1900.

In the first 49 pages of this book the author takes up *very briefly* the physical properties of the more important normal and abnormal constituents of the urine and a practical chemical test for each of the substances considered; a short discussion of the bacteriology of the urine; suggestions relative to the examination of urine for life assurance; and lastly, an enumeration of the leading characteristics of the urine in diseases of the urinary tract. The remainder of the work is devoted to 40 plates, mostly colored, and an excellent index. All of the plates were, with one exception, drawn from specimens under the author's direction, and are for the most part very satisfactory. In the plates of uric acid, ammonium urate and sodium urate, the colors are in general not a true representation of the colors of these crystals; in Plate XX the outlines of the hyaline casts are altogether too heavy; and in Plate XXI the faint color that has been given to the waxy casts is misleading, since casts that have received this name are perfectly colorless, and in this way distinguished from the so-called fibrinous casts, which are colored yellow.

La Malaria propagata esclusivamente da peculiari Zanzare. B. Grassi, Professore di Anatomia Comparata all'Università di Roma. Milano: Fratelli Treves. 1900.

Professor Grassi discusses the question of malaria as an important national problem. He pictures the condition of middle Italy during the first six months in the year, in glowing colors, as a land of health,

plenty and contentment, all of which is changed after the incoming of July in consequence of the prevalence of malarial fever. He lays down certain propositions in regard to the methods of infection and answers *seriatim* the principal objections to the modern theories of infection by the mosquito. Considerable space is devoted to the natural history of the *Anopheles*, and several very good cuts are presented showing the anatomy of the insect.

The book closes with an appeal to the ruling powers for aid in the suppression of malaria.

Medical and Surgical Nursing. A Treatise on Modern Nursing from the Physician's and Surgeon's Standpoint, for the Guidance of Graduates and Student Nurses, together with Practical Instruction in the Art of Cooking for the Sick. Edited by H. J. O'BRIEN, M.D., Professor of Clinical Surgery, Hamline University, etc. New York: G. P. Putnam's Sons. 1900.

This is a small volume of 287 pages, to which 14 writers have contributed. We have a certain doubt whether the multiple authorship method is properly applicable to this type of book. The tendency in general seems to us rather too much in this direction, and in an elementary book on nursing it is perhaps especially inappropriate. The writers have commendably omitted details of various diseases, and have appended a chapter on Cooking for the Sick, which no doubt will fill a place.

Notes on the Mosquitoes of the United States. Bulletin No. 25, U. S. Department of Agriculture, Division of Entomology. By L. O. HOWARD, Ph.D. Washington: Government Printing Office. 1900.

Dr. Howard's notes on the mosquito contain a general statement of the natural history of the different genera, with suggestions as to the use of remedies for their destruction and the prevention of their propagation, preference being given to kerosene oil as the most permanent remedy for the treatment of stagnant bodies of water. He considers permanganate of potassium and coal tar as of inferior value. Drainage of swampy areas is still more important. The work is illustrated with cuts showing some of the different species of mosquito in various stages of development.

Essentials of Medical and Clinical Chemistry, with Laboratory Exercises. By SAMUEL E. MOODY, A.M., M.D. Fourth edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co. 1900.

In this fourth edition the text has been largely rewritten, especially the clinical portion, and some new matter added. The work is divided into three parts, that is, Inorganic, Organic and Clinical Chemistry. The third portion, or that devoted to Clinical Chemistry, contains many valuable suggestions, but from the standpoint of the physician it is too brief for thorough work. The book is simply a laboratory guide and best adapted to the use of students who have access to explanatory lectures and especially to practical laboratory instruction. The danger in such books lies in the tendency among students to use them for purposes for which they were not intended and are not designed. Students are apt to be uncritical, and to get distorted or false ideas from their textbooks unless they are most carefully selected.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 1, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS

SANATORIA FOR PULMONARY TUBERCULOSIS.

THE Legislature of Massachusetts during its last session passed a resolution directing the State Board of Charity to inquire into the expediency of constructing and equipping a new building for the use of the State Sanatorium for Consumptives at Rutland; and if such construction should seem to the board advisable, it is directed to prepare a general plan of such building together with an estimate of its cost and to submit the same to the next general court. We do not know what the report of the Board of Charity will be, but the resolve of the Legislature opens up a wide field for legitimate reflection.

Of late years an extremely active discussion has been going on across the Atlantic and in our own country as to the best measures for dealing with pulmonary tuberculosis. National and international congresses on tuberculosis are being held almost yearly; the subject is under constant consideration before medical societies, by sanitarians, by philanthropists, and in the columns of the medical journals. The movement for sanatoria has developed rapidly. It is only twenty years ago that Hogt, of Berne, made the first proposals for united effort in the establishment of such sanatoria. Today there are between thirty and forty people's sanatoria for the care of suitable cases of pulmonary tuberculosis — supported not necessarily by the government, but in large measure by societies organized for that purpose, by insurance interests, by the Red Cross, by sick clubs, by employers, by trades unions — in Germany alone. The movement, in one form or another, has spread to Great Britain and to this country, and numerous sanatoria have been already started, or are being provided for either by public or private initiative on a more or less eleemosynary basis. The individual, the corporation, the municipality, the State, the United States, are all interested, are all being solicited and are all in action. The merits of this form of dealing with pulmonary tuberculosis, and the importance to the individual and

the community at large of an amelioration or eradication of this disease are generally recognized, have no longer to make their proofs. The prospective danger seems to lie in the common sentiment that "you cannot have too much of a good thing," in the tendency in this democratic country to the multiplication rather than to the perfection of what is supposed to be or going to be popular. In regard to this matter it is easier to admit that present conditions demand a remedy, that advancing knowledge and experience offer a good one in the sanatoria, than it is to agree upon the practical application of this admission; it is easier to begin the construction of sanatoria than to know where to leave off. There are estimated to be over 30,000 "consumptives" in the city of New York alone. Even if one admits that the gain to humanity and to the State justifies this form of paternalizing by Congress, by the legislatures, by the municipalities, where is the end to be unless looked for in the ultimate extermination of the disease? All cases of pulmonary tuberculosis are a danger to the community, but the advanced cases without hope of recovery are a danger to the earlier cases with such hope. The two classes should not be in contact, which means they should be separately cared for. Where is the line to be drawn? Perhaps the time has not yet come either to put or to answer this question.

One thing seems clear: that the good work of these sanatoria lies not merely in the care or even the cure of the individual tuberculous citizen, but in the propagation and dissemination through him and through his friends to the community at large by precept and by example of the gospel of hygienic, pulmonary righteousness. It is therefore from every point of view important that, if we are to have these sanatoria, they should be in all respects thoroughly well organized, equipped and provided for. This is more important than that they should be extensive or numerous. And this leads us back to our text, which was the resolve of the Massachusetts Legislature, and to the expression of the conviction that it would be wiser for the State, if it is to assume the care of pulmonary tuberculosis, to perfect rather than to enlarge its present provision for that end. If the resolve of the Massachusetts Legislature means provision for the perfection of the present undertaking at Rutland, it is well; if, on the other hand, it suggests a mere increase in the accommodations for additional patients, we should venture to trust it would not meet with the support of the judicious. We do not care to predicate whether money is better and more advantageously spent in disinfection and renovation, or in sanatoria, but we do feel sure that a too rapid sanatorial development will injure the cause at heart and retard the desired end, and we are inclined to think the movement has reached a stage where it is as important to control the indiscriminate zeal of friends as it is to stimulate the enthusiasm of the indifferent or to remove the opposition of the adverse.

RECENT RESEARCHES IN YELLOW FEVER.

WE have before us the report of the American Public Health Association, including the report of the commission late appointed by the Surgeon-General of the Army to investigate the etiology of yellow fever.¹ The work of this commission has been done by Dr. Walter Reed, U. S. A., assisted by Drs. James Carroll, A. Agramonte and Jesse W. Lazear, and up to this time comprises the clinical, pathological and bacteriological study of 18 cases of yellow fever, the cases varying widely in severity. An attempt to isolate the bacillus icteroides from the blood during life or from the blood and organs of cadavers signally failed. The writers therefore directed their attention more particularly toward the study of the bacteria from the intestinal tracts of supposed normal individuals or of those sick with other diseases, as compared with those found in patients suffering from yellow fever, and also gave very particular attention to the theory of the propagation of yellow fever by means of the mosquito. This line of inquiry has, of course, been forced into general notice by the work of Ross and others on the rôle of the mosquito in the spread of malaria. As is now well known, the theory presupposes the presence of an intermediate host, for example, the mosquito, which conveys the specific parasite of the disease through its bite from person to person. Following this idea, Dr. Reed and his colleagues experimented with 11 non-immune persons, with 9 negative and 2 positive results, in an attempt to verify the theory first proposed by Finlay. The 2 positive cases are reported in great detail, as observations upon which so much depends should be, and the writers are confident that their work will arouse new interest in the difficult problem of the method of dissemination of the disease. One of the positive cases records the history of a typical attack of yellow fever, following the bite of an infected mosquito, within the usual period of incubation of the disease, and in which other sources of infection could, they think, with certainty be excluded. The conclusions drawn from this preliminary study are that the bacillus icteroides stands in no causative relation to yellow fever, but when present should be regarded merely as a secondary invader, and that the mosquito serves as an intermediate host for the parasite of the disease. We presume the writers would not be over-dogmatic in their assumption, considering the small number of observations they have as yet been able to make. It is, however, evident that their work opens up a wide and attractive field of research, which may well prove of the very first importance in the understanding, and hence in the prevention, of this very fatal disease of tropical climates.

In connection with the work outlined above it is of interest to note that at this same meeting of the American Public Health Association, Dr. Henry B. Horlbeck, of South Carolina, read the report of the

¹ The full report of this commission appears in the current issue of the Philadelphia Medical Journal.

Committee of the Association on the Etiology of Yellow Fever, in which the conclusion was reached that the bacillus icteroides (Sanarelli) is probably the specific agent in causing the disease, and that as yet prophylaxis is still in a wholly empirical state.

It will no doubt require many and thorough-going investigations before an absolute unanimity is reached on these questions. Meanwhile, a healthy difference of opinion is certainly conducive to progress.

MEDICAL NOTES.

THE MEDICAL CLUB OF PHILADELPHIA: RECEPTION.—The Medical Club of Philadelphia tendered a reception on October 26th, at the Hotel Bellevue, to Dr. Maurice H. Richardson, of Boston. Previous to the reception the president of the club gave a dinner at the Union League Club in honor of the guest. The club has a membership of over three hundred and was organized about eight years ago to encourage a more friendly and intimate social acquaintance among members of the medical profession. Discussions of medical and scientific subjects are contrary to the provisions of its constitution. The club has a wholesome effect in cementing fraternal ties among its members and is in a most flourishing condition.

FATAL HORSE DISEASE IN MARYLAND.—Cerebrospinal meningitis, according to the *Philadelphia Medical Journal*, has broken out for the second time within the past year among horses in Southern Maryland. It is estimated that about 1,000 have died. Appeals for assistance have been received at the Maryland Agricultural College and Dr. Samuel Buckley has been sent to investigate the matter. He has been making experiments with a serum, with which by inoculation he hopes to prevent spread of the disease.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, October 31, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 170, scarlatina 26, measles 17, typhoid fever 23.

FIFTIETH ANNIVERSARY OF MIDDLESEX EAST DISTRICT MEDICAL SOCIETY.—The fiftieth anniversary of the Middlesex East District Medical Society was observed at Woburn last week. Dr. Josiah P. Bixby, president of the society, presided and introduced the speakers. Dr. Samuel W. Abbott, Secretary of the State Board of Health, gave a history of the organization, and stated that when the Massachusetts Medical Society was started a century ago it had on its rolls about 70 members; today it has 2,500. The Middlesex Society was organized in Concord, January 7, 1789, and the speaker thought it was dissolved about 1812. It might be said that that society was the parent and the Massachusetts Society was the grandparent of the Middlesex East District Society. The latter was organized October 22, 1850. At the

dinner which followed the formal meeting, Dr. H. P. Walcott spoke on the work of legislation and Justice William B. Stevens spoke for the bar.

FAMILY REFUSING VACCINATION RELEASED FROM QUARANTINE.—An English family has recently been released from isolation on Gallop's Island, having been kept there two weeks because of a refusal to submit to vaccination before landing. The members of this family had been in perfect health since leaving England, and were detained simply in compliance with the Federal law, which requires that immigrants shall be placed in quarantine during the period of incubation of smallpox, if they refuse vaccination. In this case the father and two children had never been vaccinated. There is some question as to who is responsible for the board of the family while enforced guests of the city.

MOSES C. WHITE, M.D.—Dr. Moses C. White, professor emeritus of pathology in the Yale Medical School, died at his home in New Haven, Conn., October 24th, aged eighty-one. Dr. White was born in Paris, Oneida County, N. Y. He first studied for the ministry and for six and one-half years was a missionary in China. He had been professor in the Yale Medical School for many years, and continued his active duties until last June, when he resigned and was made professor emeritus. He had been pathologist at the State Hospital and has given liberally to that institution.

DIPHTHERIA IN BROOKLINE.—Since the first of October, up to a week ago, 54 new cases of diphtheria had been reported to the Brookline Board of Health. This apparently large number is in part accounted for by the increased care now being taken through bacteriological tests to determine the existence of diphtheria even when no symptoms have appeared. The danger of a spread of the disease is thereby minimized, since all children showing positive cultural tests are taken from the schools. Rigid school inspections are being made and no apprehension is felt as to the complete ability of the Board of Health to cope with the situation.

WORK OF THE FREE HOSPITAL FOR WOMEN.—In the Out-Patient Department there have been treated during the year 7,977 patients, 878 of whom were new cases. There have been admitted to the wards 274 patients; 177 were discharged cured and 34 relieved. There have been 452 operations on 221 patients. It is proposed to enlarge the hospital by the addition of a new ward.

PRESIDENT OF TRUSTEES OF MASSACHUSETTS CHARITABLE EYE AND EAR INFIRMARY.—At the annual meeting John Homans, Jr., M.D., was elected president of the Board of Trustees of the Massachusetts Charitable Eye and Ear Infirmary.

NEW YORK.

NEW YORK EYE AND EAR INFIRMARY.—The annual meeting of the Board of Directors of the New

York Eye and Ear Infirmary, of which Dr. Richard H. Derby is executive surgeon, was held on October 25th. The report of the secretary, Dr. Gorham Bacon, showed that in the year ending September 30th there had been treated in the Dispensary Department 30,878 cases in the eye service, 9,710 in the ear service, and 7,096 in the throat service. In the hospital wards 2,257 patients were treated, representing 20,734 days of hospital care. In the treasurer's report it was stated that during the year the permanent fund had been increased by \$65,000. A training school for nurses in the special departments of the eye, ear and throat has been organized, and there are at present six pupil nurses. Adjacent to the infirmary building on Thirteenth Street a pavilion for the reception of cases of contagious ophthalmia has been erected in memory of James N. Platt by the family of the latter.

PLAGUE IN GLASGOW.—Dr. William T. Jenkins, Commissioner of the Health Department, has just returned from a visit to Great Britain made principally for the purpose of examining the sanitary arrangements of various cities, especially as to garbage and sewage disposal. While there he made some study of bubonic plague in Glasgow. There were 18 cases in the hospital at the time. They were treated by the serum processes, the Haffkine and the Yersin, and he was very favorably impressed with the results. In preventing the spread of the disease the principal precaution taken was the inoculation with serum of persons coming in contact with those affected. All the physicians at the hospital had been inoculated. Dr. Jenkins secured twelve bottles of the Haffkine serum, nine of which he sent to Health Officer Doty.

MEDICAL SOCIETY, COUNTY NEW YORK.—At the annual meeting of the Medical Society of the County of New York, George B. Fowler was re-elected president. The report of the Committee on Hygiene, of which Dr. Henry Dwight Chapin is chairman, devoted especial attention to the city's water supply. Not only the quality, but the available quantity, it was pointed out, was a matter for the society's consideration. It was a fact that the supply had not kept pace with the growth in population, and the inadequacy, unless speedily remedied, would soon give rise to serious results. Additional supply and municipal ownership were strongly urged.

OUTBREAK OF TYPHOID FEVER.—An outbreak of typhoid fever has occurred at the Boys' Disciplinary School at Parkville, Borough of Brooklyn. Thus far there have been 9 cases, with 1 death. Dr. Jewett, Inspector of Contagious Diseases of the Health Department, after an investigation of the premises and their sanitary condition, reported that the place was "a disgrace to any civilized community and a crime against the boys of the school," and on October 24th, Dr. Robert A. Black, Sanitary Superintendent for Brooklyn, ordered it closed.

Miscellany.

CLASSICAL EDUCATION FOR MEDICAL STUDENTS.

THE *Medical Press and Circular*, commenting editorially on an address in which Sir John Williams deprecated an over devotion to classical studies, says in part:

"Every hour of school and student life is of extreme importance in view of the variety of subjects that have or ought to be studied, hence the importance of throwing overboard every educational item which cannot be shown to be potentially useful to the student in his after-career. The most pressing requirements of the student at the present day are, a better acquaintanceship with his own language to begin with—that is to say, a thorough command of the language which he will have to use for all the ordinary purposes of life, a more ample knowledge of its literature, a copious vocabulary, and a culture far larger and better than he can ever hope to obtain by acquiring an elementary knowledge of Latin and Greek. If the time at present devoted to Latin and Greek were devoted to French and German a very competent knowledge of these languages might be obtained, and the time is rapidly approaching when a man who knows no language but his own will find himself deprived of inestimable opportunities of adding to his technical knowledge, in addition to depriving himself of many of the delights of foreign travel. We are pleased that one occupying so conspicuous a place in the profession should have raised his voice against an indefensible adherence to an anachronistic system of education. Schoolmasters are a stiff-necked race, but they must in the long run bow to public opinion, and in no calling so much as in medicine, perhaps, is educational reform imperative."

We are, no doubt, much less travelled in America by an adherence to ancient custom than are our English cousins; it is probable that not many of our medical students are burdened with a knowledge of Latin and Greek. We sometimes wish they were.

EXAMINATION OF DRINKING WATER IN ILLINOIS.

DURING the last few years, according to *Science*, several thousand samples of drinking water from various ordinary house wells throughout the State have been sent to the State University of Illinois for analysis and report as to quality. By far the greater proportion of these water samples have proved, upon analysis, to be contaminated with drainage from refuse animal matters, and consequently have been regarded with grave suspicion, or have been pronounced unwholesome for use as drink. The present prevalence of typhoid fever in a number of places in the State makes it desirable that the public should remember that the State has made provision for the examination of all suspected waters. It is not practicable to isolate actually the typhoid-fever germs or to prove directly their absence from waters submitted for analysis; this for the reason that the work entails more labor and time than are made available by the means which the State provides. However, the chemical ex-

amination is sufficient ordinarily to show whether the water is contaminated with house drainage or drainage from refuse animal matters or whether it is free from such contamination. Any citizen of the State may have examinations made of the drinking water in which he is interested, free of charge, by applying to the Department of Chemistry of the State University.

It would, no doubt, be advisable if this practice were general throughout the various States. It is altogether probable that by such means, carefully carried out, a considerable protection against epidemic disease might be secured.

Obituary.

SIR HENRY WENTWORTH DYKE ACLAND.

SIR HENRY ACLAND died at his home in Oxford, October 16th, in the eighty-sixth year of his age. He was the son of Sir Thomas Dyke Acland, who represented the county of Devon in Parliament for many years. The family is one of the oldest and most distinguished in Devonshire, and their estate is in the beautiful Exmoor region, the home of the red deer, through which the traveller passes in driving from Porlock to Lynmouth. Sir Henry Acland was one of the most eminent of a race distinguished in various careers. One of his ancestors was with Burgoyne in his disastrous campaign during our Revolutionary War. He was educated at Harrow, and Christ Church, Oxford. His academic studies were interrupted by ill health, and during a journey in the Mediterranean undertaken for health, he explored and made a panoramic plan of the site of Troy. He took his B.A. degree at Oxford in 1840, and became a fellow of All Souls' College. He immediately began to devote himself to the study of medicine, not a little to the concern and distress of his friends and associates belonging to a class which at that period was unaccustomed to regard it as offering a suitable career for a gentleman. He began his medical studies at St. George's Hospital, London, subsequently studying in Edinburgh, and finally graduated in medicine in 1866, at Oxford. In 1847, at the age of thirty-two, he was elected a fellow of the Royal Society. In the same year he became physician to the Radcliffe Infirmary, Oxford, a position he held for forty years. In 1850 he became a fellow of the Royal College of Physicians of London, and in 1865 delivered the Harveian Oration, his being the first oration on that foundation delivered in English. In 1851 he was appointed Radcliffe librarian to the University of Oxford, and in 1857 he was made Regius Professor of Medicine in the university. In 1858 he was elected representative of the University of Oxford on the General Medical Council, and was president of that body from 1874 to 1887. In 1860 he received the degree of LL.D. from the University of Cambridge, he received the same degree from Dublin, and the D.C.L. from the University of Durham. He was one of the few members of the medical profession in civil life to be made a Companion of the Bath, and in recognition of his services to the profession and to the cause of medicine and public health he was made a Knight Companion of that order. In 1890 he was made a baronet of the United Kingdom. In 1860, when the Prince of Wales visited the United States and Canada, Dr. Acland accompanied him as a member of his suite and as his medical adviser.

The establishment of an interest in the natural sciences at Oxford and the reorganization of its medical teaching upon a somewhat modern basis were almost entirely Dr. Acland's work. He had a great capacity for work of all kinds, and an almost insatiable interest in a great variety of subjects. He made himself felt in educational and in

sanitary questions. He was skilful with both pen and pencil, a charming talker and a most agreeable companion. He had been intimate with such different men as Sir Benjamin Brodie, Dr. Alison, of Edinburgh, Mr. Gladstone and Mr. John Ruskin. Dr. Acland made several visits to the United States, where he had not a few warm friends. He was an honorary member of some of our societies, among others, of the Massachusetts Medical Society and of the College of Physicians of Philadelphia.

LAURENCE TURNBULL, M.D.

PHILADELPHIA has again lost an eminent physician in the death of Dr. Laurence Turnbull, which occurred October 24th. His reputation depended chiefly on his work on the ear. He was a native of Lanarkshire, Scotland, and came to this country when twelve years of age. He was later graduated at the Philadelphia College of Pharmacy and the Jefferson Medical College. He was the first surgeon in America to perform the mastoid operation, being successful with the first case. Besides holding membership in various medical societies, Dr. Turnbull presided over the Section in Otology of the American Medical Association in 1880 and of the British Medical Association in 1881, and was chosen a delegate to the Section of Otology of the British Medical Association in 1888, and the Congress of Otologists that convened in Brussels the same year. After the second battle of Bull Run Dr. Turnbull served in Emory Hospital, Washington, and at Fort Monroe. He was the author of many valuable works on diseases of the ear and eye and died at the ripe age of seventy-nine years.

Correspondence.

A CASE OF MEASLES; PERIOD OF INCUBATION.

Boston, October 25, 1900.

MR. EDITOR: — The following case may be of sufficient interest to merit a brief report.

May 12th, my patient, a very intelligent woman of twenty-two years, gave a piano lesson to two sisters, aged nine and eleven years, living in Roxbury. They had an eruption on their faces and said that it was also on their chests. These children are pale, and the contrast made a vivid impression on my patient. She described the spots as pale rose red, coarse but varying in size, discrete and not elevated. The rash came May 11th and was gone the 15th. The children felt well the 12th and returned to school the 15th, although they had severe coughs. The attending physician considered it German measles. The mother states that both children had measles severely four years ago during an epidemic and were under a physician's care. She further states that an epidemic of German measles prevailed in May and that many classmates of one of her children were affected. On inquiry at their school, I find that several cases of measles were recorded in March, and that one case of German measles was recorded for the three months of April, May and June, but I could not learn the date. It was not in the class of either child. In May, I attended a child in Allston with a typical measles eruption. The mother stated that the eruption commenced two weeks previously, and that children in Allston were having an eruption of German measles, and in about two weeks an eruption of measles. This child had enlargement of superficial cervical glands, as is the rule in measles. I cannot vouch for the diagnosis of German measles in the sisters or for the prevalence of an epidemic of the disease. These sisters may not have caused my case.

My patient had never had any eruptive disease. May

15th, without apparent cause, there commenced a sharp diarrhoea of one week's duration. Dejections averaged ten a day. She used home remedies. May 23d, she consulted me for a swollen, painful left occipital gland. Rotation of the head was painful. No local cause of glandular enlargement was found. In twenty-four hours the gland was size of a tame cherry and very painful. May 25th, glands below left ear were swollen and painful. Careful examination of the throat showed nothing. Later, other superficial cervical glands enlarged.

May 27th, patient commenced to feel weak. Post-auricular glands were enlarged the 28th and turning the eyes was painful. Her right occipital gland was enlarged the 29th, and at 2 p. m. she was too sleepy to go to pupils and had severe epigastric distress. Patient and her mother noticed that patient's face was purplish, but showed no rash. After an hour's sleep there was rash on face, hands and forearms. No further examination was then made. The epigastric distress was gone. That evening the mother reported the case to me as measles. She did not know if the rash was general, but on returning found it so.

At 2 p. m., May 30th, I examined patient carefully. She complained of photophobia, slight roughness and soreness of throat, slight cough but no coryza. Eyes were suffused. The chief suffering arose from a constant pain referred to the splenic region and unaffected by respiration or position. Tongue was slightly coated and papillæ slightly enlarged. Distinct rash on hard palate, which I described as papular. Throat and tonsils somewhat swollen. There was a general rather fine purplish-red papular eruption with marked crescentic and irregular grouping. It was least heavy on the limbs. Examination of heart, lungs and liver showed nothing noteworthy. The splenic area of percussion dulness was much enlarged, extending upward to the seventh rib. The area was not measured. I was uncertain if I felt the spleen, but could not the following day. Temperature 101.2° F., pulse 98; urine free from albumin; bowels constipated, but after a laxative, continued rather loose.

June 2d, the rash was fading, and slight branny desquamation was noticed in the eyebrows, and rarely a minute flake elsewhere. Considerable cough. Patient and her mother observed carefully the disappearance of the rash. Skin was normal June 10th, and nearly so the 8th. They had noticed slight branny desquamation on face and feet. The glandular enlargement disappeared slowly.

October 10th, there was still slight enlargement of the left occipital gland. There was marked debility and her usual strength was not recovered for several months.

Very truly yours,

M. P. SMITHWICK, M.D.

METEOROLOGICAL RECORD

For the week ending October 20th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 1,987; under five years of age 710; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 496, consumption 256, acute lung diseases 187, diarrheal diseases 108, diphtheria and croup 70, typhoid fever 35, cerebrospinal meningitis 11, whooping cough 7, scarlet fever 5, erysipelas 2, measles 2.

From cerebrospinal meningitis New York 6, Baltimore, Providence, Worcester, Gloucester and Everett 1 each. From whooping cough New York 4, Baltimore, Pittsburg and Boston 1 each. From scarlet fever Worcester 2, New York, Pittsburg and Holyoke 1 each. From erysipelas New York 2. From measles New York and Boston 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending October 13th, the death rate was 17.1. Deaths reported 3,799; diarrhoea 289, acute diseases of the respiratory organs (London) 173, diphtheria 85, fever 64, whooping cough 59, measles 39, scarlet fever 27.

The death rates ranged from 10.5 in Cardiff to 24.8 in Manchester; Birmingham 18.9, Bradford 14.0, Gateshead 23.8, Huddersfield 16.5, Leeds 17.5, Liverpool 23.1, London 14.8, Newcastle-on-Tyne 18.7, Nottingham 18.0, Portsmouth 20.6, Sheffield 20.9, Sunderland 20.9, West Ham 12.6.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 27, 1900.

D. H. MORGAN, passed assistant surgeon, commissioned passed assistant surgeon from November 27, 1899.

R. E. LEDRETTER, assistant surgeon, appointed assistant surgeon from October 19, 1900.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION. — The Surgical Section will meet at the Medical Library, 19 Boylston Place, on Wednesday evening, November 7, 1900, at 8.15 o'clock.

Papers: "Operative Treatment of Thyroid Tumors," by Dr.

J. C. Warren. Drs. J. J. Putnam, S. J. Mixter and J. C. Munro will take part in the discussion.

"Results of Operative Treatment of Thyroid Tumors," by Dr. Lincoln Davis.

F. G. BALCH, M.D., Secretary, 279 Clarendon Street.

NEW YORK SKIN AND CANCER HOSPITAL.

The governors of the New York Skin and Cancer Hospital, Second Avenue, corner 19th St., announce that Dr. L. Duncan Bulkley will give a third series of clinical lectures on "Diseases of the Skin," in the out-patient hall of the hospital, on Wednesday afternoons, commencing November 7, 1900, at 4.15 o'clock. The course will be free to the medical profession.

WILLIAM C. WITTER, Chairman of Executive Committee.

RECENT DEATHS.

EDWARD R. SQUIBB, M.D., of Brooklyn, N. Y., the well-known manufacturing chemist, whose preparations have for many years maintained a world-wide repute for standard excellence, died of cardiac disease on October 26th, in his eighty-second year. He was born at Wilmington, Del., and was graduated from the Jefferson Medical College, Philadelphia, after which he entered the medical service of the United States Navy. After being promoted to the position of passed surgeon he was placed in charge of the medical station at the Brooklyn Navy Yard. Later he resigned from the navy and established his laboratory in Brooklyn. About fifteen years ago he retired from active work and since then the extensive business has been conducted by his sons, Dr. Edward H. Squibb and Charles F. Squibb. Dr. Squibb was one of the founders of the New York State Medical and of the Kings County Medical Associations.

WILLIAM H. BELL, M.D., an old New York practitioner, died on October 21st, at the age of seventy-three.

A NEW TEST MEAL.

BY A. E. AUSTIN, A.M., M.D., BOSTON,

From the Chemical Laboratory of Tufts College Medical School.

THE test meal has become an absolute requisite for the examination of stomach contents. One of the chief reasons for this is the difficulty of obtaining gastric juice from the fasting stomach; in fact, when any considerable amount of gastric juice can be obtained from the fasting stomach, it is generally considered to be in a pathological condition. Three meals have been chiefly employed for this purpose. One was proposed by Ewald, another by Riegel, and still another by Klemperer. That of Ewald, or as it is sometimes known, Ewald and Boas, consists of one to two rolls, in Berlin parlance called a *Schuppe*, which weigh from 35 to 70 grammes, and two glasses of water. For this we have an excellent substitute in the ordinary round cracker, of which two weigh on an average 30 to 31 grammes, or in the soda wafers, four of which weigh on an average 35 grammes. With this meal, the contents should be withdrawn one hour after eating.

The meal of Riegel consists of soup, a beefsteak and a roll. It is to be withdrawn three to four hours after eating. Klemperer's meal consists of half a litre of milk and two rolls, to be withdrawn two hours after eating. There are serious objections to all of these: (1) The indefiniteness of the amount of the food elements employed, nitrogen, fat and carbohydrate, and (2) that on account of the lack of fine division, the tube introduced is frequently clogged, which necessitates its removal, its cleansing and re-introduction.

The meal employed in these experiments consisted of 2 grammes of dried egg albumin compressed into half-gramme tablets. These are to be taken with two glasses of water, and the contents withdrawn one hour after taking. For the preparation of these tablets my thanks are due to the Metcalf Co., who furnished them at my suggestion. This amount of albumin is equivalent to that found in the crackers, but in a different and more soluble form. Seven per cent. of dried bread, and consequently of crackers, consists of nitrogenous substances. This calculated for 30 grammes of crackers would give 2.1 grammes of albumin, the equivalent of that found in the four tablets. The latter, however, are very much better digested than the vegetable albumin, and hence there is much less residue. True, the nature of the starch digestion cannot be determined from such a meal, but can be as easily determined from the amount of free hydrochloric present, for the organic acids, if present, are seldom in large enough amounts to disturb amylaceous digestion, and combined hydrochloric acid has no inhibitory action upon this. With this meal the contents never clog the tube, there is always a definite amount taken, and the contents filter much more readily than when vegetable albumin is used. It also avoids a large mass of starch granules, always present when making microscopic examinations. These tablets when once compressed can be preserved indefinitely, are always on hand, and can be given to the patient without his departure from the office or clinic. Furthermore, lactic acid when found is of vastly more diagnostic importance than after the Ewald meal.

When amylaceous matter has been given it is difficult to limit the disappearance of lactic acid to an hour, but in this case the acid must come from the remnants of the last meal, and hence point to a lack of motility. For cases on which to demonstrate this meal, my thanks are due to Dr. R. F. Chase, who kindly placed his dispensary service at my disposal. The meal was given to 18 patients on whom 57 examinations were made at different times, and to 16 patients only once, so that a total of 73 examinations were made. These patients had all of them symptoms which were attributed to the stomach, such as distress, heartburn, eructations of gas, nausea and vomiting. In this new departure, of course, it is advisable to compare the results of the examination with those from an Ewald meal. The following cases were selected for this purpose.

COMPARISON WITH EWALD MEAL.

D. W. was given on two consecutive days, first, the albumin meal, then the Ewald meal. With the albumin meal the amount withdrawn was 50 c. c. with no free HCl as tested with dimethyl-amido-azo-benzol, and combined HCl amounting to .3 per mille. There was no lactic acid. With the Ewald meal the amount withdrawn was 82 c. c. There was free HCl to the extent of .8 per mille, and combined HCl of .6 per mille, or a total of 1.4 per mille. Lactic acid was present.

E. B. Two examinations with the albumin meal, at an interval of five days, showed respectively amounts withdrawn of 132 and 43 c. c. There was free HCl in both amounting to 1.6 per mille, and no lactic acid; while 3 examinations with the Ewald meal, immediately following the former at intervals of seven days, showed amounts of 134, 156 and 94 c. c. The free HCl was respectively 1.5, 1.3 and 1.53 per mille, while in the last examination the combined HCl was .25 per mille, making a total of free and combined HCl of 1.78 per mille. There was a trace of lactic acid present in every examination.

A. A. With albumin meal, total amount withdrawn, 95 c. c.; free HCl, 1.49 per mille; total HCl, 2.22 per mille; no lactic acid present. With Ewald meal seven days afterwards, total amount, 122 c. c.; free HCl, 1.95 per mille; total HCl, 2.73 per mille; a trace of lactic acid, and starch in the form of erythro-dextrin.

H. L. With albumin meal, total amount, 145 c. c.; free HCl, 1.35 per mille; total HCl, 1.82 per mille; no lactic acid. Five days afterward with Ewald meal, total amount, 52 c. c.; free HCl, .8 per mille; total HCl, 1.49 per mille; lactic acid present; erythro-dextrin.

S. With albumin meal, total amount, 75 c. c.; free HCl, 1.67 per mille; total HCl, 2.4 per mille. Two weeks afterwards with Ewald meal, total amount, 88 c. c.; free HCl, .9 per mille; total HCl, 1.2 per mille; lactic acid present and erythro-dextrin.

L. With albumin meal, total amount, 15 c. c.; no free, and no combined HCl, but a total acidity of 10 parts per hundred; lactic acid present. With Ewald meal two weeks after, total amount, 40 c. c.; no free HCl; combined and total HCl, .4 per mille; lactic acid; achroodextrin.

O'N. With albumin meal, total amount, 60 c. c.; free HCl, 1.82 per mille; total HCl, 2.62 per

mille; lactic acid present. With Ewald meal five days after, the total amount, 80 c. c.; free HCl, 1.82 per mille; total HCl, 2.59 per mille; lactic acid present.

In order to present these results in a more convenient form for comparison, a short table has been prepared comprising the results already stated, and needing no further explanation:

TABLE OF COMPARISON.

Name.	Meal.	Amount Withdrawn.	Free HCl per mille.	Total HCl per mille.	Lactic Acid.
D. W.	Albumin.	50 c. c.	None.	.3	No.
	Ewald.	82 c. c.	.8	1.4	Yes.
E. B.	Albumin.	132 c. c. 43 c. c.	1.6	1.6	No.
	Ewald.	134 c. c.	1.5	1.78	Yes.
		156 c. c. 94 c. c.	1.3 1.5		
A. A.	Albumin.	95 c. c.	1.49	2.22	No.
	Ewald.	122 c. c.	1.95	2.73	Yes.
H. L.	Albumin.	145 c. c.	1.31	1.82	No.
	Ewald.	52 c. c.	.8	1.49	Yes.
S.	Albumin.	75 c. c.	1.67	2.4	No.
	Ewald.	88 c. c.	.9	1.3	Yes.
L.	Albumin.	15 c. c.	None.	None.	Yes.
	Ewald.	40 c. c.	None.	.4	Yes.
O'N.	Albumin.	60 c. c.	1.82	2.62	Yes.
	Ewald.	80 c. c.	1.82	2.59	Yes.

The first impression that one would derive from such a comparison would be that more HCl would be found with animal albumin than with vegetable albumin. By referring to our results, however, we find that HCl in the Ewald meal exceeds the HCl in the albumin meal four times out of seven. Another thing which attracts our attention is that the lactic acid is present in the Ewald meal and not in the albumin meal in all cases but two, where it is present in both. Another thing quite noticeable, that with the Ewald meal the amount withdrawn is generally larger than with the albumin meal. It is very probable that this is due to the greater need of a vegetable albumin for fluid to accomplish its digestion, or chemically speaking, its hydration. There is unquestionably an osmosis or interchange of fluids between the blood on the one side and the contents of the stomach on the other.

CHEMICAL NATURE OF GASTRIC CONTENTS WITH REFERENCE TO HCL, AMOUNT, ETC.

The course of some of the cases affords some interesting observations. On A. J., who complained of gaseous, non-acid eructations, vomiting, etc., eight examinations were made, covering a period of two months. Starting with an entire absence of HCl, the amount gradually increased until at the close the HCl had reached 1.8 parts per mille. On account of the early lack of the HCl, a quantitative test for rennin was made, which showed that milk could be coagulated with a dilution of 1-80 of the stomach contents, a result not far from normal. Lactic acid was invariably present. The increase of amount withdrawn from 12 c. c. to 72 c. c. may have been due to the increased

muscular tone of the stomach walls. This is further substantiated by the fact that, at first, suction was necessary to remove the contents, but at last voluntary compression on the part of the patient was sufficient.

The case of M. M., followed for one month with five examinations, showed a persistently low amount of HCl varying from entire absence to a total of .8 per mille. Here also the rennin was found to be active in dilutions of 1-180 and repeated microscopic examinations showed no cancer cells, when examined by the methods proposed by Henmeyer.

The case of Mary M., followed for seven weeks with seven examinations, showed the most marked variations in the HCl, due probably to nervous origin. They were respectively 1.3, .6, 0, 1.35, .8, 1.38 and 1.5 per mille, under the same conditions of meal, time of removal, etc. Lactic acid was also present when HCl was below .8 per mille, which must have come from the previous meal, since only albumin was used. On one occasion, bile was present in the stomach contents, which indicated only reflex vomiting from the introduction of the tube, since it was not persistent.

In the case of J. G. three examinations made in one week showed a total HCl of respectively .04, 1.3 and 1.2 per mille, and total amounts withdrawn of 102 c. c., 42 c. c. and 97 c. c.

The case of T. L. came nearest to being one of continuous secretion of gastric juice. At periods of from fourteen to sixteen hours after food had been taken, there were removed from the stomach on five occasions amounts respectively of 55 c. c., 80 c. c., 30 c. c., 87 c. c. and 19 c. c. This was of an almost watery consistency, perfectly clear, containing no food particles whatever, whose total HCl was .9, .7, .8 and .4 per mille. After an albumin test meal, 260 c. c. of stomach contents were withdrawn which had a total HCl of .8 per mille.

DISCUSSION OF DIFFERENT FEATURES.

Upon comparing the amounts withdrawn, we find that there was

Less than 20 c. c.	9 times.
20 to 40 c. c.	24 "
40 " 60 "	16 "
60 " 80 "	11 "
80 " 100 "	7 "
Over 100 "	8 "

Included among these results are two Ewald meals. The rest, however, were from albumin meals. The amounts withdrawn at intervals of an hour seem to depend largely upon the muscular tone of the stomach. It is very difficult, however, to set a limit beyond which we may say that hypotony or dilatation exists, and under which the stomach is normal. From the other conditions involved, it seems that with the albumin meal we may say that there is lack of muscular tone when 100 c. c. or more can be withdrawn. This is especially true if it is necessary to use suction, or if in introducing water for purposes of lavage it cannot be withdrawn readily, or a whirling motion in the funnel is noticed upon its introduction. The presence of free HCl was always determined by dimethyl-amido-azo-benzol, and was found present in 60 examinations and absent in 13. Lactic acid was determined by the modified Uffelmann test in the following way: One drop of ferric chloride was placed in a test tube, the test tube filled with water, this then divided into equal parts in two test tubes, each filled

up with water, and a drop or two of the filtered stomach contents added to one, the other serving as a control. As demonstrated by this test, lactic acid was found 40 times, 9 times with no free HCl, and twice the entire absence of free HCl was accompanied also by the absence of lactic acid. This is contrary to the teachings of Boas, who claims that lactic acid is absent when HCl is present to any appreciable amount, one hour after the meal. As our supposition is that the lactic acid must come from the previous meal, and be indicative of atony, then it should be associated with a large amount of contents. This cannot be demonstrated, however, since it is found when the amount of contents withdrawn varied all the way from 10 to 102 c.c. Lactic acid was also found when the free HCl rose to 1.8 per mille. As combined HCl has no inhibitory action upon the formation of volatile acids by their respective bacilli, no account was taken of it. A more detailed account of this association is given as follows: Lactic acid was found twice with a free HCl, of 1.8 per mille, once with 1.7, twice with 1.6, once with 1.5, twice with 1.3, twice with 1 per mille, and so on down. Its presence followed certain cases, as that of A. J., throughout the course of examination. The latter never lost the lactic acid in spite of the fact that his HCl steadily increased from nothing to 1.8 per mille.

In 40 cases only were both free and combined HCl or total HCl determined, and that by the method of Töpfer. In the rest, only the free HCl and the total acidity were determined. Of the entire number of examinations in which the albumin meal was given (73), there were, as already stated,

No free HCl in	13
Less than .5 per mille in	7
Between .5 and 1 per mille in	12
" 1 " 1.5 "	19
" 1.5 " 2 "	12
" 2 " 2.5 "	6
" 2.5 " 3 "	0
Over 3 per mille in	4

In the 40 cases where free and combined or total HCl were determined there was entire absence of both in only 3 cases. The total free and combined HCl was

Less than .5 total HCl per mille	9
Between .5 and 1 per mille	0
" 1 " 1.5 "	7
" 1.5 " 2 "	4
" 2 " 2.5 "	10
" 2.5 " 3 "	4
Over 3 per mille	6

As compared with the results of H. F. Hewes,¹ where the limits of normal total HCl were from 1.1 to 2.6, and the average from 1.2 to 2.5 per mille, 21 fall within these limits, 9 below and 10 above. Bile was present twice, and with the bile there was once associated pancreatic juice, which was demonstrated by the fact that the stomach contents in alkaline medium could both digest albumin and convert starch. Bile is not so rare in stomach contents, but is much more apt to be present in the first withdrawal in a patient, from the retching accompanying the introduction of the tube. After the patient has become accustomed to this introduction, the presence of bile is much less frequent. If it persists a long period, Boas² considers it a sign of the constriction of the duodenum, while Bouveret³ prefers to regard it not only as evidence of a constriction of the duodenum, but also of

a patent pylorus. These conditions can only be differentiated by blowing up the stomach with air. Under normal conditions no air can pass through the pylorus on account of its spasmodic closure, and hence the intestines cannot become distended.

Renin was always looked for where the total HCl was very much diminished, and no free HCl was present. The quantitative method of Boas was employed, which is as follows: One c.c. of stomach contents was diluted with water to 10 c.c. Five of this was taken in a test tube, and was again diluted to 10 c.c., and 5 c.c. more taken. The process continued until we had four test tubes with 5 c.c. of diluted contents in dilutions of 1-10, 1-20, 1-40 and 1-80. To each of these were added 5 c.c. of cooled boiled milk and a few minims of calcium chloride solution. We now have dilutions of 1-20, 1-40, 1-80 and 1-160. A control test is always prepared to guard against the possibility of spontaneous coagulation, consisting of 5 c.c. of milk, 5 c.c. of water, and the same amount of calcium chloride. These tubes are all placed in a brood oven, at a temperature of 30°, for from twenty to thirty minutes, and then note made of the coagulation.

Coagulation normally should take place in dilutions of from 1-80 to 1-160. The importance of this test cannot be over-estimated in cases of suspected cancer, being of vastly more importance than diminution of HCl or the presence of lactic acid. In all of our cases, coagulation was found in dilutions of 1-80 or over. In every case the contents were also examined with the microscope, and while several times fragments of mucous membrane of the stomach were found, nothing was seen approximating the peculiar arrangement of these cells in cancer of the stomach. These results were also verified by Dr. Timothy Leary, our pathologist, who kindly offered to assist in these examinations. Yeast fungi were always present; no degree of acidity nor use of albumin stayed their growth in any way. No sarcinae were found, fairly good evidence that in all cases no marked dilatation nor narrowing of the pylorus was present.

Among the interesting points brought out was the unreliability of the presence of lactic acid as a diagnostic symptom. It was present in the majority of cases where the Ewald meal was used, and also in very many cases where the albumin meal was used, and as a diagnostic symptom seems to have lost its significance. It is also quite evident that impaired motility is the most important condition in the so-called nervous dyspepsias, arising probably from the lack of enervation dependent upon shock or worry. It may be present with either impaired or superabundant secretion of HCl. The former condition is probably the more distressing from the formation of organic acids and gases. The importance of this motility can also be demonstrated by laboratory experiments in artificial digestion, where shaking the contents of flask or container accelerates in such a marked degree the process of digestion. It is of interest also that the increased flow of gastric juice is always accompanied by a relative increase in the amount of HCl, or it may be that lack of motility and diminished HCl are associated, and the small quantity withdrawn is due to our inability to remove the total contents of the stomach. Finally, dried egg albumin in the form of tablets seems to fulfil all the conditions that attach to a successful test meal.

SPINAL CARIES WITH ABSCESS: ANALYSIS OF CASES.

BY ERNEST B. YOUNG, M.D., BOSTON.

It has been the good fortune of the writer to be able to collect 78 cases of spinal caries complicated with abscess, and to obtain reports of the condition of those living at periods of from one to thirty-five years after the beginning of the disease, as well as the date of death of those who have already succumbed. The average time of the reports is about four and one-half years after the onset. With the exception of 18 cases, all the material comes from hospital clinics, as it is among the lower strata of society that spinal caries flourishes. These classes are the ones most liable to trauma and strains from the nature of their employments, while poor and insufficient food, bad air and inability to properly care for themselves make them good subjects for tuberculous invasion. The cases are in no way selected, except that nothing has been included where there was any doubt as to diagnosis. In addition to the cases where it has been possible to obtain full reports, a few have been utilized where the data at hand were known to be correct, even though not quite complete in all particulars.

Age and sex. — It will be seen from the cases considered under this heading, 52 males and 26 females, that the disease throughout life is about twice as frequent among males, although at different periods the ratio changes somewhat. The onset in 38 out of 78 cases occurred before the tenth year. This is undoubtedly due to the fact that both sexes are active and liable to injuries at this time. From *ten to twenty years* the ratio changes very little, but from *twenty to thirty years* the males outnumber the females nearly 5 to 1; for the female has ceased to be active as the male and at this time many of the men are performing the hardest kinds of manual labor. The figures seem to bear out the importance of trauma as an etiological factor in the disease; for as the female becomes less active, the frequency of the disease decreases, while in the male the two periods of greatest liability to injury, childhood and young manhood are each marked by a rise in the number of afflicted. After the thirtieth year, when the epiphyses of the vertebræ are firmly united, its occurrence in either sex is quite rare; yet even during the remaining years of life the males outnumber the females 2 to 1. Only 11 cases have been collected where the first symptoms occurred after thirty years of age. The youngest case was eight months old when the abscess appeared, and the oldest sixty-seven years.

Seat of disease. — Caries of the dorsal spine leads most often to abscess formation. Cervical and sacral disease with abscess seems rare at any time of life. Of 77 tabulated cases there are:

Dorsal	43
Lumbar	31
Sacral	2
Cervical	1

Under ten years dorsal disease is one-half again as common as lumbar; while throughout the remaining years of life the two regions average about the same.

Deformity. — The condition of spines of 77 cases when first seen was as follows:

No deformity	18
Slight "	30
Medium "	16
Great "	13

It would seem that abscess formation has little relation to the extent of the deformity, as those with no kyphos or a slight kyphos far exceed in number the cases with great deformity. The large kyphoses appear almost entirely when the disease begins early in life. After the twentieth year there is only one case of moderate and one of bad deformity. In one case there were two kyphoses of moderate size, one in the dorsal and one in the lumbar spine.

Abscess. — In 83 cases there are:

Psoas abscesses	63 (including 5 double psoas).
Lumbar "	21 (" 2 " lumbar).
Sacral "	2 (1 pointing in pelvis and 1 over sacrum).
Cervical "	1 (pointing in neck).

Psoas abscess is the most common when either the dorsal or lumbar spine is attacked, while double psoas and double lumbar abscesses are quite rare.

Abscesses associated with cervical or sacral disease are apparently quite uncommon.

Psoas and lumbar abscesses, when occurring in the same person, generally point on the same side of the median line; but in some few cases there is a psoas abscess upon one side of the median plane and a lumbar abscess upon the other.

As would be expected, in a few instances the pus has forced its way under Poupart's ligament and in one case has burrowed downward from a lumbar abscess into the superficial fascia of the thigh.

It is impossible to get any reliable data concerning the duration of abscesses or the date of first appearance. Often the patient has been ignorant of its presence even when filling one whole side of the abdomen and pelvis. In 2 cases the abscess has come on during treatment. These are the severe cases and both are dead. The sinuses have remained open for many years in some instances, and in others have closed within a few months. Some have the sinuses heal promptly only to break out again from time to time. Most of the sinuses remain open for a year or two, so far as can be learned, and in many cases, even with the patient in good health, they still persist.

Pain of any amount seems to become a prominent feature in many adult cases only when the abscess has reached such a size as to produce psoas contraction. While in children pain is generally referred to the abdomen, in the adult it is generally referred to the back, there being only two or three adults who have complained of abdominal pain.

Treatment. — In by far the greatest number the abscess has been treated by incision; but some have been collected of aspiration and spontaneous opening, as well as a few where the abscess has remained closed. Of 77 cases, 37 under ten years and 40 over ten years, the treatment was as follows:

	Under ten years.	Over ten years.
Remaining closed	2	8
Spontaneous opening	4	8
Aspiration	2	6
Incision	29	18
	<hr/>	<hr/>
	37	40

Two cases included under incision were aspirated, and incised shortly after. One adult and one child have been aspirated many times. One case, which opened spontaneously, was incised later.

Prognosis. — Many of the cases have been treated in general hospitals, which have as a rule no orthopedic department, and hence the after treatment has been either entirely neglected, or only partially carried out. At the same time it must not be forgotten that

this is often the fault of the patient or of circumstances which put him out of reach of skilled attendance.

The reports received from 78 cases at periods of from a few months to thirty-five years from the beginning of symptoms are given below. Ages given always refer to the time of onset, unless otherwise stated:

	Under ten years.	Over ten years.	Total.
Well	3	6	9
Good condition	19	8	27
Fair	4	3	7
Poor	3	4	7
Dead	17	11	28
	46	32	78

The average time from beginning of the disease to the last report, for those under ten years, is three years; for those over ten years, a little more than four and a half years.

Of 10 cases where the abscess remained closed the statistics are:

	Condition at onset.	Present condition.
Well	0	0
Good	3	5
Poor	7	1
Dead	0	4
	10	10

Average duration of disease is nearly four years. One child and 3 adults have succumbed at periods of from four to six years. In 2 cases the abscess is reported to have disappeared.

Spontaneous opening took place in 12 cases. The statistics are:

	Condition at onset.	Present condition.
Well	0	3 (after six, ten and thirty-six years).
Good	1	5 (after two to six years).
Fair	6	1 (after eleven years).
Poor	5	1
Dead	0	2 (after two and four years).
	12	12

Average duration of disease slightly over six and a half years.

Of 8 cases treated by aspiration alone the statistics are:

	Condition at onset.	Present condition.
Well	0	2 (1 after eleven years).
Good	2	1 (after two years).
Fair	2	1 (after six years).
Poor	4	0
Dead	0	4 (3 after one, two and thirty-three years).
	8	8

Average duration of disease about eight years; average time elapsed since operation, three years and two months; out of 4 children 3 are dead.

Incision has been the method used in 48 cases; 32 under ten years and 16 over ten years. The statistics are:

Under Ten Years.		
	Condition at onset.	Present condition.
Well	0	1
Good	3	10
Fair	15	5
Poor	14	3
Dead	0	13
	32	32
Over Ten Years.		
	Condition at onset.	Present condition.
Well	0	2
Good	2	5
Fair	5	1
Poor	9	0
Dead	0	8
	16	16

Average duration of disease in cases commencing under ten years is about six years and ten months;

while of those commencing at beyond this period, four years and two months.

Average time elapsed since operation in the first class is five years and two months, and for the second about three and a half years.

SUMMARY.

	No. Cases.	Recoveries.	Mortality.
Remaining closed	10	0	40%
Spontaneous opening	12	3	16 2/3 "
Aspiration	8	2	50 "
Under ten years	32	1	40 "
Incision, over ten years	16	2	50 "

The prognosis of spinal caries with abscess, apart from the cases where the abscess opens spontaneously, seems to be very slightly influenced by the treatment accorded the abscess, although undoubtedly affected by the proper fixation of the spine.

Considering the series as a whole, we may say that the mortality is about 35% at an average period of three years and nine months after the first symptoms, and that the mortality is slightly greater among those in whom the disease commences before the tenth year.

Unfortunately the number of patients from whom reports have been received is not very large, but undoubtedly the spontaneous opening is the most favorable outcome. When the abscess remains closed, the mortality is almost as large as when treated by incision or aspiration.

There seems to be a decided danger of general tuberculous invasion in these cases, as 3 out of 4 deaths were caused by tubercular meningitis.

Causes of death.—In both children and adults the most common cause of death seems to be a gradual deterioration of whole system, as most reports say: "Failed gradually after leaving the hospital." The causes of death in a few cases where it was possible to get a reliable report are given below: General tuberculosis, 4; amyloid, 1; tubercular meningitis, 3; shock of operation, 2; sepsis and renal, 1; phthisis, 1.

In 2 other cases, both adults, tuberculosis has attacked the genito-urinary system, and 1 is now in the last stages of the disease.

In closing, I wish to thank the staff of the Children's Hospital and the staff of the Massachusetts General Hospital for allowing me the use of their records, and also many friends who have kindly furnished me cases from their private practice.

CELLULOID AS MATERIAL FOR FLAT-FOOT SUPPORTS.

BY ALBERT H. FREIBERG, M.D., CINCINNATI, O.,
Orthopedic Surgeon to the Cincinnati, Presbyterian and Jewish Hospitals.

THE use of celluloid as material for flat-foot supports was first suggested, as far as the writer is aware, by Kirsch. By him, as well as by Schanz, in two subsequent publications, the advantages and disadvantages of its use were pointed out. Lightness, the absence of any tendency to corrode, cleanliness therefore, and the ease with which the plates can be made innocuous to foot wear have been considered its advantages; in addition to this a certain elasticity which is necessarily lacking in metal supports and which is said to contribute toward the comfort of the patient as well as the efficiency of the brace.

On the other hand it is acknowledged that celluloid plates are less durable than steel ones, that material of the very best quality must be obtained in order to obtain uniform results and that this is not always easy. It remained also to be proved whether or not celluloid plates possessed the rigidity requisite for their usefulness in the treatment of flat foot.

In undertaking to test the value of this material for the manufacture of flat-foot plates, the writer felt also the need of improvement in the process of working it. When placed in boiling water for a few minutes celluloid becomes quite soft and flaccid, but upon removing it from the water it rapidly stiffens, so that it cannot easily be manipulated with the hands. This, however, is the method recommended by Schanz in both of his communications on the subject.¹ After a few attempts made according to Schanz's directions, the writer abandoned the method of shaping the material freehand as being necessarily inaccurate and unsatisfactory. The procedure of Kirsch² seemed to promise more, involving, as it did, the use of the plaster cast and might be briefly described as follows: The corrected plaster cast is made in the usual way and having cut a piece of sheet celluloid to the desired shape, it is applied to the cast by means of a towel, the ends of which are twisted over the dorsal aspect of the cast, the middle being in contact with the sole. The twisted ends being held, the cast is now lowered into boiling water, and after a few seconds have elapsed the continued twisting of the towel ends is expected to bring the celluloid sufficiently into contact with the cast, and upon removing the whole from the boiling water and dipping it into cold for a few minutes the maximum stiffness is acquired.

After experiment with this method the writer finds that in addition to being quite troublesome the adaptation of the plate to the sole of the cast is far from being exact. In addition, however, it is believed that the use of the plaster cast in the usual manner can be improved upon both as regards accuracy and simplicity, as well in the case of metal as of celluloid, however, as material for the plate and in the treatment of flat foot.

It is assumed that it is the object of the flat-foot brace to support the depressed or weakened arch so much as is compatible with comfort, and therefore to the extent permitted by the flexibility of the foot. The flexibility of the foot, however, is a factor which will be found to vary within fairly wide limits, even in feet which are not the seat of the inflammatory stiffness so frequently present in flat foot. The amount of correction which must be made in the plaster cast is an uncertain thing and one which is really done by guess, so that it is believed to be a common experience that more or less change is required to be made in the finished plate in order to make it comfortable or efficient in the maximum, as the case may be. After considerable experiment with the following method, it is believed that it can be offered as being simpler, but also more exact than the use of a corrected plaster cast.

A pattern is first to be made which differs according to the type of support which it is desired to produce. This is made upon an impression of the sole of the foot according to the method of Schanz, except

that the writer believes the following method to be less objectionable than the use of soot or other black material, and that it furnishes at once a permanent record.

The impressions are taken upon pieces of cardboard obtained from the paper stockhouse under the trade name of "black showcard." A piece being cut of proper size, say $5\frac{1}{2} \times 12$ inches, it is fastened to a board of slightly larger size with drawing tacks, and its dull black surface is rapidly coated with a fairly thick solution of shellac in alcohol. In the meanwhile the patient has been rubbing his foot in a pan upon whose bottom ordinary talcum powder has been evenly sprinkled. The patient should bear his weight upon the foot and rub in the powder thoroughly by moving the foot about. When the spirit in the shellac has evaporated sufficiently to leave a sticky feel, but *without adhering to the finger*, the board is taken to the patient, from whose foot the excess of powder has been blown, and he is told to bear his weight upon it. While he is doing so the contour of the foot may be scratched in with a suitable sharp instrument. It is well now to draw in with white ink the outline of the impression as well as the contour of the foot. The result is shown in the figure. By interposing tissue

FIG. 1.

paper between each pair of impressions, they may be conveniently and indefinitely preserved.

To make the pattern, a piece of tissue paper is placed upon the impression, and the pattern may now be drawn with the outline of the impression and the contour of the foot in plain view. The paper is now cut out, and from this paper pattern another is cut in sheet lead about $\frac{1}{16}$ inch in thickness (known as 4-pound lead). This lead pattern is now hammered by rough guess into the shape of the future support, a horn hammer or the handle of a file being used for this purpose. Due regard must be had for the "balance" of the support while so doing. The hammering of the sole has a tendency to make the whole piece curl, and it is well from time to time to press that which is to come in contact with the sole of the shoe against a plane surface so as to be able to properly estimate the amount of arch which is being given.

This having been done, the pattern is fitted to the patient's foot and with a very little practice one is able to obtain a perfect fit with a few taps of the hammer. The patient can assist one by telling whether there is too much pressure in one spot or whether the whole pressure is disagreeable. It will

¹ Schanz: Zeitschr. f. orth. Chir., Bd. vi, S. 495; Schanz u. Mayer: Zeitschr. f. orth. Chir., Bd. viii, S. 25.

² Kirsch: Centrbl. f. Chir. 1896, S. 837.

be found best not to attempt altering the lead pattern with the finger, but always with the hammer, not forgetting the "balance" each time that it is so changed. This pattern when so fitted is intended to serve as a form on which to mould the celluloid, or in case a metal support is to be made, the pattern instead of the foot is used to make the cast upon which the workman fits the brace.

In working with celluloid the material is first cut out in proper shape, a scroll saw being best adapted for this purpose. It is well now also to finish the edges of the celluloid. Celluloid or rubber scrapers made for the use of dentists will be found well adapted for rounding the edges and they can then be made smooth with fine sandpaper.

The celluloid is now superimposed upon the lead pattern, which must be handled with some care, for while it withstands the pressure which is necessary, it can, nevertheless, be easily bent by striking the floor or any hard object with force. The celluloid is fastened to the lead pattern with clips or with rubber bands, and it is necessary to see that now and afterward during the shaping process the outer edges of celluloid and lead coincide.

By means of forceps with smooth jaws, plate and pattern thus clamped together are now lowered into boiling water, which must be of sufficient depth to

FIG. 2.

cover them; a granite-ware baking dish will be found a convenient vessel. As soon as the celluloid has begun to soften it should be gently pressed down to the pattern and when thoroughly flaccid the whole is removed from the vessel with the forceps by one hand and received by the other hand, which is protected from the heat by a towel folded several times. The celluloid, still hot by the lead underneath, is now made to fit the pattern accurately. This can be done quickly and with ease. The whole is now immersed in cold water for a few minutes and is then ready to apply to the patient. The plate may be given a finish by rubbing the whole of it with fine sandpaper.

Good celluloid is a material of great toughness and if sufficient force is used can be bent to a certain extent without heating. If any further adjustment of the edges is required, to prevent injury to the shoes, for instance, this can be quickly accomplished by using the forceps before mentioned, whose jaws are smooth and which is considerably bent on the flat. If it is desired to make a plate with an external flange, the pattern having been shaped accordingly, this must first be shaped freehand so that when the celluloid is placed upon the lead, the flange as well as the outer edges of the plate and pattern, respectively, may coincide. Figure II shows a plate made in this way.

The material which has been used in these experi-

ments is known by the trade name of "pyralin"³ and has been found of uniform quality. Three thicknesses have been used, $\frac{1}{16}$, $\frac{1}{8}$ and $\frac{1}{4}$ inch. The thickness to be used depends upon the weight of the patient and in scarcely less degree upon the flatness of the arch as shown by the impression. Material of $\frac{1}{16}$ inch is used as a rule for children only and for persons weighing less than 100 pounds.

The writer feels that he must speak with some reserve with regard to the durability of these plates, for he has been using them not quite six months. But one of the plates has been broken; this was in the case of a very active young man with perfectly flat feet and weighing about 150 pounds; the break occurred in jumping from a street car and the material was $\frac{1}{8}$ inch. The rigidity of the plate has been well tested in one patient of 172 pounds, who has been wearing it for five months. Although of $\frac{1}{16}$ inch thickness, the plate shows no appreciable change upon comparison with the pattern from which it was made. However, if such yielding occurred it could be easily remedied by reshaping it in the boiling water with the original lead pattern.

Absolute accuracy cannot be claimed for the above method, especially when celluloid is used, for it is the under surface of the celluloid which is shaped to the pattern instead of the upper, and the inaccuracy will be in direct ratio to the thickness of the material. In practice this has been found unimportant, however. In addition it does not appear that such a degree of accuracy has been reached in the treatment of flat foot as to constitute a serious objection. When the lead pattern is used to obtain the plaster cast in the manufacture of metal supports, the inaccuracy is, of course, much less.

[NOTE.—Since writing the above there has come to the author's notice an article by Mœukmøller and Kafan in the *Neurolog. Centrbl.* of September 21, 1900. This has suggested a simpler and equally efficacious method of taking impressions of the feet. The following method has been found satisfactory: With a cotton swab the sole of the foot is moistened with a solution of tincture of iron and 70% alcohol, each 45; glycerine 10. Care should be taken in order that the entire weight-bearing part of the foot may be covered with solution; if the latter is used too profusely the impression will not be clear. The patient now steps upon a piece of white cardboard for about two seconds. The image is now developed by lightly painting the card with a strong solution of tannin in 70% alcohol. Mœukmøller and Kafan use ammonium sulphocyanate in ethereal solution for developing.]

THE AGGLUTINATION BY THE PATIENT'S SERUM OF THE BACTERIA FOUND IN CYSTITIS AND PYELITIS, WITH A CONSIDERATION OF THE PLEOMORPHISM OF THE BACTERIA FOUND IN THESE INFECTIONS, ESPECIALLY AS REGARDS CHROMOGENIC PROPERTIES OF THE STAPHYLOCOCCI.

BY THOMAS R. BROWN, M.D., BALTIMORE, MD.

SINCE the demonstration of the agglutination reaction by Widal in the case of the typhoid bacillus, numerous contributions have been made which describe similar instances of agglutination in the case of other micro-organisms. Thus, besides the enormous amount of work that has been done in this connection with typhoid, considerable attention has been paid to the diagnosis of Malta fever and of tuberculosis by similar means, while numerous isolated observations have

³ Obtained from the Arlington Company, 475 Broadway, New York.

been made describing the agglutination of various bacteria by the serum of their host. This communication will deal, in the first place, with a few cases of cystitis and pyelitis in which the bacteria giving rise to these infections have been tested with the patient's serum, to see whether or no they would be agglutinated thereby. Obviously, to be able to make this test satisfactorily, we must choose those micro-organisms with at least a moderate degree of motility, so that not only the clumping of the bacteria but the variations in their motility can be definitely studied.

CASE I. This was a case of cystitis of many years' duration, due to the bacillus coli communis in pure culture, the micro-organism in this case being more actively motile, and producing its characteristic changes upon the various media more rapidly than any other colon bacillus we have ever met with. The patient was an extremely anemic, poorly nourished girl, and the lack of resistance dependent upon her general physical condition coupled with the probably marked primary virulence of the micro-organism was in all likelihood the cause of the extreme activity of the bacillus in this case. The cystitis was present in its most marked type; the injection, ulceration and contraction of the bladder were most marked, although the condition existed alone, that is, was not associated with a renal infection. The condition had undoubtedly arisen after faulty catheterization more than ten years previously, and had been present ever since, constantly increasing in severity. The urine was acid, contained enormous numbers of pus cells and a moderate number of red blood and epithelial cells, with a trace of albumin, while a bacteriological examination made under the strictest aseptic precautions demonstrated that the bacillus coli communis was present in large numbers in pure culture. As stated before, the organism was very actively motile, grew rapidly and luxuriantly on all culture media, and produced the characteristic changes therein speedily and in a marked degree. The patient's serum was obtained by the method usually employed in the case of testing the Widal reaction in typhoid fever; that is, the blood was obtained in a pipette, the end of which was of fine calibre, and after the serum had separated from the clot the former was tested with an eighteen-hour bouillon culture of the micro-organism in the usual way, that is, with dilutions of varying strength examined ten, thirty and sixty minutes after the mixing of the bacteria with the serum. In dilution of 1 to 10 the reaction was distinct in ten minutes; almost complete, clumping with almost entire loss of motility, in thirty minutes, and absolutely complete in sixty minutes; in dilution of 1 to 20 the reaction was almost as positive, while in dilution of 1 to 50 the reaction was evidently beginning in ten minutes, there being some clumping and some loss of motility; in thirty minutes the reaction was positive, while in sixty minutes it was almost complete. It will thus be seen that the reaction in this case was absolutely positive.

CASE II. This was one of an acute infection of both bladder and kidney, due to bacillus proteus vulgaris. The history of the case in brief was as follows: After an operation for chronic recurring appendicitis without abscess formation the patient was catheterized by an orderly whose technique was remarkably bad. On the third day after the operation the patient developed all the symptoms of an acute ammoniacal

cystitis with large numbers of pus, blood and epithelial cells in the urine, while four days later he developed also the symptoms of a left pyelonephritis. The culture from the kidney and from the urine was that of the bacillus proteus vulgaris (the cultures from the kidney were made directly, two weeks later, when the kidney was opened and drained to relieve the pyelonephritic condition). The urine at all times contained large numbers of triple phosphate and ammonium urate crystals, while considerable albumin was also present after the kidney became infected. The testing of the agglutinating power of this patient's serum from the cultures of the bacillus proteus vulgaris obtained in the case were made as in the preceding instance, and, as in that instance, the micro-organism was a very motile one. In dilution of 1 to 10 in ten minutes the reaction was marked, in thirty minutes almost complete, and in sixty minutes absolutely complete, while in dilution of 1 to 50 the reaction was definitely beginning in ten minutes, positive in thirty minutes, and almost complete in sixty minutes. The reaction was thus as positive as in the preceding case.

CASE III. This was one of cystitis of four years' duration, associated two years after the beginning of the cystitis with a pyelitis, both due to the bacillus proteus vulgaris. At the time of the development of the cystitis the patient was in an extremely anemic condition (hemoglobin 50%), and was obviously in a state especially suitable for the development of infection. After the development of the pyelitis, the symptoms of cystitis became markedly less, so that at the time the patient came under observation both vesical lesions and symptoms were very slight. The urine from the bladder contained numbers of pus cells, some red blood and epithelial cells and considerable albumin, was either slightly acid, neutral or slightly alkaline in reaction, and contained large numbers of the bacillus proteus vulgaris in pure culture. The urine from the right kidney obtained by ureteral catheterization contained large numbers of pus cells, some red blood cells and some renal epithelial cells, considerable albumin, was invariably alkaline and also contained the bacillus proteus vulgaris in pure culture. The urine from the left kidney was absolutely normal. The agglutination test in this instance, made as before, gave the following results: In dilutions of 1 to 10 no reaction was noticed in ten minutes, in thirty minutes there was a suggestion of slightly decreased motility and a few clumps, while in sixty minutes the reaction was still more suggestive but not positive; in dilution of 1 to 50 the reaction was not present. Thus in this case the reaction if present at all was so in a very slight degree.

CASE IV. In a case of acute cystitis due to the bacillus typhosus in a patient who did not have typhoid fever, where the vesical infection was presumably introduced by catheter, the bacilli obtained in pure culture from the urine were unfortunately not tested with the serum of the patient; the bacilli were, however, tested with the serum of another patient who was suffering with a typical attack of typhoid fever, and reacted with this serum positively even in dilutions of 1 to 80.

These 4 were the only cases of cystitis and pyelitis in which this test was made, but the absolutely positive reaction in 2 of the 3 cases in which a complete test was made, and a suggestive reaction in the third

case, suggest that this might be frequently found in cases of cystitis and pyelitis. The fact that one case in which the reaction was positive was one of an acute infection of but two weeks' duration, and the other positive case, a chronic case of many years' duration, would suggest that the reaction may begin shortly after the infection has been set up and may continue for a long period of time.

These cases, although few in number, suggest a possible means of differentiating the bacteria in those cases of cystitis and pyelitis where there is doubt about the bacteria causing the infection, and they also suggest that in this class of cases there is possibly developed a certain reactive tendency of the organism as a whole against the special infection.

The pleomorphism of many micro-organisms under varying conditions has been frequently dwelt upon by numerous bacteriologists. Thus the morphology of the tubercle bacillus may be made to differ quite markedly according to the media upon which it has grown; the motility of the typhoid bacillus varies markedly under varying conditions. The virulence of the streptococci and staphylococci lies within widely divergent limits, dependent upon many previous factors in the life history of those micro-organisms; and, of course, many other cases of like nature might be added. The factors in the development of these various forms of the same micro-organism are probably to be found by a careful study of the previous life history of the organism in question. In cystitis we have an especially favorable field for studying the pleomorphism of the organisms which give rise to this condition. Thus we may have varying grades of resistance of the patient due, in the first place, to the general condition of the patient's health, whether she is robust and healthy or anemic and poorly nourished, and in the second place, to the condition of the bladder itself, whether it has recently undergone trauma, whether it is in a condition of anemia or congestion, whether there is constant retention of a portion of the urine, etc.; and also there may be various factors definitely dependent upon the micro-organism itself. Thus the virulence may vary markedly, depending upon its previous history and habitat, whether its existence has been parasitic or saprophytic, also upon the number of micro-organisms which were initially introduced. The condition of the urine also plays an important rôle; thus upon the presence of considerable, a small amount of, or no albumin depends the fact whether or no the micro-organism will find a medium favorable for its growth.

The multiplicity of these factors has shown us marked pleomorphism in our cases of cystitis and pyelitis, over 80 of which have been carefully studied bacteriologically. The results of these experiments, as will appear in full elsewhere, go to show that the colon bacillus is the commonest cause of cystitis and pyelitis in women, while various staphylococci, the tubercle bacillus and the bacillus proteus vulgaris are also quite frequently found, and numerous other micro-organisms are found in exceptional instances. The pleomorphism of the colon bacillus in the various specimens found by us was very marked; thus its shape differed from that of a rather long, not very thick rod to a form difficult to distinguish from a coccus; its motility in some cases was very active, in the majority of cases sluggish, and in a few cases *nil*

as far as we could determine. Marked variations were also seen in its behavior upon the various media. In some cases the growth was very profuse, and the changes in the various media (production of indol in pepton, coagulation and acidification of milk, the production of gas on glucose agar) very marked and very rapid, while in other cases the growth was very scant and the changes slow and slight. Although no definite conclusion could be drawn regarding the significance of these various forms, generally speaking it seemed that the more virulent micro-organisms were those which approached more the slender rod-shaped bacillus in form, in which the motility was most marked and in which the changes produced in the various media were most marked and most rapid.

In the case of the staphylococci, morphological pleomorphism was not so marked as in the case of the colon bacillus, as one would naturally expect. The rapidity and profuseness of the growth upon the various media and the changes produced therein differed, however, quite markedly in the different cases. The staphylococci found in our cases were the staphylococcus pyogenes albus and aureus and a white staphylococcus especially characterized by its marked ability to decompose urea and the slowness with which liquefaction of gelatine was produced. We were especially interested, however, by certain peculiarities in the chromogenic properties of these bacteria. In 2 cases the growth from the urine upon agar consisted of a number of small colonies of light lemon color. Transplantations from these upon potato gave colonies of a darker yellow color, while two subsequent transplantations from this latter upon agar gave colonies with the typical orange color of the staphylococcus pyogenes aureus. In a third case the primary culture consisted of growths almost white in color, which after six successive transplantations gave colonies of the same typical color as those of the staphylococcus pyogenes aureus.

These results, while few in number, are very suggestive in regard to the relation between various members of the staphylococcus family and suggest that many of what we now consider separate species may have arisen originally from a common staphylococcus, and the variations in cultural peculiarities, in chromogenic tendencies, etc., may have been directly dependent upon the various factors, favorable or otherwise, which surrounded the special micro-organisms since that time.

THE MANAGEMENT OF ABDOMINAL TESTICULAR ECTOPIA ASSOCIATED WITH INGUINAL HERNIA.¹

BY CHARLES A. POWERS, M.D., DENVER, COL.

ON June 18, 1900, Dr. Barkwell, of Cheyenne, kindly referred to me H. C., a boy of fourteen years, who gave a history of having had a reducible bubonocoele on the right side for one year. The testis on this side had never been found in the serotum. The hernia had been unusually painful and he was unable to wear any sort of a truss. Examination revealed a right oblique inguinal hernia of moderate size, not passing beyond the external ring. The testis on that side was not in the serotum, and, as said before, it had never been found there. Just above the external ring there was a small, tender lump: this was movable and thought to be the testis.

Operation was advised and was performed under ether at St. Luke's Hospital, June 20th. The sac was found with considerable difficulty. It was small, extending to about the external ring, and contained a small cord of adherent omentum. The lower end of this piece of omentum was somewhat enlarged and this was the mass thought before operation to be the testis. The hernia was of the congenital variety, the sac being very thin and densely adherent to the cord, which it surrounded and which extended pretty well toward the external ring. With great difficulty and much patience the sac was dissected from the cord up to the internal ring. On drawing it down from the abdomen a small atrophied testis was found to lie within it, or rather within the cavity of the peritoneum proper, that is, it was lying within the peritoneum in the sense that the appendix or the intestine lies within it. The cord seemed to have turned on itself; it was atrophied and dissection of it was difficult.

The peritoneum was cut off at the upper margin of the testis, dissected well back from the cord high up and sewn off flush with the general abdominal cavity. The internal abdominal ring was enlarged upward, the peritoneum reflected backward and upward, and a prolonged attempt made to free the cord sufficiently high to permit the testis to be drawn down into the scrotum. It was not possible to do this. After dividing the cremaster muscle and other tissues, and freeing the cord to the farthest possible point, the testis could only be made to lie just above the external ring and even then there was some tension on it. Accordingly, with permission of the lad's father, the testis was removed, the cord being divided at a high point and the canal tightly closed with layer sutures of chromicized catgut. The wound was closed without drainage and healed under a single dressing. There has been no further trouble.

Testis retained in the inguinal canal is fairly common; failure of the organ to leave the abdomen is rare. In general, the causes of ectopia may be placed under two heads: (1) Inflammation when the fetus is *in utero*, this inflammation causing adhesion of the testis to adjoining parts, and (2) abnormal size of the testis or unusual narrowing of the inguinal rings and canal. The latter factors may exist singly or they may be combined.

When the testis is retained in the canal it is easily subjected to injury; this may be sudden or it may be the result of continued irritation. Not so, however, with the abdominal form of cryptorchidism, for here the organ is well protected and not more often the seat of disease than when in the scrotum. An inguinal testis is commonly inflamed or diseased. The processus vaginalis is often left open so that secretion readily finds its way into the general peritoneal cavity. The cord of an ectopic testis easily undergoes torsion. Hernia is common because of the open processus vaginalis. It is difficult for the patient to wear a truss and consequently the hernia becomes irreducible.

Finotti believes the inguinal retention of a testis to be due to congenital developmental disturbances and that such testis is therefore peculiarly subject to malignant change, especially sarcoma.

Finotti further believes that although the ectopic testis may be incapable of secreting semen, yet it is not useless, for it is the seat of another secretion which he vaguely terms "internal" — the inguinal testis is capable of secreting this "internal" fluid which is of

importance in developing and preserving the nature of man. On the other hand, Besançon and Finotti¹ think that patients with abdominal ectopia present more the feminine type or are analogous to eunuchs. This belief corresponds to that of Lucas Championnière and is confirmed by Strobe.²

The position of a given testis exerts far greater influence on the psychic than on the bodily condition of a given man. The great majority of those affected with ectopia are very nervous. Further, they may be subject to eclampsia, peripheral epilepsy, hystero-epilepsy or chorea.

One does not always know just what should be done in these cases. Bull, whose hernia experience has perhaps been greater than that of any other man in this country, believes that in general it is better not to operate on children with retained testis and inguinal hernia before the age of puberty, on the ground that the testis will probably descend, and this seems to be the general opinion of surgeons. Lucas Championnière³ reports an operation which he performed twelve years ago on a child then eleven years of age, who suffered with bilateral abdominal testicular ectopia, with bilateral inguinal hernia. The testes were sought, mobilized and transplanted in the region of the absent scrotum in a cavity dug out for each with the fingers. The vas deferens and the testicular artery were the only supports left for one of them. Each testis was transplanted separately. The general health was completely transformed within a year, and the child developed into an exceptionally strong and well-built young man. Both testes worked up from their first position, the smaller to a point about over the scar of the hernia and it had to be extirpated because of pain during physical effort. Championnière has operated on 37 cases of inguinal ectopia, 6 of which were bilateral. He always seeks to retain the testes, for they aid in the normal development of the general physique. If the vas deferens is too short to allow transplantation, castration is the only resort.

In inguinal ectopia, persisting until or beyond the age of puberty, mobilization to the scrotum should be made when possible; a thorough division of the cremaster and all surrounding fibrous tissue will often render this possible. The details of this operation have recently been set forth in an admirable way by Bevan, who lays stress on the necessity for thoroughly freeing all tissue about the cord to the highest possible point within the abdomen. Schüller's operation is practically that of Bevan. Unless the testis lies without tension and easily below the external abdominal ring, it will surely and speedily work up. The external ring should be snugly closed on the cord. In certain instances, especially when the ectopia is bilateral, failure to transplant the testis to the scrotum may warrant its being placed within the abdominal cavity.

MEDICAL INSPECTORS FOR SCHOOLS. — It is reported in the *Philadelphia Medical Journal* that Congress is to be asked to provide eleven medical inspectors for the public schools of the District of Columbia, in conformity with the report of Health Officer Woodward on the need of frequent examination of the pupils. A salary of \$500 is to be paid the physicians appointed.

Medical Progress.

RECENT PROGRESS IN THERAPEUTICS.

BY ELLIOTT P. JOSLIN, M.D., BOSTON.

THE TREATMENT OF DIPHTHERIA AT THE BOSTON CITY HOSPITAL.

DURING the last hospital year, ending February 1, 1900, there were treated at the Boston City Hospital 55% of all the recognized cases of diphtheria in Boston. The number of cases was 1,813, and of this number there were 180 deaths, or a mortality of 10%. Eliminating the deaths which occurred within twenty-four hours after entrance the mortality falls to about 7%. Such a brilliant record leads to the question, by what means were such successful results obtained? And that I might answer this question for the readers of the JOURNAL, I have been so fortunate as to secure from Dr. McCollom, of the South Department, an outline of his views on the treatment of diphtheria at the present time. And as his experience this last year has been greater than that of all the other members of the medical profession in the city combined, the importance of his conclusions becomes apparent.

In the first place, Dr. McCollom and his assistant, Dr. Burroughs, are thorough believers in antitoxin. And this belief is based not only on the steady decline of the diphtheria mortality at the hospital, but on their experience with the disease among the doctors, nurses and employés of the institution. Of 100 consecutive cases of diphtheria (clinical as well as bacteriological) occurring at the hospital among the doctors, nurses and employés, there has not been a single death! With this the case, Dr. McCollom's statement that the doctors prefer diphtheria to scarlet fever excites no wonder, and Dr. Burroughs's story of the house officer who was disgusted and disappointed because Klebs-Löffler bacilli were not found in his sore throat is readily understood. For as the young doctor said, "If they were there you could do something for me; as it is there is nothing left but to bear it."

In the second place, Dr. McCollom feels sure that the importance of giving large doses of antitoxin is not fully appreciated. Two years ago 800 consecutive cases of diphtheria at the hospital were analyzed and the mortality was 15%. A short time ago another series of 800 consecutive cases treated with enormous doses was studied and the death rate proved to be 10%. As Dr. McCollom pertinently remarks, no hard and fast rule can be laid down with the dosage of antitoxin any more than with potassium iodide. You give the latter until you get the effect, and so you must do with antitoxin. It must be administered until the characteristic result upon the diphtheritic membrane has been obtained.

But it is particularly in those severe cases which come to intubation or tracheotomy that the advantages of large doses are seen. In the early days the child would do perfectly well for twenty-four or forty-eight hours, when a discharge of thick, tenacious mucus would appear, and the child would then gradually die from the extension of the process. This tough, tenacious mucus, by the way, is positively indicative that the membrane is extending. In these cases the mortality before antitoxin was given was 87%. During the first year of antitoxin it fell to 46%, but this last

year, during which the large doses have been given, it has fallen to 32%.

No case of diphtheria should be considered hopeless, and it has been interesting to me to note how much more strongly both Dr. McCollom and Dr. Burroughs insist on this point now than they did at my earlier visit six months ago. Cases come to the hospital practically dead—the child has ceased to breathe, and there is no heart beat, yet some finally recover.

And it seems probable that the reason that the Boston City Hospital's statistics are better than those of another institution just published lies in this fact, that these severe cases are saved by the large doses. It is idle to conclude that there is any great difference in the type of cases entering the two institutions, for this is not probable. Both the hospitals alike undoubtedly get the worst cases in the community, but here the mortality is 10%, there 24%.

Various factors have tended to make the customary dose of antitoxin small. There is the question of expense, and this is certainly a cold, hard fact. Then there is the bacteriologist, who with comparatively few units neutralizes the power of half a cubic centimetre of toxin. "But who knows how much toxin is being formed under a diphtheritic patch on a tonsil? Who knows how much toxin there is along the course of this cast, just coughed up by a patient, which extended throughout the trachea, the large bronchi and many of the smaller?" A third protest against large doses of antitoxin comes from the doctor in general private practice. But his conclusions have nothing to do with hospital practice. In the former instance the cases are often mild, are early seen and need comparatively little antitoxin anyway; in the hospital conditions are different. Finally, danger of an overdose sometimes deters the doctor from injecting large amounts. It should not! "You can't supersaturate with antitoxin! If there is one thing which the history of the City Hospital has shown, it is this—that no harm results from antitoxin. Urticaria may develop, it is true, but it is no worse after large than small doses."

Dosage.—In a severe case Dr. McCollom gives 4,000 units at once. This is repeated every four to six hours until the patient begins to improve. Children under five receive 3,000 units, but above that age 4,000. To one man critically ill 8,000 units were given at one time. The man recovered.

The mortality from diphtheria at the Boston City Hospital before 1895 varied for a series of years from 50% to 46%. At the South Department two years ago it had fallen to 12%, last year it was 10%. As a result of his experience with more than 6,000 cases of diphtheria Dr. McCollom recommends the use of large doses of antitoxin.

THE USE OF GELATINE AS AN HEMOSTATIC.

Bass summarizes forty articles on the use of gelatine as an hemostatic.¹ Though we referred to this subject in our last report, its importance deserves another mention.

On February 29, 1896, Dastre and Floresco published for the first time the results of their experiments upon the coagulating influence on the blood of intravenously injected gelatine. They injected into the tibial vein of a dog a 5% solution of gelatine in

¹ Centrbl. f. Grenzgeb. d. Med. u. Chir., Nos. 6 and 7.

physiological salt solution, and found the time of coagulation of blood withdrawn from the femoral artery was lowered. Whereas blood taken before the gelatine injection required two or three minutes for coagulation, blood removed under the same precautions after the injection coagulated within ten seconds to one minute. That this is not wholly due to the setting of the gelatine is shown by the fact that coagulation also occurs when the blood is drawn and kept at 38°. At this temperature the gelatine does not stiffen, but remains fluid above the blood corpuscles, and becomes firm only when cold.

No entirely satisfactory explanation of these phenomena has yet been presented, and it therefore seems best to pass on to the practical application of the discovery.

Carnot was the first to publish (July, 1896) successful experiments with the local application of solutions of gelatine. The first case was one of hemophilia, with uncontrollable epistaxis. After the injection of a few cubic centimetres of a 5% solution of gelatine into the bleeding side of the nose, and the apposition of a tampon saturated with gelatine, the hemorrhage ceased, not to return; when after some days a hemorrhage appeared on the other side, gelatine effected a similar result. The patient finally died of the intense anemia. In a second case of hemophilia the hemorrhage did not return after the local injection of a 10% solution of gelatine. Carnot applied this same treatment with success to rectal hemorrhages by means of gelatine enemata, and to hemorrhages of the female genital organs by means of intra-uterine gelatine douches or saturated tampons. The application of a tampon soaked with gelatine often avoided the necessity of using a ligature.

In animal experimentation the control of hemorrhage after resection of extensive portions of the liver was the most surprising feature. The bleeding surface was placed in contact with a solution of gelatine for some seconds, and at the cessation of hemorrhage some cubic centimetres of the solution were poured into the abdominal cavity and then this was sewed up. Not a single one of the animals suffered from a secondary hemorrhage.

As advantages of gelatine Carnot mentions, (1) its power of hastening coagulation; (2) its behavior in essentially favoring the nutrition of the cells and thereby the organization of the thrombus; (3) its harmlessness when the necessary precautions are followed, and (4) the ease with which it is procured.

Gelatine must be perfectly sterile; but since a temperature over 115° partially destroys its coagulability, Carnot sterilizes it by a double heating at 100° at an interval of two days. The flasks are kept well closed, so that when they are required they need only to be warmed in a water bath at 38°. The solution ought not to be used too hot, because too high a temperature on the one hand delays the setting of the gelatine, and on the other hand stimulates the vessels to contract, and so destroys the direct contact between the blood and the gelatine. As a local application Carnot used solutions of 5% to 10% in .7% salt solution. He does not recommend the addition of antiseptics, because these impair the favorable nutritive action of the gelatine upon the cells. He hardly advises the subcutaneous use of gelatine on people. These results have been confirmed by many writers too numerous to mention.

How important a rôle gelatine exercises in the treatment of gastro-intestinal hemorrhages is a matter at present to be received with reservation. Carnot denies its power in hemorrhages from the stomach, bearing in mind the changes which gelatine undergoes through the action of the gastric juice. Poliakow, however, mentions a case of profuse hemorrhage due to gastric ulcer, which ceased within twenty-four hours after the third dose of 200 cubic centimetres of a 10% solution of gelatine. It returned during the next four weeks two or three times, only to be again immediately conquered by the gelatine. Bauermeister also saw quick results in 3 cases of gastro-intestinal hemorrhage with 5% to 10% solutions.

Nogues introduced gelatine in the treatment of cystic hemorrhages by injecting gelatine into the bladder in 4 cases of bleeding caused by tumors. The bladder was first carefully emptied, washed out with boric acid, and not until then small amounts of gelatine injected. These were again removed and finally the bladder filled with the gelatine solution. In 3 cases there was prompt cessation of the hemorrhage without harmful results; in 1 case so large a coagulum formed that it had to be removed through a catheter.

Gelatine has furthermore been used subcutaneously in those cases of hemorrhage not otherwise to be reached—hemorrhages into the lungs, joints, and skin—or where hemorrhage is a result of disease of the blood—hemophilia, cholemia, etc.—and finally the prophylactic injection of gelatine before extensive operations has been earnestly considered. Bass reviews the results of various authors who have worked along these various lines. A case of Costinesco is of especial interest. A patient with severe dysenteric enteritis was given an enema of gelatine without effect, but after two subcutaneous injections of 100 grammes quickly recovered. As has been said above, the solutions of gelatine for external use are customarily 5 to 10%, subcutaneously 1 or 2%, made up with normal salt solution.

The chief contraindications are diseases of the heart and kidneys.

DIABETES.

It is a hopeful sign in the treatment of diabetes that so few new drugs have been recommended as specifics during the last six months. The medical profession is beginning to realize that reports of experiments with drugs in this affection are of no value unless the amounts of carbohydrates given during treatment are controlled. If the exploiter of a new preparation can show that a patient taking 200 grammes of carbohydrates daily has 100 grammes of glucose in the urine, but under the influence of the drug in question, the diet and surroundings being the same, he excretes only 50 grammes or less, then that drug is worthy of our attention. A single observation of this sort, however, is by no means decisive. Yet if the practitioner demands that all new drugs shall meet even this criterion before he introduces them into his practice, he will be spared many futile efforts.

The amount of work which is being done on diabetes is seldom realized, and the vast amount of experience which recent writers on the subject have acquired is too often overlooked. Take for comparison the number of cases of diabetes which were treated in the Massachusetts General Hospital during the

seventy-four years, 1824-1898. These amounted to 172, yet within the last three years Naumyn, von Noorden, and Lenné have published works on the subject each based on at least twice this number of patients, and the friends of Kütz have compiled a volume in which the records of 692 of his 1,100 cases are given at considerable length. Placed side by side with such authorities, how woefully insignificant the incomplete records of 4 cases appear when reported without regard to scientific study.

There is unanimity in the minds of all those best acquainted with the subject that patients should be kept either sugar free or as near that point as possible, provided (1) that on the strict diet they can hold their weight, and (2) that they are not placed thereby in imminent danger of coma. As to the weight, it is about the best guide there is of the success of treatment, because it is not only a measure of the patient's condition, but also can be made a test of the doctor's skill. For that doctor who can maintain his patient's weight and urine in a normal condition and yet allow the most carbohydrates is the best. This is the test in the mild cases, while in the severe the task is somewhat different. Here even on an absolutely diabetic diet the urine contains sugar and in a few cases it is almost impossible to entirely remove it. All agree that in these cases for certain periods a little carbohydrate must be allowed, and the aim is to maintain the weight and for this purpose to allow the least possible amount of sugar and starch. Each case of diabetes, then, is a test of the physician and if he takes the trouble to compare the condition of his cases with those of the leaders in this branch of medicine, he will very soon see to what rank he is himself entitled.

The chief aim in the diet is of course to supply the patient with food containing a large amount of fat. Dr. Pfaff has given a suggestion in this regard which I have been able to find nowhere in the books, though every once in a while there is an individual who has adopted the custom himself. This suggestion is to use butter instead of cream in the coffee. Before adverse criticism is made it is hoped that the physician will try a cup of coffee made according to the following rule: Place a half teaspoonful of butter in a very hot cup, and when melted fill the cup with very hot coffee, stirring the meanwhile. The butter mixes thoroughly and does not rise to the surface. The amount of butter used is a half teaspoonful (6 to 10 grammes) and the cup of coffee thus prepared is equivalent to 48 to 80 calories—about half the value of a single portion of beefsteak.

A tablespoonful of cream when added to a strict diet has great capabilities. One half of it will allow an omelette, and thus a whole host of new dishes can be prepared. The other half with the white of an egg can be used in making rennet, and possibilities in the line of custards are opened up. Again, a teaspoonful will wonderfully help out a cup of coffee or an eggnog. But there are creams and creams, and, as Dr. Pfaff has advised, one must secure that which contains the least amount of sugar and the greatest amount of fat. As a rule such creams are best obtained by centrifugalizing the milk.

Most English publications on diabetes are inadequate in this respect, that while they state what foods are allowable and what are prohibited to a diabetic, they do not contain the percentage composition of the various foods. To fill this lack a publication by the

United States Department of Agriculture will be found most useful. This comprehensive pamphlet of 87 pages is entitled "The Chemical Composition of American Food Materials, Bulletin No. 28" (revised edition), and was prepared by W. O. Atwater, Ph.D. and A. P. Bryant, M.S. It was revised in 1899, and can be had for the asking by addressing the United States Department of Agriculture, Office of Experiment Stations, Washington, D. C.

(To be continued.)

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON GENERAL MEDICINE.

STATED meeting, October 23, 1900, JOHN H. HUDDLESTON, M.D., chairman.

DR. ALFRED MEYER read a paper on

THE CITY AND ITS CONSUMPTIVE POOR; A PLEA FOR A MUNICIPAL SANATORIUM OUTSIDE OF THE CORPORATE LIMITS.

He estimated the total number of consumptives in the Greater City of New York to be between 25,000 and 30,000. The total deaths from consumption for the current year and the total number of incipient cases annually were both estimated at 8,100. Yet the total number of consumptives in all the public and private hospitals in the boroughs of Manhattan and the Bronx on January 20, 1900, was only 1,010, and the average daily number of cases charged to the city in these boroughs was 365 for the current year. The Department of Charities from January 1 to October 1, 1900, admitted 1,839 cases, and in this period 635 cases died. In the year 1899 twenty-six private hospitals in Manhattan, Brooklyn and the Bronx admitted 3,050 cases, and 924 cases died in these institutions.

It was not generally known, he said, that the first organized effort to secure proper hospital care for consumptives was made as long ago as 1855, when a society was organized for this purpose in New York, among whose managers were such well-known men as Peter Cooper and Dr. Alonzo Clark. The same arguments were urged then as now. At the present time, however, we had the three following additional ones: (1) The possibility of earlier diagnosis; (2) the greater chances of success in the treatment, and (3) the danger of infection. Having referred to the prospect of there being a State hospital for incipient cases in operation within the next fifteen months, he said that nothing has yet been done by the city, under the act passed by the legislature authorizing any city in the State with a population of 250,000 to establish a sanatorium for consumptives outside its corporate limits. While an adequate sanatorium for the city of New York would cost \$3,000,000, and require \$1,000,000 annually for its maintenance, he thought that an efficient start could be made with \$300,000; and that was all that was asked for at the present time. There was no conflict, as many had supposed, between the Department of Charities and the Department of Health in regard to the matter. While the vastness of the problem was deplored, the benefits of such an institution were freely admitted

by all the authorities. The objections raised were on the score of expense; but would any one think of returning to the old system of a volunteer fire department because the paid department was expensive?

The great question is not what will it cost, but will it pay? Enormous sums are now spent for the care of advanced cases that are hopeless which would be the means of restoring to lives of usefulness large numbers of individuals if employed for the proper treatment of incipient cases. The striking advantages of country treatment were well shown in the results obtained at the sanatorium for consumptives of the Montefiore Home at Bedford, Westchester County, which was only a comparatively short distance from the city. There was no fear that the hand of private charity would be palsied when the city undertook this work. There was an ample field for public and private endeavor.

Dr. Meyer then advanced a number of reasons for a city sanatorium. Among them were the following: Popular opinion in favor of the plan; the increased hopefulness of the medical profession as to the curability of the disease; the meagreness of both private and public endeavor up to the present time, as shown by the statistics quoted; the object lesson that would thus be furnished by New York to other cities; the great benefit arising from the instruction of inmates in hygienic rules; the saving of many lives. The agitation of this question, he said in conclusion, must and will bear fruit.

DR. JOHN B. COSBY, Commissioner of Health, said he had the assurance of his colleagues on the board that they would do everything in their power to have the sanatorium established. The great difficulty was to secure the money, and it was on the score of expense that the mayor had vetoed the bill passed by the last legislature which made the establishment of such a sanatorium mandatory on the part of the city.

A letter was read from Commissioner of Charities JOHN W. KELLER, in which he said he was heartily in accord with any movement looking towards relief from this great scourge. He was glad to report that the city's facilities for treating consumptives would soon be greatly amplified. In February next the Manhattan State Hospital for the Insane will have to vacate Blackwell's Island, and the three buildings there now occupied by it will revert to the Department of Charities. These, with the new pavilion at Bellevue Hospital, will be devoted to phthisis cases.

DR. H. M. BIGGS said that in 1894 he presented to the Department of Charities a scheme for the care of the consumptive poor. Three things were declared necessary: (1) A receiving pavilion at Bellevue; (2) a building on Ward's Island for advanced cases, and (3) a cottage sanatorium in the country for incipient cases. He suggested that the latter should be located at Central Islip for the reason that the city already owned a large tract of land there, with an institution for the insane, and there were thus afforded unusual facilities for economy of administration. President Porter, of the Board of Charities, approved of the scheme, but it was found that there was not at the time sufficient money to carry it into effect. Then came the "State care for the insane" agitation, and afterwards a certain number of wards in the City Hospital and portions of the almshouse on Blackwell's Island were set apart for tuberculous patients. Later, when the insane were removed from the Metropolitan

Hospital, wards were also arranged there. In the following administration (Mayor Strong's) the construction of a pavilion for consumptives at Bellevue Hospital was ordered, and this was only now just ready for occupancy.

In regard to the number of cases of phthisis in New York, Dr. Biggs was convinced that this was far greater than Dr. Meyer had estimated. He then gave a *résumé* of the various steps which the Health Department had taken since 1889 for the repression of the disease. When the first report of its consulting pathologists (Drs. Prudden, Loomis and Biggs) was received, it was referred to a number of prominent physicians in the city with the request for an expression of opinion as to the duty of the board in regard to cases of phthisis. It was a noteworthy fact that with a single exception (that of Dr. Janeway) every one of these physicians was opposed to the board's taking any action whatever. Since 1897, when the reporting of cases was made compulsory, the reduction in the mortality from consumption had been very great. If the alternative were presented of devoting a certain sum of money to the care of a limited number of incipient cases, or of expending the same sum in diffusing information regarding the disease and in renovation and disinfection he would prefer the latter. At the same time he was very strongly in favor of the establishment of such an institution as that contemplated by Dr. Meyer.

JOHN P. FAURE, ex-Commissioner of Charities, expressed his extreme gratification at the agitation of this subject, and stated that when he was in charge of the Charities Department there was no opportunity to separate the phthisis cases. He was very much impressed with the great good that could be derived from devoting special efforts to the accomplishment of special objects. As an illustration he referred to the reduction of infant mortality that had resulted from the system of floating hospitals carried out by St. John's Guild, in the management of which he had been actively engaged ever since the inception of the work. Again, while on a second visit to Denver he had been very much interested in learning that a group of poor young men had by their united efforts been able to secure a ranch in the vicinity of the city where consumptives with limited means could have the benefit of the climate at a minimum expense.

Letters were then read from the REV. DR. J. M. BULKLEY, president of the Seney Methodist Episcopal Hospital in Brooklyn, and from JACOB H. SCHIFF, president of the Montefiore Home, and short addresses made by FREDERICK STURGES, vice president of the Presbyterian Hospital, and CHARLES C. SAVAGE, president of Roosevelt Hospital. All expressed themselves strongly in favor of the city sanatorium, and spoke of the impossibility of treating phthisis in general hospitals, where, as a rule, all the beds are required for acute cases.

DR. NELSON H. HENRY, member of the Assembly for the last two years, said that the people of the State of New York had been educated up to the point where they found it necessary to do something, not only for human, but also for bovine tuberculosis. It was true that the appropriation for the State Sanatorium had been cut down from \$250,000 to \$50,000; but still we must not be discouraged. Such a project as that advocated this evening should get the active support of both the medical profession and the public at

large. There are two points to be attended to: (1) Removal of incipient cases to salubrious conditions, and (2) hospitals for advanced cases near the centres of population. At the same time careful attention should be given to the improvement of tenement house conditions and of the housing and the care of cattle.

Dr. H. W. BERG said that the Charities Department was already taking care of the very bad cases of advanced phthisis. Was it its duty to care for the incipient cases also? Under favorable conditions a considerable proportion of cases could be cured. The best treatment, however, was not by drugs or by anti-toxin serum, but that received in well-conducted country sanatoria.

Dr. LEONARD WEBER said that there was no question that the best treatment was to remove the patient to a country sanatorium. Such sanatorium need not be far away. He would suggest, as regards the city of New York, two sanatoria for the consumptive poor, one to be located in Rockland County, near the Dunderberg Mountain, for the boroughs of Manhattan and the Bronx, and one at Mount Kisco, in Westchester County, for the other boroughs. Such institutions should have a good cuisine and good arrangements for hydrotherapy, and should also afford good opportunity for walks. He thought it would be advisable for the various city dispensaries to have a special department for pulmonary tuberculosis, with a competent bacteriologist in constant attendance.

Dr. S. A. KNORF said that the problem was not a simple one, and, in his opinion, arrangements should be made at once for (1) sanatoria for incipient cases; (2) hospitals for advanced cases; and (3) measures for dealing with bovine tuberculosis. All these should be begun and carried on at the same time. To secure these, combined effort was required, and any appropriations that could be obtained from the authorities should be divided between the three objects mentioned.

A resolution was then adopted urging the municipal authorities to take action in accordance with the act passed by the legislature in regard to the establishment of sanatoria for cities, and also providing for the appointment of a committee of three to bring the attention of the Council of the Academy to the matter.

Dr. MEYER said that he had expected that Controller Coler would be present, and that he had every reason to believe that that official would do all that was in his power to secure the desired appropriation. Moreover, President Murphy, of the Health Department, had given him authority to say that he would use every possible endeavor in furtherance of this object. With regard to the increased accommodations referred to by Commissioner Keller, which would soon be available for consumptives, while these would be a great gain for advanced cases, the incipient cases would still remain to be dealt with; and it was for these that the country sanatorium must be provided. He was inclined to agree with Dr. Biggs that the number of consumptives in New York was underestimated in the paper, but he had purposely made his statements cautious and conservative lest he should be accused of magnifying the evil and the danger. While he agreed in the main with Dr. Knopf, he thought that at the present time the most important matter was to secure some provision for the care of incipient cases.

Recent Literature.

Kirke's Handbook of Physiology. By W. MORRANT BAKER, F.R.C.S., and VINCENT DORMER HARRIS, M.D. (Lond.), F.R.C.P. Revised by WARREN COLEMAN, M.D., Professor of Physiology in the Woman's Medical College of the New York Infirmary, etc., and CHARLES L. DANA, A.M., M.D., Professor of Nervous and Mental Diseases in the New York Medical School, etc. Fifteenth American edition. With upwards of 500 illustrations, including many in colors. New York: William Wood & Co. 1899.

In England "Kirke's Physiology" is a well-known textbook, and in this country, in former years, it was considered one of the best. Newer books, are, however, making their appearance and claiming a large amount of scientific attention; so much so, in fact, that probably in a few years this publication will be a thing of the past.

The title page of this book announces that it is the fifteenth American edition, but the title page fails to announce from what English edition the present volume has been compiled.

A prefatory note, over the name of Warren Coleman, announces the fact that "the form of the book has been left untouched in the main." To one who had been familiar with "Kirke's Physiology" for perhaps more years than he cares to remember, this announcement, on reading the book, is found to be hardly necessary.

The introductory chapters are practically the same in this edition as they were in former years, but several changes have been made in order to bring the book a little more up to date than it formerly was.

The description of the movements of the stomach in digestion is of uncertain age, particularly so when we consider the recent work of Cannon and others who have done much to lighten the darkness surrounding this important organ.

The account of the phenomena of coagulation of the blood is good, but, as in the majority of books, the student is treated to a long dissertation on the history of the experiments which aided (?) us in arriving at our present state of knowledge concerning this vital process.

On page 226 begins a discussion on the cause of the heart beat, or, perhaps more accurately described, a consideration of the physiology of cardiac muscle. The less said about this the better. We may remark, however, that it is questionable if Stannius's ligature, as a physiological experiment or explanation, has the value the authors seem to attach to it.

The chapter on the Liver gives us nothing new, and the chapter is carelessly printed, the whole line at the bottom of page 377 being reproduced on the top of page 378. Truly this is carrying the old style of printing a little *too* far. No reference is made to Delépine's work on the liver as a biliary gland, dividing it into vascular and biliary lobules.

Perhaps the most pleasing portion of the whole book is the latter part of the chapter on Secretion, dealing with internal secretion: here, certainly, the work is clearly put, and a student is not overwhelmed with a mass of doubtful experiments. The chapter on Muscle-Nerve Physiology consists of 21 pages, of which 7 pages are devoted to a description of appa-

tus. This chapter is short, and what information is given is not given any too well.

The chemical physiology contained in the book is of the ordinary description.

The plates and cuts scattered throughout the book are bad; the proof reading has been carelessly done (see above, one instance of carelessness); the paper and printing are very bad, and the binding is ordinary. The style of the book would be better had finer paper and better type been used, and the size of the volume consequently reduced. The American revisers should have insisted upon *hygienic* conditions in a *physiological* textbook. Let us suggest another improvement—acknowledgments for some plates used (those on blood crystals, for instance) and more references given to original work throughout the text.

Kirke's Handbook of Physiology. By W. D. HALLIBURTON, M.D., F.R.S., Professor of Physiology, King's College, London. Fifteenth edition. With upwards of 650 illustrations, including some colored plates. Philadelphia: P. Blakiston's Son & Co. 1899. [Printed in Great Britain.]

In this edition, Mr. Publisher, why not let poor Kirke's name alone? As Halliburton announced in his preface to the fourteenth edition, "the book is a new one" and has to a "great extent been rewritten." Properly speaking, the book is "Halliburton's Handbook of Physiology," and the professor should be pleased with it.

The introductory remarks are well written and the opening chapters on elementary histology are remarkable for lucidity and conciseness. To one who believes that the study of physiology is useless without a good preliminary foundation of histology, this fact will be appreciated.

After considering the histology of the tissues, Halliburton passes on to the physiology of muscle and nerve. These chapters are good, and a student will find here all the main experiments involved in the study of these structures, together with good descriptions of the apparatus employed. The chapters dealing with the circulation of the blood show a goodish portion of Hill's hand. On page 247 we find a reference to one of our American physiologists, Dr. Porter, citing his experiments on the mammalian heart apex and oxygen pressure. Other well-known authorities quoted are Gaskell, Langley, Pickering, Hill, in fact all the well-known authorities on circulatory physiology. (It may here be pointed out that throughout the book credit is invariably given, not only to original workers, but also borrowed plates are acknowledged. "Render unto Cesar the things that are Cesar's!" A pleasing feature, truly.) A break in logical arrangement occurs at this point by the introduction of chapters on Respiration and on Ductless Glands. Then we arrive at, perhaps, the best portion of the book, that is, a description of the blood and the phenomena of coagulation. To a student this chapter must be a regular godsend, leading him gently but clearly through the intricacies of coagulation and explaining the various (to him) complex substances found in the blood. The chapter on the Ductless Glands, dealing with internal secretion, is too short; it has evidently been very cautiously written. Too much attention has been given to old work and hardly enough to more modern explanations and experiments.

Respiration is practically the same as is found in all good textbooks.

A rearrangement of the several chapters considering the various phenomena of digestion could be carried out with considerable benefit to the readers. For instance, the chapter on the Mechanical Processes of Digestion could well follow the description of the alimentary canal, then let us have foods and the descriptions and actions of the various digestive juices, ending with absorption. The chapters on the Nervous System are up to date, are clearly written, and contain many capital illustrations. With regard to the rest of the book, it only remains to be said that the chemical physiology contained in the volume is beyond reproach. The remaining branches are dealt with in the ordinary manner.

The book is beautifully illustrated throughout. Too much praise cannot be given for the fine quality of the paper and the clearness of the cuts. "Printed in Great Britain" can be seen on the title page. Is this a challenge to American publishers? Certainly I have yet to see the physiology published entirely in America that will equal this book in cuts, printing and paper. Take notice, ye American publishers! The binding is neat, and of the usual textbook character.

To students and even to those more advanced in the study of physiology this book should be very welcome. The reviewer has pleasure in recommending it very highly to all those desiring a pithy and well-written physiology.

[REVIEWER'S NOTE. — It may seem strange to the uninitiated on reading the above reviews to find *two* books, both called "Kirke's Handbook of Physiology"; the reader will naturally stop and wonder which is *the* book. To explain this peculiar anomaly, by giving a short history of "Kirke's Physiology," this note is written.

About the year 1850 Dr. Kirke, with the aid of the late Sir James Paget, produced in England "Kirke's Handbook." This book, in vulgar parlance, "filled a long-felt want." It passed through many editions, until at last Kirke died; then, after passing through various minor changes, the editorship of the volume was assumed by Mr. Baker and Dr. Harris, and by them the book was kept up to date, Mr. Murray, the publisher, owning the book. In this country the book was reproduced by Lea Brothers & Co., and by them sold to Messrs. Wm. Wood & Co. (What they sold is a mystery, as they had no rights to sell.) This firm never had permission to use either the late Mr. Baker's or Dr. Harris's name in connection with their publication. Still the publication and the sale went merrily on. Over four years ago Dr. Harris and Mr. Baker resigned their offices as editors. Mr. Baker is now dead and Professor Halliburton assumed sole control, producing the present English publication, or Blakiston's American edition. Although Mr. Baker and Dr. Harris have had no connection with the book for over four years, Messrs. Wm. Wood & Co. still produce a Kirke claimed to be edited by these men and revised for American consumption by Warren Coleman and Dr. Charles L. Dana. In Wood's edition under review, several illustrations can be seen (those on blood crystals) which have been *lifted* bodily from Halliburton's edition and no acknowledgment made. There is also a remarkable similarity between the two editions in parts of the text. Perhaps this may be explained by the theory of telepathy!

Of the two editions I understand that Blakiston's is the only edition published in this country with the owner's permission and from which the editor, Professor Halliburton, receives any remuneration. However, the present unfortunate state of International Copyright Law places no legal obstacles in the way of Messrs. Wood & Co's producing

the book as they have done, but there is no doubt that fair-minded people will be shocked to find that in the noble profession of medicine, men are found who assist in such questionable proceedings, even after personal protests not only from Mr. Murray — the owner — but also from Professor Halliburton. To sum up the whole matter, it simply means that Blakiston's is the authorized edition, while Wood's is not. *O tempora, O mores!!*]

A Treatise on Diseases of the Nose and Throat. By ERNEST L. SHURLY, M.D., Professor of Laryngology and Clinical Medicine, Detroit College of Medicine, etc. New York: D. Appleton & Co. 1900.

This is a new textbook on laryngology for the use of the general practitioner and student rather than for the specialist. In common with many of the existing textbooks on the subject it contains about 700 pages, about 200 illustrations in the text and 6 colored plates, in this case mostly from Grünwald.

The opening chapter is a short perfunctory review of the anatomy of the region, illustrated by some very good photographs of frozen sections. Although the author appreciates that the chapter on anatomy is the one which is the most helped by illustrations, a few more outline sketches could be added, to the benefit of the student. The chapters on syphilis and tuberculosis show the hand of a master; especially in the latter subject no one will dispute the author's claim to the title. The complicated and important subjects included under the head of neuroses are clearly and practically treated. The same may be said of diphtheria. There is a good section on leucoplakia, a subject which the student often seeks in vain in his textbook, with a table to distinguish it from similar appearances. It is a little hard to see why atrophic rhinitis and ozena should be classed as separate and distinct diseases. In both cases the etiology is acknowledged to be in doubt, and in both places many of the authorities quoted referred to both the fetid and non-fetid forms. The chapter on neoplasms of the upper air passages is less satisfactory than most of the others. The arrangement is confusing. The etiology, description and treatment of ordinary nasal mucous polypus alternate with those of rare and totally dissimilar neoplasms, whereas from its clinical importance at least it should stand boldly out, and even from a pathological standpoint there is much about it which does not apply to other tumors. The class of new growths which might be included under a head of fibroid tumors of the nasopharynx does not receive proper attention. The few pictures of patients suffering from advanced malignant disease are worse than useless; they are disfiguring. Deformities of the nasal cavities are judiciously and concisely discussed. The section on injuries to the external nose is poor. The chapter on the accessory sinuses consists of a short sketch, especially of the antrum. The very vexatious subject of ethmoiditis has been largely simplified by omission.

The author has brought to bear good judgment and common sense in dealing with the different diseases of this part of the body. It is refreshing, for instance, to find the writer of a didactic textbook tell his students that many persons go through life whose nasal passages showed considerable deflection or spur or deformed turbinals, and who apparently have suffered no inconvenience whatever. And again, "Similar instances of relief from neuralgia and other neuroses by the cor-

rection of intranasal diseases could be adduced; still, before formulating principles or rules of action on this evidence, we must remember that accidents to or operations upon other parts of the body, even where intranasal disease exists, may produce similar fortuitous results."

The book is essentially American. It can be said without reflecting anything but credit on both that it contains much from the *Transactions of the American Laryngological Association*. It bristles with the names of American laryngologists. In some cases it almost seems as if the author, in an excess of modesty, had shrunk from asserting the simplest propositions, and had hunted up some confrère to whom he could give the credit. If names had been omitted except in reference to original work on the subject, and if in the latter case a bibliography had been inserted showing where the original work could be found, the text would be improved for the casual reader, and the references made more valuable for the more thorough student. The arrangement of the subject is unusual, and perhaps not quite so clear, especially for the class room, as the common one based on the anatomical regions. These criticisms are, however, trivial. As a whole, the book is attractive, judicious, well written and well balanced.

A Treatise on Nasal Suppuration, or Suppurative Diseases of the Nose and Its Accessory Sinuses. By DR. LUDWIG GRÜNWARD, of Munich. Translated from the second German edition by WILLIAM LAMB, M.D., M.C., M.R.C.P. (Lond.). New York: William Wood & Co. 1900.

Grünwald's book on suppurative diseases of the nasal cavities has become a necessity in the equipment of the student or practitioner whose work includes this part of the body. Even if we differ from the author in details, there can be no doubt that his work, and his book based on the work, are both of the greatest importance and value.

The object of the author is primarily an argument that nasal suppuration in the great majority of cases depends upon local or circumscribed disease. From this it follows that where a purulent discharge from the nose is present as a symptom, the nasal cavities and the accessory sinuses must be carefully investigated, and the source of pus being found, surgical treatment is generally necessary for its cure. At the same time he shows that the detection of focal suppuration requires a high degree of investigation and patience.

Many readers will not be prepared to trace quite as many morbid conditions to a localized focus in the nose or accessory sinuses as the author invites us to do. That nasal polypus is a secondary symptom is generally, but not universally, accepted; but that "ozena" is secondary to a localized suppurating focus will probably for some time to come be considered not proven. The etiology of "ozena" has long been in dispute. As the author says, "All kinds of fallacies have been assumed with regard to ozena, and have been received with that enthusiasm which interpretation of facts, however false, always elicit, if only the facts appear to have been obtained by exact methods." His observations lead him to believe that no case occurs without focal suppuration, though not necessarily from an accessory sinus.

The relation of diseases of the nose and sinuses to

different disturbances in the eye and ear, to headache and neuralgia, to asthma and irritation in the pharynx and larynx include a vast field for observation and research. The author may be considered over-zealous in bringing symptoms of doubtful origin into his line, but he is essentially judicial and not dogmatic in his reasoning. He has already induced a change for the better in the diagnosis and treatment of these conditions.

The book is not an elementary one. A knowledge of and frequent reference to the anatomy of the region, as well as practical experience, or at least previous study of diseases of the nose, is essential to the reader. It is the best treatise of its size on the diagnosis and treatment of suppurative diseases of the accessory cavities at our command. We find in different parts of the book concise general statements which should be put in italics and given to students to learn. For example, "One must always remember that almost every cavity in the nose is equally competent to act either actively as a suppurating centre or passively as a reservoir in which pus is simply retained." By injections and douches, "even if pus do not find its way into the middle ear it is at least possible that it may be driven into deeper regions of the nose." "Rule of thumb methods are most of all to be deprecated in chronic empyema of the antrum. The objects to be kept in view are always the same: free drainage for pus, and the removal of those secondary changes which keep up the suppuration and interfere with the cure."

Of the translation and general appearance of the book nothing can be said except in praise. A certain lack of clear subdivision and sequence is characteristic of all German books, and it would have been impossible to remedy it more than has been done. The English-speaking workers and students in this subject are to be congratulated on having so excellent a translation, and should make full use of their opportunity.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In twenty volumes. Volume XX, "Tuberculosis, Yellow Fever and Miscellaneous, General Index." New York: William Wood & Co. 1900.

This twentieth volume is the last of the "Twentieth Century Practice," and the series is now complete. This volume has 906 pages, of which the first 490 pages are devoted to two very important general subjects, Tuberculosis and Yellow Fever; a very full analytical index of the whole work occupies 304 pages, and the other 112 pages are taken by several short articles on miscellaneous subjects, among them being one on Poisoning with Snake Venom, by Dr. Thomas R. Brown, of Baltimore, and one on Mushroom Poisoning, by Beaumont Small, of Ottawa.

In a short preface to this final volume the editor allows himself a few words of thanks to his collaborators and of explanation to his public. There have been some unavoidable delays, and some deviations from the natural order of issuance of volumes, but not more than might be expected in a work covering so much ground, spread over so much time and dependent upon so many contributors. Some who were to have contributed died and had to be replaced, and

no less than nine well-known medical writers have passed away since contributing their last medical writing to this international encyclopedia.

The general subject of tuberculosis is subdivided. The Bacteriology, Pathology and Etiology are dealt with in one article by Dr. A. J. Lartigau, of New York; next comes a chapter on Symptomatology, by Dr. H. W. Berg, of New York; then a division on Diagnosis, Prognosis, Prophylaxis and Treatment, by Dr. S. A. Knopf, of New York, and finally a chapter on Tuberculosis of the Skin, by Dr. J. T. Bowen, of Boston.

The article on Yellow Fever occupies 95 pages and is by Dr. Wolfred Nelson, now of New York, formerly a member of the State Board of Health of Panama.

This volume is quite up to the general standard of the series, which taken in its entirety constitutes a medical encyclopedia of genuine value.

Diseases of the Chest, Throat and Nasal Cavities.

By E. FLETCHER INGALS, A.M., M.D., Professor of Diseases of the Chest, Throat and Nose, Rush Medical College, Chicago, etc. Fourth edition. Pp. 787, with 255 illustrations. New York: William Wood & Co. 1900.

The third edition of this popular textbook was published in 1894. In this one, the fourth, several additions or improvements of former chapters appear, increasing the size of the book by about 80 pages. The section on Diseases of the Chest has been improved by revision of the chapters on Bronchitis, Pneumonia and Tuberculosis, and the addition of an excellent chapter on Diseases of the Mediastinum. Other changes in many parts of both sections bring the work up to the present time.

The reasons for the popularity of this textbook are evident: the arrangement is clear, the description concise, and the treatment practical. Space is allotted to the different morbid conditions in good proportion to their clinical importance. By judicious condensing the author has succeeded in getting a great deal into a small space. The book is too small to be satisfactory for reference, except that the author's opinion on many subjects is valuable. It is especially fitted for the undergraduate medical class. In some colleges the chest is combined with the nose and throat in the courses of instruction, and for such it is convenient to have the subjects bound in one volume.

Syphilis and the Venereal Diseases. By JAMES NEVINS HYDE, Professor of Skin, Genito-Urinary and Venereal Diseases, Rush Medical College, Chicago, etc., and FRANK HYDE MONTGOMERY, Associate Professor of same. Second edition. With 58 illustrations. Philadelphia: W. B. Saunders & Co. 1900.

This work, the first edition of which deservedly occupies a place of merit in the somewhat overburdened list of publications which are devoted to the subjects with which it deals, may in this, its remodelled second edition, properly claim rather more than to have maintained its former standing, its authors having distinctly added to its value by the introduction of material which puts it on the plane of some of the best of its modern contemporaries. In arrangement of subject matter it is conspicuously good, in style concise and lucid, and its practical quality is notable.

The first portion of the volume, which deals with syphilis, is amply and well illustrated, in several instances by excellent colored plates copied from the atlas of Mraček, and is perhaps the most instructive and valuable part of it, the latter half having no distinctive excellence as compared with a number of other similar treatises recently published which treat of urethritis, its complications and sequela.

The work does not invite criticism in an adverse sense, but rather by way of suggestion, as, for example, it strikes us that perhaps a rather more extended consideration of syphilis of the internal organs than is here accorded them (for example, the lungs and genito-urinary organs) would have been acceptable. And the parts of the work devoted to gonorrhoea and to stricture would have been benefited by fuller illustration, for example, of organisms with which the gonococcus is liable to be confounded, colored facsimiles of the endoscopic field, and a larger number of the varieties of stricture and their effects upon structures involved in or adjacent to them.

The subject of sexual hypochondriasis is presented in an unusually clear and forceful manner, and the chapter relating to it has a certain touch of philosophy that gives it originality and adds to its interest. The volume will repay a careful consideration on the part of either student or practitioner.

Mental Affections. By JOHN MACPHERSON, M.D., F.R.C.P.E. Pp. 379. London: MacMillan & Co., Ltd. New York: The MacMillan Co. 1899.

This work, which is modestly labelled "An Introduction to the Study of Insanity," is the first thoroughgoing English exponent of what might be called the "new insanity," that has appeared and may be said to inaugurate a new epoch in the textbook literature of mental diseases. Not only is the neuron doctrine effectively applied therein, but auto-intoxication and the microbial toxins are assigned leading rôles in the causation of mental disturbances of nearly every degree. In fact, the author's predilection for toxins as the basis for all forms of insanity, a presumption for which he admits there is no direct proof, carries him, in our opinion, much too far. Nevertheless, unless one keeps in mind the fact that much of the investigation underlying the toxic theory of the causation of mental and nervous diseases has been imperfect and that only recently have indisputable counterfactors been brought to light, he will find it hard to overcome an inclination to side with a writer whose points are so well taken and whose argument appears to be so conclusive. His pathology, both general and special, as well as his pathological symptomatology, evince a thorough knowledge of the most advanced views on the subject and his opinions regarding the inter-relationship of the neuroses, the psychoses and the diatheses, are most suggestive and helpful. The chapters on the evolution and etiology of insanity are of especial interest, and show, together with a wide range of general information, great insight into the operation of general causes and a nice discrimination as regards the value of the various factors in the production of mental disease. His advice as to treatment is sound and practical. As a whole, the book is a valuable and opportune contribution to our knowledge of the subject, and one that thinkers and workers in this department of medicine are sure to welcome.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 8, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

HENRY JACOB BIGELOW.

A MEMOIR.

As the generations of medical men come and go, and as the constantly increasing number of younger physicians gradually fill the places of their elders, it naturally and inevitably happens that the influential men of the past are in a measure, at least, forgotten. It is often hard for a man starting in his career to realize how great a debt he owes to his predecessors, and how much the privileges which he enjoys represent the work of those who have gone before. This is not so much due to ingratitude as to ignorance and lack of that keen interest in the development of his profession which demands of him a knowledge of the past. To very many now in the active practice of their profession in this community the name of Dr. Bigelow brings up personal recollections of a most vivid sort; to others the actual remembrance of the man is nothing more than a dim memory, and to a rapidly growing number even this is lacking, and nothing remains but the knowledge of what he accomplished. It has been said that however distinguished a man may have been there are always others to fill his place, which is clearly only a partial truth. Occasionally it happens that a man takes so unique a place in the work of his particular calling that his loss is permanently recognized, however well the work which he inaugurated may be carried on by his successors. We could easily name a dozen physicians in the history of the medical profession in Boston who may claim this unusual distinction, and there can be no doubt that one of these is Dr. Bigelow.

We have before us the recently published memoir of this eminent surgeon, prepared under the direction of his son, together with his published and some of his hitherto unpublished contributions to medicine and allied subjects. The four volumes in which this material is presented are a fitting memorial to a man whose professional work was closely associated with a critical epoch in the development of medical art and

medical teaching. The first volume contains an appreciative and concise account of his life and habits of thought. The writer of the sketch, whose name is withheld, is judicial in his estimate of the character and attainments of the man, permitting the reader quite clearly to see the combination of attributes which made up his somewhat unique personality. His conservatism, especially in the matter of medical teaching, and in his relation to the Harvard Medical School; his extraordinary versatility and his not infrequent dogmatism and intolerance are presented in a sufficiently candid spirit. At the conclusion of the memoir one feels as if he had been introduced to a man of undoubted genius, with many of those minor peculiarities which seem so inseparably associated with distinguished ability. The account is charmingly written and should be generally read not only by those who knew him in life, but also by the greater number who knew him only through what he accomplished. Over 100 pages of the volume are taken up with memorials, resolutions and obituary notices, which throw still further light on the estimation in which he was held by his associates and friends. Oliver Wendell Holmes's personal sketch is perhaps of particular interest in this connection.

The three remaining volumes are concerned respectively with Anesthesia, address and other papers; Orthopedic Surgery, medical papers; Dislocations and Fractures of the Hip; Litholapaxy. These are naturally of varying interest and varying permanence. The work on the hip and on stone are, of course, classical, and will always remain one of Boston's substantial contributions to medical knowledge. Many of his medical papers on more or less general subjects are entertaining and forcible, though it was certainly not in this field of literary endeavor that he especially excelled. His ideas, though always the product of careful thought, were frequently not progressive, and missed the broad point of view. Nevertheless, the Medical Faculty of Harvard University have put on record the following statement:¹ "As a member of the faculty he was distinguished for the ripeness of his judgment, the wisdom of his conclusions and the clearness and force of his arguments. Whether as advocate or opponent he was sure to add new light to the subjects under discussion, and was always to be recognized as a leader of men." His papers on vivisection show the curious contradictions of his mental attitude. His breadth of vision was not large enough to permit him to see the advantages and necessity to knowledge, of experiments on animals, no doubt because his immediate interest lay in the practical application of his special art rather than with the theoretical aspects of the whole subject of medicine.

It is a source of congratulation that these books have appeared to renew interest in the life and work of this really remarkable man. We have too few such memorials of the men who have left a definite impress upon their times.

A NEW EMPLOYMENT FOR WOMEN.

No sooner do the various employments which are open become filled to overcrowding than new ones appear, so that there seems always to be something for every one to do. Women's vocations are rapidly becoming practically the same as men's, and their entrance into the fields of active work is in fact leading them into regions where men may not go. The whole profession of nursing is pre-eminently a woman's work, and the sterner sex appears quite willing to yield this sphere of activity to them without question or dispute. A new suggestion has come through the columns of a New York lay contemporary, which contemplates that women fitted by nature and training for such employment devote themselves to the task of visiting persons who are ill or despondent, for the purpose of cheering them along the road toward the recovery of physical or mental health. It appears that a woman, whose name is quite unknown to us, has taken upon herself this sort of work as a calling. She goes for a certain time each day or less often, as the case may be, to persons who are incapacitated for the ordinary social enjoyments of life. In each instance she naturally uses her judgment as to what sort of amusement her client requires, whether conversation or reading aloud, or silence. In this instance the success of the plan is reported to have been so great that the woman's time is completely occupied, and she finds herself independent of the wearing monotony which is a companion's lot, who is continually devoted to the interests of a single patient. "In the case of one invalid," our contemporary writes, "she devoted the two hours spent with her daily to writing letters for the sick woman, and that furnished the means of passing the time so quickly that it never grew wearisome to the 'cheerer' and greatly improved the patient. Other similar expedients came to mind in different cases and the tedium of the companion's life was never noticed in this newer method of 'cheering by the hour.' The doctors find that an advantage to the patient in this system is the interest aroused by the arrival of the woman every day, whereas if she were always to be found, her presence would awaken no interest, if indeed it did not become irksome. The visitor, who comes from the outside every day, brings into the room an atmosphere of freshness quite impossible to one who remains there permanently."

A possibility occurs to us which should not pass unmentioned, and that is that the tendency toward gossip with which some women are said to be endowed would under this arrangement have a rare opportunity for development were it not held in strictest control. That women of the right sort are capable of discretion in such a matter can, however, not be doubted.

This appeals to us both as a feasible and reasonable idea; it is clearly a new sphere for the right sort of women, of whom there are, no doubt, many in search of just such work, if they but knew it. It requires no great stretch of the imagination to conceive of the

¹ Journal, November 6, 1890.

systematic organization of such a scheme. Any physician who practises medicine is well aware, whether or not he publicly proclaims the fact, that much of his most time-taking and arduous work consists in cheering on his chronic patients to another day or week of endurance, and also that his success, in the popular acceptance of the term, depends in great measure upon his ability in this regard. Such work is, no doubt, necessary, but it has, we confess, always seemed to us a type of treatment not quite in accord with the full dignity of his calling. Here is a legitimate way out of the difficulty, to delegate to an appropriate person the function of combating the *ennui* of invalidism. No doubt the work of our busiest practitioners would thereby be diminished, but their time could then be devoted to different things, and the patients, we venture to believe, would not in the long run be losers thereby. The physician might well direct the form of amusement or diversion his patients should have, but let the actual work be done by another. It is a field which the nurse evidently does not fill, nor the so-called companion. There is no element of novelty in their presence, but an outsider gifted in the art of entertainment might fill a place in the lives of many invalids which the doctor does in part, more or less unwillingly. At any rate the experiment is worth trying; we say it in all seriousness.

MEDICAL NOTES.

NEW BUILDING FOR RUSH MEDICAL COLLEGE. — Rush Medical College is to have a new building to cost \$80,000, for which Dr. Nicholas Senn has just given \$50,000. The building is to be called Senn Hall. Primarily, the new building will be for clinical purposes. In addition to complete arrangements for clinical work there will be classrooms and laboratories.

SIR WILLIAM MACCORMAC'S SERVICES IN THE FRANCO-PRUSSIAN WAR RECOGNIZED. — We learn from the *Lancet* that the German Emperor has recently conferred upon Sir William MacCormac the "Kaiser Wilhelm" memorial medal in recognition of his services during the Franco-German War of 1870-71, and Her Majesty the Queen has been graciously pleased to grant her permission to him to accept and wear the medal. The medal was not long since instituted by the present emperor in memory of his grandfather, "Der Grosse Kaiser."

DR. ALFRED STENDEL APPOINTED AT THE PENNSYLVANIA HOSPITAL. — Dr. Alfred Stengel, well known as the editor of the *American Journal of the Medical Sciences*, and director of the Pepper Laboratory, at the University of Pennsylvania, has been appointed visiting physician to the Pennsylvania Hospital to succeed the late Dr. Da Costa.

PAN-AMERICAN MEDICAL CONGRESS. — The Pan-American Medical Congress will hold its sessions in Havana, Cuba, December 26, 27, 28 and 29, 1900.

Communications are solicited. Information may be obtained of the secretary, Dr. Tomas V. Coronado, of Havana.

A SUSPECTED CASE OF PLAGUE IN BREMEN, GERMANY. — A sailor from a vessel arriving recently at Bremen from South Africa has developed symptoms suggestive of plague, and is now under the observation of experts to determine the diagnosis.

"SWALLOWING" A DIAMOND. — We are indebted to Surgeon-General Bidie, C.I.E., (I.M.S. retired) for sending us a local report of a curious case recently tried in Calcutta. A young man, having provided himself with a new suit of clothes, walked into a jeweller's shop and asked to look at a parcel of diamonds. He went to the window for better light, and presently it was discovered that the largest diamond, valued at Rs. 10,000, had disappeared. The gem did not appear, and it was suspected that it lay concealed in the man's throat. A skiagram was taken and revealed a foreign body in the throat which could not be dislodged. At the trial an old criminal swore that the concealment of stolen articles in the throat was a well-known habit of Indian thieves. An artificial dilatation of the pharynx is produced by the means of a round leaden bullet, which is "swallowed" and brought up several times a day until a pouch is made which fulfils for stolen articles—coins and jewels—the same function as the crop in birds and rumen in ruminants. — *British Medical Journal*.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, November 7, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 158, scarlatina 46, measles 20, typhoid fever 15.

MORTALITY STATISTICS. — The number of deaths reported to the Board of Health for the week ending November 3d is 184, as against 193 the corresponding week last year, showing a decrease of 9 deaths, and making the death rate for the week 17.3. The deaths from consumption were 22, pneumonia 19, whooping cough 1, heart disease 22, bronchitis 10, marasmus 3. There were 7 deaths from violent causes. The number of children who died under one year was 33; under five years, 49; persons more than sixty years, 30; deaths in public institutions, 60.

BERI-BERI VICTIMS TO BE SENT TO CALCUTTA. — Of the four Hindus who have been under treatment for beri-beri at the Boston City Hospital, one has died and three have recovered. The survivors have been sent to New York by the British Consul, whence they will be sent home to Calcutta. They came to Boston some weeks ago in the British steamer *Arava*.

NEWTON, MASS.. DISTRICT NURSING ASSOCIATION. — The annual report of the association shows that two nurses have been regularly employed during the year, who have made 5,096 visits to patients. Two hundred

and seventy-three cases have been cared for; 17 have died, and 13 sent to the Newton Hospital.

TYPHOID FEVER IN NORTHAMPTON, MASS. — Dis-closures made by the local Board of Health have shown within the town limits the presence of an epidemic of typhoid. The district most infected is known as the Bay State section, where 50 cases have so far been reported. It is probable that other cases will develop.

A NEW AMBULANCE FOR BROOKLINE, MASS. — The ambulance designed for the contagious hospital is about to be delivered to the Brookline Board of Health. It is a light vehicle, so arranged that it can receive two stretchers, one for children and the other for adults.

APPOINTMENT OF DR. ALFRED SCHAPER. — Dr. Alfred Schaper, formerly assistant professor of histology at the Harvard Medical School, has been appointed to a professorship of anatomy at Breslau, Germany.

NEW YORK.

A TRIBUTE TO DR. EDWARD SQUIBB. — In a recent editorial article the *Brooklyn Eagle* pays an eloquent tribute to the character and achievements of the late Dr. Edward Squibb, who was for so long an honored citizen of that borough. It was, it says, as a manufacturer of medicines for the use of physicians he won and deserved, among those for whose recognition and commendation he strove, a reputation that was a fitting reward for long years of strenuous and absolutely conscientious endeavor. Every doctor knew that the Squibb preparations were exactly what the names of them indicated and that they could be prescribed with perfect confidence that the patient would get what the prescription called for. There was never any question about this. Substitution and adulteration were lost arts, so far as the Squibb laboratory was concerned, and its owner set and long maintained almost alone the standard that has been equalled but never surpassed by the best American pharmacutists. Of course, many laboratories now exist modelled on the one he established, but they are successful and honored in proportion as they follow the copy he set. He was a great power in Brooklyn, yet he never advertised, he never made addresses. He wrote only within the lines, on the subjects and for the members of his own profession. He abhorred publicity or praise. Yet his influence on medicine, on medical thought, on medical practitioners, and sympathetically on public health, was not unlike that of the Gulf Stream on climate or that of the Nile on soil.

DEATH OF A LEPER. — Lee Hing, one of the four Chinese lepers who were isolated on Ricker's Island in 1893, died at the almshouse on November 3d. At one time the four escaped, but they were all captured and returned to the island. Soon afterwards, by a decision of Health Commissioner Cyrus Edson, made after a consultation with prominent dermatologists, to the effect that leprosy is not a contagious disease in

this climate, the four were set at liberty. Lee Hing returned to his friends in Mott Street, New York, but finding that he was practically ostracised, he applied to the city authorities to be taken care of. He was then sent to the almshouse, where he lived and finally died in a small isolated building set apart for his use.

FROM CHÂTEAU D'IF TO CHÂTEAU DE SING SING. — Edmond Dantes has been condemned to imprisonment again — this time, however, not in the terrible Château d'If, but in the more prosaic Château de Sing Sing. An individual with the name of Dumas's immortal hero was on October 31st sentenced to one year in State Prison for removing John Hall's name from a diploma issued by the New York College of Pharmacy and inserting his own, by which he was enabled to obtain a position as clerk in a Second Avenue drug store. It seems that Dantes worked in Paterson, N. J., for Hall, and while the latter was away on a vacation appropriated his diploma and came to New York to secure a situation by means of it.

GARBAGE RENDERING IN BROOKLYN UNCONSTITUTIONAL. — By a decision handed down by Justice Andrews, of the Supreme Court, the law prohibiting garbage rendering in the Borough of Brooklyn, which was passed by the last legislature, has been declared unconstitutional. This was in a suit against the Board of Health brought by the New York Sanitary Utilization Company, which in 1897 entered into a contract with New York and Brooklyn to render all their garbage on Barren Island, and expended over \$500,000 in building a plant for the purpose. The Health Department, by the act referred to, was empowered to put a stop to the garbage rendering on Barren Island.

DEATH OF GEORGE WASHINGTON HORNER GREEN. — Again the champion "old nigger" is dead. George Washington Horner Green, a former negro slave, died October 31st in the almshouse at Hempstead, Long Island, at the reputed age of one hundred and twenty-three years. He is said to have been born on a farm in New Jersey, on January 1, 1777. He was sold to a Virginia planter named Horner, by whom, it is alleged, he was sold to General Washington. Having been manumitted in 1812, he came north, and has ever since resided on Long Island. He was married several times, and is said to have been the father of thirty-seven children, most of whom are dead.

CITY BUDGET FOR 1901. — On October 30th the budget, which represents the estimated cost of the Government of the City of New York for the year 1901, was passed by the Board of Estimate and Apportionment. While the total appropriation shows an increase of \$7,321,440 (fully 80 per cent. of which increase, according to Controller Coler, was caused by mandatory legislation at Albany), the amount assigned for the Department of Health is \$12,671 less, and that for the Department of Public Charities \$1,322 less than in 1900. The appropriation for the Health Department is \$1,053,990.

Miscellany.

THE REFORM OF MEDICAL ORTHOGRAPHY.

The *Medical Press* comments on what it regards as an Americanism, namely, the effort to reform medical orthography. We are also inclined to place ourselves among the conservatives in this matter, and find considerable food for reflection in the following paragraph: "A correspondent calls us to account for our want of sympathy with the efforts of our American confrères to simplify the orthography of medical terms by eliminating redundancies and by approximating the spelling to the pronunciation of words. We must confess to a certain conservatism in matters orthographical, nor is this to be wondered at when one recalls the years of labor devoted to the acquisition of the knowledge how words should be spelled. We are free to admit that the dislike which the sight of truncated and mutilated words inspires does not repose upon any logical basis, and, further, that in many instances the orthodox manner of spelling a word, far from giving a trustworthy clue to the etymology, is often at variance with its true derivation. Our correspondent's appeal to educated men to abstain from discomenancing the movement in favor of reform is somewhat wide of the mark in so far as it is based on the assumption that the educated are more amenable to reason in this matter than the unlettered. The reverse is probably the case. To bid the scholar discard one of the most tangible results of a long and tedious education is about as reasonable as to bid the physician to "throw physic to the dogs." To plead that this is prejudice and not reason, is deliberately to ignore the fact that most things in this world are decided by custom, for example, prejudice, rather than by any act of the reason. That the reform for which he pleads will come to pass at some future time we cannot doubt, but as yet, though the spirit is willing the flesh is weak, and the repulsion which American mangled terminology inspires on this side of the ocean is still strong."

A QUESTION OF MEDICAL ETHICS.

DR. CHARLES LYMAN GREENE writes a forcible paper in the October number of the *St. Paul Medical Journal*, in which he speaks in no uncertain terms of the practice, apparently more prevalent in the West than here, of receiving commissions for patients sent in consultation. The Minnesota State Medical Society, at which the paper was read, has unanimously adopted the following resolutions:

WHEREAS, it has come to the knowledge of this society that the paying and receiving of commissions on cases referred by one practitioner to another is an established custom, among a certain small number of physicians, and

WHEREAS, we, the members of this society, regard such practice or practices as reprehensible, degrading, unethical and unprofessional and believe that their maintenance threatens the very existence of scientific and humane medicine, it is hereby

Resolved, That the giving or receiving of commissions as above described, after this date, shall be considered as constitutional grounds for expulsion from this society.

Resolved, That our delegates to the American Medical Association shall be and are hereby requested to use their

influence in every possible way to make the above described offence cause for expulsion from the national association.

Obituary.

E. J. CUTTER, A.B., M.D.

DR. EDWARD JONES CUTTER, A.B. (Harvard), 1877; M.D. (Harvard) 1881, was born at Peterboro, N. H., July 5, 1855. He was the son of Edward Stearns Cutter (A.B., Dartmouth, 1844) and Jaquette Swan. He was educated at Amherst and Manchester, N. H., and later at the Public Latin School in Boston. He was house officer at the Boston City Hospital from July, 1880, until January, 1882, when he was appointed assistant resident physician at the State Almshouse at Tewksbury. In November, 1882, he became assistant resident physician at the Boston City Hospital. In 1884 he began practice in Leominster, where he filled an honorable position as physician and citizen to the time of his death at Waverley, Mass., October 22, 1900.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 3, 1900.

A. M. D. McCORMICK, surgeon, commissioned surgeon from November 11, 1899.

R. E. LEDBETTER, assistant surgeon, ordered to the "Constellation."

C. BIDDLE, surgeon, detached from the "Texas" when put out of commission and ordered home to wait orders.

C. H. WHITE, medical director, detached from the Naval Museum of Hygiene, Washington, on reporting of relief, and ordered home to wait orders.

G. P. BRADLEY, medical inspector, ordered to duty in charge of the Naval Museum of Hygiene, Washington, November 15th.

H. E. AMES, surgeon, detached from the "Kearsarge" and ordered to the "Massachusetts."

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — The regular meeting of the society will be held at the Medical Library, 19 Boylston Place, on Monday, November 12th, at 8 o'clock.

Paper: Dr. Frederick Coggeshall will read a paper entitled "The Relation of Pelvic Disease to Nervous Disorders." Drs. J. J. Putnam, Kilburn, Baker, Knapp, Storer and others have been asked to take part in the discussion.

ARTHUR K. STONE, M.D., Secretary, 657 Boylston Street.

RECENT DEATHS.

WILLIAM ARTHUR ZABRISKIE, M.D., of New York, died suddenly on October 24th. While on his way to visit a patient Dr. Zabriskie was seized with an attack of epilepsy and in falling to the sidewalk fractured his skull. He was a graduate of the College of Physicians and Surgeons, New York, in 1883.

WALLACE A. SIBLEY, M.D., one of the best known medical men in Monroe County, N. Y., died at his home in Rochester, on October 28th, from organic disease of the heart.

BOOKS AND PAMPHLETS RECEIVED.

Report of the Commissioner of Education for the Year 1898-99. Vol. I. Washington, 1900.

A Book of Detachable Diet Lists: For Albuminuria, Anemia and Debility, Constipation, Diabetes, Diarrhea, Dyspepsia, Fevers, Gout or Uric Acid Diathesis, Obesity, Tuberculosis and a Sick Room Dietary. Compiled by Jerome B. Thomas, Jr., A.B., M.D. Second edition, revised. Philadelphia: W. B. Saunders & Co. 1900.

Malaria according to the New Researches. By Prof. Angelo Celli, Director of the Institute of Hygiene, University of Rome. Translated from the second Italian edition by John Joseph Eyre, M.R.C.P., L.R.C.S. (Ire.), D.P.H. (Camb.). Introduction by Dr. Patrick Manson, Medical Adviser to Colonial Office. Illustrated. London, New York and Bombay: Longmans, Green & Co. 1900.

A Dictionary of Medical Science, containing a Full Explanation of the Various Subjects and Terms of Anatomy, Physiology, Medical Chemistry, Pharmacy, etc. By Robley Dunglison, M.D., L.L.D. Twenty-second edition with appendix. Revised and enlarged, with Pronunciation, Accentuation and Derivation of the Terms. By Richard J. Dunglison, A.M., M.D. Philadelphia and New York: Lea Brothers & Co. 1900.

The American Illustrated Medical Dictionary: A New and Complete Dictionary of the Terms Used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry and the Kindred Branches, with their Pronunciation, Derivation and Definition, including much Collateral Information of an Encyclopedic Character; together with New and Elaborate Tables of Arteries, Muscles, Nerves, Veins, etc. By W. A. Newman Dorland, A.M., M.D. Illustrated. Philadelphia and London: W. B. Saunders & Co. 1900.

Address.

PUBLIC HEALTH LABORATORIES.¹

BY THEODORE SMITH, M.D., BOSTON.

George Fabyan Professor of Comparative Pathology, Harvard Medical School; in charge of the Pathological Laboratory of the Massachusetts State Board of Health.

The marvellous development of sanitary science during the last quarter of the nineteenth century has been due chiefly to the determination of medical science to utilize physics, chemistry and biology, those fundamental departments of experimental science, in its efforts to control disease. The expression of these efforts are the various laboratories in which the problems of preventive medicine are being analyzed with the aid of these fundamental sciences. The rise of microbiology contributed largely to the creation of these laboratories, and in microbiology the special departments of preventive inoculation and serotherapy, with which the names of Pasteur and Behring will ever remain associated, have been the chief factors in the still further expansion of laboratory facilities.

In the professional as well as the lay mind the word laboratory is usually associated with study and investigation, with the discovery of new facts or with the rectification or overthrow of old ones. Not infrequently, however, we find that the work of the laboratory is looked upon as a kind of modernized alchemy, and the results expected from it are in accord with this conception.

When we turn to the actual operations of the laboratory devoted to sanitary science, and endeavor to summarize the work undertaken there, we find different classes and grades, some approaching our ideal of laboratory occupation, others far removed from it and approaching closely executive work. Many laboratories have sprung into existence only because of a practical necessity. They are the diagnostic and analytic laboratories, serving directly the practical health officer in the control of the various agencies that tend toward disease. On the other hand, laboratories devoted solely to investigation in special departments of sanitary science are still rare. But everywhere an effort is being made to turn at least a fraction of the available energy toward the solution of problems continually arising in the routine work of bacteriological and chemical analysis, in order that from time to time we may give the results of this very routine work a truer or at least a more rational interpretation.

In making this effort several difficulties are encountered. In the routine work of the laboratory, which deals with so much and such varied material, and which constitutes probably four-fifths of the work exacted of laboratories devoted to public health, there is opportunity given for fine inductive reasoning whose results put to the test of experiment may yield very valuable results. Unfortunately, however, either the time for the careful study of the accumulating statistics and facts is wanting, or else the physicians served by the laboratory neglect to furnish the desired data and render the bulk of the material on hand almost worthless.

Another difficulty arises from the close relation between the laboratory worker in sanitary science and

the public. Leaving aside as well known the frequently discouraging encroachments of politics upon the functions and functionaries of the laboratory, there is danger that the genuine scientist may be misunderstood, undervalued and eventually driven out entirely. The history of science convincingly shows that the most far-reaching discoveries are least appreciated at the time of their promulgation, and the same holds true in a lesser degree for the results of investigations of lesser value. As regards some of the disadvantages of science serving the people through their representatives I have already spoken recently, and I need not dilate upon them at this time. They are inherent in the nature of things and cannot be altered. Another problem which confronts us is the disposition of funds at our disposal, in such a manner as will conduce to the best interests of the subject to which we are devoting ourselves. We must choose those lines of work, if there be any choice at all, which will yield useful results of a high order, and in this choice we may often be in conflict with our employers, because science tends to look more for the remote, practice for the immediate results.

These are undoubtedly some of the considerations which have been of influence in bringing us together as a section of this association. We realize, furthermore, that even the individual laboratory guided and conducted along the most approved lines cannot but gain by association with others, and that the inductions reached by one laboratory may be put to the test by this association of many laboratories. We, individually, stand especially in need of encouragement, sympathy and appreciation, without which the solitary efforts of the investigator are likely to wither or remain undeveloped. Here among men of kindred thought, that lack of appreciation of individual effort, for which we cannot blame the world at large, should be amply compensated.

I have already classified our work as consisting of investigation, and routine work created by investigation. Let us briefly examine these two kinds of work, so intimately associated with one another. Of the two I unhesitatingly put the investigation first, as the soil on which the practical work may properly develop and bear fruit. We, as a body, need above all things to emphasize the importance of research and the desirability of having proper provisions made for it. The diagnostic, analytic and executive work we know will continue to flourish, and it may eventually conceal and obscure entirely the soil on which it lives, and which needs continual enriching and tilling in order that there may be fruit as well as foliage.

Let me define a little more minutely what the relation of research to practical sanitary work may be conceived to be. When we are conducting experiments in the laboratory we are studying a certain number of known or controllable interacting factors in order to learn the result of their action. The highest kind of experimental work deals with the largest number of such factors, either by eliminating them from or bringing them into the problem. The true test of the accuracy of such experimental work is the successful repetition of it by competent men, leading to the same unequivocal results. It follows that whenever uncontrollable factors or such as escape our analysis are present, our results will vary and lack final scientific value. When in the study of public health problems we pass beyond the confines of the laboratory,

¹ Introductory address of the chairman at the opening of the second annual meeting of the Section in Bacteriology and Chemistry of the American Public Health Association, Indianapolis, October 22, 1900.

we enter a quite different field, because we are likely to encounter so many buried links in the chain of causation, and so many known elements which cannot be controlled or eliminated. Hence the larger study of nature's problems must appeal to the laboratory for aid in disentangling the interwoven lines of force which enter into the making of disease. To the undefined factors we, as laboratory workers, must turn for our subjects of study ever and again. We must bring them together with those we have studied, and thus, by gradually enlarging our sphere of experiment, we slowly but steadily approach the real conditions, those that present themselves in the everyday life of the community and the State. The nearer we approach this limit, the more applicable and hence the more useful our work becomes, either by establishing new, positive facts, or by destroying current but false beliefs.

This steadily progressive march of the analysis of phenomena of health and disease from simple to complex is, however, not always maintained. Much laboratory work is like the movement of a crab, backwards, a continual disavowal of conclusions deemed well established for a time. The difficulty lies less in the perversity of the experimenter than in the perversity of his environment. He is forced by circumstances to take up problems, not in the order in which they seem to him most accessible to solution, but in the order in which they happen to occur in the world he is serving. He is set down in a clearing in the forest with his instruments of precision, and directed to survey it in its relation to landmarks to him inaccessible and invisible.

Again, the work thrust upon us through the accidents of the world at large must be attended to promptly if at all, because the very material under observation is changing and will not suffer delay, or else because the pressure from without is too great. Hence our work is likely to be fragmentary and unfinished, and to have that flavor of the practical which does not commend itself to more academically placed brethren. However, work done with some practical end in view may be fully as scientific in its spirit, method and outcome, and as valuable to the progress of science as any of the traditional work of college or university. Whoever unearths a few consecutive links of the phenomena of cause and effect is entitled to the world's gratitude, be these links near one end of the chain or the other. In all things nature has applied the same principles and displayed the same degree of ingenuity, and where can it be said has she exercised more of it than in the ever-shifting battleground of the infectious diseases where the cunning of two different orders of living beings is exerted not only to protect themselves but to find a breach in the other's armor?

The peculiar situation of the public health laboratory as I have outlined it should make the investigator very cautious concerning the conclusions he may publish and maintain. Conservatism is of the utmost importance since all new facts applied to everyday life tend to disarrange to a greater or less degree existing relations. It is always safe to underestimate our inferences, and safer still to draw conclusions only when all doubts are silent. The publication of experiments need not be deferred, even if they do not point to a definite outcome, since they may help and stimulate others to carry the proof farther. In our relation

to those whose duty it is to formulate and enforce rules for the protection of the public health and who depend upon us for sound, unbiased advice at critical times, we should always clearly state the limitations governing our work. If the conditions of the problem presented conform to those in our experiment then we can predict a certain result, but if there are additional variable factors which we have not included in our study then our information cannot be final. Just here the opportunity for research on the part of the practical sanitarian enters. By unearthing and defining the new and variable elements in the larger practical problem and transferring them to the laboratory for consideration his work may become of inestimable value to sanitary science.

The need for continued investigation both within and without the laboratory is thus only too obvious, and before leaving this theme I yield to the temptation of illustrating it from the general problem of the etiology of infectious diseases, to which I have given more or less attention. This problem demands the services of bacteriology, or more broadly, of microbiology and of pathology. In the domain of bacteriology we are just emerging from the rather onesided and superficial study of bacteria and their gross physiological characters, and beginning to realize that the character of an infectious disease is due to the host as well as to the parasite, and that the interaction of the two organizations causes modifications in both. We are thus confronted by conditions whose complexity was not anticipated ten or fifteen years ago. We have learned, among other things, to recognize quite a host of micro-organisms which have the power to produce pathological conditions but which are evidently secondary to other agencies. It has been the custom to denominate as secondary those bacteria which follow in the wake of other pathogenic forms, and which lead to various complications of the primary disease, and which are frequently the immediate cause of death. But there is evidence that perhaps all pathogenic microbes are in a sense secondary, in so far as their invasion is permitted only by morbid conditions largely undefinable at present; some of these may resolve themselves into the effects of other micro-organisms not at present known or under suspicion, others may be due to changes in our food and environment influencing the physiological mechanisms. Our investigations must therefore go back of the specific micro-organisms to more primary agencies or conditions, for prevention begins as far back as the scientific analysis of pathogenic influences can reach. In the meantime applied hygiene must try to suppress with every possible means those causes actually in sight, be they primary or secondary, in order to interrupt the chain of agencies leading to disease. The practical benefit to be derived from the most profound study of etiology resides in the fact that the farther we go back of the immediate causes of disease the more easily and economically can they be controlled, and the more weapons we are able to furnish the sanitarian from which to choose in his combat with disease. Among the problems which are today clamoring for attention I may mention all those that group themselves about the conception of immunity, the toxins, antitoxins and bactericidal forces, the variations of pathogenic bacteria, and the interrelation of human and animal infections. There is ample opportunity for both bacteriologist and pathologist to exercise in this restricted

field the highest degree of scientific acumen and sagacity in the application of physical, chemical and biological methods to the study of disease.

Passing to the routine tasks of the public health laboratory, we have before us the problem of methods and procedures to which this section has for the time being committed itself. We wish to learn how we can most thoroughly and successfully do these tasks and at the same time force them to disgorge, as it were, facts new to science; how we can so homogenize our processes that those valuable inductions to which I have referred can be reached by a utilization of material from all laboratories. We also wish to learn how we can congeal our methods and yet have them alive and progressive.

To the investigator, methods are ever changing with the objects of research, because the method to him is simply a path to the result. Whenever the latter has been attained, the path is abandoned and another laid out towards some other goal. The history of science is a witness to the fact that the most commanding geniuses have always created new methods rather than use those of their contemporaries or predecessors. The reason is obvious. Every discovery of a new fact demands a new method, or at least a profound modification of existing ones. Discoveries are now and then accidental, and may rest on errors in the application of existing methods. From this point of view methods and procedures are of very high significance in science. They are in effect the embodiment of the various factors which determine the result, and they approach the nearer to the actual processes of nature the greater the number of controllable elements which enter into the problem. With the attainment of certain results and their practical application for the differentiation and classification of facts, there comes the necessity for the simplifying and perfecting of methods for the use of that large and growing army of workers engaged upon the diagnostic and analytic tasks of our laboratories, upon whose industry and faithfulness we must depend for the routine performance of work demanded by the public health. They must follow the beaten path, and we must make it as short and direct as possible.

The essential value of such methods from which uncertain factors have been largely eliminated resides in the accumulation of data of more or less uniform character. These may become of great value in leading to new theories and inferences when the numerous data are subjected to careful comparative study. To demonstrate the truth of the new theories evolved, new methods may be needed. We may illustrate our statement by drawing upon some simple and familiar facts obtainable by a study of the fermentative capacities of bacteria. The examination of a large series of closely related colon forms has shown that those which fail to act upon lactose and saccharose belong to the distinctly pathogenic or invasive forms. The inference which may be drawn is that in the acquisition of parasitic habits the fermentative action upon these sugars is not brought into play and the function gradually lost. To prove this inference it would be necessary to modify a colon form by passages through animals. For only by such an experiment can we effectually banish certain other inferences which rise up to cloud our convictions, such as the view that bacillus coli is not the direct ancestor of

the pathogenic group, but that both are derivatives of an ancestral form and that the existing colon forms are no longer modifiable into the invasive types. Here a new class of experiments should enter with new methods to test the inferences obtained by the horizontal application of a certain method and a summation of the results. Unless we are content to have our science build itself up on hypotheses or theories until it becomes topheavy, we must continually devise new experiments to test them. The relative merit of the statistical and the experimental method in disclosing truth of a higher order need not detain us here. They are both essential and they supplement one another.

In the formulation of methods for general use we must continually bear in mind certain tendencies which are likely to take possession of us. In the first place, we must be charitable towards work done with other methods, although, it must be confessed, it is often difficult to steer between the rejection of such results, occasionally embodying the germ of new and highly original facts, and the acceptance of work done slovenly and in defiance of accredited methods. The so-called schools in pure and applied science are largely built upon methods of work. Some fifteen years ago we were familiar with the Pasteur and the Koch school of bacteriology, now things of the past, because the respective technique has been made universal. All that can be said of such schools is that their value is temporary and their continued recognition harmful.

Crystallized methods are thus both a safeguard and a danger. They guide us and make our results homogeneous. They may also petrify our modes of thought if we too slavishly adhere to them. We must, in short, bear in mind that all codification of procedures and methods is too much like the fencing in of our ignorance. While the thought that it has been well secured and that it cannot escape may be of great comfort and a means of relaxation to us, it may not advance science or increase its utility. Lastly, codified methods may stifle opportunity for discovery by being too top-heavy and hence by occupying too much time. The truly sagacious enquirer, however, soon knows where to throw out ballast so as not to encumber his journey too much.

In the choice of methods we should therefore clearly define to ourselves our purpose. If we are seeking the solution of new problems we must create new ways and means. If we are making collective investigations to secure and broaden the basis of accepted facts, our technique must be both uniform and detailed. But the duty of this laboratory section consists not only in codifying methods, but also in continually examining and testing new devices and processes. Methods will forever remain in a state of flux and all that we can do is to see that the flow is uniform and rapid and that the assimilation or rejection of what is encountered on the way is fairly complete.

It is reported in the *Journal of the American Medical Association* that Francis Schlatter, the "divine healer," while on a recent visit to McKeesport, Pa., applied to the mayor for permission to hold outdoor meetings in the public square to preach divine cure, but was refused.

FEEDING IN TYPHOID FEVER, WITH A REPORT OF CASES.

BY GEORGE W. MOORHOUSE, M.D.,
Resident Physician to the Lakeside Hospital, Cleveland, O.

At a meeting of the Cleveland Medical Society, held December 8, 1899, the writer presented a paper¹ with the above heading detailing the experience of the Lakeside Hospital for a period of eight months in the use of a more generous diet in the treatment of typhoid fever than is the usual practice. During that time there were 40 available cases out of a total in the hospital of 57 individuals with typhoid fever. Five of the cases died, a mortality of 8.8% ; death was due in 2 cases to toxemia, and in 3 to perforation, and all of these had been kept, from the time of entrance to death, on milk diet. There were no deaths in the series of 35 who were fed early. There was a total of 11 relapses in 57 individuals, or 19%.

In seventeen months of the writer's service in this hospital, March 1, 1899, to July 31, 1900, 150 individuals with typhoid fever have been discharged from the hospital, including the 57 individuals of the first report, and it is the purpose of this paper to consider the effect of early feeding in typhoid fever on the basis of this experience.

In addition to precautions designed to prevent the spread of the disease to other patients and to the attendants, the general treatment and management of cases of typhoid may be very briefly told. Their mouths and throats are kept clean by the use of sprays and mouth washes, and they are guarded so far as is possible from unnecessary exertion. The temperature is taken every three or four hours, and when above 102.5° F. a tub bath is given. The initial temperature of the bath is 85° F., and this is reduced in proportion to the temperature of the patient, but not usually below 68° F. An initial dose of calomel is given to about one-half the cases ; later, enemata are relied upon to relieve constipation until well along in convalescence, except that in the service of one of the visiting physicians calomel in doses of $\frac{1}{5}$ grain three times daily, combined, if this does not prove effectual, with podophyllin, usually in the dose of $\frac{1}{16}$ grain, is not infrequently employed. In another service the use of some of the commoner mild laxatives in case of a sudden exacerbation of temperature in convalescence, or even during the latter part of defervescence in case of constipation, has been frequent. For tympanites turpentine stupes and enemata with turpentine were used with satisfaction ; in the same condition an emulsion of turpentine was given to a few patients, but with so little apparent good effect that its use was not extensive. Other than the above there has been very little medication unless stimulation seemed necessary. Alcohol, usually in the form of whiskey, was the stimulant most frequently used, and it is probable that a large proportion of all patients who were sick enough to demand any considerable number of baths received some alcohol in the course of the disease. Strychnia takes second place in the list of stimulants. Next to strychnia strong coffee was a not infrequent order, 4 ounces every four hours, and in a certain class of cases, particularly those with well-marked

apathy, it gave very striking and gratifying results. Digitalis was used in one or two desperate cases. In patients with profound toxemia, infusions of salt solution were used a few times, and this is a procedure that deserves, in the opinion of the writer, a more thorough trial than it has yet been given. As the general condition of the patient improved after entrance, frequent inquiries were made as to the return of the appetite, and when that was noted, soft typhoid diet was ordered, usually at once without direct reference to the temperature. With a return of the appetite, however, the temperature was almost invariably falling. At times a patient might be hungry very shortly after complaining of severe abdominal pain, or after having had a hemorrhage from the bowel, or while the temperature was still very high, and in such cases the feeding would very likely be withheld for a time. In the original paper, I say : " Furthermore the appetite and not the temperature has been made the guide to the continuance and to the increase of the diet once begun, and a number of patients went through an entire relapse without any decrease in the diet, the appetite holding good during the entire time." This statement is true to a great extent in the entire series, although the writer has, a little more frequently than before, ordered the patient back on to a milk or other liquid diet on the occurrence of a rise of temperature, to see what effect it might have on the subsequent course of the fever. This procedure, however, has in no case seemed to cut it short in any way. On the other hand, in cases with persistent anorexia, associated with a falling temperature, the visiting physicians have manifested a disposition to tempt the appetite of the patient by ordering the larger variety of the soft typhoid diet.

As to sitting up, the general rule was that the patient must have been for 10 days with a normal temperature, and, in view of the tendency of a typhoid's temperature to become subnormal after the febrile period has passed and to remain so for a considerable length of time, a normal temperature with reference to the first propping up in bed was interpreted as one which never reached a higher level than 98.6° F. In case the temperature varied within practically normal limits, but frequently reached 99° or 99.5° F., the first bedrest was postponed for a time, usually to the end of the second week of such temperature.

In December, after the first eight months' experience, a series of typhoid diets was adopted at the Lakeside Hospital, for the purpose of simplifying the orders for patients with typhoid fever, and as an aid in making their care uniform throughout the hospital. The diets adopted are as follows :

Milk diet. — The standard for a milk diet shall be 8 ounces every two hours, subject to special directions as to night feedings. Watch stools for undigested milk. Report and record failure to take full amount.

Liquid typhoid diet. — In twenty-four hours : Milk, 8 ounces four times ; milk, 6 ounces with tea or coffee, $\frac{1}{2}$ to 1 ounce twice ; albumin water, 8 ounces twice ; beef tea, 8 ounces once ; malted milk, 8 ounces once ; chicken broth and barley water, each 3 ounces once ; beef juice and barley water, each 3 ounces once. Those liquids which are to be given only once in twenty-four hours may be replaced by equivalent amounts of any of the following : Broths, milk-whey, slip, junket, strained soups or gruels.

¹ Cleveland Journal of Medicine, vol. v., No. 2, February, 1900.

Soft typhoid diet. — Add to the liquid or milk diet: (1) Ice cream, well-cooked rice (boiled), broths may be thickened with it; (2) soft boiled or poached egg on soft toast, blanc mange and milk puddings, calf's foot and other gelatine jellies; (3) gruels, crackers or bread softened in milk or broths, macaroni, finely minced and scraped meats. The increase in diet to be very gradual, one addition the first day, two the second, etc., scraped beef on the fourth or fifth day.

Typhoid convalescent diet. — Add to anything already given the following in about the order mentioned. Soft parts of oysters, a tender sweetbread, chop, squab,² game (small),² chicken, fish, cutlet, steak, rare roast beef. Mealy baked potato may be given with any of the meats.

Full typhoid diet. — Six A. M., milk; 8 A. M., breakfast, a cereal with cream and a small amount of sugar if desired, milk with tea or coffee, egg on toast, bread or toast with butter if desired; 10 A. M., bread and butter, with gruel or milk, or broth with egg; 11.30 A. M., dinner, soup which may be thickened, some meat, as chop, or cutlet, or fish, or steak, or roast beef, or the soft parts of oysters, or sweetbreads,² or squab,² or small game,² mealy baked potato, or rice, or macaroni, or spaghetti, with a simple dessert, as ice cream, or blanc mange, or milk pudding; 2 to 3 P. M., like 10 A. M.; 4 to 4.30 P. M., supper, creamed chicken, or a bit of cold meat, as chicken or roast beef, bread, and milk flavored with tea or coffee; 6 P. M., cocoa or gruel or broth. At night, milk two to four times.

These directions are furnished with the diet lists. Any change from a less to a more generous diet must be gradual. The between-meal feedings of liquids are important as limiting the amount of solid food taken at one time, their importance increasing in proportion to the earliness of the order for the generous diet.

The writer does not claim the merit of originality for the above diets and, except for the greater certainty that he will be understood in the article, would not report them. The liquid typhoid diet and the soft typhoid diet are modelled on the lines of diets he was acquainted with in his medical service at the Massachusetts General Hospital in Boston. The full typhoid diet is an adaptation to conditions prevailing with us of the diet used by Dr. Bushuyev³ and while it may seem that the meals recur with great frequency, one or two feedings used by that observer have been omitted from this schedule.

The standard liquid diet has been milk, for Dr. Fitz's⁴ study of the subject seems to show that the mortality on a milk diet is somewhat less than that on other liquid diet. On the relatively rare occasions when milk was very repugnant to the patient the liquid typhoid diet was ordered, and still more rarely milk was wholly omitted from the bill of fare. In such cases the change to a more liberal diet was made as promptly as possible. Full typhoid diet was added to this list for the sake of completeness at the time of the adoption of the other typhoid diets, and in view of its possible use in case any of the physicians to the hospital should desire to begin the use of solids at a very early stage of the disease: furthermore it was

designed as a possible variant to the convalescent typhoid diet. Its use has not been extensive.

During seventeen months from March 1, 1899, to July 31, 1900, 150 cases of typhoid fever have been discharged from the Lakeside Hospital. Of this number 33 are not reported, while 117 are reported. With regard to the cases not reported, 3 were given soft diet so late that they may be said to have been on a liquid diet for the usual length of time. In 5 cases the diagnosis is not absolutely assured; in all of these the course of the fever while the patients were under observation in the hospital was mild and short, and with one exception the Widal reaction was never obtained. Had the reaction been obtained in the 4 cases which did not show it they would be considered certain though mild cases of typhoid fever. The case in which it was obtained had been a soldier during the Spanish-American War, and while in camp in the United States had been sick with "malaria," and it was impossible to decide with any certainty from the history given for the previous illness that it had not been typhoid. While in the hospital he had a slight fever and dysenteric evacuations of the bowels. The subsequent history of another doubtful case is known and the length of time which elapsed before the patient fully recovered her normal strength makes the diagnosis of typhoid very probable. Either from a continuance of the liquid diet to the usual time in convalescence, or on account of such a departure from the routine procedure as regards diet here described, 11 private cases are not included in the report of feeding. One case became dissatisfied and was discharged against advice a few days after entrance on a milk diet. One case while still on a milk diet perforated, was operated upon and recovered. Twelve cases died before any change from milk, 8 of toxemia and 4 of perforation; ⁵ 1 case, to be mentioned in detail below, was changed from milk to soft diet before the temperature was normal, had a relapse, was again put on milk diet, nine days later perforation, operation, death.

One hundred and seventeen cases were given soft typhoid diet before or very shortly after the temperature became normal.

The report in the first paper considered only one change of diet to each patient fed early. When, however, we consider the second orders of soft diet for those patients who, on account of a return of the fever, were put back on milk diet, and each increase in diet ordered early in convalescence, we have a much larger number of diet changes upon which to base our conclusions. The following statements show the sequences to diet orders, except those from a more to a less liberal diet, and are 174 in number or, excluding those twice counted, 159.

CLASS Ia. Feeding on normal⁶ temperature, followed by slight irregularities of temperature, 5 cases:

Soft	diet on second day of normal temperature, 2 cases.
"	" fourth " " " 1 case.
Convalescent	" first " " " 1 case. ⁷
"	" second " " " 1 case. ⁸

⁵ One gave no Widal reaction on repeated trials. An autopsy, however, demonstrated the correctness of the clinical diagnosis.

⁶ With reference to feeding, any day's temperature is considered normal when its highest rise is 99° F. or below, provided that the temperature of previous days give reasonable assurance that it will not go above that point.

⁷ In this case the greatest rise, to 100° F., occurred after bedrest.

⁸ Temperature (sub)normal eleven days before a relapse; relapse-like rise of seven days' duration occurred ten days after feeding was begun; patient did not seem sick; spleen palpable for the first time in the illness.

² Used only for private ward patients.

CLASS Ib. Feeding on normal temperature; no subsequent rise, 39 cases :

Soft diet on first day of normal temperature	5 cases.
" " second " " " "	5 "
" " third " " " "	1 case.
" " fourth " " " "	4 cases.
" " fifth " " " "	3 "
" " seventh " " " "	1 case.
" " eighth " " " "	1 "
" " ninth " " " "	1 "
Convalescent diet on second day of normal temperature	2 cases.
" " third " " " "	4 "
" " fourth " " " "	3 "
" " fifth " " " "	2 "
" " sixth " " " "	2 "
" " seventh " " " "	1 case.
" " eighth " " " "	2 cases.
" " tenth " " " "	1 case.
House " fifth " " "	1 "

CLASS IIa. Feeding before normal temperature, followed by relapse-like rise of temperature, 21 cases :

	Cases.	Duration.
Soft diet, relapse (?) begins at once	4	8, 11, 13 and 14 days.
" " " in 2 days	1	15 ⁹
" " " " 4 " "	1	27
" " " " 7 " "	2	10 and 10
" " " " 8 " "	1	5
" " " " 9 " "	1	11(b) ¹⁰
" " " " 10 " "	1	10 ¹¹
" " " " 11 " "	2	4 (b), 21 (b)
" " " " 12 " "	1	10 (b) ¹²
" " " " 15 " "	1	3 (b)
" " " " 17 " "	1	13 (b)
" " " " 21 " "	1	8 (b)
Convalescent diet, relapse (?) begins at once	1	16 days.
" " " in 11 days	1	7 (b)
" " " " 20 " "	1	7 (b)
Full " " " at once	1	17

CLASS IIb. Feeding followed by slight or irregular fever not thought to be relapse, 13 cases.

	Cases.
Irregular temperature subsequent to feeding is continuous with similar temperature previously	12
Irregularity occurs after ten days of normal temperature and is associated with anemia and bedrest	1

CLASS IIc. Defervescence apparently unaffected by food, 84 cases :

	Cases.
Soft diet, lysis undisturbed	60
" " " until increase of diet 7 days after	1
" " " " " 27 " "	1
" " " " " 42 " "	1 (b)
" " " 8 days, relapse (?) of 5 days' duration	1
" " " 9 " " 11 " "	1
" " " 16 " " 10 " "	1
" " " 11 " " 4 " "	1
" " " 11 " " 22 " "	1 (b)
" " " 12 " " 10 " "	1
" " " 15 " " 3 " "	1
" " " 17 " " 13 " "	1
" " " 21 " " 8 " "	1
" " " 14 " " then irregular temperature	1 ¹³
" " " 22 " " " "	1 ¹⁴
Convalescent diet, lysis undisturbed	6
" " " 11 days, followed by relapse (?) of 7 days' duration	1 (b)
Convalescent diet, lysis undisturbed, 20 days, followed by relapse (?) of 7 days' duration	1 ¹⁵
House diet, lysis undisturbed	2

CLASS IIId. Defervescence apparently hastened by feeding, 11 cases.

I have frequently been asked regarding the degree of fever present when these patients were first fed. This interesting question is answered as to the patients who were fed before the temperature became normal

in the following chart, which shows the average¹⁶ highest temperature on the day of feeding and for seven days preceding and following that event. It also indicates the extreme range of highest temperature for the same day in the vertical line. None but the highest temperatures for the day are considered. The highest point in the line shows the highest temperature for the day of that patient whose temperature registered the highest, the lowest point of the line shows the highest temperature of the day for the patient whose temperature registered the lowest.

The total number of deaths in the series was 13. All were on a milk diet at the time of death, but 1 had been put on soft diet on the twenty-sixth day of the disease, with a very moderate appetite and a temperature which ranged from 99° to 101.5° F. His next day's temperature did not rise above 100.5° F. and in the morning touched normal. From that point on the temperature gradually ascended. On the fifth

day of soft diet the notes say that the appetite was good, an increase in the appetite coincident with the increasing elevation of temperature. On the evening of the sixth day of the feeding the temperature was 102.8° F.; the next morning, the seventh day of the feeding and the thirty-third of the disease, his temperature was 100° F.; the appetite remained good to fair, but he was ordered back onto milk diet; for the succeeding nine days his temperature remained quite steadily high. Nine days after the order for soft typhoid diet had been changed to one for milk he perforated, was operated upon, but did not recover. In the remaining 11 cases death occurred in from seven to fifteen days from the time of entrance while still on a milk diet. Thirteen deaths in 150 cases gives a mortality of 8.67%. What the mortality of this series would have been had they been limited to a milk diet for from seven to ten days after the temperature had reached normal, as they should have been to conform to the teaching of the usually ae-

¹⁶ Average is used throughout this paper as the more familiar and convenient term. In no instance, however, is it the average which is used, but the mean which varies a little from the average, and is usually considered the more reliable and significant unit for the expression of the range of any series of values. The mean in this case is that temperature which has an equal number of temperatures lower and an equal number higher than itself.

⁹ Relapse continued to perforation.
¹⁰ Certain cases are twice counted as to their behavior subsequent to a single diet order; all such are marked (b) in the place where they were thought *less* properly to belong.
¹¹ Elevation of temperature continued to discharge of patient "against advice," before the completion of defervescence.
¹² Elevation of temperature associated with phlebitis.
¹³ Patient unruly, got out of bed.
¹⁴ Irregular temperature, associated with anemia and bedrest.
¹⁵ Discharged "against advice," before defervescence was completed.

cepted authorities, it is impossible to conjecture, nor have we here any series kept uniformly on milk diet with which to compare these results.

It is possible, however, to find a moderate amount of evidence in the literature of typhoid which bears on this question. In 1897 Dr. Shattuck¹⁷ reported that, from 1886 to 1893, he had had under his care at the Massachusetts General Hospital, 233 cases of typhoid fever treated with a milk diet, with a mortality of 10%, and that from 1893 to 1897, 147 had been treated with a more liberal diet, with a mortality of 8.1%. Dr. R. H. Fitz¹⁸ in a very interesting article on typhoid fever at the same hospital for the past seventy-eight years, covering the whole period during which typhoid fever has been differentiated from typhus in this country, gives later figures on the same subject. According to this article, Dr. Shattuck's mortality from 1893 to 1898 was 11.3%, as compared with that of 15.1% among patients using largely a milk diet.

The most interesting experience in the liberal feeding of typhoid patients which has come to my notice is that of a Russian army surgeon. An abstract of the original report is given by Thayer in his article on typhoid fever in the first volume of "Progressive Medicine." The entire number of patients with typhoid fever entering the hospital with which Dr. Bushuyev was connected, 154 in all, were divided, as equally as possible, between him and a colleague. The patients of the latter, 74 in number, received the treatment common in that hospital, and this included as to diet two litres of milk and one or two soft boiled eggs in the day. Dr. Bushuyev's patients, 80 in number, at entrance were put upon a liberal diet, very similar to the one described earlier under the name of "full typhoid diet." In a small number of cases he was unable to get the patient to take solid food, and when this was the case he was put on a milk diet, and Dr. Bushuyev called it forced feeding. The forced feeding was discontinued as soon as possible. The statistical results are interesting, but Dr. Bushuyev does not profess to be able to draw any very positive conclusions from so small a number of cases. The general mortality was 10% on the liberal, and 12.1% on the milk diet. The average duration of the fever after entrance was 18.9 days for those liberally fed, and 22.3 days for those on milk.¹⁹ The average stay in the hospital was forty-two days for those liberally fed, and 49.2 for the others; this represents a gain to the hospital of one year, two hundred and eleven days for a single patient. Of the patients liberally fed only 8.3% were discharged incapable of duty, but of those who were kept on a milk diet 15.4% were so discharged. Of the patients who died, the average day of death was the twenty-eighth of the disease for the patients liberally fed and the twenty-sixth for those on milk.

The objection of those who fear to give solid food early to patients with typhoid fever on account of its supposed liability to cause either hemorrhage or perforation seems to be that the food by mechanical irritation may in some way cause either one or the other of these serious accidents. In no case in the 117 given soft

diet, most of them when the temperature had still a considerable daily range, as may be seen by reference to the chart, did we have intestinal hemorrhage as a sequel. The only case in which intestinal perforation was a sequel to feeding has been described at length above and it is hard to see how anything in the list of "soft typhoid diet" could mechanically have caused perforation of the intestine nine days after the return to milk diet.

The status of the question of the relation of feeding to relapse is quite different, and is one not altogether easy to settle. In this series the writer will report 30 relapse-like rises of temperature, 9 before and 21 after feeding, a total of 20% of relapses to 150 patients, or 18% of relapse after feeding in the 117 fed early. Either 18 or 20% of relapse is a somewhat higher proportion than the highest usually reported, and is about twice as high as the percentages most commonly reported. The writer feels confident that he has included among the cases of relapse a considerable number that would not have been so classified by others. There are several reasons for this belief. Osler²⁰ says that "a relapse is a repetition, sometimes only a summary of the original attack, and that two of the three important symptoms — step-like temperature at onset, roseola and enlarged spleen — should be present to determine the diagnosis of a relapse." The records on these cases are not in all respects satisfactory, in that negative examinations have not always been recorded; however, in 6 of the cases in which it is stated that a relapse occurred after feeding there is some indication, positive or nearly so, that in the relapse the spleen was increased in size as compared with the days just previous to the relapse; in about the same number we are able to say that there is no discoverable increase in size of the spleen or fresh eruption of the rose rash. About the remainder the writer is unable to state with positiveness in view of the silence of the histories on the points in question, but in many, possibly in a majority, of these cases, negative examinations were made but not recorded. In the matter of the temperature we are not in doubt; all had the step-like elevation of temperature. In the table, when speaking of the duration of a relapse, the time is counted as including the first day on which the temperature reached 99° F. in its rise, when that took place from a normal level, to the last day on which it reached the same point; on this most generous basis of counting the duration of a relapse we have them of only five, four and three days' duration. Another reason why it seems probable that rises of temperature which have not usually been called relapse are here included is that in all but one or two cases they have seemed very mild. There has been one death in relapse and this, in the 30 instances which have been called relapse, is a mortality of 3.3%. Hare²¹ reports from the literature a mortality of 9.1% in 252 cases of relapse.

There are some other interesting questions which may be considered with reference to the possible relation between feeding and relapse which will be very little affected by the possible incorrectness in the diagnosis of the condition, provided only that the same considerations have determined in each instance whether a given rise of temperature shall or shall not be called a relapse, and this is the case. It is probably

true that the usual arguments against early feeding in typhoid fever, so far as they refer to the occurrence of a relapse, would lead one to believe that if feeding in the manner detailed is a cause of relapse and is therefore "improper feeding" such relapse is to be expected immediately upon the issuance of the order for the more generous diet. The chart, which shows the average highest temperatures in the patients who were fed before normal temperature on the day of the first feeding, and for one week before and one week after that time, a total of fifteen days, indicates very clearly that feeding does not interrupt the defervescence.

The important features in these diet lists are two, the articles permitted, and the directions for the increase in diet, ensuring the gradualness of any increase from a less to a more generous diet level, but the new level was fully reached in the average case in about four to five days, whether it was a change from milk to soft or from soft to convalescent diet. There were in the entire number fed 117, 159 orders increasing the diet at a stage of the disease early enough to make it seem advisable to report them, and in only 10 of these cases, 6.3% of all instances of increase of diet, was there any irregularity of temperature which could have been called a relapse within a period of seven days from the time of the increase in the diet; 11 more, or 6.9%, had the step-like rise of temperature in from eight to twenty-one days after the order increasing the diet, a total of 13.1% of relapse at any period after increase of diet, while no such change occurred in 138, the remaining instances.

The average stay in the hospital on a milk diet has been ten days; the average time elapsing from the first order increasing the diet to an order for the patient to be propped up in bed with a bedrest was eighteen days. These two events divide the first twenty-eight days of the average patient's stay in the hospital into two convenient periods. In the first 9 relapses occurred, and in the second there were 21. Since "the true relapse usually sets in after complete defervescence,"²² and since the defervescence is not completed until after the end of the first period, it would scarcely need the fact of feeding at the beginning of the second period to explain the greater number of relapses taking place in it.
