Now as to the lesson to be learned from these cases it seems to me to be this: Operate as early as possible, but operate even after the time when the whole of the diseased tissue can be removed if earlier operation is possible. In Case I the amputation was performed on the third day, but twenty-four hours later than the writer now believes it should have been done. The disease had already extended to the chest wall and the man died two days after operation, having in the interval *showed a marked remission* in the severity of his septic symptoms prior to death. In Case II the amputation was performed on the fourth day through diseased tissue. The disease made a last vain effort to progress after the operation, the emphysema extending as far as Poupart's ligament, but the operation removed the bulk of the disease and enabled the patient to take care of the remainder. Recovery followed. In Case III amputation just below the shoulder-joint was performed on the third day, at a time when the infection had extended over the shoulder and chest to the sternum. Both flaps were very emphysematous. The boy recovered.

In the face of such evidence it is hard to see how any surgeon can refrain from operating even if he fails to get the case at a time when his operation can remove all the diseased tissue.

REPORT OF CASES IN WHICH THE BACILLUS AÉROGENES CAPSULATUS WAS FOUND.

BY JOSEPH H. PRATT, M.D., AND FRANK T. FULTON, M.D.,
From the Pathological Laboratory of the Boston City Hospital.

IN November, 1891, Dr. Welch reported the discovery of a gas-producing bacillus in the blood and tissues of a man who died after the rupture of an aneurism of the aorta. In 1892, Welch and Nuttall¹ published a careful study of this organism, which they named the bacillus *aërogenes capsulatus*. Their description was so complete that little has been added by subsequent investigators. Dunham,² in 1897, showed that the bacillus *aërogenes capsulatus* produced spores on blood serum. But even this is not a constant feature, and spore production has not been observed in any of our cases. In 1893, E. Fraenkel³ demonstrated that the organism was the cause of gaseous phlegmons. In 1896, Welch and Flexner,⁴ in an elaborate paper, showed that the organism had marked pathogenic properties and was the cause of a variety of pathological processes. Doubtless the gas bacillus is a more common and widespread infectious agent than is generally supposed. Bloodgood⁵ has recently collected 22 cases of emphysematous phlegmon due to this organism.

Five* cases of invasion of the body by the bacillus *aërogenes capsulatus* have been observed at the Boston City Hospital during the past eighteen months. Two of these were surgical infections and are reported by Dr. Thorndike in this number of the JOURNAL. In the remaining three cases the micro-organism was found at autopsy, (1) in the blood and tissues of a man whose liver was ruptured by a fall; (2) in the pus of multiple abscesses of the liver; (3) in the fibrinopurulent exudate in a case of general peritonitis.

CASE I. RUPTURE OF LIVER; DEATH IN TWELVE HOURS; BACILLUS AÉROGENES CAPSULATUS IN BLOOD AND EMPHYSEMATOUS TISSUES.

Foster C., age twenty-six years. Admitted to Dr. Burrell's service at the Boston City Hospital, January 5, 1899, in a state of shock. Early that morning he had fallen the distance of two stories, striking on his left side and abdomen. It was found that he had fractured three ribs. Internal injuries were suspected. The bladder was irrigated with boracic acid. The fluid came back clear. He went into a condition of collapse, and, although stimulated, failed to rally, and died the same day at 6 P. M.

Autopsy (99.3) by Dr. Mallory, sixteen hours after death. Body 169 centimetres long; very stoutly built; rigor mortis marked. Lividity of face, neck, upper part of thorax, and dependent portions of body. Subcutaneous tissues of neck, upper part of thorax and lower portions of abdomen emphysematous. No evidence of post-mortem decomposition. Peritoneal cavity contains about 300 cubic centimetres of fluid and clotted blood. Peritoneum covering intestine beaded with small vesicles containing gas. Pleural cavities free from adhesions except over right apex, where several old fibrous adhesions are present. Pericardial cavity contains an excess of fluid; the serosa is stained red due to diffuse inhibition of blood coloring matter. Surface of heart shows everywhere beneath the pericardium minute bubbles of gas. Lungs are congested.

* Since this paper left our hands another case has occurred. At autopsy, in a patient dead of cerebral hemorrhage, on section of the liver some bubbles of gas escaped from the blood-vessels. Cover-slips showed an organism identical morphologically with the gas bacillus. There were no gas blebs in the liver. Some of the blood was inoculated into a rabbit and typical emphysema developed. A capsulated bacillus was recovered from its blood in pure culture which possessed the characteristics of the bacillus *aërogenes capsulatus*.

A few interstitial blebs present. No evidence of any injury to lung. Heart: Weight, 349 grammes. Valves and cavities normal. Many bubbles of gas of various sizes beneath endocardium, especially of left ventricle. No gas in the heart's cavities or in the blood-vessels. Spleen: Weight, 210 grammes. Rather firm; on section lymph nodules fairly distinct; pulp dark in color. Gastro-intestinal tract: Stomach empty. Nothing unusual found in mucous membrane of intestine.

Liver: Weight, 2,560 grammes. In the left lobe is a long curved fissure beginning at the insertion of the round ligament and running parallel with the anterior border of the left lobe for a distance of 16 centimetres, and from three to four centimetres above it. In the right lobe is a similar fracture running parallel to the right border and five centimetres from it. It begins six and a half centimetres from the anterior edge of the liver and runs backward nine centimetres, and then extends at right angles and reaches almost to the right edge of the liver. The fracture of the left lobe extends through to the capsule on the under surface. There is another extensive fracture on the under surface of the left lobe running from before backwards across the middle. It begins near the anterior edge and runs back 14 centimetres, and then extends three centimetres towards the lower border of the liver. There is another extensive fracture beginning near the angle formed by the fracture just described and extending five centimetres, just up to the point of entrance of the portal vein. Still another fracture extends posteriorly from the portal vessels almost to the attachment of the diaphragm. On section, liver substance yellowish; lobules made out with difficulty.

Kidneys: Combined weight, 300 grammes. Apparently perfectly normal. Bladder empty beyond about two cubic centimetres of a turbid secretion evidently due to desquamation of epithelial cells. Testicles normal; adrenals normal. Pancreas large; small tear in the upper surface near the head, filled with small amount of clotted blood. Brain could not be examined. Organs of neck normal beyond some emphysema of the connective tissues. The seventh, eighth and ninth ribs on the left side, in the axillary line, are fractured. Aorta: A few slightly elevated yellowish streaks along posterior wall. Intima of aorta stained red with blood coloring matter. Subpericardial tissues where the gas bubbles are present and the emphysematous tissue over upper portion of thorax show the presence of numerous large bacilli, morphologically identical with the gas bacillus of Welch. They stain by Gram's method.

Anatomical diagnosis.— Multiple fractures of liver with hemorrhage into abdominal cavity; fracture of pancreas, fracture of seventh, eighth and ninth ribs on left side; extensive emphysema due to the bacillus *aërogenes capsulatus*; fatty infiltration of liver; fragmentation of the myocardium.

Bacteriological examination.— Twelve anaërobic cultures were made on various media from different parts of the body. In these there was a scanty growth, if any at all, of the large bacillus present in the cover-slip preparations. In none of the tubes was it found in pure culture. Attempts to grow it by transplanting from the original cultures and by animal inoculation failed. Some gas blebs appeared in a glucose agar tube inoculated with blood from the liver. A cover-slip preparation showed the bacillus in small numbers, and a variety of other organisms. There was no gas formation in glucose bouillon, contained in a Smith fermentation tube, nor in a gelatine stab culture inoculated with blood from the heart.

The organism was found in the original cultures from the following situations: Heart's blood, spleen, liver, lung, trachea, intestinal contents, subcutaneous fat over thorax, pectoralis major muscle. Aërobic cultures upon blood serum were made from the heart's blood, spleen, liver and kidney. In all the streptococcus pyogenes was present, and in addition a growth of a white staphylococcus was obtained from the liver and heart's blood. In the water of condensation of each tube were large bacilli, staining by Gram, and morphologically identical with those pres-

ent in the anaërobic cultures. These bacilli were not present on the surface growth of any of the aërobic tubes. As the blood contained vast numbers of the bacillus, it is not improbable that those found in the cultures were simply transferred from the tissues, and that no multiplication occurred upon the artificial media.

Microscopical examination.—Tissues were fixed in Zenker's fluid, imbedded in paraffine, and then stained with eosin followed by Unna's alkaline methylene blue. Heart: There is a marked fragmentation of many of the muscle cells. Often there is a space of twenty or thirty microns between the broken ends. Sometimes the fracture is near the end of a cell, sometimes near the centre. There are no areas of necrosis. The striæ of the muscle cells are well shown. The capillaries are congested. They contain a very few large bacilli. There are none of the organisms in the tissue outside of the blood-vessels. Blood clot from the heart shows large masses of the bacilli. They are also scattered diffusely throughout the fibrin in great number. Pectoralis major muscle: The muscle fibres appear normal. The veins are distended and contain a great number of the bacilli. Some vessels are apparently completely occluded by them. Here and there in the connective-tissue septa are large masses of the organisms; no other forms of bacteria are seen.

Lung: There is a serous exudate and some hemorrhage into the alveoli. The blood-vessels are congested; they contain great masses of bacilli; the alveoli also contain them, but in less number. No organisms are present in the bronchial tubes. Spleen: Contains much blood and there are large numbers of bacilli in the splenic pulp. Some of the cells of the lymph nodules show degenerative changes. In the lumina of the larger veins are a great many of the organisms.

Liver: Marked fatty infiltration. No bacilli in bile-ducts; fairly numerous in portal vein.

Kidney: The epithelium of many of the convoluted and straight tubules takes the stain poorly or not at all. The blood-vessels are moderately congested and contain the bacilli. The bacterium found in all the organs is a large, thick bacillus with square or slightly rounded ends; occasionally leptothrix-like forms are seen. It stains somewhat irregularly with methylene blue and also with aniline-gentian violet. It is not decolorized by Gram's method. No spores are demonstrable.

This case presents a puzzling but interesting feature. There was marked subcutaneous emphysema associated with the presence of a bacillus morphologically identical with the bacillus aërogenes capsulatus. Cover-slip preparations and tissues from various parts of the body show that this organism was present in great number, yet it was not possible to grow it upon artificial media. That the bacilli were dead when the autopsy was performed is, we think, the true explanation of these facts. Immediately after death the body was placed in the cold-storage room of the mortuary, where the temperature is usually maintained in winter a few degrees above the freezing point, but frequently falls, especially at night, to 26° F. The body was in the cold chamber sixteen hours. Of course some time elapsed before the deeper portions were cooled to the temperature of the refrigerator.

That the vitality of the gas bacillus is quickly destroyed by cold was recognized by Welch and Flexner. They record the following observations: In a case of inflammation of the urinary tract, "cover-slips from renal abscesses, renal pelvis, ureters, bladder, and perineal wound, showed a large number of bacilli with the morphology of the gas bacillus. . . . Contrary to our custom, cultures were not made at the time of the autopsy, but the organs, wrapped in wet cloths, were put on ice. Culture tubes inoculated the following day did not show the gas bacillus." In

another case, "Dr. Blumer cultivated the gas bacillus from the kidney at the autopsy, and the following day failed to obtain it in cultures from the same organ, which had remained during twenty-four hours wrapped in wet cloths on ice."

The portal of invasion in our case is doubtful, but as the organism was found in the intestinal contents, it is not improbable that in the fall the walls of the intestine were so injured that the gas bacilli were able to pass into the circulation. The widespread distribution of the gas bacillus would indicate that it entered the circulation during life, but its multiplication was probably chiefly post mortem, before the body was sufficiently cooled to inhibit its growth.

CASE II. CARCINOMA OF COMMON BILE-DUCT; CHOLETOMY; MULTIPLE ABSCESSSES OF LIVER, FROM WHICH THE BACILLUS AËROGENES CAPSULATUS WAS ISOLATED.

Nathaniel R., age sixty-three years; rope maker. Admitted to the service of Dr. Thorndike, September 10, 1899. Family history negative. Personal history negative. Present illness began two weeks ago, with an attack of sharp pain localized in the epigastrium. This was followed by nausea, vomiting, and a severe chill. Since that time the patient has been constipated and has had no appetite. One week ago his urine became dark-colored, and at about the same time he became jaundiced. The diagnosis of obstruction of the common duct was made. At operation, eight days later, the gall-bladder was found considerably distended with bile and surrounded by adhesions. It contained two pea-sized black concretions. The obstruction was not located. The gall-bladder was sutured to the abdominal wall and drained with iodoform gauze. The patient appeared to improve until the fourth day, when vomiting set in, with considerable epigastric pain. Inability to retain anything taken by mouth continued until the patient's death, seven days after the operation.

Autopsy (99.156) by Dr. Fulton, thirteen hours post mortem. Body of a man sixty-three years of age, fairly well developed, but poorly nourished. Length, 172 centimetres. Marked rigor mortis. Much lividity of dependent parts. A marked general jaundice. No subcutaneous edema. No caput medusæ. No dilatation of superficial vessels. No enlargement of the axillary lymph nodes. About six centimetres to the right of the median line and on a level with the umbilicus is a closed linear incision, seven centimetres in length, extending upward and outward. Peritoneum smooth. Appendix vermiformis 11 centimetres in length, free, extends down into the pelvis. Its lumen is patent throughout. Mesenteric lymph nodes not enlarged. Pleural cavities: Lungs are adherent in many places by strong fibrous bands. Pericardial cavity smooth, contains a few cubic centimetres of straw-colored fluid. Heart: Weight, 315 grammes. The muscle is soft, brown, and on section shows a number of small, firm, whitish, irregular areas, some of them three to four millimetres in diameter. Coronary arteries smooth; valves normal. Frozen section shows very slight amount of fat and an abundance of brown pigment.

Lungs: Voluminous; the right larger than the left. Posterior portions are dark-colored and on section are moist, exuding a frothy fluid on pressure. Anterior portions are dry on section and in general deeply pigmented. Bronchial mucosa is deeply congested and covered with a thick layer of mucus. Bronchial lymph nodes are much enlarged, very black, some of them calcified. Spleen: Weight, 230 grammes. Capsule is smooth for the most part, but is adherent over its posterior portion. It is firm, and on section is grayish red. Malpighian bodies are prominent and trabeculae easily seen. There is no increase in pulp. Stomach normal. Intestines: Small intestine contains a slimy, dark, greenish material. The colon is filled with light, clay-colored feces.

Liver: Weight, 200 grammes; dark red; friable; mark-

ings distinct. Here and there over the surface are small whitish areas, the largest three by four millimetres, which, when cut into, exude a grayish-white purulent material. A smear from this shows many pus cells and numerous large bacilli, with rounded ends, staining by Gram's method. On section these areas are seen in considerable numbers throughout the liver. The walls of these abscesses are fairly well defined and have a greenish, translucent appearance. The gall-bladder is the seat of an operation. The intestines are closely adherent to it and to each other in this region. It has been incised and contains no bile. The incision contains two small pieces of gauze drainage. The common duct is dilated throughout its length, the circumference being 4.5 centimetres. Just beneath the papilla biliaria is a small, firm nodule about one centimetre in diameter, which is freely movable beneath the mucosa, and is not attached to the pancreas. The gastrohepatic lymph nodes are enlarged, some measuring 1.5 centimetres in length. The opening of the common duct admits a probe with some difficulty. The pancreatic duct is dilated, having a lumen of about three to four millimetres, from which a clear fluid drops on section. The inferior portion of the pancreas is hard and nodular, and, for the most part, pale and homogeneous on section, but shows one small yellow patch about two millimetres in diameter. Retroperitoneal lymph nodes enlarged and very firm; the largest measure about two centimetres in length. On section they are pale, dry and homogeneous.

Kidneys: Weight, 290 grammes. Capsule slightly adherent, leaving a granular surface when stripped off. Tissue pale red; diminished consistence. Cortex measures three to four millimetres. On section, surface pale; the glomeruli appear as minute red points, and the cortex and the pyramids are not well differentiated. Some fat in the cells of the tubules. Adrenals normal. Bladder normal. Genitalia normal. Aorta: A few scattered, irregular, white, raised patches on the intima. In the thoracic portion is a small patch of calcification, measuring about one centimetre in diameter. Thyroid normal. Tracheal lymph nodes slightly enlarged.

Anatomical diagnosis.—Carcinoma of the common bile-duct with involvement of pancreas and retroperitoneal lymph nodes; multiple abscesses of liver; dilatation of pancreatic and common bile-ducts; chronic diffuse nephritis; chronic fibrous myocarditis; chronic fibrous pleuritis; chronic localized fibrous peritonitis; brown atrophy of heart; jaundice; cholecystotomy.

Bacteriological examination.—Smears from the liver abscesses stained by Gram's method show many well-preserved pus cells, large numbers of large bacilli, straight with rounded ends, staining deeply. A good many medium-sized bacilli with rounded ends, which decolorize, and a few scattered cocci occasionally in pairs retaining the stain. A few of those, morphologically like the large ones, decolorize. Anaerobic cultures in milk, agar, and bouillon all showed the three forms above mentioned. Two loopfuls from the surface of an agar culture were suspended in about one centimetre of bouillon, and injected into the ear vein of a rabbit which was killed in fifteen minutes, put in the thermostat at a temperature of 36°, and left for twenty hours.

Autopsy.—Abdomen of the animal greatly distended; marked general subcutaneous emphysema, particularly over thorax and inner side of thighs. Abdomen punctured with a trocar. The escaping gas burns with a blue, extremely hot flame for one minute. Smears from the subcutaneous tissues show the large bacilli in considerable numbers. Gas blebs abundant in the subcutaneous connective tissues. Small amount of serosanguinous fluid containing oil droplets in the peritoneal cavity. Fundus of stomach and spleen congested. Thorax contains much gas. Lungs greatly collapsed. Heart and large arteries and veins contain gas. Heart's blood contains many characteristic large bacilli. Lungs contain many bacilli. Liver very friable, a few gas blebs seen on surface and bubbles can be squeezed from it. Gall-bladder shows bacilli in smears. Kidney pale, granular and friable, containing no

gas but many bacilli. Cultures made from heart's blood, peritoneum and liver. In most of the cultures the three organisms are found. In the cultures from the peritoneum the large bacillus predominates. There is much gas produced in the water of condensation and in the agar. Milk is coagulated, decolorized, and digested. The organism produces characteristic colonies on blood serum. The medium-sized bacillus which decolorized by Gram's method is motile in twenty-four-hour cultures, acidifies milk, grows diffusely on potato, produces gas in glucose bouillon, forms indol in glucose-free bouillon and does not liquefy gelatine. It is the bacillus coli communis. The lanceolate coccus is often in pairs, forms minute pinpoint translucent colonies on blood serum, shows a very slight growth on potato, coagulates and decolorizes milk, produces no gas and no indol. In ten days gelatine is liquefied along the stab and also over the entire surface to the depth of one centimetre. A guinea-pig, weighing 100 grammes, was inoculated subcutaneously with one cubic centimetre of a twenty-four-hour culture; no symptoms developed. It is a non-pathogenic organism not identified. Cultures from heart's blood and spleen negative. Kidney and lung contain a diplococcus, with the same characteristics as that in the liver, and the colon bacillus.

Microscopical examination.—Tissues were fixed in Zenker's fluid, imbedded in paraffine, and stained with eosin followed by Unna's methylene blue. Sections of the liver show a slight cirrhosis, but the chief interest is in the abscess formation. In each of these is an area of necrotic, structureless material, portions of it hyaline, staining deeply with eosin, portions finely granular, staining with methylene blue. Immediately surrounding this are numerous poorly preserved polynuclear leucocytes and some phagocytic cells. Surrounding the abscess is an ill-defined wall composed of connective tissue containing a few liver cells and infiltrated with leucocytes and many eosinophiles. Beginning abscesses are seen in connection with the bile-ducts. In some cases the ducts are simply dilated with leucocytes, while the epithelium remains intact. In others, farther advanced, the epithelial wall remains on only one side of the abscess. About the ducts the tissue contains many plasma cells and numerous eosinophiles. From these appearances, it seems fair to assume that the infection entered by way of the bile passages. No bacteria are found in the sections except some which are morphologically and in staining reaction like the gas bacillus. Even these are not very abundant. They are found in connection with the abscesses and some are within the bile-ducts.

This case resembles closely that reported by Larkin⁶ in which there was obstruction of the common duct and multiple hepatic abscesses. In connection with the fact that no gas formation took place in the liver, two of the cases mentioned by Bloodgood⁵ are of interest. One was a laceration of the scrotum in which the gas bacillus was found in the tissues but was unaccompanied by emphysema. The other was a case of infection after ligation of the femoral artery for a popliteal aneurism. Gangrene of the leg followed the operation. Symptoms of infection accompanied by emphysema of the tissues appeared on the tenth day. The gas bacillus was found and the leg was amputated. Two months later a second amputation was done for the granulating stump. The bacillus aerogenes capsulatus was again found in a small subcutaneous abscess, but there was no gas. In a unique case reported by Gwyn,⁷ in which he repeatedly isolated the organism from the blood during life, there was also no formation of gas.

CASE III. PERFORATING GASTRIC ULCER; GENERAL PERITONITIS, IN WHICH THE BACILLUS AEROGENES CAPSULATUS WAS THE PREDOMINATING ORGANISM.

John D., age twenty-three years. Shipping clerk. Admitted to the service of Dr. Monks, November 25, 1899.

Family history negative. Personal history of no importance, except that for the last two weeks the patient has been indisposed and has lost weight. Has complained of distress after eating; no vomiting; no hematemesis. November 25th, in the afternoon, the patient was suddenly taken with cramp-like pains all over the abdomen. Pain continued until admission twenty-four hours later. No vomiting until after admission. On admission, patient was in much pain, pale and anxious. Pulse 130 and weak. Abdomen immensely distended, tender, tympanitic except in flanks, where there is some movable dullness.

Operation.—The abdomen was opened, and a dirty brownish fluid with much fibrin and gas escaped. Peritoneum red and roughened. The patient failed rapidly and the operation had to be abandoned before the perforation was found. Death occurred two hours later.

Autopsy (U. 99.36) by Dr. Fulton, sixteen hours post mortem, at the undertaker's, in the presence of friends. Partial autopsy only permitted. Organs not removed. Peritoneal cavity filled with a dirty brown fluid. Some gas escaped on opening. Peritoneum covered with scattered flakes of fibrin. Intestines much congested. Here and there are dark areas about one centimetre and less in diameter, apparently hemorrhages into the intestinal wall. Mesenteric lymph nodes enlarged. Appendix normal. Spleen somewhat increased in size and quite soft. Stomach: On the anterior surface is a round opening measuring seven millimetres in diameter, through which gas and stomach contents escape. Stomach much dilated. Permission obtained to remove stomach. The opening mentioned is two centimetres below the lesser curvature; six centimetres from the esophageal opening, and 11 centimetres from the pylorus. Over an area, five by six centimetres, surrounding the opening the peritoneal surface is whitish, opaque, with evidence of slight recent adhesions. From the inner surface the perforation is seen to be funnel-shaped, the inner orifice being 1.75 centimetres in diameter. The walls are very sharply defined, giving the appearance of having been punched out, except that they are slightly terraced, indicating the different coats of the stomach. The wall at this point measures one centimetre thick, thinning gradually for a distance of two to three centimetres from the ulcer. Posterior surface is slightly congested. No other ulceration.

Anatomical diagnosis.—Simple perforating ulcer of the stomach; acute general fibrinopurulent peritonitis; hemorrhages into intestinal wall; hyperplasia of mesenteric lymph nodes.

Bacteriological examination.—A smear from the peritoneal exudate shows vast numbers of large, thick bacilli which resemble morphologically the bacillus *aërogenes capsulatus* and stain deeply by Gram's method; a moderate number of medium-sized bacilli, and a very few slender bacilli, both of which decolorize by Gram, and a few lanceol-shaped cocci or short bacilli, often in pairs, not decolorizing. One culture made from the peritoneal cavity. The medium bacillus noted in the smears gives the cultural characteristics of the bacillus *coli communis*. After the smear was examined and the large bacillus noted, the tube was cultivated anaerobically (in a Buchner jar). A few large, thick bacilli were found in the water of condensation. This was inoculated into the ear vein of a rabbit, which was killed in fifteen minutes and placed in the thermostat over night. Autopsy the next morning. Animal much swollen and gives off an offensive odor. Peritoneum punctured and gas allowed to escape but cannot be demonstrated definitely to burn. Much subcutaneous emphysema. Gas and a chocolate-brown, oily fluid in the peritoneal cavity. Gas in pleural cavities and large blood-vessels; none in the pericardium. Smears from the subcutaneous tissue, heart's blood, liver and peritoneal cavity show many large, thick bacilli not decolorizing by Gram's method, and with an easily demonstrable capsule. Cultures show the bacillus *aërogenes capsulatus*, the bacillus *coli communis*, and an unidentified small bacillus.

In this case of acute general peritonitis the gas bacillus was the predominating organism in the exu-

date. It has already been well recognized as at least a contributing cause of peritonitis, and Welch and Flexner⁴ report a case of peritonitis due to perforating cancerous ulcer of the duodenum in which the organism was obtained in pure culture. They also report three cases of peritonitis due to the perforation of typhoid ulcers in which the gas bacillus was present, but in association with other organisms. They also mention a case of perforating gastric ulcer in one of their stock rabbits in which the peritoneal exudate contained the gas bacillus.

CONCLUSIONS.

Only one of our five cases (Dr. Thorndike's first case) was a pure infection with the gas bacillus. This case shows what marked pyogenic properties the gas bacillus may possess. In three cases the organism appeared to gain entry into the tissues from the gastrointestinal tract. In two, infection was probably referable to dirt containing the gas bacillus which gained access into the body through wounds of the skin.

Our first case shows how readily the organism may be destroyed by cold.

The lesions produced by the gas bacillus on muscle tissue are most remarkable. This was shown in both the cases of emphysematous gangrene reported by Dr. Thorndike. In some places the muscle fibres were broken into small pieces, varying in size and shape. The fragments were separated one from another and laid in different planes. Their torn edges were distinct; their striæ well preserved. The appearance was of débris thrown about by an explosion. In other places degeneration and digestion of the muscle fibres appeared to have taken place. This digestion is shown by the soft, mushy consistence of the muscle fibres, which can be teased apart with the greatest ease.

Clinical Department.

A NEW METHOD OF INTRA-ABDOMINAL OPERATION FOR RETROVERTED UTERI.

BY GEORGE W. KAAN, M.D.,
Assistant Surgeon, Free Hospital for Women; Instructor in Clinical Gynecology, Tufts College Medical School, Boston.

The present methods for holding the uterus in position, in cases where the abdomen has been opened, are practically three; namely, folding the round ligament upon itself and stitching the folds together; drawing the two round ligaments into apposition ante-

rior to the uterine and suturing them there; and finally, ventral fixation or suspension. The operations upon the round ligaments have not met with popular favor, and apparently most operators prefer some form of ventral suspension or fixation, even while feeling that it is not the ideal operation.

Fixation of the uterus brings it into permanent apposition with the abdominal wall and into an abnormal position, perhaps not so bad as retroversion, yet bad enough to be productive of many disagreeable symptoms, and a dangerous position for subsequent pregnancy.

Suspension of the uterus brings it into temporary abnormal apposition with the abdominal wall, and is intended to be followed by the formation of bands of adhesion, of uncertain length and strength, extending from the fundus to the anterior abdominal wall. The results are not always satisfactory; the uterus may be attached too high or too low on the abdominal wall, and the adhesion bands may stretch enough to allow the uterus to return to its retroverted position. Furthermore, cases have been mentioned of fatal intestinal obstruction due to these bands.

In view of my experience and that of others with the above operations, I have lately tried a new method, to which as yet I can see no objectionable feature, and which leaves the uterus in a more normal position, with natural unimpaired mobility from the start.

In all cases of retroverted uteri the round ligaments, with the peritoneal covering, are elongated, and my method consists simply in puckering them upon a gathering string, and so shortening them that the uterus is brought into normal position. In the cases I have operated upon this is exactly what has happened.

I have picked up the round ligament and peritoneum together with a double hook, about midway between the cornu of the uterus and the internal abdominal ring; then passed a suture of silk subperitoneally from the uterus as far outward along the round ligament as seemed necessary. The tissue is puckered along this suture, the two ends of which are then tied together with moderate traction. To avoid its cutting through, the silk used is of medium size, and is passed into the tissue of the fundus at its point of entrance, and through ligamentous tissue at its exit. The strain on this stitch, however, is not nearly so great as upon the stitches of a ventral suspension, which drags the uterus out of position.

I have had this operation in mind for some time, but have tried it only lately. It surely avoids the defects of other operations, but its value must be determined by extended trial, and I submit it to the profession, hoping it may be tried by others.

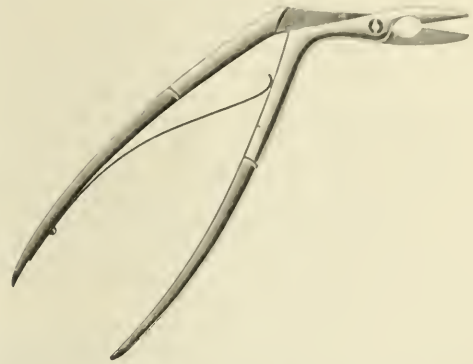

New Instrument.

A NEW NASAL SCISSORS FOR THE REMOVAL OF THE LOWER TURBINATE.

BY CAROLUS M. COBB, M.D., BOSTON.

IN removing the whole or a part of the lower turbinate bone, I have found a pair of scissors, which Codman & Shurtleff, of Boston, made for me, to be of very great advantage. The accompanying cut gives a very good idea of the instrument. It is much more convenient to use than the turbinate saw and leaves a

cleaner cut than does the saw. The fault with most nasal scissors is that the blades are not firm enough to cut through the body of the turbinate; the blades either slip by each other or one is not able to put force enough onto the handles to make the point cut anything more than the mucous membrane. The

blades of this instrument are short and the whole so strong that the blades will cut through any part of the lower turbinate. The shape of the instrument allows the operator to reach any part of the lower turbinate that can be reached by the saw or by any other instrument except the cold wire snare.

TWENTY-FIRST ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 1, 2 AND 3, 1900.

FIRST DAY.

AFTER the announcements of the Committee of Arrangements and executive session, Dr. ROBERT F. WEIR, of New York, gave the Presidential Address on

PERFORATING ULCER OF THE DUODENUM.¹

The perforation usually is located within one and one-half inches of the pylorus, more commonly on the anterior wall: in 80 per cent. of the cases the ulcer is single, in eight per cent. it is double, while in the remaining cases more numerous perforations occur. The cause of ulceration is difficult to determine: it has been attributed to habits of life, to circulatory disturbances, to the naturally delicate condition of the mucous membrane, to sepsis, burns, etc. Lockwood has collected 138 cases of burns treated by modern methods, and duodenal ulcer occurred in only one case. The affection is comparatively rare, occurring in about two per cent. of all necropsies. Patients are of all ages, but it is more common between twenty and fifty. In many cases healing occurs without serious results, but in some cases cicatricial contraction results. The symptoms are often vague, and may be entirely wanting. The patient's previous history is of great importance; there is usually pain, tenderness and vomiting; hematemesis, blood in the stools and jaundice may be present. Pain usually follows some time after eating; hematemesis is less frequent than with gastric ulcer; vomiting of importance if combined with

¹ See No. 18, p. 445, of the Journal.

other symptoms; jaundice rarely follows cicatricial contraction. Blood in the stools generally gives them a tarry appearance, but in some cases the blood may be bright red. Great advances have been made in the diagnosis of such conditions of late, and Weir believes that the differentiation from gastric ulcer is not impossible. The symptoms of perforation are sudden acute pain, vomiting, shock. Later the symptoms of localized or general peritonitis supervene. The obliteration of liver dulness is not of much value, as resonance may result from a distended colon. As in perforating gastric ulcer, the mortality depends much upon the time elapsing between perforation and operation. Of 13 cases operated upon over thirty hours after perforation all died. In the earlier cases the perforation was often not found or sutured, but among later cases the perforation has been found and closed in 35 per cent. of the cases, and there is much less confusion of the diagnosis with various forms of intestinal obstruction, appendicitis, etc.

The treatment of non-perforating duodenal ulcer is seldom surgical, although in some cases gastro-enterostomy may be considered. In operating, Weir advises a long incision along the edge of the rectus muscle, then the fascia is cut transversely. If the perforation is not discovered on the anterior wall after wiping away the exudate the posterior wall should be examined. Methylene blue taken by the mouth may aid in the diagnosis. The perforation is closed by two or three rows of sutures. Excision of the ulcer is unnecessary. Closing of the perforation is but half the battle; the careful cleansing of the peritoneum is of the highest importance. If dilatation of the stomach or obstruction to the flow of bile results from cicatricial contraction, gastro-enterostomy may be performed. Weir has prepared a synopsis of 51 cases, including one case in which he personally operated, upon which he based his paper.

DR. WILLIAM L. RODMAN, of Philadelphia, read a paper on

GASTRIC ULCER, NON-PERFORATING; HEMORRHAGE.

The paper was based upon an exhaustive study of the statistics, and Dr. Rodman devoted his attention mainly to the treatment. He showed the fallacies of the statistics on this subject by Mayo Robson. The various operations which have been practised for hemorrhage were discussed. Gastro-enterostomy has been most commonly performed, and probably will continue to be because of the difficulty in locating the ulcerated vessels. In 55 necropsies the splenic artery was found to be ulcerated 17 times. Excision of the ulcer is the ideal operation unless there are strong adhesions, and the mortality in those cases in which this operation has been performed is less than that of gastro-enterostomy. Operation for acute hemorrhage is advised, with limitations, but operation for chronic hemorrhage is always indicated.

DR. J. M. T. FINNEY, of Baltimore, read a paper on

PERFORATING ULCER OF THE STOMACH.

Finney mentioned the great interest which has been taken in this subject of late, the increased number of operations and the many exhaustive papers which have recently been published. It was not until twelve years after Mikulicz first operated, in 1880, that the first successful case was reported by Kriege.

During the first sixteen years only 78 cases have been reported, but since then the number has rapidly increased until, with Finney's own recent tabulation, the number up to date is 268 cases. Of 35 patients that have been treated in the wards of Johns Hopkins Hospital for gastric ulcer, perforation has occurred in but one case, and death resulted before operation could be completed. The affection is most frequently met in young women of the lower walks of life; in men it usually occurs after forty years of age.

The site of the ulcer is more commonly on the anterior wall of cardia, next most frequently the pylorus, then along the lesser curvature, and, finally, the posterior wall. In about 20 per cent. of the cases there is more than one perforation. The severity of the symptoms arising depends on the size of the perforation, the amount and character of gastric contents, the variety and number of bacteria present. If the stomach be empty the chances for recovery are much more favorable. The stomach is capable of sterilizing itself, as the acid gastric juice kills many bacteria, but many may persist buried deeply in the mucosa. There are no symptoms of impending perforation, but Finney believes that the blood count and the finding of leucocytosis is of great diagnostic value. It is improbable that over five per cent. of patients with perforation recover without operation, and if operation is delayed septic peritonitis will supervene in case no limiting adhesions form. The less opium given the better in these cases. Operation should not be delayed until the patient has recovered from shock, but the sooner performed the better will be the results. Early exploratory operation is urged in case there is doubt as to the diagnosis. Cocaine anesthesia is sufficient in such cases; cover-slip preparations and cultures may be taken and the abdomen closed, provided no lesion is found. If necessary to continue the operation a general anesthetic may be administered. The cause of death in these cases is usually sepsis, but there has been much improvement in the results of late. While the percentage of recoveries, which is now placed at 87 per cent., may be somewhat too high, it is a great improvement over the five per cent. of recoveries which follow without operation.

WM. J. MAYO, of Rochester, Minn., read a paper on

MALIGNANT DISEASES OF THE STOMACH AND PYLORUS.

Mayo considers carcinoma of the stomach a strictly surgical disease. Early diagnosis is of the highest importance, and the surgeon should not wait to have the physician make it for him. Exploratory incision is as justifiable as in the case of the breast and uterus. The curability of malignant disease depends upon the histologic structure of the growth, its location, extension to neighboring tissues, glandular involvement and the general condition of the patient. If the tumor has a large amount of stroma its growth will be slow, and the reverse. Disease of the cardia is generally easily diagnosed, but radical intervention is likely to be impossible, and while diagnosis of disease of the pylorus is difficult the prognosis is much better. Infection of the lymphatic glands is not as common as in malignant disease of some other organs, and if present radical operation will probably be impossible.

In the beginning each operation is an exploratory

incision for methodical examination, having in view the question of radical operation, palliation or the inadvisability of attempt at relief. Even after the abdomen is opened it is often difficult to determine whether the growth be malignant. Mayo believes that in the future the more radical operation of gastrectomy will be more frequently performed. He points with pride to the fact that the first total gastrectomy was performed by Connors, an American; while Schlatter was successful, he was not original. In the case of more localized growths pylorotomy by Kocher's method is preferred. Operation in two stages: first gastro-enterostomy and some weeks later pylorotomy shock the patient less and give opportunity for him to gain strength before the final operation, but there is likely to be some trouble with adhesions if this method is followed. Curetting or the use of the cautery as a palliative measure is not favored. Gastro-enterostomy is the most generally useful palliative operation. Whether it be performed by suture will depend on individual preference and experience. Mayo uses the Murphy button without suture. He questions the supposed advantages of posterior gastro-enterostomy by von Hacker's method, and personally prefers the anterior operation. If the anastomosis between stomach and intestine be made about an inch above the lower border of the stomach regurgitation of intestinal contents and vomiting of bile will be uncommon. Entero-enterostomy in addition to gastro-enterostomy is usually but an unnecessary complication of the operation.

SECOND DAY.

DR. FREDERICK KAMMERER, of New York, read a paper entitled

BENIGN OBSTRUCTION OF THE PYLORUS.

Obstruction of the pylorus may be either congenital or acquired: there may be acute stenosis at birth as the result of fetal peritonitis, or congenital hypertrophy may exist.

Acquired stenosis most commonly is an after result of gastric ulcer; it may result from occlusion by benign tumors, from syphilitic gumma, from gall-stones obstructing the pylorus, from spastic contraction from hyperchlorhydria. If medical treatment fails, daily lavage, rest and careful diet, surgical treatment is indicated. Kammerer mentioned surgical treatment by dilatation of the stricture, simple division of adhesions and resection of the pylorus, but he devoted most of his paper to the discussion of pyloroplasty and gastro-enterostomy. Study of a large collection of statistics shows the present mortality of pyloroplasty to be 15 per cent., while that of gastro-enterostomy is 17 per cent., but the mortality of the latter operation is much lessened now and it is doubtful if it is really higher than that of pyloroplasty. The mortality of resection of the pylorus is about 28 per cent., according to Mikulicz; that of Loretta's operation is also great and both these procedures have practically passed out of use. Adhesions may reform after pyloroplasty, causing return of obstruction, but not after gastro-enterostomy. Gastro-enterostomy is likely to be followed by regurgitation of fluids from the intestine, perhaps as the result of the formation of spurs, kinks or twists. Anterior gastro-enterostomy does not empty the stomach so freely in the recumbent position, and in some cases complications arise from the small intestine encircling

the colon, hence posterior gastro-enterostomy is preferred. Kammerer has performed eleven posterior gastro-enterostomies with Murphy's button, with one death from exhaustion and one from pneumonia. In the remaining cases the after results were excellent; there was no difficulty from spur formation or regurgitation. As to the after results from these operations, the motor function is generally increased and there is reduction in the size of the stomach, but never to normal. There is no reflux of bile and intestinal fluids after pyloroplasty, but there is less reduction in the size of the stomach than after gastro-enterostomy, and there is the possibility of recontraction from inflammatory thickening or reformation of adhesions. The fact that the results are always as good after gastro-enterostomy, and sometimes much better, makes this the operation of choice in such cases.

DR. B. F. CURTIS, of New York, read a paper on

GASTRIC DILATATION — GASTROPTOSIS.

In a discussion of the anatomy of the stomach Dr. Curtis called attention to the fact that under normal conditions the pylorus can scarcely be palpated and the lesser curvature not at all. Dilatation may arise from obstruction to the outlet of the stomach from benign or malignant tumors or from atony of the stomach walls, or from a combination of these causes. Atony of the stomach walls in its turn may result from some constitutional disease or from repeated overloading. The prognosis in atonic dilatation under medical treatment is unfavorable and operation is indicated when the patient is losing ground under systematic lavage and dietetic and medical treatment. The mortality of the operation of gastroplication is low and in properly selected cases the results are good; the choice of cases is difficult, however.

The details of the operation have been variously modified from the simple folding and suture first proposed by Bircher. Dr. Curtis favors Weir's method, using several rows of sutures. Gastroptosis may be of three varieties; there may be simply fixation of the cardia and sagging of the pyloric end; this may be so extensive that we have to deal with a vertical stomach, or both cardia and pylorus may be fixed and the stomach sag in a U-shape. Dr. Curtis mentioned five operations without any accidents; improvement is not difficult to obtain whatever method of operation be adopted.

DR. F. S. WATSON, of Boston, read a paper on

HOOR-GLASS CONTRACTION OF THE STOMACH.

Hour-glass contraction of the stomach has existed as a surgical affection for only ten years and during that time 35 cases have been operated upon. The methods employed have been gastro-enterostomy, plastic operation and gastro-anastomosis by Wöfler's and Watson's own method. Dr. Watson first folds the stomach with the constricted part as a hinge; the sac nearest the pylorus is then fastened to the cardiac portion by four stay sutures and then the two sacs are securely sutured before opening the stomach; a longitudinal opening is then made in the stomach wall and the double partition between the two sacs is excised. The first patient upon whom Dr. Watson operated gained forty-two pounds in the year after the operation; she remains well and is doing her work five years after the operation. In a second case, a woman who had a long history of gastric ulcer was taken

with symptoms of perforation. Operation was performed and the perforation was sutured. The abdominal cavity and pelvis were infected at the time of operation, and the patient died four days later. At the necropsy the stomach was found to have an hour-glass shape, a fact that was not recognized at the time of operation because of adhesions. The pyloric end was also pulled up and attached to the lesser curvature by adhesions. As regards the choice of operation, Dr. Watson believes that gastro-enterostomy should not usually be performed in such cases, because the digestive function of the second sac is lost; after plastic operation there is danger of recontraction of the opening and the operation is not applicable if the opening between the two pouches is small. Under favorable conditions gastro-anastomosis is the preferable operation; if adhesions exist they should be freed if the patient's condition permits.

Dr. JOHN C. HEMMETER, of Baltimore, read a paper on

DIAGNOSIS OF CANCER OF THE STOMACH.

The only diagnosis of carcinoma that is of interest to the surgeon is the early diagnosis, and as there is a period of three months before any definite signs appear, this is very difficult. The first symptoms resemble those of nervous dyspepsia or chronic gastritis. The methods necessary for chemical and microscopical investigation are time robbing and not generally suited for general practice. Such symptoms as pain, dyspepsia and the appearance of blood are of little value, because found in other conditions. The absence of free HCl is an important symptom, but it may not be present, even at the end of the disease. The presence of lactic acid is a sign of stagnation and is not present till there is pyloric obstruction. It is present in about 84 per cent. of the cases of cancer. The *Oppler-Boas* bacillus is present in 53 out of 55 cases of carcinoma, but, like lactic acid, it may be present with benign growths. There is little hope of a diagnosis from gastroscopic examination and it is not without considerable danger. The use of the x-rays is futile and electrodiaphany is of no value until there is great thickening. Curetting the stomach by the stomach tube gives positive evidence of carcinoma if the growth has disintegrated. The appearance of atypical and asymmetrical mitoses in the cells of the tissue undergoing transformation if present is highly suggestive.

Until we gain a knowledge of the true nature of the disease, early diagnosis and successful treatment will be impossible and gastric surgery can be only palliative. In all cases of nervous dyspepsia or chronic gastritis, if there is no benefit resulting after four weeks' medical treatment, if there is lessened peristalsis and no free HCl, if atypical mitoses are found, exploration is indicated.

Dr. A. T. CABOT, of Boston, read a paper on

ADHESIONS OF THE STOMACH.

Ulcer of the stomach or duodenum and inflammatory conditions of the gall-bladder most frequently give rise to adhesions. The symptoms, if mild, often remain unrecognized, and may simulate biliary colic. Pain may be a marked symptom or it may be moderate and pass unnoticed; it does not radiate to the shoulder and is not spasmodic. In cases in which there is a history of ulcer, or the symptoms of stone

in the gall-bladder, Dr. Cabot believes that operation for the freeing of adhesions is often advisable, even if the pain be not severe. His results, after such operations, have been very favorable.

GASTRIC FUNCTIONS BEFORE AND AFTER GASTRO-ENTEROSTOMY.

Dr. C. S. FISCHER, who read this paper, believes that the results of German investigators who have studied this subject are of little value because of the short time that their patients were under observation. He reports a case that was under observation for four years for disturbance of motor function and hyperacidity before operation. This patient remains under observation two years after operation; the hyperacidity continues and has been progressive, the dilatation is less and the motor function is improved. In another case the hyperacidity was reduced, but becomes pronounced after emotional disturbances. Fischer believes that structural changes begun before operation are likely to continue after operation; in general, the motor function is improved and the intestinal function is also improved.

STRICTURE OF THE ESOPHAGUS FOLLOWING TYPHOID FEVER; GASTROSTOMY.

Dr. FREDERIC S. DENNIS, of New York, presented this paper. A man of thirty-five was shown before the society, and in Dr. Dennis's absence his paper was read by the Secretary. During the latter part of an attack of typhoid fever of three months' duration, the patient was taken with a burning sensation in the lower part of the esophagus, and later difficulty of deglutition followed. He was treated by dilatation with bougies for three months, but his condition became progressively worse. Rectal feeding was resorted to, but the patient became bedridden from exhaustion; he lost flesh until he weighed but 100 pounds, he was cyanotic, almost pulseless, and in such constant agony that he begged for any form of relief. At the time of operation he had taken no food by the stomach for three months. Gastrostomy was performed and since then the patient's condition has progressively improved; he now works hard, weighs 180 pounds and is able to enjoy life in spite of this method of feeding.

DISLOCATIONS OF THE HIP; DEMONSTRATIONS ON THE CADAVER ILLUSTRATIVE OF THEIR MECHANISM.

Dr. OSCAR H. ALLIS, of Philadelphia, presented this paper. He called special attention to the value of this method for purposes of demonstration before classes. He demonstrated on the cadaver the method of producing different dislocations, their signs and the method of reduction, verifying his statements by incisions. He laid special stress on the necessity for fixation of the pelvis during reduction, the fact that the most important factor in reduction is to find the opening in the capsule from which the head escaped and that by traction the head may be drawn up on the acetabulum and then pushed in by an assistant. By this method reduction can be accomplished even if the bone be divided.

THIRD DAY.

Dr. W. W. KEEN, of Philadelphia, opened the discussion on

SURGERY OF THE STOMACH.

Malignant disease of the stomach is of more importance at the present than non-malignant disease, because of its greater frequency and because of the great difficulties in diagnosis. During the past few years the specialist on gastric diseases has given the surgeon great aid in the diagnosis. Hemmeter has called attention to the fact that if operation is to be successful it must be performed within the first three months of the disease, and if the specialist finds any probability or even a possibility of this disease exploratory operation is indicated. There is little danger in exploratory incision, but there is danger in late operation that we shall be able to accomplish nothing. If a palpable tumor is present recurrence is almost inevitable.

DR. M. H. RICHARDSON, of Boston, believes that all methods of diagnosis should be exhausted before we resort to exploratory operation, but in case of doubt open the abdomen as soon as possible in all surgical affections of the stomach. In case of hemorrhage operation is not advisable unless medical means have failed. Perforation demands immediate operation, but the diagnosis is sometimes difficult. In case of carcinoma the time for operation is before the tumor is felt, but not one case in fifty is suitable for operation at the time it comes to the surgeon. Total extirpation probably has a more limited field than was at first believed.

DR. T. A. MCGRAW, of Detroit, described a method of performing gastro-enterostomy by means of an elastic ligature, which he introduced some years ago, but abandoned for Murphy's button. He gave the details of a case in which he performed anastomosis in this way, but the patient died of inanition fifteen days later; at the necropsy it was found that the stomach was united to the ileum only about three feet above the ileocecal valve. The method of anastomosis is to pass the needle through about an inch of stomach and intestine and tie firmly. It takes about three or four days for the ligature to cut through.

DR. DUDLEY P. ALLEN, of Cleveland, reported a case in which he operated on a patient that was apparently moribund. A perforation was found low down on the posterior wall; gauze was packed down to the perforation and recovery followed. Cultures taken from the abdomen at the time of operation failed to demonstrate the presence of any bacteria and possibly that accounted for the favorable result. In another case in which he operated for gall-stones the patient died seventeen days later from hemorrhage from a gastric ulcer. In a third case a patient who had vomited blood and passed blood by the rectum was found to have an ulcer connecting the stomach with the colon. Dr. Joseph Ransohoff, of Cincinnati, advises operation for malignant diseases of the stomach in two stages: preliminary gastro-enterostomy, then, about two weeks later, pylorotomy.

DR. CHARLES B. NANCREDE, of Ann Arbor, Mich., reported a series of experiments which show that infection with the colon bacillus is not ordinarily the cause of death, but if morphine is administered, a fatal result is likely to follow. He emphasized the desirability of statistics as to the results of pylorotomies by the members of the Association. He does not believe there is 90 per cent. mortality after this operation; if so, it is not a justifiable procedure.

DR. JAMES E. MOORE, of Minneapolis, mentioned a case that was referred to him by a specialist on stomach diseases. There had been previous good health till within three weeks, then the only symptom was pain and absence of free HCl. On opening the abdomen the disease was found too extensive for removal. In case of hemorrhage from gastric ulcer the ulcer would often be found if exploration were continued to the duodenum.

DR. S. H. WEEKS, of Portland, Maine, states that operations for carcinoma up to the present time have not proved curative, and he advocates gastro-enterostomy in such cases. He favors operation with the use of sutures rather than by Murphy's button. He uses catgut sterilized by boiling in juniper oil as a suture material.

DR. L. C. TIFFANY, of Baltimore, believes that pylorotomy is justifiable only in rare cases. He has operated in a number of cases referred to him by Hemmeter and invariably found enlarged glands which precluded further intervention. As in the case of oöphorectomy and appendectomy, the pendulum will probably swing in the direction of useless exploratory intervention, until we learn by experience, by actual handling of cases, the real conditions and indications for operation.

DR. R. F. WEIR, of New York: While a diagnosis is impossible, we operate for the relief of such symptoms as pain, hemorrhage and dilatation. As yet it is not definitely settled what operations and what methods are most desirable. Weir personally prefers posterior gastro-enterostomy in combination with entero-enterostomy, using Murphy's button. During the past year he has operated upon 11 cases with no deaths. In exploratory operations cocaine anesthesia might be much more frequently used.

DR. ARMSTRONG, of Montreal, considers many cases of gastric hemorrhage, such as capillary bleeding, amenable to medical treatment, but the severe hemorrhage which arises from deep ulceration generally requires operative treatment. Repeated hemorrhages of considerable amount also demand operative treatment. In operating, a large opening should be made near the middle of the anterior wall of the stomach to give plenty of room for exploration.

DR. L. M. TIFFANY, of Baltimore, called attention to the fact that by incising the gastrocolic omentum and passing the hand up behind the stomach, it is possible to turn the stomach practically inside out in examining the mucous membrane for ulcer.

THE METHODS OF CLOSING ABDOMINAL INCISIONS.

DR. M. H. RICHARDSON, of Boston, read this paper. He advocates through-and-through suture as quicker, more convenient, less likely to leave dead spaces which fill with blood and tend to produce infection, and he believes that there is no more tendency to hernia. After using various materials for suture he has adopted silkworm gut for closing the abdominal wall and silk for all other ligatures and sutures. It is questionable whether union is any more secure after suturing like tissues than if peritoneum be sutured to fascia, and fascia to muscles. The number of hernias through the scars of abdominal incisions is insignificant. In five years only nine such cases have come to the Massachusetts General Hospital, though over 1,500 abdominal operations have been performed. In some cases interrupted

buried sutures of the fascia may be inserted with advantage after through-and-through sutures have been first inserted before they are tightened and tied. It is well to first thread both ends of the suture with a needle, and the needles are then passed through the abdominal walls on each side from within outward.

DR. J. B. DEEVER, of Philadelphia, stated that he agreed with Richardson entirely. He confines his incisions to the muscular wall of the abdomen, preferably through the rectus muscle, not through the linea alba or linea semilunaris. He also uses silkworm gut and silk as suture material; never catgut.

DR. WEIR, of New York, believes that there is good in both methods. He uses the layer suture. The suture should not be drawn too tight so as to strangle the tissue and interfere with repair. He thinks that the percentage of ventral hernias is greater than estimated by some previous speakers.

DR. G. R. FOWLER, of Brooklyn, thought that when experts disagree on matters in which they have had wide experience, the middle course is usually the safest. Fowler uses what he calls the crossed suture, a kind of double figure of eight, which crosses twice in the tissues. The suture is easily inserted, easily removed and efficient. The skin ends are farther apart from the edge of the incision, and they are passed through a bolster of thick rubber tubing.

DR. COLEY, of New York, favors the layer suture, and has used catgut for the buried suture material for nine years. Out of 150 hernia operations since he began using gloves he has had but one infection, and that could be traced to imperfect sterilization of the skin. He has seen many sinuses resulting from the use of silk.

DR. S. J. MIXTER, of Boston, does not use either method exclusively. There are great differences in the way in which sutures are inserted. If through-and-through sutures are used the different layers should be picked up with care and they should not be drawn too tightly.

DR. GEORGE B. JOHNSON, of Richmond, Va., after extensive trial of both methods prefers through-and-through suture, as it destroys dead spaces and does not leave weak places in the abdominal wall.

DR. NANCREDE, of Ann Arbor, Mich.: The man who uses one method acquires dexterity with it, and can use it with better advantage. By repeated experiment it has been proven that catgut can be reliably sterilized by boiling in cumol, and if germs are found on the ends of it they are the same as those on the operator's hands.

DR. CARSON, of St. Louis, prefers catgut as a suture material.

DR. RANSOFF, of Cincinnati, uses continuous sutures in layers and fastens by the use of perforated shot.

DR. RICHARDSON stated that his objection to catgut is not that it cannot be sterilized but it does not tie well and is not permanent enough. Silk never gives trouble in aseptic wounds.

STRANGULATED HERNIA THROUGH A TRAUMATIC RUPTURE OF THE DIAPHRAGM; LAPAROTOMY; RECOVERY.

DR. E. W. WALKER, of Cincinnati, read this paper. A man of twenty-nine was struck by a falling tree and was only prevented from being completely crushed by one of the branches. Pain in the chest, nausea

and vomiting, constipation and extreme shock resulted. After a time the vomiting became stercoraceous. The bowel was pulled down, relieving the obstruction, and an attempt was made to suture the diaphragm. Rapid recovery followed and the patient has been in good condition since the injury.

DR. S. J. MIXTER, of Boston, reported a case in which a man was taken with severe pain near the umbilicus while pumping a hand-engine. On opening the abdomen it was found that the intestines were protruded into the thoracic cavity through a rent in the diaphragm. The thoracic and peritoneal cavities were both contaminated with feces and death followed a short time later.

DR. R. MATAS, of New Orleans, considers the transpleural route most favorable in such cases; this is the opinion of Italian surgeons who have had most experience in these operations following stab wounds.

A CASE OF SUBPUBIC HERNIA OF THE BLADDER THROUGH THE PELVIC FLOOR; OPERATION.

DR. F. B. HARRINGTON, of Boston, reported this case. A woman of forty-six, who had a large tumor of the labium majus, was taken suddenly with retention of urine. Several years previously she had been operated upon for a large edematous fibroid of this region; the fibroid had recurred and pulled down the bladder. Catheterization reduced the size of the tumor considerably, but all efforts at reduction were unavailing. Operation was performed, reducing the hernia, and recovery followed.

DR. W. W. KEEN, of Philadelphia, read a paper entitled

EXTIRPATION OF A VERY LARGE ANEURISM OF THE RENAL ARTERY.

DR. M. H. RICHARDSON, of Boston, read a paper on

A CASE OF ACUTE TUBERCULOSIS OF THE MESENTERIC GLANDS OF THE ILEOCECAL COIL; REMOVAL; PERMANENT RECOVERY.

DR. DE FOREST WILLARD, of Philadelphia, read a paper entitled

CONGENITAL CYSTIC TUMOR OF THE PELVIS.

A neurotic man had for several years had severe pain extending down his leg, and his physicians had made a diagnosis of neuritis. The pain did not follow the course of any nerve and it was not continuous. Later on a tumor appeared in the region of the groin. Various diagnoses were made, including malignant disease of the inguinal glands or of the ileum. On operating it was found that the tumor came out of the pelvis, passing over Poupart's ligament and forming a sausage-shaped mass in the groin. Hundreds of yellowish bodies, somewhat bean-shaped, were removed; they were laminated and in color resembled fat. The cyst which contained them was so intimately connected with the iliac and femoral arteries that it was impossible to remove it, and the cavity was packed with gauze. The specimen was examined by a number of competent pathologists, but as yet none of them have been willing to express an opinion as to the character of the growth. The patient died a short time later from nephritis, from which he had been suffering for some time.

DR. LEONARD FREEMAN, of Denver, read a paper entitled

UNION FOLLOWING PATHOLOGICAL FRACTURE OF THE FEMUR DUE TO SECONDARY CARCINOMA; SPONTANEOUS DISAPPEARANCE OF CARCINOMA OF THE LIP.

A woman of thirty-five, who had had a hard carcinomatous nodule of the breast removed some time previously, fractured her femur while turning in bed. Extension apparatus was applied, although union was not expected. After four weeks it was found that firm union had resulted. Microscopic examination of a specimen removed after the woman's death showed it to be carcinoma, which had invaded the bone through the Haversian canals. In a second case, a man had had an apparently typical epithelioma of the lip which disappeared. Later the submaxillary glands became enlarged and were removed. Microscopic examination showed the growth to be carcinomatous.

The following officers were elected for the ensuing year: President, Roswell Park, of Buffalo; First Vice-President, John E. Owens, of Chicago; Second Vice-President, Clayton Parkhill, of Denver; Secretary, Herbert L. Burrell, of Boston; Treasurer, G. R. Fowler, of Brooklyn; Recorder, De Forest Willard, of Philadelphia; Member of the Council, Robert F. Weir, of New York; Members on Committee of Arrangements, W. S. Halsted, of Baltimore, and W. J. Mayo, of Rochester, Minn. Next annual meeting to be held in Baltimore, May 7, 8 and 9, 1901.

Recent Literature.

The Irrigation Treatment of Gonorrhoea, its Local Complications and Sequela. By FERD C VAL-
ENTINE, M.D. Profusely illustrated. New York:
William Wood & Co.

This book of 212 pages and a carefully prepared index, is written for the instruction of the general practitioner of medicine, by a man whose knowledge of and experience in the treatment of gonorrhoea make his opinions of value. The ground covered by the author is considerably greater than the title of the book indicates, for the subjects of acute and chronic gonorrhoea are considered at some length and always from a most practical point of view. The irrigation treatment, with which the author's name is so prominently associated, is, as one would expect, given great prominence in the consideration of various methods of treatment, and it is described with the greatest care and attention to the smallest details. Short chapters on The Proofs of Cure of Gonorrhoea, and The Marriage of Gonorrhoeics bring to an end a most concise summary of the present-day knowledge of the disease. If one had a criticism to offer it would be that certain methods of treatment, notably treatment by the aid of urethroscopy, are so simply and practically described as to unduly encourage their use by men of inadequate skill and experience. The book is attractively printed and the illustrations are numerous and adequate.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 7, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to .

DAMRELL, & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE TWENTY-EIGHTH ANNUAL REPORT OF THE LOCAL GOVERNMENT BOARD OF ENGLAND (1898-99); SUPPLEMENT. REPORT OF THE MEDICAL OFFICER.

THIS report embraces the operations of the Medical Department of the Local Government Board of England (practically the general Board of Health) and contains much matter of interest to physicians and to sanitary authorities.

The report contains the latest digest of the vaccination returns of England, those of 1896, which shows that out of 914,205 births registered in that year, after deducting those who had died during the year, and others whose vaccination had been postponed by medical certificate, there still remained 25.6 per cent. who were unaccounted for. The percentage in London unaccounted for was 26.4 and that of the rest of England was 22.3. These percentages were larger than those of any previous year since records were begun in 1872, having increased from 8.8 per cent. in London to 26.4 per cent., and from 4.5 per cent. in the rest of England to 22.3 per cent. The report further states that 110,728 consecutive primary vaccinations had been performed under the Board's auspices, *without the occurrence of a single case of so-called insusceptibility.*

Under the amended vaccination acts of 1898, the Board was authorized to offer to vaccinate "with glycerinated calf lymph, or such other lymph as may be issued by the Board." The Board, therefore, established laboratories for the production of such lymph, appointing Dr. Frank R. Blaxall as bacteriologist with several assistants. The demand for this lymph proved to be in excess of the supply, the number of tubes issued in the first three months of 1899 being 126,038.

The operations of this establishment summarized were as follows: (1) The selection of healthy calves from three to six months old; (2) their supervision as to healthfulness; (3) vaccination of the calves and subsequent collection of the lymph at the animal vaccine establishment; (4) preparation of the glycerinated

emulsion; (5) testing of the emulsion by culture and otherwise to ensure its freedom from harmful organisms; (6) transference of the emulsion to capillary tubes; (7) compilation of the records received from public vaccinators. Each calf is slaughtered under supervision of a qualified veterinary surgeon. No lymph is sent out till a certificate has been received to the effect that the animal was healthy. In the first three months only one calf was found to be diseased, some tubercular lesions being found. None of the lymph of this animal was issued, although careful investigation failed to reveal any tubercle bacilli in it.

Several of the valuable appendices to the report contain the statements of medical inspectors relative to local inspections, hospital accommodation, sewage disposal, water supply, and the housing of the working classes.

The inspection of an unusual outbreak of measles at Burton-on-Trent, by Dr. Theodore Thomson, gave rise to the following comments of the Board:

"In order to successfully control measles in a borough of this description, where children suffering from the early stages of and incubating that disease are constantly liable to come into contact, the measures that are most likely to avail are isolation in hospital of the children first attacked, and the strict exclusion from school of all children living in houses where the disease prevails, to be followed, if need be, by actual closure of the schools. To attain the desired end with the least interference with the system of elementary education, it is as necessary for the school officials daily to seek the required information from their scholars and to transmit it to the sanitary officers as it is for the sanitary officers to transmit to the school officials information gained from the notification returns. And, above all, the time when these measures have most chance of success is at the very onset of the outbreak. Indeed, not only can no sanitary authority be expected to maintain in readiness means of isolation for more than a limited number of cases of measles, but the value of hospital isolation for preventing the extension of this disease is generally limited to quite the initial period of an outbreak."

A considerable part of the volume is occupied with reports of inspection of distant parts of the British Empire invaded by the plague and of the measures taken to prevent its entrance into England. These measures are summarized by the Board as follows:

"Briefly stated, the system adopted in this country in such cases is the medical examination of all persons on board; the removal to hospital of any person either suffering from plague or suspected to be so suffering; the disinfection of articles believed to have had opportunity of becoming infected, and of those portions of the vessel occupied by the sick; the registering on board of the names and addresses of all the remaining persons, including the crew, such persons being then free to leave the ship and to go to the addresses given; and lastly, the transmission to the sanitary authorities of the names and places of residence of

persons leaving the vessel for their respective districts, with a view to such persons being maintained under supervision of the medical officer of health during the ten days which have been determined on as representing, in so far as administrative purposes are concerned, the period of incubation of plague. The system embodied in these measures is that which England has now for a long period adopted with regard to exotic diseases; it aims at arresting at our ports actual cases of foreign disease, plague, cholera and yellow fever, and of securing the disinfection of articles which may reasonably be held to have incurred risk of infection. For the rest it imposes no restrictions on either individuals or articles imported; but it relies on the internal sanitary administration of the country to control at the onset any infection which may perchance evade the precautions adopted at our ports. Thus far it has been singularly successful, as regards all the three diseases to which it has been applied, and the responsibility which devolves under it on local sanitary authorities so to organize their local public health departments that they shall be always prepared effectually to deal with any chance infection which may reach them from abroad has had the inestimable advantage of helping to secure at the same time a standard of health at home which has resulted in an immense saving of life."

With reference to the part played by merchandise in the transmission of infection, the Board continues as follows: "Some nations and persons have, in sheer panic, attempted to impose almost universal prohibition on the importation of all articles from countries where plague prevails; and in their most pronounced form these attempts have, in so far as the interests of this country are concerned, culminated in occasional suggestions to prohibit the export of grain from plague-infected ports, or to destroy cargoes of grain, such as corn and rice, when carried by a vessel on which one or more cases of plague have occurred. With regard to such proposals, I have taken the responsibility of advising that no prohibition either as to exportation or importation, under the circumstances referred to, was called for; and further, that no futile attempts at the disinfection of cargoes such as those of grain were justifiable, except in so far as the local medical officer of health had evidence that any individual sack or sacks of grain had had opportunity of becoming infected, or afforded indication of having been soiled by, or of having been eaten into by rats whose dead bodies gave evidence of the occurrence of the disease in them. Thus far, my action, which has often been followed by the use for food of the cargoes concerned, has been fully justified by the results.

In taking this attitude as regards the importation and exportation of articles of commerce in general, I have been influenced by the following considerations: *Firstly*, as regards grain cargoes, there is an absence of anything that can be regarded as evidence to show that plague is communicable to man by means of an article of diet, and there is, further, evidence

which goes to show that even when grain is purposely infected with the plague bacillus, that organism dies in a few days when the grain is dry, as when packed for transit. *Secondly*, there is overwhelming evidence to the effect that cargoes from infected vessels have failed to communicate the infection of plague, even under circumstances when nearly every condition present seemed to favor such communication."

He further cites the fact that in 1835 plague prevailed as an epidemic among the employes of every grade who were engaged in the warehouses of the Egyptian Government. Notwithstanding this, bales of cotton handled by these laborers were transmitted to the principal ports of Europe to the number of nearly 100,000 bales, without a single case of plague resulting. No precautions whatever were taken by way of disinfection.

"Having regard," the medical officer continues, "to our present knowledge concerning the etiology of bubonic plague, I feel justified in holding the view that, in so far as danger of the introduction of that disease into this country is concerned, the first and most important point to be held in view in our port sanitary administration is such strict medical inspection of persons arriving from infected countries as shall go to secure the detection and immediate isolation of those mild attacks which are mainly identified with slight or indolent bubonic enlargements and indications of general malaise. Next to this, and always to be observed, is the disinfection of all articles of clothing, etc., which have had opportunity of becoming infected, either before they were packed for the journey or since. *Thirdly*, comes the disinfection of those portions of the vessel which may have been used by patients suffering from or suspected to have had the plague. And, lastly, measures should be adopted to prevent the conveyance of the disease to the shore from an infected ship by means of rats, which are peculiarly susceptible to the plague infection.

"But no system of inspection or other restriction is perfect, and hence, for the rest, we must trust to such local sanitary administration of our towns, villages and hamlets as will deprive a disease such as plague of the means of diffusing itself should a chance case make its way inland."

HOSPITAL STATISTICS.

WE have from time to time taken occasion to allude to and criticise the disease statistics commonly published in hospital reports. Statistics at best are proverbially fallacious, and it is clear to one reading over the lists of diseases as they occur in the various departments of a large hospital and are finally published in the hospital reports that the standard of classification is usually wholly vague, that no proper distinction is made between disease processes and prominent symptoms, and that diseases are not, as a rule, properly grouped. The result of this is the narration of a

series of conditions which lack statistical value because of the arbitrary and fortuitous way in which they are classified. It must, however, be recognized and admitted that owing to the fact that many so-called diseases are known only by their prominent symptom, and that our knowledge is on many sides incomplete, a scientific classification is a matter of great difficulty. The question at once arises, for instance, as to whether we shall classify by etiology or by pathological anatomy or by symptomatology. If we look over a hospital report we usually find that no one of these methods is exclusively used. We speak now of tuberculosis and not of phthisis, of nephritis rather than Bright's disease, of appendicitis rather than of the various inflammatory affections of that region which used to confuse the nomenclature. As our knowledge advances on the etiological and pathological side we are able to classify with more and more accuracy. There is, however, a great field where no such accurate knowledge exists, and then we fall into the error of classifying merely by symptoms, and giving to certain symptoms, for example, hemorrhage, hemiplegia, vertigo, a significance which in no way belongs to them. The inevitable result is a confusion and repetition under different names, which does little toward making statistics of value.

The faults, therefore, which we find in hospital case statistics are inherent in the nature of the subject and are certainly not peculiar to any one institution. In editorial comment on the last report of the Boston City Hospital we said in part, in our issue of September 21, 1899: "In the report before us, we find in one place apoplexy, cerebral hemorrhage and hemiplegia classed as separate diseases; in another we see multiple sclerosis and disseminated sclerosis given as distinct from one another. Under unclassified gynecological diseases are named the following conditions: Bursitis, caries of vesicle, debility, hepatic colic, infaney. Under surgical diseases, among many others equally extraordinary, are apoplexy, hysteria, delirium tremens, premature birth, general paralysis. Since so much work is necessarily put upon this portion of hospital reports in general, it is unfortunate that a classification is not agreed upon by the various departments, that some sort of order may be brought out of the chaos, and such statistics rendered really serviceable. We simply take this report as an example of an almost universal failing."

In a more recent review of the last Massachusetts General Hospital report, we said in speaking of the disease statistics: "The diseases are not carefully tabulated and are of small value as statistics or for purposes of reference. Dementia, neurasthenia and hysteria, for example, are classified as surgical diseases, as is also miscarriage. As we have before had occasion to say, such statistics are worthless unless prepared with scrupulous care. The difficulty seems inherent in the system, and is by no means peculiar to the Massachusetts Hospital." Certain persons have felt that some of the foregoing assertions are unjust,

that such statistics are not useless, and that the tabulation is far better than we were inclined to allow. That they have a certain interest to those wishing to get a general outline of the amount of work done at a hospital we are quite willing to admit, but we are equally sure that it is unjustifiable to regard any statistics of value, as statistics, which do not strictly conform to some fixed standard of classification. A reform of some sort is definitely needed, and as a suggestion we should say that the value of such tabulations will be in proportion to the simplicity of the classification. In the second place, it is highly desirable that a somewhat uniform system be adopted in our large institutions, to the end that comparisons of accuracy may be made. The over-refinement of detail which is so conspicuous a feature of the ordinary tables should be abolished to give place to a rational system which will at least have the merit of being logical and correct as far as it goes. We find precisely the opposite tendency in the long-drawn-out narration of minor symptoms, masquerading as diseases, which have no claim to be regarded as disease processes and which can fill no logical place in a rational system of classification designed to be of statistical value. We plead merely for a simple and logical method of tabulation based on what knowledge we have of disease. If this could be done, this portion of the conventional hospital report would be converted to a useful end.

MEDICAL NOTES.

AMERICAN NURSES IN PARIS.—Physicians having patients who are to visit Paris this summer may be interested to know that a number of American graduate nurses may be obtained in that city. They are graduates of St. Luke's and the Presbyterian Hospitals of New York, and are women of experience and character. They are under the charge of Mrs. Emma Keith Borth, 102 Rue Vangirard, who refers to some of the most prominent physicians of New York.

RECEPTION BY THE MEDICAL CLUB OF PHILADELPHIA.—The Medical Club of Philadelphia will hold a reception at the Hotel Bellevue on Saturday evening, June 9th, in honor of Drs. Abraham Jacobi, of New York, Alonzo Garcelon, of Maine, George H. Simmons, Secretary of the American Medical Association, James Morrison Bodine, of Louisville, Frank Billings, of Chicago, and the President-elect of the American Medical Association.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, June 6, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 80, scarlatina 54, measles 91, typhoid fever 21.

NEW YORK.

"EFFECT OF SUMMER HEAT UPON THE PUBLIC HEALTH."—On May 28th, Dr. Henry D. Chapin

read a paper on "The Effect of Summer Heat upon the Public Health." In the course of it he remarked, "It is estimated that there are 146,600 children under the age of three years now living in the Boroughs of Manhattan and the Bronx. This immense number subsists principally upon milk. Recent studies show that if cow's milk can be properly cooled, it will keep a considerable time, and this is much better than relying too largely upon superheating. Here is where the subject of ice comes properly under the physician's notice. Any difficulty in the free procuring of ice by the poor during the heated months, whether from a natural scarcity of that article or from a cornering of it by commercial greed, is a public calamity." In the discussion of the paper Dr. A. Jacobi also attacked the ice trust, saying, "Commercial enterprise should not be disturbed, but when it goes to the length of destroying life, some check ought to be put to it. We punish men for erecting bad buildings, and when a wall tumbles down and kills a person a great hue and cry is raised, and new and more stringent laws are made. When commercial enterprise is sure to kill thousands of children and adults, should it not be interfered with? Physicians should certainly take a lively interest in this matter."

A DEATH FROM SCALDING AT AN INSANE HOSPITAL.—Kate Donnelly, a patient in the female department of the Manhattan State Hospital for the Insane on Ward's Island, was recently scalded to death by another patient, Mary Brennan. It seems that two of the attendants carried the former to a bathroom and placed her in the tub, and while they were bending over the tub the Brennan woman, who has a mania for playing with water, entered and turned on the hot-water faucet. To preclude the possibility of patients handling the faucets themselves while bathing, the water is turned on and off by an arrangement several feet distant from the tub, and it was thus that the precaution taken to guard the patient proved the very means of disaster in this case. The instant that the hot water was turned on one of the attendants started to turn off the faucet and the other to secure the Brennan woman, but in the meanwhile the helpless patient in the tub was so severely scalded that the injuries resulted in death. The two attendants, who were students in the junior class of the Training School for Nurses, have since been discharged.

BASKET BALL AMONG THE INSANE.—At the women's games on the grounds of the Manhattan State Hospital for the Insane at Ward's Island on Memorial Day, which were refereed by Dr. Archibald Campbell, a spirited basket-ball match was played by a team of "chronics," dressed in brown, and one of "acutes," in blue. Over eight hundred patients, seated on two sides of the lawn, watched the contest with intense interest.

MEETING OF NATIONAL VOLUNTEER EMERGENCY SERVICE MEDICAL CORPS.—The first meeting of the founders of the "National Volunteer Emergency

Service Medical Corps," was held on June 2d. The purposes and plan of organization of this new body, the design of which is to provide prompt and efficient medical or surgical service, with skilled nursing, in case of sudden war, riots, epidemics or public disasters of any kind, are to be fully explained by its originator, Dr. J. Adelphi Gottlieb, of New York, in a paper before the Section on State Medicine of the American Medical Association at the Atlantic City meeting.

RECREATION PIERS. — The six recreation piers of Manhattan, three on the Hudson and three on the East River, were thrown open for the season on May 26th, and on May 28th a new one on the East River, in front of Williamsburgh, Borough of Brooklyn, was opened with appropriate ceremonies. On June 1st the new Hamilton Fish Park, a small East-Side park on Houston Street, was opened in the presence of nearly ten thousand children of the tenements. It contains an ample playground, a gymnasium, a bathing-house, and two fountains.

A CENTENARIAN. — Mrs. Hannah Kennedy died at her home on Columbus Avenue on June 1st, at the age of one hundred and one years. She was born in Ireland and came to this country after the death of her husband, thirty-seven years ago. She leaves six children, seventeen grandchildren and five great-grandchildren.

Miscellany.

MEETING OF THE ASSOCIATION OF MILITARY SURGEONS.

THE ninth annual meeting of the Association of Military Surgeons of the United States was held at the New York Academy of Medicine on May 31st and June 1st and 2d, with Col. Charles H. Alden, Assistant Surgeon, U. S. A., presiding. The following officers were elected for the ensuing year: President, Brig.-Gen. A. J. Stone, Minnesota; First Vice-President, Medical Inspector John C. Wise, Washington, D. C.; Second Vice-President, Brig.-Gen. J. F. Calef, Connecticut; Secretary, Lieut.-Col. Charles Adams, Illinois; Treasurer, Lieut. Herbert A. Arnold, Pennsylvania. In his annual address, the President stated that over one hundred and fifty members of the Association, nearly one-half its active membership, were selected for commissions in the United States or volunteer services during the Spanish-American War. This war, he said, has already had the effect of attracting attention to the need of our National Guard and the importance of a more intimate union between the United States and the State military forces. The present Congress, he believed, would provide more liberally than formerly for the needs of the State military, and further steps would probably soon be taken to unify the military resources of the nation. At the conclusion of the address a committee was appointed to take steps towards the establishment of a military medical journal. It consisted of the following members: Drs. A. J. Stone, Charles Adams, W. C. Borden, C. P.

Wertenbaker and John C. Wise. Colonel Griffith then announced that the gold medal offered by Dr. Eno Sander, of St. Louis, for the best essay on "Military Surgery," had been won by Capt. W. C. Borden, Assistant Surgeon, U. S. A., Washington, D. C.

In a paper on "What Should be the Standard of Vision Required of Enlisted Men in the United States Army?" Dr. Myles Standish called attention to the fact that in European countries enlisted men are permitted to wear glasses, while they are not in the United States. In a great many instances he thought an injustice was done to applicants for admission both to the army and to West Point, who were rejected without adequate reason. In a paper on "Field Work in the Philippines," Dr. F. W. Kemp stated that, in his experience, nine-tenths of the deaths on the field of battle were the result of wounds which are not necessarily fatal if the flow of blood is stopped at once. For this reason he regarded the first-aid packet as of incalculable value, and he urged a thorough instruction of officers and men in first aid. He also advocated the employment of Chinamen as litter-bearers, instead of Americans, in tropical countries; stating that he had used them for this purpose in the Philippines, and had found them absolutely tireless and totally without fear under fire. In a paper on "The Utilization of Native Troops in Colonial Possessions," Dr. L. L. Seaman also advocated the use of the Chinese. Among their recommendations as soldiers were, first, their temperance, and, second, their cheapness. The Chinese soldiers cost Great Britain about five dollars in gold per month, this amount including both pay and rations. In the Philippines, he said, there are at present twenty-five regiments of volunteers whose term of service expires in June, 1901, and he recommended that as the ranks of these regiments become depleted the battalions be reformed so that there will be in each regiment two battalions of Americans and one battalion of Chinese or Filipinos, the full complement of American officers being retained. Among the other papers read and discussed were the following: "The Value of the Schumburg Method of Purification of Water for Military Purposes," by Dr. J. H. Huddleston, of New York; "Method of Transportation of Wounded on Ships of War," by Dr. John C. Wise, U. S. N.; and "The Management of Quarantinable Diseases and Cordons," by Dr. C. P. Wertenbaker, of the U. S. Marine-Hospital Service. The annual dinner of the Association was held at the Murray Hill Hotel on the evening of June 1st.

DEATH CERTIFICATES IN RURAL DISTRICTS.

THE town clerks in the rural districts of the State of Massachusetts are undoubtedly not responsible for all the statements as to the cause of death which they annually publish in the reports of their respective bailiwicks. Bad spelling and bad chirography are not confined to prescription writing. Certificates of death come in for their share, and when State documents continue to be crammed with errors it is hardly reasonable to expect more of town reports.

The following curiosities are to be found in the reports of a dozen town officials in their reports of 1899, as causes of death: Intra menruged hemorrhage, athenna, focal impostin, cataubalis epidemicus, mul-

tiple garamati, embalesue, septic endocentitis, osteo myelitis of ilicium, puerfural eclanprice, intescrantal tumor, condylamotor, chronic cyndocarolitis, iliacutitis, hypithiticial suicide, spina befoilo.

Obituary.

E. O. SHAKESPEARE, M.D.

DR. E. O. SHAKESPEARE, of Philadelphia, died suddenly June 1st at the age of fifty-four. He studied medicine at the University of Pennsylvania and was graduated from that institution in 1869. He was later connected with the Medical Department of the University as assistant at the Eye Clinic and Lecturer on Operative Eye Surgery. He was also during his life, president of the Pathological Society of Philadelphia, pathological and ophthalmic surgeon to the Philadelphia Hospital, a member of the College of Physicians of Philadelphia, of the American Medical Association and was president of the Section of Pathology in the International Medical Congress.

In 1855 he was commissioned by President Cleveland to investigate Asiatic cholera in Europe and India, and he spent a year in that work. During the war with Spain, Dr. Shakespeare was appointed a brigade-surgeon, with the rank of major of volunteers, and at the time of his death he was acting as a member of the commission attached to the office of the Surgeon-General at Washington to investigate the causes of typhoid fever in the United States Army.

cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 471, acute lung diseases 265, consumption 254, diphtheria and croup 68, diarrheal diseases 36, scarlet fever 16, whooping-cough 20, cerebrospinal meningitis 17, typhoid fever 13, erysipelas 13.

From whooping-cough New York 14, Baltimore, Providence, Charleston, Springfield, Holyoke and Salem 1 each. From cerebrospinal meningitis New York 7, Baltimore and Lynn 2 each, Boston, Washington, Worcester, New Bedford, Somerville and Chicopee 1 each. From scarlet fever New York 10, Boston 3, Pittsburg 2, Newton 1. From typhoid fever New York 6, Pittsburg 2, Boston, Baltimore, Washington, Providence e and Newton 1 each. From erysipelas New York 11, Baltimore and Medford 1 each.

METEOROLOGICAL RECORD

For the week ending May 26th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

SOCIETY NOTICE.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The annual meeting will be held on Tuesday, June 12th, at 12 o'clock m., at the Medical Library, 19 Boylston Place, Boston.

The following papers will be read: "Autopsies and Physical Examinations," by District Attorney R. O. Harris.

"The Coroner System in the United States at the Close of the 19th Century," by Dr. S. W. Abbott.

The members of the medical profession are cordially invited.
JULIAN A. MEAD, M.D., Secretary.

RECENT DEATH.

WILLIAM HENRY O'HEARN, M.D., M.M.S.S., died in Lawrence, June 4, 1900, aged thirty years.

BOOKS AND PAMPHLETS RECEIVED.

The Clinical Examination of Urine, with an Atlas of Urinary Deposits, including Forty-one Original Plates, mostly Colored. By Lindley Scott, M.A., M.D. Philadelphia: P. Blakiston's Son & Co. 1900.

A Text-Book of the Medical Treatment of Diseases and Symptoms. By Nestor Tirard, M.D. (Lond.), F.R.C.P. Adapted to the United States Pharmacopoeia by E. Quin Thornton, M.D. Philadelphia: Lea Brothers & Co. 1900.

A Memoir and Works of Henry Jacob Bigelow, A.M., M.D., LL.D., Member of the Massachusetts Medical Society, Emeritus Professor of Surgery in Harvard University, etc., and Foreign Honorary Member of Clinical Society of London, etc.

Surgical Anesthesia; Addresses and other Papers. Orthopedic Surgery and other Medical Papers. I. The Mechanism of Dislocations and Fracture of the Hip. II. Litholapaxy; or, Rapid Lithotomy, with Evacuation. Boston: Little, Brown & Co. 1900.

Cholangiostomy: Two Cases Recovering. Case History and Photograph. Eleven Cases of Castration and their Histories. Ovarian Pregnancy; Report of a Case at Full Term. By B. Merrill Ricketts, Ph.B., M.D., Cincinnati, O. Reprints. 1899-1900.

Annual and Analytical Cyclopedia of Practical Medicine. By Charles E. de M. Sajous, M.D., and one hundred Associate Editors, assisted by Corresponding Editors, Collaborators and Correspondents. Illustrated. Vol. V. Philadelphia, New York and Chicago: F. A. Davis Co. 1900.

Address.

REALISM IN MEDICINE.¹

BY A. T. CABOT, A.M., M.D., BOSTON,
Surgeon to the Massachusetts General Hospital.

MR. PRESIDENT AND FELLOWS OF THE MASSACHUSETTS MEDICAL SOCIETY:—When I received the compliment of an invitation to address you to-day I first thought that here was an opportunity to present some surgical subject that would have a general interest. Before I had settled on a theme, however, I remembered that this was the year 1900, and I felt that it would be plainly unfitting, at our last meeting in the nineteenth century, to ask you to confine your thoughts to any narrow field of research. For we are just finishing the hundred years in which medicine and medical study have done more for the world than had been accomplished by the disciples of Esculapius in all previous time.

Wallace, in his recent book entitled "The Wonderful Century," draws a striking comparison between the achievements of human endeavor in the nineteenth century and in all preceding ages. He takes account of the discoveries which have been of sufficient weight to turn the current of thought or to profoundly modify the lives of men. In parallel columns he places these lists of notable events; on one side those which preceded the year 1800, and on the other those which followed it. Certainly he is justified in calling this a wonderful century, for twenty-four important discoveries are credited to it, while he has found but fifteen discoveries of similar magnitude in all past time.

However we may differ with Wallace in some of his estimates, we must agree, I think, that this comparison is substantially a fair one, and must recognize that, measured by such tests as we can apply, the world and the conditions of life upon it have been more altered by man in the past century than in all time that had gone before.

In no realm of human thought has this recent advance been more rapid than in that of medicine, and in none other has it been of such wide and lasting benefit to humanity.

When we name surgical anesthesia, cellular physiology and pathology, antiseptic surgery, and the germ theory of disease, we have an array of gifts for which the human race may well feel grateful to the medical men of the nineteenth century. Looking back through all past time, we find that in the seventeenth century Harvey discovered the circulation of the blood, and that in the eighteenth century Jenner introduced vaccination. Here the list of medical contributions of the first rank ends, four in the present, two in all past centuries. And of these two, vaccination, while working great good, did not admit of scientific explanation or understanding until the investigations arising out of the germ theory opened our eyes to the significance of acquired immunity.

It would be manifestly impossible in the time at our disposal to review in any detail the progress of medical science in the three generations just past, and I do not mean to task your patience with an attempt at such recital. But I think it may be well worth our while to take note of the discoveries which mark epochs

in medical progress and which have occurred within the memory of many of those here present. A consideration of the direction of the research or study which led to them may help us to draw from them lessons, or deduce from them curves of thought which will guide us along the best lines in the century that we are just entering.

A brief consideration of the history of medicine shows that it may, for purposes of study, be divided into two periods. Of these the first is that long period from the birth of known time up to the beginning of this century, during which idealism prevailed and theory succeeded theory only to be in its turn superseded by some newer invention of a more ingenious thinker. The second period is that of realism, in which theories are not allowed to stand unless they can be shown to rest on demonstrable facts. It is not claimed that this, the inductive method, had not been used in medicine prior to the present century. Far from it, for the two already mentioned achievements of the past, namely, the discovery of the circulation of the blood and vaccination, were both obtained by men following realistic methods, searching for facts and basing their theories on these facts only after they had been thoroughly tested.

It can be fairly asserted, however, that it is only within the past hundred years that inductive reasoning has become the prevailing influence in medicine, and that abstract ideas have come to be discredited. Now and then, even in the remotest times, men who were born observers attained some insight into the realities of things. Such men often solved the practical difficulties that were presented to them in the best manner and introduced rational methods of treatment which did much to keep medicine out of disrepute during that long period when error masqueraded in the cloak of philosophy. The questions that were intelligently handled in those early times were mostly anatomical or surgical, and dealt with the visible or easily accessible parts of the body. The moment that obscure functions or the hidden causes of disease came under discussion, then the all-pervading idealism resumed its sway and the wildest speculation and theorizing prevailed.

Thus at the time when surgeons met the serious difficulties of an operation for stone in the bladder in a rational and enlightened manner, their medical brethren were treating pneumonia, typhoid fever and other diseases that taxed the endurance of their patients to the utmost, by bleeding and other methods of depletion, which still further reduced the strength so greatly needed.

It is true then of all time that medicine has owed its successes to its use of inductive methods. It has reached lasting results only when it has rested its theories on accurately observed facts. We recognize the human senses as being, on the whole, reliable observers, worthy of acceptance as witnesses to the facts.

No one would for a moment deny that our senses are fallible and often deceived; but they are the only witnesses we have and we must make the best of them. They must not be easily trusted and their observations must be constantly verified by independent investigations. This constant re-examination and verification or disproof of work done has been a marked feature of medical progress in this century.

Louis, the great clinician, who was active at the time when idealism was losing its hold and realism

¹ The Annual Discourse read before the Massachusetts Medical Society, June 13, 1900.

was coming to the front, said: "As often as I have formed an *a priori* idea and had afterward opportunity to prove the facts, I have invariably found that my idea was false." Here is the testimony of an honest man, striving after the truth and forced to recognize the fallibility of the human mind when acting without the constant control of the observant senses.

The present, consistent and ever advancing progress of medicine toward a solid and enduring position among the arts and sciences of the world dates from the time when medical men came to Louis's way of thinking, and ceasing to be content with the so-called systems of medicine which had their origin in the minds of ingenious closet naturalists, sought to establish a foundation of fact for the superstructure of their thought.

It was then that they ceased to be animists, vitalists, Brunonians or animal magnetists and began to be scientific investigators, searching after the truth with the best powers of observation that nature had put at their disposal.

They were no longer content with the pleasing and fleeting shows of the imagination, but when they found a fact which kept its integrity through all the tests that their ingenuity could apply, they duly prized it and put it by, to use when they could make it applicable. Such tested facts and the beliefs founded on them were kept under constant scrutiny, and if an improved method of investigation was discovered, the previously trusted facts were re-examined and rejected if found wanting.

The scientific spirit is one of skepticism, hard to convince and very annoying to the intuitive thinker. But the nineteenth century has shown us that this patient piling of fact upon fact builds up structures of an interest and beauty before which the wildest dream of the idealist pales and with a quality of durability which is in strong contrast to the ever changing beliefs of the past.

The history of surgery affords, perhaps, as good an illustration as is possible of the triumph of the materialistic, the modern scientific method over the old idealism.

Who can tell us better the aspirations and hopes which seemed justified under the old régime than Ambroise Paré? No one better represents the high ideals of the surgical art in the past than he. In 1575 he said: "God is my witness, and men are not ignorant of it, that I have labored more than forty years to throw light on the art of surgery and bring it to perfection. And in this labor I have striven so hard to attain my end that the ancients have nought wherein to excel us, save the discovery of first principles; and posterity will not be able to surpass us (be it said without malice or offence), save by some additions such as are easily made to things already discovered."

To-day this prophecy sounds ludicrously short-sighted; yet it remained true for almost three centuries and forecast with considerable accuracy the course of surgery up to the time of the scientific upheaval which realism brought about. Could Paré come back to earth at this time, what joy he would take in the triumphs of modern surgery, for he loved his art truly and disinterestedly, and he would freely forgive the manner in which his prophecy has been belied. Not the least part of his pleasure would be in finding that with all the extraordinary advances that surgeons have made, they still hold fast to the ligatures that he

gave them for the control of hemorrhage. Paré was the great realist of that day. He delighted in close observation and dared to follow what he saw.

To trace a little in detail now the paths along which the modern advances have been made, we find that at the beginning of the century the human senses, while recognized as credible witnesses and depended upon in a measure for the investigation of truth, were found to lack the acuteness necessary for penetrating many of the secrets of nature; and human ingenuity began to be turned to efforts to assist the perceptions and to widen their scope.

The power of the eye had for a long time been increased by the use of lenses, and the wish to aid its penetration into the depths of the body led to the invention of the ophthalmoscope, the laryngoscope, the cystoscope and other combinations of mirrors and lenses which brought the various cavities of the body within the reach of direct observation. Efforts in this direction will not pause till man ceases to be an inquisitive animal. Every year sees improvement in all such methods of investigation and a consequent widening of our knowledge of the hollow organs. Finally, at the end of the century, the remarkable discovery of Röntgen has enabled the vision to penetrate and discover the secrets hid in solid tissues.

In the meantime, the sense of hearing was not neglected. Something was known of percussion in the seventeenth century and a rude auscultation of the borborygmi in the bowels had been practised before that; but the thorough and efficient use of these methods of diagnosis waited for Laennec, who, in the first half of this century, by his invention of the stethoscope, greatly aided the sense of hearing and opened the way for the modern practice of auscultation and percussion, which has reached such perfection that the relative positions of deeply lying organs can be accurately made out; and the lightest whisper in lung or artery is heard and understood.

Even the sense of touch has had its range of usefulness widened. For modern surgery affords so many opportunities for the correction of ideas gained through palpation that the accuracy of deductions drawn from what it is possible to feel has been greatly increased, and a modern abdominal or pelvic examination is as great an advance on the less assured methods of a century ago as are the modern means of locomotion over the old stage coach.

Extraordinary as have been these advances in the investigation of living conditions under the earnest and constant pressure of clinical workers, it is when we turn to regard what has been accomplished by the post-mortem study of tissues healthy and diseased that we approach that part of achievement in medicine which will make this century memorable.

Much had been done in the way of accurate observation of morbid conditions prior to the present century, but it was after the improved lenses of the modern microscope made possible the close study of the individual cells that medicine made the forward stride which placed it in the ranks of exact science. Many men contributed to this result; for with the awakening of interest in the objective study of medicine, the laboratories, where such existed, were thronged with eager investigators, and if the time served, many of these might be mentioned with honor and reverence, for they advanced nearly abreast into the newly opened regions of cellular pathology.

It is impossible, however, to speak of this movement without mentioning the name of Rudolph Virchow, who will ever be remembered as the one who stepped forward from the ranks and led this advance. I well remember my first impression of Virchow when I went to Berlin in 1876 to study in his laboratory. He was not at first sight an imposing figure, and one would not have picked him from a crowd as the foremost medical thinker of the time. Any sense of disappointment on this score was, however, soon dispelled when he was seen at work. If I had brought no other impression from my foreign study I should have felt amply rewarded by the opportunity of seeing that trained intellect, backed by unrivalled powers of observation, leading the way through the most complicated pathological problems and making that way so clear that we wondered we had not seen it for ourselves. His eye seemed to penetrate to the centre of the organ he was examining, and we students used to say it was as good as a No. 7 Hartnack objective. One might well feel that to have been associated with him was a liberal education in medicine.

The habit of verifying with the microscope appearances dimly seen with the naked eye, and studying out the cellular changes involved, laid the foundations of modern pathology. At the same time, the optical instrument makers were constantly improving the lenses and methods of illumination in the microscope, so that it was possible from year to year to get a more and more accurate idea of the cells and of the changes that occurred in them as the result of morbid processes. Embryology, too, threw much needed light on the life history of the cell and upon the characteristics of different tissues.

This patient work of investigation required for its proper prosecution institutions devoted to the scientific study of medical problems, and it also required adequate means for the support of the investigators. Such institutions and the necessary endowments hardly existed in this country until the last quarter of this century, so that the earlier American students who wished to be properly instructed in these higher methods of research were forced to go abroad to seek the opportunity. Especially in Germany, they found good laboratories and inspiring teachers, and they came back after their probation inoculated with the skeptical, investigating Tenon habit. Even if they were soon plugged in the everyday work of their profession, and found but little time for the further prosecution of purely scientific work, still this habit of inquiry and of constant scrutiny of conditions passing under their eyes clung to them, and was of the greatest service in their practice and in such study of their cases as they could make.

A man with his standard of work thus raised was no longer content with a name as the explanation of a set of symptoms, but felt driven to seek out and understand the morbid process which caused the observed phenomena, and, if possible, to learn the cause of that morbid process. He had thus ceased to be an empiric and had become a scientific practitioner of his art.

The arousing of this spirit throughout the medical world has been perhaps the best gift of this century to medicine. The establishment of the cellular histology and pathology marks one goal reached by this movement, which is pressing on with a still accelerating speed.

We now come to speak of the second great contribution which this scientific spirit has made to the century. I refer to the germ theory of disease. The manner in which this discovery was made and in which the facts thus far established have been reached is most encouraging, and awakens inspiring hope for the future. For it was not revealed by any flash of inspiration to a closet thinker, nor was it accidentally stumbled upon by an erratic investigator groping far ahead of his time. On the contrary, it came as the logical result of concerted human effort, stepping forward constantly from fact to fact. It was the most complete possible demonstration of the worth of this sort of study. There could be no more convincing proof of the value of laboratory work than this. When the cause of a disease is discovered by such investigation, and its authenticity is shown by its power to reproduce the same disease, we at once feel that we have here solid ground from which to start for further researches.

It was this achievement, perhaps, more than any other, that informed the world that at last medicine was ceasing to be merely an art, and was taking its place among the exact sciences.

We cannot speak of the germ theory without thinking of certain illustrious men. The names of Pasteur and of Lister will at once occur to you all. We must not forget, however, that long before Pasteur's discovery of the influence of micro-organisms in producing fermentations, important work had been done by Vogel, Davaine, Schulze, Chevreul and many others. It remained for Pasteur to so illuminate the facts that thenceforward no one could doubt that the minute organisms associated with putrefaction and other fermentative changes were really the cause of those changes, and not an accidental accompaniment or result of them.

Lister was deeply impressed by these discoveries. It had long been observed that subcutaneous injuries were quick to heal and followed a usually afebrile course, in marked contrast to the suppurations and fevers that accompanied the healing of open wounds. He was at once struck by the important bearing that Pasteur's discovery had upon this hitherto unexplained fact, and conceived the idea that the putrefaction produced in animal fluids by the action of organisms might be responsible for the unfavorable course of healing in wounds exposed to the air. To test the correctness of this hypothesis he devised means of excluding organisms from wounds. The success of his efforts in this direction compelled the attention of surgeons, and led by rapid steps through antiseptic to the aseptic surgery of the present day.

The discovery of this application of the germ theory threw the door wide open for the surgeon to enter safely into the inner recesses of the body, and to interest himself in the functions and disturbances of organs that had before been as sealed books to him.

The triumphs of the new surgery might well fill a discourse. It is with difficulty that I turn away from so fascinating a subject. To one whose surgical activity began with the introduction of antiseptic principles and who has grown up with the growth of modern surgery, it might well be forgiven if he dilated somewhat upon the triumphs of this golden age in which the power wielded by the surgeon has so wonderfully grown year by year. We are constantly urged forward by the encouragement, Be bold; be

bold, and but rarely are checked by the admonition, Be not too bold.

I cannot, however, allow myself the pleasure of such a digression, but must be content to point out that all this splendid achievement is one step in the onward progress of medical science, and that we owe it to the patient, plodding work of investigation that had gone before.

The interest of every laboratory, and indeed almost every microscope, was now turned to the scrutiny of fluids and tissues, for the purpose of discovering the individual organisms which caused each disturbance. One after another the bacilli, streptococci and staphylococci were ferreted out and classified, and with the aid of solid gelatine media, they were presently obtained in pure cultures and their individual characteristics were made demonstrable.

It was now found that special organisms produced special diseases with such certainty that in cases of doubt the detection of the microbe involved in a morbid process at once settled the character of that process. Thus a malignant pustule could be at once distinguished from an ordinary furuncle or carbuncle and the appropriate treatment could be adopted early.

In the presence of such exact knowledge the nomenclature of disease improved, and instead of speaking of erysipelas, lymphangitis or cellulitis, it now became usual to say, a streptococcus infection of such and such an extent. We ceased to use the terms scrofula or consumption, but began to speak of tuberculosis of this or that organ, and to demand a demonstration of the correctness of our diagnosis by the recognition of the bacilli.

These well-known instances of our changed conceptions of familiar diseases are selected as illustrations of the fundamental alteration of our habits of thought wrought by these newly learned facts.

The next natural step in the investigation of the action of micro-organisms within the body was the study of the effects of these organisms on the tissues and of the provisions that nature made to resist their deleterious action and to limit their growth. Considerable progress has been made in this research.

It has been shown that the blood serum has a certain amount of destructive power and that the white blood cells are active in the attack upon them. It has also been found, in the case of certain germs, that their growth in the body produces a future immunity of greater or less duration, and in the case of the Klebs-Löffler bacillus this immunity has been traced to the blood serum, which acquires, under the influence of the organisms, a positively antidotal power.

The action of the antitoxic serum obtained from horses treated with the diphtheritic poison is so well known to you all that it would be both superfluous and tedious to dwell upon it here. It is, however, perhaps the high-water mark reached by this modern investigation of disease. To learn the ultimate cause of a disease and then, by a study of this cause, to obtain the knowledge which enables us to meet and vanquish the morbid elements after they have obtained a foothold in the body, is certainly an achievement to be proud of.

It is natural that other organisms should have been studied with the object of discovering similar antitoxins. Efforts in this direction with the tetanus bacillus have yielded results that are decidedly hopeful.

And the organisms of relapsing fever, cholera, the plague and tuberculosis have also yielded sera which seem to have some power in either checking or protecting against the parent disease. These are results most encouraging in view of the comparatively short time during which investigations in this direction have been under way. Much, however, remains to be done.

I now wish to turn aside for a moment to speak of an achievement which has been of incalculable benefit to medicine and mankind, but which lay out of the line of the regular advance of scientific medicine and stands by itself as a gift made by empiricism. I allude to the discovery of surgical anesthesia. No consistent, experimental study preceded and led gradually up to the final triumph. To be sure, an unconsciousness which, if not too deep, could be recovered from had been produced by carbonic dioxide, and as early as the year 1800 it became known that nitrous oxide gas would produce a temporary unconsciousness to pain, but even this latter agent, which has since been shown to have some degree of efficiency, was at that time deemed so unsatisfactory that it attracted little attention.

At this time, when the world was unprepared for such good fortune, the knowledge of the anesthetic properties of sulphuric ether was given to Thomas G. Morton, a Boston dentist, who was without scientific training, but who was possessed of the idea that surgical anesthesia was possible and who, in his effort to compass it, was ready to take any hint that came to his ears as to an agent by which it might be obtained. His good luck led him to hear that sulphuric ether, when inhaled, produced a temporary unconsciousness. Knowing no more than this, ignorant of the possible dangers of the drug, he risked his reputation and future peace of mind by trying it. Had ether possessed dangerous qualities and caused the death of the first patient, or had that patient been so unfortunate as to die from asphyxia, a mishap that might well have happened with the then incomplete knowledge of proper methods of etherization, Morton would have probably gone to jail and later to a dishonored grave. He took those risks and Fortune smiled on the brave, albeit reckless, man. His was the venture and his is the honor.

Surgical anesthesia was thus discovered, as it were, by accident. It came as a revelation rather than as a result of consecutive steps leading to that goal.

It is interesting to notice, too, that it was revealed at the very time when experimentation upon animals was beginning to be necessary to medical research. It seems to have been pre-arranged that when man's development reached the point of needing to study the phenomena of life upon the living, then his intelligence should compass the relief of pain.

This discovery, as I have said, lay to one side of the line along which scientific medicine was advancing; but it has been of incalculable aid to that advance. How greatly the triumphs of aseptic surgery would have been curtailed if surgical anesthesia had not been attained. And in experimental medicine it has done far more than to alleviate the pain of necessary operations. Without it, many of the most important investigations would have been impossible. For the delicate dissections and manipulations necessary in physiological research could not have been made on animals conscious and struggling.

(To be continued.)

CLOSING STATEMENT FOR THE REMONSTRANTS TO THE MASSACHUSETTS HOUSE BILL NO. 917, ENTITLED "AN ACT FOR THE FURTHER PREVENTION OF CRUELTY TO ANIMALS," BEFORE THE JOINT COMMITTEE ON PROBATE AND INSOLVENCY, MARCH 15, 1900.

BY HAROLD C. ERNST, A.M., M.D., BOSTON,
Professor of Bacteriology in the Harvard Medical School; President of the Boston Society of Medical Sciences.

MR. CHAIRMAN AND GENTLEMEN OF THE COMMITTEE:—We are glad to hear the counsel for the petitioners acknowledge this morning that all the experts are on our side in this matter, for that is, of course, where we think they are, and I have to say for myself that I need so much more time for the "summing up" for the remonstrants than the petitioners will take, for the reason that there seems to be so much more to say on our side of this question.

In beginning what I have to say for the remonstrants to the bill before you, I should like to present for your consideration the following extract from one of the clearest writers of the day.¹

"The insidious growth of selfishness is a disease against which men should be most on their guard; but it is a grave though a common error to suppose that the unselfish instincts may be gratified without restraint. . ." (Page 41.) "The fatal vice of ill-considered benevolence is that it looks only to proximate and immediate results without considering either alternatives or distant and indirect consequences. A large and highly respectable form of benevolence is that connected with the animal world, and in England it is carried in some respects to a point which is unknown on the Continent. But what a strange form of compassion is that which long made it impossible to establish a Pasteur institution in England, obliging patients threatened with one of the most horrible diseases that can afflict mankind to go—as they are always ready to do—to Paris, in order to undergo a treatment which what is called the humane sentiment of Englishmen forbids them to receive at home! What a strange form of benevolence is that which, in a country where field sports are the habitual amusement of the higher ranks of society, denounces as criminal even the most carefully limited and supervised experiments on living animals, and would thus close the best hope of finding remedies for some of the worst forms of human suffering, the one sure method of testing the supposed remedies, which may be fatal or which may be of incalculable benefit to mankind!² . . .

"It is melancholy to observe how often sensitive women, who object to field sports, and who denounce all experiments on living animals, will be found supporting with perfect callousness fashions that are leading to the wholesale destruction of some of the most beautiful species of birds, and are in some cases dependent upon acts of very aggravated cruelty."

That we are obliged to fight against exaggerated statements will, I think, be evident to you from this, which is taken from the *New England Antivivisection Society Monthly*, October, 1899: "What is vivisection, and what can I do to help the crusade against it?"

Answer: Vivisection is the mutilating, cutting and burning of living animals; they are dissected, roasted, boiled and skinned, when alive and in full possession of their faculties. Nerves are dissected out, laid bare and connected with the poles of a powerful battery from which currents of electricity are passed over these nerves; this probably causes the greatest agony of which sentient beings are capable. At the present time, the only way to attack this horrible crime is by printing and circulating information so as to let the public know just what vivisection is, and how much it is done.

"The New England Antivivisection Society has been organized and incorporated for this purpose. In order to accomplish its object it must have money to pay its office rent, and for printing and postage; every additional member increases its influence, apart from the income from membership. At present it has several hundred members, and it wants to have several thousand before the end of another month" (a hope evidently disappointed, for at the hearing the treasurer testified that the membership of this Society was "several hundred"); "every dollar given aids the work directly; all of its officers serve without pay, a thing that can be said of no other society of its kind in this State; annual membership is five dollars; associate membership is one dollar, which does not give the right to vote; life membership is one hundred dollars. The New England Antivivisection Society opposes vivisection, (1) because the number of animals vivisectioned, with unknown and inconceivable agony to each one, is probably several thousand each day; (2) because anesthetics are very seldom efficiently used; (3) because the results of vivisection are as near to absolute worthlessness as it is easy to get, in fact cause great and absolute harm; (4) because, as recent revelations in the *Transcript* and other papers abundantly show, vivisectioners of prominence and supposed character are, almost without exception, untruthful, and cannot be relied upon to speak the truth about their own acts," and so on.

These statements are so positive, and if true would be so overwhelming, that it is hardly conceivable that they would have been put forth with no better evidence to support them than has been offered here, and of this evidence and by whom given I shall speak later.

At the outset it should be stated that vivisection includes *not* merely the dissection of anesthetized animals, but all the great series of inoculation experiments that have been mentioned to you—those made for purposes of diagnosis, for the preparation of toxins and antitoxins of various kinds, as well as for the purpose of securing further light on our knowledge of the causation of disease. As an illustration, it may be said that the passage of such a bill as is before you would prevent all studies upon bubonic plague, which is now threatening our shores.

To show that we are here voicing the sentiment of the medical and scientific workers of the country, as well as those of this State, I beg to present the following votes of the most important scientific bodies of the country.³ There are sixty-nine such societies here represented, and others have voted since that time, as did these, in opposition to the retributive legislation such as is here proposed.

² See also Seton-Thompson in the current *Century Magazine*.

³ Senate Document No. 31, 54th Congress, Second Session.

I am indebted for much of the next following legal statement to the report of the hearing held before the Legislature on this same subject four years ago:

"There are probably three things, Mr. Chairman, in regard to which you and your Committee wish to be satisfied: Whether vivisection is useful, productive of valuable results; whether there are abuses within this State which you ought to regulate; whether there is such secrecy in the practice of it that you cannot find out whether there are abuses or not. As to its usefulness, that is a matter of expert opinion. The medical profession is a very large one and contains men of all sorts of training and all sorts of opinions. It is possible to select, as the proposers of this bill have done, certain names of physicians who are opposed to vivisection — or who *were* opposed to it, for it is noticeable that almost all the opinions quoted are old opinions, not based on facts which correspond with the practice of vivisection as it exists to-day. Speaking generally, however, it is possible to say that the great consensus of medical opinion — trustworthy, authoritative opinion throughout the world — is in favor of vivisection, as productive of the very highest good, and as being actually indispensable to the progress of medicine. A few years ago, this question was submitted by the Government of Germany, through the Minister of Public Instruction at Berlin, to the universities. Among other questions asked was: Whether the Faculty considered vivisection an indispensable method of research, which medical science could not possibly give up without positive damage to itself. The University of Berlin, among others, answered the questions, and the Faculty were unanimous in their opinion that vivisection *is* indispensable to the progress of medical science, and that the renunciation of the practice would not only do positive damage, but would cause an absolute paralysis of medical science, and would bring about the annihilation of its further progress. The same questions were put to the other great universities in Germany, and they returned answers to the same effect.

"The second point is as to the existence of any abuses that this law can correct or influence in the slightest degree more than that already on the statute books, and we submit that there is no evidence of the existence of any. No such evidence has been submitted by the supporters of this bill as existing in this State, and we have had representatives of the men engaged in research upon animals here, from whom it has not been possible to gain any knowledge of such abuses; they have all testified, or would have testified if the specific question had been asked of them, that none such exists to their knowledge.

"Finally, as to the point of secrecy, there is no secrecy in the laboratories of any of the men who have testified here, and none in those of others, so far as we know. Any properly minded person can obtain admission to any one of these laboratories at any time, so far as a desire to conceal what is going on is concerned. It may of course be conceivable that at the time of application there may be some specially delicate operation in progress which might delay the freest admission for a few moments; and, of course, what goes on in the Medical School is not open to the promiscuous public and should not be, and properly so. An irresponsible person, coming there without credentials, and with the fixed purpose (although this might not be known) of obtaining evidence that

might be used to excite the public mind and cause agitation, should not be admitted; but nobody in the community who will take proper pains to be introduced, and who will come to the Medical School in an open manner, will be excluded."

I want to call the attention of the Committee to the present provision of the law, for if it is proposed to alter the law, it is pretty important to know what the law is now. We have⁴ a law against cruelty: "Whoever overloads, overdrives or overworks, or deprives of necessary sustenance, or cruelly beats or mutilates an animal, or procures this to be done to any animal; or having charge or being in custody of any animal, inflicts unnecessary cruelty upon it, etc., is punishable by imprisonment in a jail for a period not exceeding one year, or by a fine not exceeding two hundred and fifty dollars, or both" (a punishment more severe than expressed in the bill before you). "A corporation which violates this provision is punishable by fine and is responsible for the knowledge and acts of its agents or servants. Officers are authorized to arrest, without a warrant, persons who are suspected of being guilty of this act, and, finally, there is a most stringent and unusual provision to the effect that when a complaint is made to a court or magistrate, and when the complainant believes, and has reasonable cause for believing, that this law is being violated in any particular building or place, and the magistrate or court is satisfied that there is reasonable cause, he may issue a search warrant to search the building. There is, therefore, in Massachusetts a law, applicable to vivisection, of the most extreme kind, which would enable any person who could satisfy a court that he has reasonable cause to suspect that cruelty was being practised in a Massachusetts medical school, or elsewhere, to procure a search warrant to search the premises and discover the animal and the parties cruelly treating it, and to cause the arrest without a warrant of the persons who are suspected of practising the cruelty. There is also a later act, passed in 1894, which absolutely prohibits the practise of vivisection in all public schools in this Commonwealth, and prohibits the exhibition of the body of an animal on which vivisection has been practised; so that this agitation is directed, as indeed has already been practically acknowledged, against the professional schools, for vivisection is not practised in any other schools in this Commonwealth."

We are constantly hearing quoted in such agitations as the present Dr. Parvin's opinion in regard to the usefulness or not of the study of vivisection. So important has this opinion been thought that the American Humane Society has seen fit to print for distribution "excerpts" of the address, — italicizing here and there, — and these excerpts have been made use of in all agitations of the nature of this bill, but not with — what shall it be called? — a *quite fair* presentation of the author's statements; as, for example, in the pamphlet of the American Humane Society, page 15, we read: "Should the law restrict the performance of vivisection? I think it ought, chiefly as an expression of public sentiment and for moral effect."

But the publishers of this pamphlet do not give the remainder of this sentence, which in the original runs on as follows:

"For violations of its provisions could usually only be discovered by a system of espionage, by the employment of detectives, of spies and informers, utterly

⁴ Public Statutes, Chap. 207, paragraph 52.

alien to our system of government, and who are, as a rule, abominable."

Westcott⁵ says; "If we had depended upon the results of experiments on living animals for the introduction of chloroform or ether into surgical practice, we might never have had those blessings." In contrast to this, W. H. Welch,⁶ in his address on "The Influence of Anesthesia upon Medical Science," says; "The opponents of animal experimentation have endeavored to utilize for their purposes the alleged absence of experiments upon animals as the basis of this discovery. As a matter of fact, even leaving out of account the pioneer experiments upon animals by Humphrey Davy with nitrous oxide, the first successful trial of ether as a general anesthetic for human beings by Morton was preceded by his demonstration of the power of this agent to produce in dogs unconsciousness and insensibility to pain. It would be strange, indeed, if these striking results of experiments upon animals had no influence in inducing him to test their applicability to human beings. It must, however, be admitted that the production of anesthesia in man by inhalation of ether was not preceded by such numerous and properly conducted experiments on animals as were required to afford any adequate conception of its effects or its possibilities of danger." In other words, Dr. Morton took a very serious risk in his experiments at the Massachusetts General Hospital — without, as we should think to-day, having made the necessary preliminary experiments upon animals to fully study the effects of the agent he proposed to use.

We have been told here that the results of vivisection are useless in advancing our knowledge of disease. Such statements *can* be made only by those who are helplessly or wilfully ignorant of the facts, and as illustrations in point, I present to you these plates of the results of the treatment of cretinism with injections of thyroid extract, and the colored representations of the behavior of the diphtheritic membrane after the administration of diphtheria antitoxin; the latter can be seen any day of the year at the South Department of the Boston City Hospital. It seems to me, gentlemen, that the change represented in the condition of one such child as is pictured among the cretins is a justification for the work that we are defending.

One of the witnesses for the bill in one of his communications to the public press takes ground that I believe to have been quite unintentional. Because Dr. Joseph Winters, of New York, has not been in accord with the general feeling in regard to the specific nature and value of the antitoxin of diphtheria, his name has been used to give implied added weight to the assertions against the value of animal experimentation in medicine. The following letter of Dr. Winters will demonstrate that his name must be absolutely excluded from any arguments against this method of investigation in the future.

NEW YORK CITY, March 1, 1900.

MY DEAR DR. ERNST:—Your letter to Dr. Park has been referred to me by him. I cannot understand how my attitude on animal vivisection could have been called in question. Vivisection has done so much for localization of disease processes of the nerve centres that every well-read medical man must feel it imperative that he should favor this valuable guidance for the surgeon in the relief of diseases of the nervous system. But for ani-

mal vivisection there could never have been a Claude Bernard, a Charcot, a Ferrier, and hosts of others equally well known, and valuable workers in diseases of the nervous system. All that they have done for the medical profession and for mankind throughout the world has had as its basis the results of vivisection. In every department of medicine every well-trained clinical physician realizes the debt he owes to the writings of those who have so patiently conducted experiments on animals in the physiological laboratory. All they have done is a thankless task. Very few physicians there are in the world who would be willing to relinquish the fascinations of practical medicine for the thankless task of the experimental physiologist. It grieves me to think that the value of this work should be questioned by intelligent, thoughtful and rational people, where the enthusiastic antivivisectionists are to be classed. Would that they could realize how much their misguided efforts are interfering with the well-guided, humane efforts of the vivisectionist. It seems to me that the antivivisectionist should visit the laboratory of the vivisectionist, and see how humanely he conducts his work, before he raises his voice or takes his pen in hand. One visit to any well-directed laboratory would still his voice. Again, he should know that a large part of the success for the relief of the suffering of mankind by medical men is due to the discoveries made in the physiological laboratory by the vivisectionist. The most advanced of sympathetic practitioners of to-day would, I believe, relinquish that which is dearer to them than their own lives, namely, their efforts to relieve the sufferings of their fellow beings, were they deprived of the inspirations afforded them by the results of experiments on animals.

Excuse me, dear doctor, for this lengthy communication, but I am deeply grieved and chagrined that my name could be used by one who opposes the value to mankind of animal vivisection.

Sincerely yours,
JOSEPH E. WINTERS.

Certain representatives of the clergy and others who have experienced the benefits of the antitoxin of diphtheria have appeared before you to state their feelings in regard to the effectiveness of this treatment as it has appeared in their own experience, and with their testimony, the following letter should be submitted for your consideration:

OAK PARK, ILL., March 9, 1900.

MY DEAR DR. STONE:—I shrink, as I suppose every humane man does, from the infliction of needless pain upon any living creature. So far forth I hold with the most intense antivivisectionists. But I am persuaded that it is sometimes necessary to cause pain that pain may be prevented. I do not doubt that some vivisection has been performed with needless cruelty; on the other hand, I know some men who constantly perform it, and who are most tender-hearted, high-minded men. I favor such restrictions as put a check upon cruelty without restricting the progress of science.

I was often at the Medical School Laboratory four years ago when my children were sick with diphtheria, and saw much there and at the Boston City Hospital of the preparation and use of antitoxin. Just in proportion as I love my own children I am willing that certain guinea-pigs should be experimented upon if necessary for their sakes. I am not willing that a single guinea-pig should be tortured needlessly, but I want the man who takes the life of my child in hand to do no needless experimenting upon the child in order to save guinea-pigs. My own impression is that vivisection is sufficiently restricted in Massachusetts. If further restrictions are to be made, it ought to be done with the approval of the more intelligent physicians.

Yours very truly,
W. E. BARTON.

⁵ Boston Transcript, March 1, 1900.

⁶ The semi-centennial of anesthesia, Boston, 1897.

It has been said here that the antitoxin of diphtheria does no good, and when the statistics are quoted, the reply is that they are falsified, and that the percentage of mortality is brought down by adding cases that are not diphtheria, that are diphtheria *only* because the diphtheria bacillus is present in them without symptoms, or that moribund cases are excluded in making up the returns. The only place of convenient access that I know where a record is kept of cases treated with and without antitoxin of diphtheria is Lawrence, Mass., and I have here the mortality statistics of that city for the thirteen months from January 1, 1889, to February 1, 1900. The total cases of diphtheria there reported is 393. Of this number there were treated with diphtheria antitoxin 274, with a mortality of 10.2 per cent. There were 119 cases treated without antitoxin, with a mortality of 26 per cent. If antitoxin was accessible in these latter cases, a very serious responsibility lies on the shoulders of the physicians of those patients who were allowed to die without trying its beneficial effects.

The antitoxin of diphtheria is prepared by the injection of horses, and the use of their blood serum. The horses are bled at more or less frequent intervals, and that the treatment is not cruel may be seen by the photographs I present to you, which show that the animals are fat and healthy looking (having been used for the production of antitoxin for from two to four years, and constantly bled in that time), and by the assertions that I am able to make in regard to these animals, that the bleeding was not attended by any pain, as was constantly shown by the fact that they would eat from the hand while being bled, and that the trocar could be introduced in many cases without any restraint whatever, and never with more than a "twitch" lightly applied.

In their abstract of the bill before this Committee, the petitioners have summarized matters as follows:

RESTRICTIONS.

(1) "All experiments on living animals must be performed with a view to the advancement of knowledge by new discovery." This will prevent the daily application of methods of recognizing and preventing disease that have become matters of routine, such as the recognizing of hydrophobia, always made by inoculation experiments, and the preparation of vaccine virus, now always made upon calves, the preparation of the antitoxin of diphtheria, and other diseases attacking man and the animals themselves, or the utilization of any new discoveries that may be made in this direction, if indeed any are made under such a restrictive measure.

(2) "Any one performing an experiment must previously obtain a license from the Secretary of State." This is practically a prohibitory measure, for the bill requires that a license shall be obtained for each experiment, and no worker has the time to secure permission for each experiment he may be called upon to carry on, notably in the direction of diagnostic or curative procedures, which must be attended to at the time, and will not permit of delay (illustrated by Dr. Burrell's case of anthrax in his testimony).

(3) "All pain to the animal must be prevented by the use of chloroform or ether," which seems to us to be absurd, for it practically prevents the use of any other means for deadening pain, or any possibility of the discovery of any new agent for the suppression of

pain in the future, such as chlorotone, now being tried.

(4) "If pain is likely to continue after the effect of the chloroform or ether has ceased, the animal must be killed before recovering therefrom;" in other words, no physician is to be allowed to take advantage of what most of us are sure is the most certain means of helping his patient in diphtheria and other like diseases; no one anxious to help the cause of suffering humanity is to be allowed to do so except in the line of what can be accomplished in the course of an hour or two, and by what practically amount to anatomical studies.

(To be continued.)

THE MECHANICS OF LATERAL CURVATURE OF THE SPINE.¹

BY ROBERT W. LOVETT, M.D., BOSTON,
Assistant Surgeon to the Children's Hospital.

THE present paper is a preliminary one, and reports a series of observations made on the normal movements of the spine in the cadaver, and the living model, studied especially with reference to the mechanism of scoliosis. The subject is so extensive and the problems involved are so intricate that it is not possible for the writer to do more at present than to call attention to certain demonstrable facts and to certain deductions to be drawn from them.

It is a well-recognized fact that in lateral curvature of the spine, at least in cases of moderate grade, the lateral bending is associated with a twisting of the vertebrae in the long axis of the spine. To the latter phenomenon the word rotation is applied by common consent.

A large amount of literature has been accumulated in the attempt to explain the mechanism of scoliosis, especially to account for the existence of the rotation, but among the theories dealing with the subject there is no one wholly satisfactory. For the most part they are very complicated; they differ widely from each other, and no one meets with general acceptance. It is perhaps hardly worth while to enumerate them, as they may be found in such books as Hoffa and Lorenz.²

These theories have for the most part been formulated either from purely theoretical considerations or by reasoning back from the pathological changes found in more or less advanced cases. As neither of these methods has so far yielded satisfactory results, it may be advisable to turn to the study of the normal movements of the spine to see if in them is to be found any explanation of the phenomena observed in scoliosis.

Bradford's experiment.—One previous attempt has been made and published in this line of investigation by Bradford, who demonstrated that in the cadaver a rotary lateral curvature of the type seen in life might be produced by superincumbent weight coming obliquely upon the spinal column. This important experiment demonstrated that in the normal spine of the cadaver exist conditions capable of producing the phenomena found in scoliosis when super-

¹ Read before the American Orthopedic Association at Washington, May 1, 1900.

² Hoffa: *Lehrbuch der orth. Chir.*, 1898, p. 370; Lorenz: *Path. und Ther. der Seitl. Rueckgratverkrummungen*, 1886, p. 17.

incumbent weight falls obliquely upon the column.³ Some similar work on the cadaver was done by Dr. E. G. Brackett, but was never published.

The experiments described in the present paper were made by the writer during the past six months, in part at the Harvard Medical School by the courtesy of Prof. Thomas Dwight, to whose supervision and suggestions he is greatly indebted. The work was undertaken with a hope of contributing something to the present knowledge of the normal movements of the spine without especial reference to scoliosis, but early in the investigation certain phenomena bearing so closely on the causation of scoliosis were observed that the rest of the investigation was deferred and the time devoted wholly to the question of the causation of rotary lateral curvature. It is the hope of the writer to pursue the rest of the investigation at some future time.

Movements of spine. — The movements of the spine are generally accepted as being four in number:⁴

- (1) Flexion (forward bending).
- (2) Extension backward bending).
- (3) Lateral bending (side bending).
- (4) Torsion.

Although this classification is usually found in the books it has been often recognized that torsion is in some way associated with lateral bending. That lateral flexion probably does not exist as a pure movement has for some time been recognized by some if not all anatomists, and has been taught for some years by Professor Dwight. As long ago as 1844 Henry J. Bigelow⁵ wrote: "The principle of torsion is illustrated by bending a flat blade of grass or a flat, flexible stick in the direction of its width. The centre immediately rotates upon its longitudinal axis to bend flatwise in the direction of its thickness. In the same way the spine, laterally flexed, turns upon its vertical axis to yield in its shortest or anteroposterior diameter." Occasional references are found to the association of torsion with lateral flexion,⁶ but no definite recognition of the relation between the two seems to exist.

It is the purpose of this paper to show that lateral flexion and torsion of the spine are associated parts of one compound movement and that neither can exist without the other. That, however, in side bending from the flexed position the torsion is diametrically opposite from what it is in the extended position and that the spine follows the laws governing flexible rods in this regard.

(1) *Flexion* apparently exists as a pure forward movement and its amount varies greatly with the flexibility of the individual.

(2) *Extension* apparently exists as a pure backward movement and its amount varies greatly with the flexibility of the individual.

(3) *Lateral flexion* of the spine apparently does not exist as a pure movement. Something very like a pure lateral flexion is found experimentally in one position of the trunk, but owing to the complex conditions existing it is not possible to measure it with sufficient accuracy to say how pure the movement is

or with how much torsion it is associated. In general, lateral flexion in any position of the trunk is associated with torsion.

The cadavers used in these experiments were six in number and had previously been used in the dissecting-room. The sternum and contents of the chest and abdomen, as well as the arms and scapula, had been removed, as well as the abdominal and most of the back muscles.

Experiment, cadaver: Flexion. — If the pelvis of a normal cadaver is fixed in a vice and the upright spine flexed, and by a cord attached to the atlas pulled to the left side, a very marked torsion occurs through the whole column, and each vertebra appears to change its relation to the one below it, not only in the lateral movement that it makes, but by torsion around the long axis of the spine. And this torsion always occurs in one direction in flexion, the bodies of the vertebrae turning toward the convexity of the curve and the spinous process toward the concavity. Each vertebra twists upon the one below it in the long axis of the spine, the body turning in one direction and the spinous process in the other. In the cadavers experimented upon the torsion of the cervical vertebrae upon the last lumbar in side bending amounted to perhaps forty-five degrees in flexion. This torsion is slight in the lumbar region and marked in the dorsal region, especially between the fourth and twelfth dorsal vertebrae.

In the photograph (Fig. 1) thin boards are shown fastened to the chest and pelvis to mark the lateral plane of each, and hat pins were driven into the spinous processes of the first sacral, one of the lower dorsal, one of the upper dorsal, and one of the lower cervical vertebrae, to mark the anteroposterior axis of each vertebra. By having both of these modes of measurement at the same time, it may be shown that the variation of the boards corresponds to the torsion of the vertebrae — as represented by the pins driven into them.

Model: Flexion. — The same experiment was then made upon two models. Both were young women, professional models and markedly flexible; one had been upon the stage as a dancer, and the other kept herself flexible by exercises to enable her to take difficult poses without lameness. If the model bends forward and flexes her spine to the left the same phenomenon occurs that is seen in the cadaver. The spinous processes turn to the concavity of the curve; that is, to the left, which means that the vertebral bodies turn to the convexity and the right side of the chest becomes more prominent behind; that is, the rotation is backward on the convex side of the curve, as in the rotation of scoliosis. In the experiments the models were ignorant of the purpose of the experiment and were told to bend to the left without twisting.

Fig. 2 shows Model 1 with boards fastened to pelvis and chest in a similar position to that of the cadaver in Fig. 1. Fig. 3 shows Model 2 in the same position as that of the cadaver in Fig. 1 with cardboard indicators fastened over the spinous processes by sticking plaster. The rotation backward of the chest on the convexity of the curve may be seen in both Figs. 2 and 3.

In reply to a possible criticism of the experiment, that the scapulae, ribs and muscles cause an apparent rotation of the boards in the living model which does

not exist, it may be said that the direction of the boards and indicators have been shown to correspond to each other in the cadaver, and each one of these taken separately behaves in the model as it does in the cadaver. Moreover, the rotation of the spinous processes of the vertebrae in the live model can be easily appreciated by the fingers, showing that it is a real torsion and not an apparent one.

Lateral bending, then, in both cadaver and model in positions of marked flexion is accompanied by torsion, and this torsion is in this position always in one direction, and is of the same type as the rotation seen in scoliosis; that is, backward on the convexity of the curve, or, in other language, the bodies of the vertebrae turn toward the convexity of the lateral curve. Various attempts were made to reverse this torsion while making side bendings in the flexed position by pulling the vertebrae apart, pressing them together, etc., but in all cases in both cadaver and model the type of torsion described above persisted.

Cadaver: Extension.—If the spine of a cadaver is fixed in an upright position in a vice which clamps the sacrum, and if this spine is hyperextended (bent backward) and pulled to the left in this extended position by a cord attached to the atlas, a torsion takes place, but this torsion is exactly the reverse of the one occurring in the similar pull to the left made in the flexed position. The spinous processes rotate toward the concavity of the curve and the type of the rotation is the reverse of that usually seen in scoliosis in life (Fig. 4). This torsion occurs less in the lower dorsal and lumbar region than does the one described in speaking of flexion, and is located higher in the column. The method of observation was by boards and pins, as in the flexion experiment.

Model: Extension.—If, now, a model is asked to extend her spine and then to bend to the left, it is noticed that the board marking the lateral plane of the chest turns backward on the side of the concavity of the curve, which is the reverse of the condition found in side bending in flexed positions; that is, in the model the rotation of the vertebral bodies must be toward the side of the concavity. This type of torsion is constant in all side bendings in the extended positions as observed in models and in patients.

Fig. 5 shows the Model 1 bending to the left with backward rotation of the chest on the left side.

Fig. 6 shows Model 2 bending to the left in an extended position, with cardboard indicators fastened to the skin over the sacrum, the upper lumbar, the middle dorsal, and the lower cervical region. It will be seen that the indicators show a marked rotation of the spinous processes in the dorsal region toward the convexity of the curve, and the bodies must rotate toward the concavity. Compared with Fig. 4 it will be seen that the indicators point in the same direction as in the cadaver placed in the same position, and compared with Fig. 3, a photograph of the same model bending to the left in the flexed position, it will be seen that the indicators point in the opposite direction.

In the intact spine of the cadaver, therefore, and in the model, side bending in the extended position is accompanied by torsion of the vertebral bodies toward the concavity of the curve; in other words, the rotation is backward on the concavity of the curve, which is the reverse of the condition ordinarily seen in life in scoliosis.

Experiment, cadaver: Flexion and extension.—As the complicated movements of the spine in these experiments introduced an element of mixed planes most confusing to the observer, the following experiment was undertaken by Professor Dwight and the writer at the suggestion of the former, in order to obtain a graphic record of the torsion: A spine was placed upright in a vice at the edge of a table three feet from the floor; a hole was bored through the eleventh dorsal vertebra from behind forward; that is, in the median plane of the body. Through this hole was passed a brass rod five feet in length, which projected three feet behind the spine and a short distance in front of it. This rod, of course, represented the anteroposterior axis of the vertebrae. By means of a plumb line, dropped from the rod, the direction in which this rod pointed could be projected upon the floor and its variations in the horizontal plane recorded graphically. This eliminated any element of confusion on the part of the observer by giving a permanent and accurate record. The spine was then flexed, and before being bent to either side, the direction of the indicator was projected. The spine was then bent sideways to the right and to the left in the flexed position and the direction of the indicator recorded in those positions. It was then extended and bent to the right and left in the extended position and a diagram was obtained (Fig. 7). The crossing of the two lines to the right of the median plane, one for right flexion and one for right extension, shows plainly enough that there exists one type of torsion for side bending in flexion and another for bending to the same side in extension.

Pure lateral flexion.—If one type of torsion changes to the other type in going from flexion to extension, there must be a position between marked flexion and marked extension where the planes cross, and in this position, if anywhere, the purest lateral flexion must exist. By experiment in both cadaver and model this plane was found to be in slight flexion of the spine in the upright position, perhaps fifteen degrees in front of perpendicular. In the sitting position in the model, this plane exists in a slightly more extended position than when standing upright. In the upright position of the soldier, side bending is accompanied by the extension type of torsion.

Reasons for torsion.—It is obvious from these experiments that there must be some fundamental reason for the constant occurrence of one type of torsion for side bendings in flexion and the occurrence of another type in extension, as well as for the constant association of torsion with side bending. The vertebral column is a flexible rod capable of bearing great weight. It is not equally flexible in all directions, but it is of course capable of some movement in all planes, and as such, should come under the control of the laws governing flexible rods in general. The extent of any of the movements of the spine are, of course, greatly influenced by the shape of the vertebral bodies, the curves of the spine, the character of the articular processes, the resistance of the ligaments and the relative strength of the muscles. But in spite of these complicating elements, it seemed worth while to investigate the behavior of flexible rods in general under similar conditions. Professor Dwight suggested that this line of investigation might be of use.

To Professor Hollis, of Harvard University, the

FIG. 1. Spine fixed in vice, flexed and bent to the left. The boards mark the plane of the pelvis and chest. The bat pins are driven into the spinous processes. The torsion of the spine is shown by both boards and pins, the bodies turning to the right.

writer is indebted for much information on the mechanical side of the question.

From the mechanical point of view, torsion results from any motion in which all the particles of a straight flexible rod do not move in parallel planes. Consequently, if such a rod is bent in two planes at the same time, torsion must inevitably occur. The vertebral column is not a straight flexible rod, but one bent in the anteroposterior plane by a series of gentle curves; side bending must therefore inevitably lead to torsion, because it means bending in two planes. Nor does the fact that the intervertebral discs permit motion in all directions affect the question, because from a mechanical point of view the vertebral column behaves in general as it would if it were a homogeneous flexible rod, and one does not have to wait for torsion to occur until the intervertebral discs are compressed and the edges of the vertebrae come into contact, for, from a mechanical point of view, the torsion begins with the beginning of the side bending. It therefore seems very unlikely that pure lateral flexion of the spine ever exists.

A strip of sponge rubber, half an inch in diameter and fourteen inches long, rotates in the same way that the vertebral column does in the same position. It rotates in one direction for side bending when bent forward and in the opposite direction for side bending when bent backward, and the rotation follows the same rule observed in the vertebral column in the cadaver and in life. A lateral curvature, in what corresponds to the flexed position of the spine, may be produced in the rubber strip following the same rule of rotation seen in life; that is, the front of the rod turns towards the convexity of the lateral curve. An artificial lateral curvature in the rubber strip, made in what corresponds to the extended position of the spine, results in a reverse rotation to that from the rotation of the flexed position. A piece of rattan, a gum-elastic catheter, a piece of rubber tubing, or a strip of sponge rubber, round or square, behave all in the same way, and rotate in the same direction as does the spine when placed in a similar position to those described in the experiments on the model and cadaver except that they allow pure side bending in the lateral plane.

For side bendings, when bent forward, the flexible rod rotates one way, and when bent back and to the same side it rotates the other way. So far as this analogy goes, the spine, therefore, in its rotations does no more than to follow certain laws governing flexible rods, and the elaborate theories to account for the occurrence of rotation in scoliosis may be replaced by the statement that the spine behaves in general as any flexible rod would under similar condition so far as rotation is concerned.

Articular processes.—Although it is easy to understand that the column of vertebral bodies by itself might easily behave as a flexible rod, yet the articular processes cannot be left out of account. They must be an important factor in determining torsion, and they must do one of two things. Either they must fall in with the behavior of the flexible column of bodies and serve to carry out the rotation which would occur without them, or they must obstruct or reverse the rotation which would occur in the column of vertebral bodies alone.

Experiments, cadaver: Spine without vertebral bodies.—The experiments to be given seem to show that

when the articular processes are in contact they merely serve to accentuate the same rotation that would be present if the column of vertebral bodies were by itself.

Two vertebral columns, which had been previously used and which had conformed to the usual rule, were prepared for experiment by removing the column of bodies by cutting through the pedicles. The columns experimented upon then consisted of laminae and articular processes with their ligaments. The ribs were not removed from these columns. These could no longer be regarded as flexible rods, and were only anatomical preparations to demonstrate just what part in rotation the articular processes would play if left to themselves.

Each of these spines was then placed in a vice as in the experiments described above and pulled to the side in the same way. When the spine was extended and pulled to the left rotation occurred of the same type as in the intact column in the similar position, a rotation of the ribs backward on the side of the concavity. That is, the articular processes alone do the same thing in side bending in the extended position that the intact column does (Fig. 8).

In side bending from the flexed position, however (Fig. 9), the spine without bodies rotates in just the reverse direction from that of the intact spine in the same position, the rotation of the ribs being backward on the side of the concavity. This, of course, suggests that in side bending in the extended position the articular processes are active, but that in flexed positions they are not.

To see if this state of affairs really existed, a spine which had been used and which had followed the rule was sawed longitudinally in such a way as to divide each articular process in the long axis of the spine. The portion on the outer side of this cleft was removed, giving a view of each articulation. The spine was then flexed, and it was found that as moderate flexion began the articular joint surfaces in the dorsal region, which was the particular field observed, began to separate, and in extreme flexion were separated by an interval of perhaps one thirty-second of an inch. As the spine was extended they seemed to come into close contact at about the point where the flexion rotation changes to the extension rotation. In marked extension they were firmly in contact.

The conclusion from this is that the column of vertebral bodies alone, without articular processes, would rotate in just the same way in side bending in flexion and extension that the column does with articular processes present. That in flexion they are not sufficiently in contact to determine the rotation, but that in extension they are in contact, and are the active factors in determining the rotation which occurs in extension. That rotation is, however, in the same direction that it would be if the column consisted of vertebral bodies alone. They apparently serve to accentuate and carry out the behavior of a flexible rod in general, although they undoubtedly aid in preventing pure lateral flexion of the spine.

Leaving for a moment out of consideration the behavior of the column without vertebral bodies, and confining ourselves to the intact column in the cadaver and the model, it is shown by the experiments that there is one torsion for side bending in flexion and a diametrically opposite one for side bending in extension, and that the type of torsion seen in scoliosis in

life is the one occurring in side bendings in flexion where, in orthopedic terms, the rotation is backward on the side of the convexity of the curve.

(4) *Rotation*.—The fourth motion of the spine mentioned at the beginning of the paper must now receive attention. If lateral flexion is associated always with rotation, if the two are component parts of one composite movement, one would expect as a corollary to what has gone before that rotation could not exist without causing lateral flexion.

An experiment was made on the cadaver, which was fixed as described above and the atlas sharply rotated to one side. A well-marked lateral deviation of the spine took place.

Model No. 1, seated on a stool, was told to twist to one side but not to bend laterally in so doing; Fig. 10 shows that a well-marked lateral deviation of the spine occurred in this experiment. A similar photograph was taken of model No. 2, showing exactly the same condition. It therefore seems as if torsion of the trunk could not occur without lateral deviation.

Accepting the fact that in the spine lateral flexion cannot exist without torsion, it is plain why rotation should accompany any degree of lateral deviation of the spine; they are two parts of one movement and neither can exist alone.

Causes of lateral deviation of the spine in life.—To account for the phenomena found in rotary lateral curvature one has then only to formulate the factors which will cause the spine to be held to one side of the perpendicular; compensatory lateral deviation must occur and with it rotation. Such causes are manifold and well recognized, for asymmetry is the rule rather than the exception. Neither the head nor the pelvis can vary from their normal relation without producing some degree of compensatory lateral deviation somewhere in the spine.

Asymmetry of the head is a factor not often taken into account. Asymmetrical position of the head is favored by the fact that in most cases the condyles of the occiput are not in their best contact with the superior articular surfaces on the atlas when the head is held straight; a closer and better contact is generally obtained by a slight twisting of the head. This fact was pointed out to the writer by Professor Dwight. Ocular defects causing improper balance of the head are an obvious cause. One has only to observe the faulty carriage of the head in many cases of scoliosis to see that here is a condition of importance and often too marked a condition to be accounted a result of the scoliosis. Asymmetry of the pelvis as described by Barwell must be accounted as a not infrequent cause of asymmetrical positions. Asymmetry of the spine itself and unequal thickness of the vertebral bodies on the right side as contrasted with the left must be remembered as a demonstrated condition.⁷ Shortening of one leg is so common that it fails to attract the attention that it deserves.⁸

All these defects of conformation must lead to some lateral deviation of the spine. It depends upon the individual whether these are taken care of by nature in some compensatory way, or whether they

cause a deviation notable enough to be classed as a deformity.

Aside from the structural defects causing asymmetry and consequent lateral deviation, are to be found the vicious postures resulting from attitude and occupation, which must be accounted another important factor in producing scoliosis.

Type of rotation in scoliosis.—In flexion it may be repeated that side bending of any part of the spine must be accompanied by rotation of the vertebral bodies toward the convexity of the curve. Inasmuch as the great majority of cases of scoliosis show this type of rotation, it is evident that such scoliosis must have had its beginning during flexed positions of the spine. It is a well-known fact that many cases of scoliosis are produced by round shoulders, and the muscular development of patients with scoliosis is as a rule below the average. Poor muscular development of course predisposes to a flexed position of the trunk.

It seems likely that the beginning of scoliosis is much more often acquired by children in the sitting than in the standing position, because the sitting position makes flexion of the spine more easy than does the standing position.

An experimental scoliosis with rotation is shown in Fig. 11, in which the Model 2 was asked to its squarely, but at ease, on an inclined seat. The indicators on the skin over the spinous processes show that the bodies of the vertebrae have rotated toward the convexity of the lateral curve.

Reverse rotation.—The "reverse rotation," where the rotation of the vertebral bodies is backward on the side of the concavity of the curve, has been described as occurring in life, and has been somewhat discussed.⁹ Although the writer is not yet prepared to accept the fact that this apparent type of rotation is anything more than a slight lateral deviation with excessive rotation, yet the experiments above related show how the so-called "reverse curve" in scoliosis might occur from an anatomical point of view. If a column is curved laterally in the extended position this type of rotation must be found. One has only to examine a dried vertebral column to see that lateral motion between the dorsal vertebrae when their articular processes are in contact must result in the rotation of the bodies toward the concavity of the lateral curve. Moreover, such a type of rotation is an intrinsic property of any flexible column bent to the side in the extended position.

School furniture.—In the prophylaxis of scoliosis, from this point of view, correct school furniture seems to be of the greatest importance. Sitting to one side in the flexed position is to be avoided on anatomical grounds, and it is interesting to note that the weight of opinion has inclined to the style of chair and desk in which the edge of the desk overhangs the edge of the chair, the so-called "minus distance." It is easy to see that an arrangement of school furniture which allows a growing child to sit for hours with a flexed position of the spine, with muscles tired and stretched, is one which predisposes to a deformity which is associated with the flexed position. Inasmuch as we have seen that torsion causes of itself lateral deviation of the spine, the twisted posi-

tion that children assume in writing, especially in connection with flexion, must of itself be accounted a direct cause of scoliosis, inasmuch as it causes lateral deviation of the spine. It has been demonstrated¹⁰ that children who sit squarely at their writing, and who learn the upright style of writing, show a smaller percentage of scoliosis than children who learn the slanting hand, a fact easily explained from this point of view.

Treatment.—Of course, theoretical conditions such as those given above are of value only in so far as they may influence prophylaxis and treatment. Scoliosis on this supposition may be assumed to be a deformity arising from superincumbent weight, coming obliquely upon a spinal column in the flexed position. The correction, so far as possible, of asymmetrical attitudes and the prevention of undue flexion of the spine would seem to constitute the prophylaxis.

In the treatment of the condition when it exists, on this supposition, much emphasis must be laid on the detection and correction where practicable of the causes of asymmetrical attitudes. It is not always possible to do this. A short leg can be compensated for by a thicker sole, but an asymmetrical pelvis cannot be rectified.

The second and more important deduction to be made from the experiments is the importance of securing and maintaining the spine in a position of extension at the seat of the deformity. If the rotation of the extended position is the reverse of that of the flexed position, the use of extension as a means of treatment deserves a much more important place than it has received.

It is easy to see from this point of view why symmetrical gymnastics, cultivating the extensor muscles, such as those described by Teschner,¹¹ are of so much value; and it also explains what many of us have found out empirically, that it is desirable to hold and exercise the spine in positions of extension.

The problem seems to be, from an anatomical point of view, to bring the articular processes into firm contact, and to get their influence in counteracting the rotation acquired during flexion, as well as to call upon the intrinsic property of the spine as a flexible rod to reverse in extended positions the rotation acquired in the flexed positions. In a case of dorsal lateral curvature it is not enough to give backward flexions which shall take place chiefly in the lumbar region; such backward flexions must be made so far as possible to take effect in the region where the lateral deviation exists. It is the extended position of the deviated region that one wishes to bring about.

Given a fairly movable spine with a primary curve to the right in the dorsal region, and a rotation backward on the right side of the curve, the correction of such a rotation must be most easily made by exercises given to induce extension of the dorsal part of the spine where the deviation exists. By calling upon the intrinsic property of the spine to reverse in extended positions the rotation acquired in flexed positions, it would seem that we were pursuing the most rational course. It would seem also that forcible correction should also be made in the position of extension of

the spine and that a forward thrust at the seat of the lateral deviation should diminish the rotation.

When, however, it comes to the question of fixed curves and deformed vertebrae, the question is one of such complexity and difficulty that it is impossible from these experiments to speak at present as definitely as one can in cases more nearly normal.

The use of symmetrical extension exercises and of side bendings in the extended position is, therefore, from an anatomical point of view, most important.

Gymnastics.—It must be evident from what has been said that simple gymnastic exercises are safer than complicated ones. Many persons prescribe exercises of such complexity and intricacy that no one can possibly judge just what he is doing. If side bendings inevitably cause torsion and torsion lateral deviation, they are dangerous gymnastic elements to introduce into a problem already difficult enough. Safety lies in prescribing only exercises of which one can estimate the anatomical effect.

The writer is fully aware that this paper leaves out of consideration the subdivision of lateral curvature into the varieties according to their etiological types as well as the various types of curves. Given, as we have in the spine, the mechanism ready to produce a scoliosis and a superincumbent weight coming obliquely upon the column from some of the causes mentioned above, the column will yield where it is weakest; it may be in the lumbar region or in the dorsal. Compensatory curves will occur, bony deformity will result if the condition continues, and the complicated structure of the parts involved will allow of almost infinite variety in the location and the character of the curve. The ribs, of course, follow the rotation of the vertebrae to which they are attached. The writer has endeavored to deal only with the broader aspects of the question and to avoid generalizations from clinical experience.

SUMMARY.

This paper may be summed up in a few words as follows:

Torsion and side flexion of the spine are parts of one compound movement and neither exists to any extent alone. Lateral deviation of any part of the spinal column is therefore necessarily associated with torsion (rotation) at the seat of the deviation.

In flexed positions bending is associated with torsion in one direction, in extended positions by torsion in the opposite direction. In this it follows simply the mechanical law governing flexible rods, which rotate in general in the same way in corresponding positions. From the kind of torsion observed in scoliosis it is obvious that the deformity originates in the flexed position of the spine. The correction of the rotation would therefore seem to be logically made by throwing the spine into extended positions and in taking side bendings from extended positions.

Sitting in the flexed position by school children is likely to be harmful, and sitting in a twisted position of necessity induces lateral deviation temporarily. The immediate cause of lateral deviation is, as a rule, to be found in some asymmetry of development or posture which leads to an oblique direction of superincumbent weight, causing the spine to deviate from the middle line.

MALARIA AND MOSQUITOES.

BY IRVING C. ROSSE, M.D., F.R.G.S., WASHINGTON, D. C.

MUCH that has lately appeared in the journals relative to malaria and mosquitoes is at variance with the medical experience and personal observation of myself and others. The mention of a few facts of a different nature, which seem inconsistent with the allegations of tropical medicine that the mosquito is an agency in the spread of malaria, may therefore be in order.

More than usual experience as a traveller in such latitudes as tropical America, Africa, the vicinity of the North Pole, and many out-of-the-way islands never visited by the globe-trotter, has brought me into much practical contact with the question. Medical geography, however, does not explain such incongruities as the observance of malarial fever in mountainous places like the Island of Mauritius, the high Sierras of Spain, or in certain parts of Japan and Alaska, while there is almost exemption, for instance, in the marshes around the city of Mexico and in certain islands wanting in altitude, as Saint Helena and Bermuda. Moreover, the very old modern notion which attributed to living organisms the production of malaria, has been more labored than advanced since the days of Vitruvius and Columelle, who believed paludism owing to insects that inhabited marshy regions. The question as to the nature of malaria has varied according to the epoch, and although of late years its investigation has assumed more scientific direction and development, many vague generalities still prevail both among the people and physicians. For instance, all the common affections incident to atmospheric vicissitudes, bad cooking and general irregularity of living that obtain in Washington are called malaria. I have known Bright's disease, cancer of the stomach, and even basilar meningitis, chronic alcoholism, dorsal tabes, and other nervous affections to be mistaken for malaria and treated as such. Some of the veriest nonsense has been written as to the notions concerning malaria; on the one hand, the metaphysical hypothesis of the marsh acting as an occult power, on the other, that of living organisms being concerned in its production. In the present development of the subject an order of mind not content with studying phenomena only seems to be satisfied with the sensuous notion conveyed by the bacillus malaria, and its transmission by the genus anopheles.

It is claimed that a single mosquito may infect an individual, or, in fact, several individuals, for the investigators have found numerous parasites in the salivary glands of mosquitoes by whose bites they aver they have experimentally produced malaria in healthy subjects. Two Italians want us to believe that nearly all of forty-two harvesters near Rome had become affected with malaria at the end of July or early in August from mosquito bites, while a physician from the London School of Tropical Medicine has erected a bungalow in the most malarial part of the Roman Campagna to collect and send mosquitoes to England to bite healthy persons and thereby produce experimental intermittent fever. If experience counts for anything, it is safe to say that the persons volunteering for the test will never have the fever.

I am not aware that Arctic voyagers have ever suffered from any form of malaria after encountering

mosquitoes, which have caused great annoyance to explorers as far north as man has penetrated. Myriads of mosquitoes make life almost unendurable in northern Siberia, and Arctic mosquitoes as encountered during the cruise of the United States steamer *Corwin* in the Arctic Ocean surpassed anything of the kind I ever experienced elsewhere. So annoying were they at times that it was almost impossible to use instruments in taking observations when the position of a spot on shore was to be determined. On one occasion at a desolate spot on the top of Chamisso Island, about two hundred feet above the sea, we found an astronomical station that had been established by the English in search of Sir John Franklin, and near it was a notice telling of a bottle with information buried so many feet to the magnetic north. Curiosity, of course, prompted to get it by all means, but the mosquitoes coming in such myriads actually caused the search to be abandoned. Many of the *Corwin's* crew were seriously incommoded by their bites and stings on exposed parts of the body, one man's neck and face being so swollen from this cause as to result in temporary loss of eyesight. Yet not a single trace of malaria occurred in any of the crew, except in the case of a man who had come from the Chagres River a few weeks before. Perhaps the mosquitoes were not anopheles, although their bite and venom was as sharp as that of their southern congeners.

On another occasion when surgeon to a training ship with a healthy crew from a New England port, a stay of several days was made at the Delaware breakwater. Sleep was impossible during the several days of acute misery spent there, owing to extreme annoyance of the mosquitoes. No one questions the notorious reputation of the Chesapeake peninsula for malaria and anopheles, and if there be anything in the alleged transmission, an epidemic of malarial fever should have occurred. But such was not the case. Many months afterward not the slightest trace of paludism had appeared in any of the crew.

I may also cite similar instances where healthy people from the North have been temporarily exposed to bites in the vicinity of Norfolk, Va., at Tybee Island, Ga., the New Orleans quarantine, and on the Rio Grande River, all points at which anopheles prevail — yet not one of whom has been affected by malaria.

During a considerable residence in southern France and in Italy, I had frequent occasion to study this question. Monte Carlo is most prominently associated in my mind with broken sleep caused by mosquitoes during an autumnal visit. Yet among those of my personal acquaintance with the same experience none has since showed the slightest trace of malaria.

A similar remark applies to Leghorn and to Rome, where, owing to the most important changes in public hygiene that Europe has ever witnessed, malarial fever is seldom seen except among the poorer classes. Englishmen and Americans, who constitute two-thirds of the foreigners in Rome, now reside there for years without an attack of malaria, in spite of mosquitoes and of what the Italians consider their eccentric and imprudent habits. I am aware that the books written on the climate of Rome and the Campagna would alone make a library of more than one thousand volumes; hence, further digression would be almost as extensive as the decayed grandeurs of the

classic city itself. The old tradition of applying to every ailment from a cold to enteric fever the generic term "Roman fever," a vague disease that has no place on the nosological table, has created a prevailing notion hard to correct. As a matter of fact, the study of mortuary statistics and the sanitary condition of Rome, where I spent some time as sanitary inspector for the Government, show that with the exception of London, it is the best watered, the best drained and healthiest capital in Europe, and that a European or a native of New England runs greater risk of contracting malarial fever in Washington, where it is more prevalent and where anopheles are equally aggressive. The latest medical information from South Africa shows the entire absence of malaria in many localities where mosquitoes are most troublesome. An old and experienced practitioner of New Orleans tells me that the same is true of Louisiana, notably among residents of the salt marshes extending from six to fifteen miles inland from the Gulf. On the other hand, I am told that malarial fevers are common in the foot-hills of Virginia, as at Charlottesville, where mosquitoes are such a negligible quantity as to be almost unknown.

Perhaps the foregoing remarks lack the more labored details of "malarial parasitology" and the com-
munity of scientific observers, who may place different interpretations upon an unsettled question. According to the best entomological authority, the gnats herewith mentioned were in most instances of the genus anopheles. The facts relative thereto are honestly submitted for what they are worth without inclination or bias, and speculation is left to the reader.

Reports of Societies.

AMERICAN ORTHOPEDIC ASSOCIATION.

FOURTEENTH ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY 1, 2 AND 3, 1900, HARRY M. SHERMAN, M.D., OF SAN FRANCISCO, PRESIDENT.

FIRST DAY.

DR. V. P. GIBNEY presented a paper entitled

THE SIMPLE AND EFFICIENT TREATMENT OF CALCANEUS PARALYTICUS IN YOUNG CHILDREN,

in which he advocated treatment by means of plaster of Paris in complete extension, changing the plaster every three or four months.

DR. L. A. WEIGEL, of Rochester, spoke of the danger of excoriation, and referred to a case in which the foot was still in the calcaneus position because there was no form of dressing which could be applied to such a case without risk of producing gangrenous ulceration.

DR. JOHN RIDLON, of Chicago, remarked that the idea of improving the function by prolonged and constant retention in an appropriate position was not new, for Mr. Hugh Owen Thomas had practised this method systematically in a large number of cases. The object was to keep up a state of tension, and for this purpose he used a shoe with a wedge sole, two and one-half inches thick at the heel and thin in front, reinforced by a bar extending two-thirds of the length of the shoe and up the back of the leg to the calf.

DR. H. P. H. GALLOWAY, of Toronto, referred to a class of cases in which, he said, the shortening of the tendo Achillis caused either supination or pronation according to the direction the foot happens to be given.

DR. A. B. JUDSON, of New York, said he had abolished the joint at the ankle. The first effect of the apparatus was to transfer the weight of the body from the anterior part of the foot to the anterior side of the upper part of the skin. In cases of extreme calcaneus the gait could be made absolutely perfect if managed in this way.

A FINAL REPORT ON THE USE OF PURE CARBOLIC ACID IN THE TREATMENT OF TUBERCULAR AND PURULENT DISEASES OF JOINTS AND BONES.

DR. A. M. PHELPS, of New York, read this report. His plan is to lay open the capsule for about two-thirds of its extent, irrigate the joint cavity with 1-1,000 bichloride of mercury solution; then fill it with pure carbolic acid, and after this had been allowed to remain for just one minute, wash it out first with strong alcohol, and afterward with a two-percent. solution of carbolic acid. In the last eighteen months he had operated upon 70 cases. The results had been very satisfactory, and, on an average, the cases of excision had been discharged from the hospital at the end of three weeks.

DR. ROBERT W. LOVETT, of Boston, said that at the Children's Hospital in his city they had endeavored to prevent abscesses by putting the patients to bed whenever there was irritative muscular action about the joints. When an abscess had formed, the joint was freely opened, irrigated with bichloride and drained.

THE MECHANICS OF LATERAL CURVATURE OF THE SPINE.¹

DR. ROBERT W. LOVETT, of Boston, read this paper.

SOME OF THE PROBLEMS INVOLVED IN THE TREATMENT OF LATERAL CURVATURE OF THE SPINE.

DR. NEWTON M. SHAFFER, of New York, described by means of diagrams his conception of the mechanical principles involved, and stated that he had arrived at practically the same conclusion as had Dr. Lovett.

THE RELATION OF DEFORMITY OF THE PELVIS TO LATERAL CURVATURE OF THE SPINE.

DR. H. P. H. GALLOWAY, of Toronto, read this paper. He said that many writers had considered pelvic distortion to be the effect of the lateral curvature, but personally he was inclined to believe it was the cause. It seemed more logical to look for the faulty construction in the foundation than in the superstructure.

SPASMODIC LATERAL CURVATURE OF THE SPINE.

DR. ARTHUR J. GILLETTE, of St. Paul, presented in this communication a report of several cases of hysterical curvature.

THE RESULTS OF MY OBSERVATIONS IN LATERAL CURVATURE OF THE SPINE, CLINICALLY, MECHANICALLY AND PATHOLOGICALLY.

DR. A. M. PHELPS, of New York, gave in this paper a description of a post-mortem study on a severe

¹ See page 622 of the Journal.

case of rotary lateral curvature. The subject was forty-five years of age. Throughout the whole region of curvature he had found extensive degeneration of muscles, more marked on the convex side. The intervertebral cartilages on the concave side were totally destroyed. He concluded from this study that it was futile to expect to cure lateral curvature of the spine after changes in the bone had taken place. He was of the opinion that all the machines for forcible correction now in use are of but little value.

DR. E. H. BRADFORD, of Boston, insisted that there were certainly some cases in growing children that were benefited by treatment.

DR. L. A. WEIGEL said that he had frequently seen the most rigid muscles relax thoroughly after forcible correction, and even this degree of improvement was worth striving after.

DR. SHAFFER said he felt firmly convinced that lateral curvature of the spine is dependent primarily on changes in the muscles, though quite probably an underlying cause was to be found in the nervous system.

DR. H. AUGUSTUS WILSON, of Philadelphia, suggested that lateral curvature might sometimes result from an asymmetrical hip action in apparently normal subjects.

DR. PHELPS replied that only the physiological curve could be cured. It was not necessary to do myotomy in mild cases in young children, yet at the present time he was cutting more than one-third of his cases of lateral curvature.

DR. A. B. JUDSON spoke in admiration of Dr. Lovett's ingenious and convincing model, and added that in 1876 he had himself advocated, and in one case practised, the application of a spinal brace for the production of extreme lordosis in cases of lateral curvature, on the ground that as in rotation the anterior part of the column was affected by deviation from the median line, it was good practice to shift the weight of the body from the anterior to the posterior part of the column. Had he then looked as far ahead as Dr. Lovett had done, he would, in all probability, have thought even more favorably of the method. He now believed that it promised many advantages.

ANTERIOR SUPPORT SUPPLEMENTING THE TAYLOR BRACE IN POTT'S DISEASE.

DR. GEORGE B. PACKARD, of Denver, the author of this communication, spoke of the advantages of anterior support, and the carrying forward of the ribs which resulted from the sinking forward of the upper dorsal spine.

A SUSPENSION PRESSURE CHAIR FOR SCOLIOSIS.

DR. PHILIP HOFFMANN, of St. Louis, described this inexpensive apparatus. It is the pressure chair described by Dr. Bradford, to which has been added lateral steel bars, four feet and a half high, which meet in an arch overhead. To the arch is attached an apparatus consisting of a system of compound pulleys. It is intended as an accessory gymnastic apparatus.

RESULTS OF TREATMENT OF CONGENITAL DISLOCATION OF THE HIP.

DR. E. H. BRADFORD, of Boston, made some remarks on this subject, and presented a pathological specimen illustrating both the operative and the bloodless method of effecting reduction. He advocated ex-

posing and incising the portion of the capsule which covers the acetabulum, and thus constitutes one of the obstacles to successful treatment. By suture of the capsule after reduction one could, in a large measure, prevent relapse.

DR. GIBNEY heartily commended his suggestion.

DR. RIDLON thought it was possible in young patients in whom the head and neck of the femur were fairly developed, to replace the bone by the bloodless method, but in order to get a permanently good result it was necessary to make and maintain considerable abduction. Failure was not infrequently due to a neglect to prevent flexion of the leg.

DR. HARRY SHERMAN, of San Francisco, said that he had tried, in one or two instances, Dr. Bradford's method of suturing, but had become convinced that if the head were placed in between the two lateral halves of the pocket, it would be quite as stable as if it had been sutured. This pocket was a very definite obstacle which could be appreciated in an open operation.

DR. BRADFORD said that he had seen a few cases that had relapsed after a year. He characterized the bloodless method as one which sacrificed precision to the timidity of the patient. Before operating by the cutting operation all the contractions of the soft parts should be overcome, either by stretching or by open incision and myotomy. He did not feel that he could operate successfully on patients over six years old.

A NEW BACK BRACE FOR POTT'S DISEASE.

DR. JOHN DANE, of Boston, exhibited this brace, the object of which was to combine the advantages of a plaster-of-Paris jacket with those of an anteroposterior brace. The usual apron is dispensed with, and there is a high cross piece with straps passing around under the arms.

TENDON TRANSPLANTATION IN THE TREATMENT OF PARALYTIC DEFORMITIES.

DR. W. R. TOWNSEND, of New York, presented this paper. He declared that in many patients suffering from drop-wrist the function could be more or less restored by tendon transplantation. Among the cases cited was one of his own, a case of right hemiplegia, pes equinus and drop-wrist. Here the tendon had been shortened by lapping one portion over the other, fastening it by the method previously described by Dr. Joel E. Goldthwait.

A CASE OF CONGENITAL DISLOCATION OF THE SHOULDER, WITH RADIOGRAPH.

DR. JOHN L. PORTER, of Chicago, present by invitation, reported this case.

DR. JOEL E. GOLDTHWAIT approved of the method pursued by Dr. Townsend in his case, that is, going directly through the interosseous membrane, because in the foot where the anterior tendons had been made posterior tendons and carried around the leg the results had not been very satisfactory. In some of his own cases of tendon transplantation the results had been surprisingly good.

DR. WEIGEL thought it was absolutely essential in certain cases to completely divide the tendon, and cited a case in illustration.

DR. BRADFORD said that in some cases he had taken special pains not to completely divide the tendon, believing that this secured a more powerful muscle. He had operated on one hand by the method de-

scribed by Dr. Townsend, and when last seen the child seemed to have gained.

A CASE OF TUBERCULOSIS OF THE ASTRAGALUS WITH ANCHYLOSIS AND SUBSEQUENT AMPUTATION.

DR. V. P. GIBNEY, of New York, reported this case, occurring in a girl of sixteen who had sprained her ankle. At first the case had seemed to be one of synovial tuberculosis. She had been treated by braces for about twelve years, but had recently returned with extensive tuberculous disease of the astragalus. Removal of the astragalus had not proved sufficient, and, after consultation, the foot had been amputated. The specimens were exhibited.

DR. GOLDTHWAIT showed in this connection a water-color drawing of a case of excision of the knee, in which the tissues about this joint had been found infiltrated with tuberculous material, and some of the fringes hanging down two inches or more. No central tuberculosis could be detected.

(To be continued).

AMERICAN MEDICAL ASSOCIATION.

FIFTY-FIRST ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., JUNE 5-8, 1900.

GENERAL SESSIONS.

FIRST DAY.

THE general sessions of the American Medical Association were held in the Marine Hall of Young's Pier, DR. W. W. KEEN, of Philadelphia, presiding.

Governor Voorhees was to have delivered the first address, but was absent, and the Acting Governor of the State and President of the State Senate, HON. H. M. JOHNSON, welcomed the Association. MAYOR H. P. STOY and DR. THOMAS S. REED, of Atlantic City, also made brief addresses of welcome.

DR. PHILIP MARVEL, of Atlantic City, read the report of the Committee of Arrangements, and DR. WM. J. HERDMAN, of Ann Arbor, Mich., in his report of the General Business Committee, presented several resolutions relating to the workings of the Association, which were adopted. The text of the Annual Address of the President of the Association, DR. W. W. KEEN, which was delivered at this time, appeared in the last issue of the JOURNAL.

The report of the Treasurer, DR. HENRY P. NEWMAN, of Chicago, showed a gratifying increase in membership and receipts. The receipts for the year ending December 31, 1899, were over \$39,000. The cash now on hand amounts to \$13,556.56, and this, together with a loan of \$3,000 and \$10,000 in Government bonds, gives a total of assets of \$27,396.86.

The Secretary, DR. GEO. H. SIMMONS, of Chicago, reported that a copy of the Code of Ethics had been given to every medical student graduated this year. He recommended the general adoption of the metric system. A letter from the Secretary of the Wayne County (Mich.) Medical Society, urging interstate reciprocity in the matter of licenses to practise medicine, was read.

DR. U. O. B. WINGATE, of Milwaukee, reported for the Committee on Department of Public Health, that the main work of the Committee had been in reference to quarantine regulations and legislation.

DR. H. L. E. JOHNSON, of Washington, D. C., reported for the Committee on National Legislation, mentioning a number of bills recently presented to Congress, which the Committee had favored.

DR. E. ELIOT HARRIS reported for the Special Committee on Revision of the Constitution and By-Laws.

DR. REYNOLDS, of Kentucky, made a motion that two members from each of the various sections and the army and navy corps be appointed for the third Pan-American Medical Congress, to be held in Cuba this year.

By resolution offered by DR. WM. J. HERDMAN, and adopted, the name of the General Business Committee was changed to General Executive Committee.

DR. EDWARD JACKSON, of Denver, Col., was elected on the Committee of Prize Essays for ensuing year. The Executive Committee urged a decrease in the number of papers on section programmes, which are often so overcrowded.

After some further routine business and announcements the meeting adjourned.

SECOND DAY.

DR. W. L. RODMAN, of Philadelphia, delivered the

ORATION ON SURGERY.

The text of this appeared in the last issue.

DR. VICTOR C. VAUGHAN, of Michigan, delivered the

ORATION ON STATE MEDICINE.

After the report of the General Executive Committee, DR. T. J. HAPPEL, of Tennessee, read the report of the Board of Trustees. This report showed the finances of the Association to be in an excellent condition. The receipts for the year ended December 31, 1899, were \$109,115.33; the total expenditures were \$93,609.40, of which \$77,641.01 was for the Journal of the Association. The total amount invested in United States bonds and the Indianapolis loan is \$13,812.50, and the total cash on hand is \$14,355.51, making an aggregate of \$28,168.01 in the Treasurer's hands January 1, 1900. Recent expenditures leave a real balance at present of \$4,131.36 available for debts.

The report of the Committee on the American Medical Association Medal was read by DR. GEORGE M. GOULD, of Philadelphia. Six essays were submitted to the Committee, and the one recommended by the Committee was entitled "Quantitative Tests for Proteolysis," by A. L. Benedict, A.M., M.D., of Buffalo, N. Y. The Association accepted the Committee's report. Dr. Jackson was appointed on the Committee for the ensuing year.

The report of the award of the N. Senn gold medal was next read by DR. W. S. RODMAN, of Philadelphia. The winner was the author of the essay entitled "Exstrophy of the Bladder," by Dr. F. Frederick Connell, of Chicago.

The Committee on the Reorganization of the Army and Navy Medical Corps, of which Dr. Thomas H. Fenton, of Philadelphia, is chairman, failed to report.

DR. J. C. WILSON, of Philadelphia, chairman of the Rush Fund, reported new contributions during the year, from various medical societies, of \$938.01,

and a total on hand of \$11,330.05. After the report of special committees, and the transaction of miscellaneous business, the meeting adjourned.

THIRD DAY.

After reading of the minutes and announcements by Dr. MARVEL, of the Committee of Arrangements, Dr. J. M. ALLEN, the Third Vice-President, took the chair. Dr. JOHN A. WITHERSPOON, of Nashville, Tenn., delivered the "Oration on Medicine."

The Secretary of the General Executive Committee next reported.

The resolution of Dr. L. B. TUCKERMAN, that the National Legislative Committee, in conjunction with the Special Committee on the Reorganization of the Army and Navy Medical Corps, cause to be drafted a bill providing for adequate instruction in hygiene and sanitation in the national military and naval academies, was adopted.

The matter of selecting a place of meeting for next year was referred to the General Executive Committee.

The recommendation that the prize medal be open for competition to members of the Association only was adopted.

The Committee endorsed the action of the Prize Medal Committee, and accepted the medal offered as a model for future medals. It was resolved to appropriate \$500 annually for the encouragement of scientific research, provided no one individual prize exceed \$100.

The name of the Section on Neurology and Medical Jurisprudence was changed to Section on Nervous and Mental Diseases.

Dr. STONE, of Minnesota, read the

REPORT OF THE NOMINATING COMMITTEE.

It was unanimously adopted, and the following officers were declared elected for the ensuing year:

President, Dr. Charles A. L. Reed, of Ohio; First Vice-President, Dr. A. W. Calhoun, of Georgia; Second Vice-President, Colonel Woodhull, of Maryland, U. S. Navy; Third Vice-President, Dr. Philip Marvel, of New Jersey; Fourth Vice-President, Dr. W. E. Quine, of Illinois; Treasurer, Dr. Henry P. Newman, of Illinois; Secretary, Dr. Geo. H. Simmons, of Illinois; Assistant Secretary, Dr. Wm. Davis, of St. Paul; Librarian, Dr. Geo. Webster, of Illinois.

Board of Trustees.—Dr. Miles F. Porter, of Indiana; Dr. E. Fletcher Ingals, of Illinois; Dr. W. L. Rodman, of Pennsylvania; to fill the vacancy caused by the resignation of Dr. Charles A. L. Reed, Dr. James M. Matthews, of Kentucky.

Judicial Council.—Dr. James R. Guthrie, of Iowa; Dr. G. B. Gillespie, of Tennessee; Dr. R. C. Moore, of Nebraska; Dr. Ida J. Heiberger, of District of Columbia; Dr. John B. Roberts, of Pennsylvania; Dr. Charles L. Rodman, of Connecticut; Dr. L. L. Jepson, of West Virginia.

The Address on Surgery.—Dr. John A. Wyeth, of New York.

The Address on State Medicine.—Dr. John M. Kober, of the District of Columbia.

The Address on Medicine.—Dr. N. S. Davis, Jr., of Illinois.

Place of Meeting.—St. Paul, Minn.

Committee of Arrangements.—Dr. John F. Fulton, Chairman, of St. Paul.

The newly-elected President, Dr. REED, having been called away by telegram, was now installed, and made a short address of acceptance. The special committees followed. The Committee on Revision of Constitution and By-Laws reported. The resolution that men graduating from four-year medical schools only should be eligible for membership to the Association after 1901 was adopted. Under miscellaneous business Dr. Denslow Lewis, of Chicago, brought before the Association the matter of the publication of his paper, read at Columbus last year, and made a motion that the Association should vote a special order for its publication in the *Journal of the American Medical Association*. The matter was referred to the General Executive Committee to be reported Friday.

FOURTH DAY.

After the reading of the minutes of Thursday's session, and report of the Committee of Arrangements, the elections of officers of sections was announced as follows:

Diseases of Children.—Chairman, Samuel W. Kelley, Cleveland; Secretary, William E. Darnell, Atlantic City.

Diseases of Women.—Chairman, Harry P. Neuman, Chicago; Secretary, C. S. Bonniwell, Cincinnati.

Surgical.—Chairman, A. J. Ochsner, Chicago; Secretary, Martin B. Tinker, Philadelphia.

Neurology.—Chairman, W. P. Tomlinson, St. Peter, Minn.; Secretary, F. S. Pearce, Philadelphia.

Ophthalmology.—Chairman, J. A. Lippincott, Pittsburg, Pa.; Secretary, E. C. Ellett, Memphis, Tenn.

Materia Medica.—Chairman, N. S. Davis, Jr., Chicago; Secretary, J. N. Upshur, Richmond.

Laryngology.—Chairman, John Nahand Mackenzie, Baltimore; Secretary, George C. Stout, Philadelphia.

Cutaneous Medicine.—Chairman, W. L. Baum, Chicago; Secretary, R. R. Campbell, Chicago.

Stomatology.—Chairman, R. R. Andrews, Cambridge, Mass.; Secretary, Eugene S. Talbot, Chicago.

Practice of Medicine.—Chairman, J. M. Anders, Philadelphia; Secretary, W. Britt, Philadelphia.

Business Committee.—A. E. Baldwin, Chicago; G. V. I. Brown, Milwaukee; M. H. Fletcher, Cincinnati.

Physiology and Dietetics.—Chairman, Elmer Lea, New York City; Secretary, R. Harvey Cook, Oxford, O.

State Medicine.—Chairman, Ernest Wende, Buffalo, N. Y.; Secretary, J. H. Hurty, Indianapolis, Ind.

Dr. DENSLow LEWIS, of Chicago, brought up the matter of the publication of his article on "Gynecologic Consideration of the Sexual Act." The Executive Committee reported against the publication of the article, which report, after considerable discussion, was adopted. The Committee also reported in favor of continuing the pathologic exhibit from year to year, under charge of the newly-formed pathologic section, and that \$500 be appropriated for the exhibit. The resolution was adopted.

The pathologic exhibit was one of the features of the meeting. It comprised over 1,500 specimens and photographs, under the direction of Dr. Frank B.

Wyun, of Indianapolis, secretary of the unofficial committee on pathologic exhibit, and of the provisional pathologic section. The idea originated three years ago with the Indiana State Medical Society, and was this year, for the first time, made part of the work of the Convention, though unofficially, and will hereafter be a permanent part of the work, under the newly-formed pathologic section. The exhibition is intended as a practical, interesting and instructive object lesson to the members of the Association, and embraces a large number of specimens of almost every pathologic condition. The chief features were the collection of gross specimens of the lungs, heart, liver, kidneys, intestines, etc.; the 95 specimens of diseased meats, showing trichinosis, actinomycosis, cholera, etc.; and a large collection of photographs and skiagraphs, the microscopic and bacteriologic exhibit, and the sanitary exhibit of the Marine Hospital. The specimens were furnished by colleges and specialists from all over the country.

The work of the National Committee on Legislation was approved. This committee has recommended a number of bills lately before the Senate, and suggested a number of new bills regarding national medical affairs.

SECTION ON SURGERY AND ANATOMY.

FIRST DAY.

The meeting was called to order by the Chairman, DR. H. O. WALKER, of Detroit, who delivered the Annual Address, entitled

A RETROSPECT OF SURGERY OF THE STOMACH.

In the two decades since Billroth gave the first impetus to gastric surgery great progress has been made. Operative measures may be divided into two great classes: those for benign affections and those for malignant disease. Among the benign affections was mentioned stenosis of the pylorus. For the relief of this condition he prefers the operation of pyloroplasty, provided the pylorus is not greatly hypertrophied or bound down by adhesions; in such cases gastro-enterostomy is the operation of choice. For the relief of gastroptosis the operation of gastroplication has given good results; operations shortening the ligaments are of double value; gastropexy may be indicated in certain cases. He has operated in two cases for hour-glass contraction of the stomach. The first patient was a woman of thirty-seven who had suffered with digestive difficulties; a tumor could be felt in the epigastric region. On opening the abdomen a constriction was found near the middle of the stomach giving it an hour-glass form. Partial resection was performed. The patient died on the seventh day following operation. Partial resection was performed on a man of fifty-seven for the relief of a similar condition; death followed on the fifth day from giving way of the sutures. Early diagnosis is highly important in the case of malignant disease, and the stomach specialists have given surgeons much aid in this respect of late years. Pylorectomy is advocated in the case of freely movable tumors. Dr. Walker has previously reported a successful pylorectomy; in two other cases his patients died as a result of the operation. If the disease is more extensive gastro-enterostomy is indicated. He has used Senn's plates, Murphy's button, and simple suture with equally good results. The mortal-

ity of this operation has been growing less. In the preparation for operation he advises preliminary free purgation, careful attention to asepsis and care in manipulation. It is better to ligate first and then cut than to cut and then ligate, as is the usual custom; the approximating sutures should not be drawn too tight so as to cause death of the tissues. The operation of total gastrectomy is yet under judgment. He has experimented with the operation on dogs. Of 12 operated upon one died on the table and the others died in from three to forty-eight hours after the operation; two from sepsis and nine from hemorrhage and shock. In closing Dr. Walker advised exploratory operation in all obscure cases.

DR. W. L. RODMAN, of Philadelphia, read a paper entitled

NON-PERFORATING GASTRIC ULCER WITH AND WITHOUT HEMORRHAGE.¹

DR. TURCK, of Chicago, mentioned the spasmodic contraction of the pylorus which may occur specially with hyperchlorhria as a form of pyloric obstruction in which operation is not indicated. In gastric myesthesia medical means may fail to restore muscular power. Accumulation of mucus which decomposes and causes septic conditions may occur. The pyloric sound was mentioned as a means for more exact diagnosis. X-ray photographs were shown showing that the sound had passed through the pylorus into the intestine. The general condition of the patient is not always thought of in considering the contraindications for operation; this is the reason why many patients die four or five days after operation from such causes as renal insufficiency or auto-intoxication. The importance of skill and perfected technic on the part of the surgeon was emphasized.

DR. FENGER, of Chicago, thought that he had discovered a method to avoid the constant vomiting which often follows gastro-enterostomy, but vomiting occurred in the fourth patient operated upon by this method, and he finds himself as far from this desirable result as ever. Instead of presenting a paper on this subject, as he originally intended, he demonstrated from a series of drawings the position of the palate, epiglottis, etc., during anesthesia. In certain cases in which there is danger of suffocation from the tongue falling back he passes a silk thread around the hyoid bone with which to draw it forward, and he showed that this would give more room for breathing than any other method.

THE DIAGNOSIS AND TREATMENT OF CHOLELITHIASIS.

DR. W. J. MEANS, of Columbus, O., reported 20 cases that had come under his observation in which the diagnosis of cholelithiasis was made. He operated in 10 of these cases without any mortality. Death resulted in three of the 10 remaining cases in which operation was not performed. Gall-stones were found at the time of operation in every case but one. In four cases the affection followed typhoid fever. The importance of the following symptoms was emphasized: pain, nausea and vomiting, jaundice, clay-colored stools, high-colored urine, pruritus and tenderness over the gall-bladder. In making the diagnosis it should not be forgotten that the disease almost always occurs in patients over thirty years old. Operation in uncomplicated cases is almost free from danger and

¹ See No. 23, page 586, of the Journal.

Dr. Means believes that early operation will reduce the mortality almost as much as early operation for appendicitis.

CHOLECYSTECTOMY WITH SPECIAL REFERENCE TO REMOVAL OF THE MUCOUS MEMBRANE OF THE GALL-BLADDER IN CERTAIN CASES AS A SUBSTITUTE.

Dr. W. J. MAYO, of Rochester, Minn., read this paper. Total removal of the gall-bladder is indicated in most cases of severe traumatic injury, gangrene, phlegmonous processes and in malignant disease. In cases of chronic suppuration or prolonged mucous discharge he recommends removal of the mucous membrane as a substitute for cholecystectomy. The operation is easily performed, it is less dangerous and the results in seven cases which he has operated upon by this method are excellent. The method of operating in cases in which the gall-bladder has been previously drained was also given.

THE IMPORTANCE OF EARLY OPERATION FOR BILIARY CALCULI.

Dr. M. H. RICHARDSON, of Boston, read this paper. He believes that gall-stones should be removed by operation as soon as the diagnosis is reasonably certain, unless some lesion of some other organ of the body makes operation more hazardous than leaving the stones. His own experience has led him more and more to favor early operation. Early operation is attended by almost no mortality; it is but little more dangerous than the operation for appendicitis in the interval. The dangerous cases are those in which cholemia is present; in these cases the danger is as great as in operating for acute appendicitis. He has had 13 deaths and about 100 recoveries following operations on the biliary passages; in but few cases was the operation undertaken early in the attack. All his operations on the common duct were successful. In one case death followed later from malignant disease of the liver. The frequency with which malignant disease of the liver follows inflammatory affections seems to favor early operation. He gave brief notes of his fatal cases. All the patients had suffered from the prolonged mechanical effects of gall-stones; in many cases operation was undertaken as a forlorn hope; in others there were severe complicating diseases; several of the patients were of an advanced age. Among conditions indicating operation are mentioned: a single attack of biliary colic in case a faceted stone appears in the stools (if the stone be smooth operation is not indicated); successive attacks of colic even if of moderate severity.

Dr. WYETH, of New York, endorsed Dr. Richardson's views entirely.

Dr. MYNTER, of Buffalo, commended Dr. Richardson for calling attention to his fatal cases; these cases are often the most instructive. He mentioned a case in which he removed 565 stones from the gall-bladder. One of his patients died from capillary hemorrhage; one died after operation on the common duct. Jaundice is not as important a symptom as some speakers would lead us to believe; it does not appear while stones remain in the gall-bladder, but only when they are being passed. Dr. Mynter considers intermittent pain and tenderness the most important symptoms, and when these are present he operates. As illustrat-

ing the difficulties of diagnosis he mentioned two cases: in one of these he operated for appendicitis and found the gall-bladder distended with stones; in the second case he operated for gall-stones and found the inflamed appendix adherent to the gall-bladder.

Dr. SENN, of Chicago, believes that in the x-rays, in the hands of experts, we have a certain means of diagnosis of gall-stones. Dr. Senn considers the removal of the mucous membrane of the gall-bladder, as suggested by Mayo, difficult to accomplish, and infected mucous membrane is likely to be left behind. He protests against the extreme views that had been presented with regard to operation in all cases of gall-stones as soon as the diagnosis is made, and believes that we should operate only in cases in which there is danger to life from the symptoms caused by stone.

Dr. GRAY, of Jersey City, reported an operation for the removal of several large stones.

Dr. MARCY, of Boston, mentioned a case in which biliary colic had recurred three years after operation, and a gall-stone was passed in the stools. He favors Dr. Richardson's views as to early operations. In doubtful cases surgeons fail in performing their duty by not operating.

Dr. DEEVER, of Philadelphia, believes that ultra-conservatism is a dangerous doctrine; late operation will not save lives. He has never yet been successful in diagnosing gall-stones by means of the x-rays. In uncomplicated cases he finds operations on the gall-passages easy.

Dr. WYMAN, of Detroit, believes that the remedial power in cholecystostomy is not generally appreciated.

Dr. RICKETTS, of Cincinnati, approves of all that Richardson said as regards early operation. The early operation is usually one of the easiest in surgery; late operation with a contracted gall-bladder is one of the most difficult.

Dr. OCHSNER, of Chicago: In every case of death mentioned the fatal result was due, not to the operation, but to the delay. Early operation is comparatively harmless, because practically extraperitoneal, and because the contents of the gall-bladder are aseptic. Symptoms referred to the stomach are among the earliest usually mentioned. Mayo's operation of the mucous membrane is theoretically difficult but practically very easy, and gives satisfactory results.

Dr. BEVAN, of Chicago, does not agree that all cases should be subjected to operation as soon as a diagnosis is made. In his dissecting-room experience he found gall-stones in 16 per cent. of all subjects, and in the post-mortem room stones are found in 25 per cent. of the patients over sixty years old, yet by no means all of these needed operation for gall-stones.

Dr. GRANT, of Louisville, considers it unwise to operate for conditions which are producing no symptoms. He has not found the x-rays of any value in diagnosis.

Dr. SUMMERS, of Omaha, Neb., advises passing the finger through the foramen of Winslow when using the Murphy button.

Dr. MEANS, in closing, stated that he had found the x-rays of no help in cases in which the presence of stone was later demonstrated at the post-mortem or at operation. He does not agree with the ultra-conservative views that were expressed, and does not believe that stones exist any considerable length of time without producing symptoms.

Dr. MAYO stated that he did not advocate operation in two stages, as some had understood him, but removes the mucous membrane from the bladder in cases in which cholecystotomy has failed to cure.

Dr. RICHARDSON believes that there is too great a tendency to conservatism among most practitioners; they do not bring their cases to the surgeon until too late to be benefited, and it is necessary to call attention to the need for earlier intervention.

SECOND DAY.

THE PRESENT STATUS OF THE MURPHY BUTTON,

by J. B. MURPHY, of Chicago. In Dr. Murphy's absence his paper was read by Dr. EVANS. It is now eight years since the anastomosis button was first used in operating on a human being. Murphy states that he has been so frequently misquoted and misunderstood, and the button has been so frequently improperly constructed and incorrectly used that it is time to consider the actual results which have been attained. Up to April 1, 1900, one of Murphy's assistants has collected 1,620 cases in which the button has been used, not including 111 cases collected by Murphy in 1895. The mortality has been reduced to 20 per cent., and should not be over 10 per cent. Seven hundred cases of gastro-enterostomy by Murphy's button have been collected, with a mortality of 19 per cent.; in 166 non-malignant cases there were 97.7 per cent. of recoveries. Entero-enterostomy has been performed in 750 cases, with a mortality of about 19 per cent., and in non-malignant cases it has been only 14.4 per cent. In no cases is the button of greater value than in cases of strangulation and gangrene requiring resection. Cholecystenterostomy had been performed in but 11 cases previous to the invention of the button, and it was primarily devised for use in this operation. Of late years he has used the button only in cases of irremovable obstruction, but probably it might better be used in many other cases rather than to undertake more extensive operative measures. Considering the fact that operations have been performed in all parts of the world, in many cases by unskilful operators, often in the case of patients *in extremis* and with imperfectly constructed buttons, it is strange that the results are so good as they are.

A historical review was then given of the various mechanical devices which were in use previous to the discovery of the button. Among the advantages of the use of the button which were mentioned were the fact that sutures are not needed, which shortens the time of operation, the ideal approximation which is obtained, the fact that cicatricial contraction is less likely to occur than after other methods, and that the physiologic function of the intestine is not interfered with. To use the button successfully a considerable knowledge of surgery is necessary, and most of the unfavorable results are from lack of skill of the operator. The objections to the use of the button are the danger of the opening becoming occluded, and that it may be retained for a long time. In all the cases collected but 11 cases of occlusion are reported, with only three deaths. This danger may be easily avoided by careful attention to diet. In many cases in which it has been thought that the button was not passed it has been found later not to be in the body, even in some cases in which operations were undertaken for its removal.

COLOSTOMY FOR PERMANENT FECAL FISTULA.

Dr. J. A. WYETH, of New York, described a method of operating for a thorough understanding of which the drawing that was presented would be necessary. The essential feature is the pulling up of the slack of intestine formed by the sigmoid flexure from below to the region above the point at which it is desired to form the artificial anus. This gives storage room for fecal matter, so that it may be retained for some time, and that the patient will not be troubled with incontinence of feces.

THE TREATMENT OF OBSTINATE CONSTIPATION BASED ON NEW POINTS IN THE ANATOMY AND HISTOLOGY OF THE RECTUM AND COLON.

Dr. J. R. PENNINGTON, of Chicago, discussed the anatomy of the sigmoid flexure and rectum at some length and demonstrated a large number of carefully prepared specimens and drawings illustrating the points brought out in his paper. He showed that the sigmoid flexure is not confined to the left iliac fossa, as is usually stated in text-books, but it may occupy the pelvis or extend into the right iliac fossa. The results of a series of careful histologic examinations by Dr. Evans, of the University of Illinois, of numerous specimens of the rectal valves were given. These examinations show that the valves may contain mucosa, muscular layer and serous coat, or only part of the normal intestinal wall may be present. An abnormal position of the sigmoid flexure or large rectal valves may give rise to constipation. To relieve this, Pennington has divided the valve with a knife, in one case with resulting peritonitis; he has also used the canterly and the results were not entirely satisfactory. He called attention to an instrument which he calls the valve clip, designed to cut a section out of the valve, and demonstrated a table which is a modification of one devised by Martin.

Dr. TUTTLE, of New York, mentioned five cases in which Murphy's button had not been observed to pass, but no harm had resulted. He criticised Wyeth for using the term fistula, and considers the term artificial anus more suitable to designate fistulas established by operative measures. He believes that in his method Wyeth has struck the keynote in preventing constant and uncontrollable fecal discharge. Tuttle commends Pennington's work.

Dr. FINLAYSON, of Iowa, reported a case of obstinate constipation in which he found the sigmoid flexure entirely on the right side.

Dr. MARTIN, of Cleveland, stated that six years ago he made the researches and employed the methods reported by Pennington as his original work. Nelaton in 1850 and Jacobi in 1862 called attention to the fact that the sigmoid flexure may be located on the right side. Most cases of stricture of the rectum are really hypertrophy of the rectal valve. All cases of idiopathic dilatation of the colon should be examined carefully to make certain that they do not arise from this cause. There is no danger in valvotomy if the proctoscope is used, for then we can see what we are doing.

Dr. PENNINGTON, in closing, expressed the belief that operation as proposed by Martin is dangerous.

REPAIR AFTER RESECTION OF THE INTESTINE.

Dr. W. A. EVANS, of Chicago: The fact that no cases of stricture are reported following operation, in

view of the numerous operations of the past ten years, seems good evidence that such trouble is unusual. Evans has found the amount of scar tissue that results from such operation to be unusually small; the fibres which give rise to stricture are circular, and these circular fibres are not found in the connective tissue. This is probably due to the fact that in scar tissue the fibres form in the direction of the tension. In cases operated upon some time previously it is difficult to even find the site of anastomosis. We may conclude from these studies that the dangers of stricture are not great enough to make it necessary for us to consider some other procedure as a substitute for end-to-end anastomosis.

DR. WIGGIN, of New York, in his experience has found no difficulty as to stricture following end-to-end anastomosis and he prefers this method of operating. In experiments on animals he has found it difficult to locate the site of union. He prefers to use horse-hair as a suture material, as it is elastic and prevents bad results which may result from swelling. Evans in closing stated that in a number of text-books the dangers of stricture following end-to-end anastomosis are emphasized, and this led him to make this series of investigations. The dangers are certainly not great.

APPENDICITIS; COLITIS AS AN ETIOLOGIC FACTOR;
THE QUESTION OF REMOVAL OF THE APPENDIX
IN ALL CASES OPERATED UPON.

DR. MILES S. PORTER, of Fort Wayne, Ind., mentioned a case in which appendicitis began with colitis and stated that since then he had seen a number of other cases in which the appendicitis seemed to take its origin in an inflammatory condition in the colon. He believes that a knowledge of this etiologic relation is important as to the prophylaxis of certain cases of appendicitis. In certain cases of appendicitis the patients, if subjected to excision of the appendix, will die, but if simply incision and drainage is practised they will recover. The number of cases of recurrence after incision and drainage without removal of the appendix is comparatively small.

APPENDICEAL FISTULA.

DR. J. B. DEEVER, of Philadelphia, read this paper. He considers fistula one of the most important sequels of appendicitis. Such fistulas are of two types, external and internal. External fistulas are of two kinds: those leading to abscess cavities which are only suppurating sinews and tend to spontaneous recovery, and those communicating with the lumen of the intestine in which there is fecal discharge. Internal fistulas communicate with some of the surrounding viscera. Among the causes mentioned were the cutting out of sutures, particularly in cases in which the cecum is much inflamed, the continued use of the drainage tube, and particularly a gangrenous condition in cases in which operation has been too long postponed. He believes that many cases of perinephritic abscess arise from abscess of the appendix behind the colon. He mentioned cases in which he had found appendiceal abscesses emptying into the lung, the bladder and the ureter. The most favorable internal fistulas are those which break into the ascending colon or cecum. The treatment of these cases will vary with condition of the patient. As a rule they close spontaneously; they should be kept

clean, irritation by syringing, etc., should be avoided and if they persist, operation should be performed. If an abscess cavity is present the mouth of the sinus should be opened widely, in some cases it may be scraped, and it should be packed with gauze. For the cure of internal fistula it may be necessary to open the peritoneum, and remove the appendix; in some cases resection and end-to-end suture must be performed. Great stress was laid on importance of the avoidance of fistula by early operation.

DR. SENN, of Chicago, has seen more fistulas following operation than without operation, and he does not believe in operation as a preventive of fistula. Operation in all cases as soon as a diagnosis is made is extreme, and extremes in surgery are dangerous. Ordinary expectant treatment will bring about recovery in 80 per cent. of all cases of appendicitis. The operation for fistula is usually dangerous and he is conservative about advising it in such cases in which it seems probable from the history that the fistula leads into the cecum.

DR. M. PRICE, of Philadelphia, endorses Dr. Deaver's views. In 125 operations performed as soon as the diagnosis was made he found pus in all but two cases. He advises the use of gauze instead of a tube for drainage. The statement that 80 per cent. of all cases recover without operation he believes incorrect and dangerous.

DR. DAWBARN, of New York, entirely agrees with Dr. Deaver that we cannot be too radical in dealing with the appendix. It is so generally possible to prevent fistula that when it occurs it may be usually ascribed to faulty technic. He advises the insertion of a purse-string suture about necrotic areas in the cecum which seem likely to give rise to fistulas.

DR. HAMILTON, of Columbia, believes that most fistulas will recover if a nourishing liquid diet and tonics are given together with massage and care as to cleanliness.

DR. MYNTER, of Buffalo, favors the position taken by Dr. Deaver. When pathologic conditions are present such as are found in appendicitis medical treatment can do no good. He agrees with Dr. Porter that in the case of large abscesses after the fifth day it is best simply to incise and drain. He has found periphlebitis a more important sequel of appendicitis than fistula.

DR. KEEN, of Philadelphia, called attention to the discussion on the subject of appendicitis which occurred at the meeting of the American Surgical Association thirteen months ago. Two questions were considered: Shall all cases of appendicitis be operated upon as soon as the diagnosis is made? And shall we remove the appendix in every case? Both of the questions were decided in the negative by all present, except Drs. Deaver and Hart. In 300 necropsies on patients that had died from causes other than appendicitis Dr. Hektoen found that the appendix had been at some time inflamed in 100 cases, yet these recovered and died from other causes. Each case of appendicitis should be considered by itself, and not only the condition of the patient, but the skill of the surgeon who is to operate should be considered. A surgeon who operates only once in three months should not undertake it unless absolutely demanded. As general rules may be stated that no case should pass the second attack without operation; all cases of considerable gravity should be operated upon and in most cases

the appendix should be removed. It is rare that fecal fistula does not heal spontaneously. In operating for fistula Dr. Keen usually makes the abdominal opening at one side of the fistula, excises, inverts, closes with Lembert sutures, and packs with gauze.

DR. McRAE, of Atlanta, said probably in 75 per cent. of all cases recurrence follows if the appendix is not removed. To break up adhesions in every case in which suppuration is present, as suggested by Price, he believes is dangerous. In operations during acute attacks he considers the greatest danger to be ventral hernia, and not fistula, as stated by Deaver. Most fistulas close spontaneously. Gauze drainage he prefers to use of the tube.

DR. MURPHY, of Chicago, congratulated Deaver on his successes in repairing the defective work of others and his labors to prevent such defective work. Granting that 80 per cent. of all patients with appendicitis recover without operation, the results are not as good as after early operation, for probably all but about two per cent. recover from such operations. This is a saving of 18 per cent. of lives over the conservative methods of treatment. The diagnosis is easy in every case within twenty-four hours, and there are few towns so small that good surgical skill is not available within a few hours. The mortality of early operation is probably not over one per cent. and that is from primary perforative peritonitis. Dr. Murphy has not lost a case that was operated on within the first twenty-four hours. He believes that we should refuse operation in those cases in which suppurative peritonitis is present; the responsibility for death should then rest with the physician who has allowed the patient to reach such a condition.

DR. GRAY, of Jersey City, believes in operation as soon as a diagnosis is made. Any surgeon with common sense and ordinary skill can perform the operation. He pleads for operation in cases of general peritonitis; we should eviscerate on hot towels, sponge the intestines, peel off patches of adherent lymph, wash with salt solution and drain freely in such cases. He has saved a number of patients by such treatment.

DR. HALL, of Cincinnati, believes that we should give the desperate cases a chance.

DR. BOLT, of New York, operates upon every case, if not moribund. If there is recovery from the first attack there is danger of a second attack, and danger from immediate perforation.

DR. FENGER, of Chicago, considers the question of first importance, "How shall we get the patient out of the attack alive?" This is not always best accomplished by operation. Operation in the interval is safest, hence it is best not to operate as soon as the diagnosis is made, if there seems to be a possibility of recovery from the attack. The patient is put in a hospital and carefully watched, and if the symptoms increase in severity operation is performed.

DR. ASHTON, of Philadelphia, agrees with Deaver as to the advisability of early operation; it is never possible to tell what the patient's condition will be the next day.

DR. LAPLACE, of Philadelphia, thought the mortality too high in appendicitis; every case could be saved at some stage by operation, and this is usually early in the attack. It is never possible to tell whether the infection is caused by a mild or virulent germ, and the only safety lies in early operation.

DR. OCHSNER, of Chicago, advises withholding ab-

solutely all food and cathartics, thus avoiding nearly all peristalsis, which tends to pull away the protecting omentum. If this treatment is followed abscess formation will not occur in some cases, and if it does occur it will be localized and readily successfully treated. The mortality of operations during the interval is much less than if performed during the attack.

DR. PORTER, in closing the discussion, stated that he is absolutely opposed to breaking up adhesions in case of abscess formation as suggested by Price. He does not believe that recurrent attacks follow in 75 per cent. of the cases in case the appendix is left. Murphy gave a wrong impression when he stated that he would not operate in case of septic peritonitis. We should give every man a chance for recovery, no matter how desperate the case.

DR. DEAVER, in closing, stated that he was certain of only two things in connection with the subject of appendicitis: the method of making a diagnosis, and that all cases should be operated upon as soon as a diagnosis is made.

Officers.—The officers of the Section chosen for the ensuing year were: Chairman, Dr. A. J. Ochsner, of Chicago; Secretary, Dr. Martin B. Tinker, of Philadelphia.

(To be continued.)

SECTION ON THE PRACTICE OF MEDICINE.

FIRST DAY.

The Chairman, DR. GEORGE DOCK, of Ann Arbor, delivered the Chairman's Address.¹

DR. GEORGE M. GOULD, of Philadelphia, read a paper entitled

A SYSTEM OF PERSONAL BIOLOGIC EXAMINATIONS THE CONDITION OF ADEQUATE MEDICAL AND SCIENTIFIC CONDUCT OF LIFE.

DR. C. N. B. CAMAC, of New York, read a paper entitled

HOSPITAL AND WARD CLINICAL LABORATORIES.

Rarely is any one finding in medical science the open sesame to the secrets of disease. The clinical laboratory makes no claim other than that it may add its fraction to the whole in the estimation of the changes in disease processes. The workshop of the clinical diagnostician is the sick-room, the bedside, and the ward. Those who object to the establishment of clinical laboratories do so on one of the following grounds: (1) Diagnosis is satisfactorily made without these tests; (2) the laboratories require too much space. But it is found that an area of 6x6 feet or at most 10x10 feet is ample and all that is requisite is a table and a window. Gas and running water are helps; but the alcohol lamp and the ordinary wash-bottle can be made to do; (3) the cost of establishment and maintenance is too great. Three hundred dollars will fully equip one of these ward laboratories, including a microscope with an oil-immersion lens and a cabinet for instruments and reagents. This laboratory should be kept clean on account of its proximity to the beds of the patients. Fifty dollars per year is ample to cover the running expenses; (4) the tests require too much time and are too difficult. In order to overcome this objection internes should be appoin-

¹ See No. 28, page 581, of the Journal.

ted to all hospitals, whose sole duty it should be to attend to this side of ward work. Among the advantages of this method of laboratory work may be mentioned: (1) The increase in the number of competent observers that such routine work would develop; (2) the production of accuracy in diagnosis and in treatment; (3) the accurate taking of records. Such a method may, with profit, be applied to dispensaries. In this way clinical pathology will become the link between the clinician and the pathologist.

DR. M. HOWARD FUSSELL, of Philadelphia, read a paper entitled

EXAMINATION OF THE BLOOD, ITS VALUE TO THE GENERAL PRACTITIONER.

The vast majority of physicians do not make blood examinations unless they are suggested by the consultant. In some cases the blood examination is as important and in other cases it is more important than the examination of the urine, and it is already acknowledged that an examination of the urine is necessary in every case. As a general practitioner, the author examines the blood in all obscure cases. As a result of such an examination: (1) The physician will avoid administering iron to a patient because the face is pale, since all pale people are not anemic; (2) it will be found that patients with flushed faces often have decided reduction of the hemoglobin and of the number of red blood corpuscles; (3) patients with cardiac and pulmonary symptoms are sometimes diagnosed as cases of organic disease, when a blood examination would reveal chlorosis; (4) blood examination will positively indicate the presence or absence of malaria; (5) the diagnosis between leukemia and other organic conditions, such as tuberculosis and carcinoma of the stomach, may be made; (6) the blood examination combined with the Widal test will diagnose between typhoid fever and malaria, or, possibly, show a combination of the two diseases; (7) counting the leucocytes will often give satisfactory results in clearing up obscure conditions. The physician does not need to take a microscope to the bedside of the patient; if the diluting tube is surrounded by a rubber band the blood may be preserved for a long time and the counting done at leisure.

DR. WILLIAM OSLER, of Baltimore, said that he had been impressed by the value of the ward laboratories. They are essential to the hospital and to the dispensary. The benefit of a clinical laboratory to the patient in the dispensary, where the diagnosis should be made, is inestimable.

DR. SIMON FLEXNER, of Philadelphia, read a paper entitled

DYSENTERY.

The paper treated of the results of the study of cases of dysentery made in the army hospitals in Manila during the summer of 1899. The dysentery in the tropics does not conform to a single type. It is a mistake to think that tropical dysentery is always amebic in origin. Three groups of organisms have been thought to be the cause of the disease: (1) The pyogenic cocci; (2) the bacillus coli communis, and (3) the ameba coli. Amebic dysentery is not confined to the tropics, and the status of the ameba coli in the production of the disease has undergone a change because the organism can be found in the normal stools. Tropical dysenteries occur in which the

ameba coli is not present. These cases are acute in character, lasting from six to eight days, or they may run into a chronic form. Secondary lesions, such as abscess of the lungs and liver, are rare. A bacillus was found in these cases which was not the bacillus coli communis. This organism is not found in the normal intestine and a blood serum from a patient with the acute form of the disease agglutinates a pure culture of the organism. In the early stages of the disease the organism is present in large numbers; but as the disease becomes more chronic it diminishes in number, and later may disappear entirely. The bacillus agrees with a micro-organism obtained from the stools of patients suffering from dysentery in Japan by Shiga, the bacillus dysenteriae. The lesions of the acute form of dysentery are different from those of the ordinary amebic dysentery. Small animals may be rendered immune and animals that were immunized in November last are still alive. It seems to be possible to produce a preventive serum.

DR. JOHN H. MUSSER, of Philadelphia, read a

NOTE ON TROPICAL DYSENTERY.

A soldier, age thirty-two years, had been in Puerto Rico for fifteen months, and for eight months of that time had had dysentery. The disease was characterized by colitis and proctitis, prostration and emaciation, pigmentation of irregular degree but of uniform extent. The skin presented many boils and purpura was present. The stools contained no fresh blood and but little mucus. The mouth had the appearance of a malignant case of scorbutus. There was no periodicity in the intestinal symptoms. The blood of this patient agglutinated a pure culture of the bacillus of Shiga, which was brought by Dr. Flexner from Manila. The patient died and at autopsy it was found that the anatomic changes in the intestine were very slight.

DR. WILLIAM OSLER, of Baltimore, had also seen a case in the person of a soldier from Puerto Rico. The blood of this patient also agglutinated the bacillus of Shiga. An attempt was made to agglutinate this organism with blood serum from cases of amebic dysentery without result. This seems to indicate that there are two types of dysentery. He thought that the epidemic of dysentery that is at present raging in Japan might be like those epidemics that are seen in jails and hospitals in this country occasionally.

DR. NORMAN BRIDGE, of Los Angeles, asked Dr. Flexner whether typhoid fever might not occur coincidentally with this form of dysentery. Or, if this does not occur, will the blood of the dysenteric patient agglutinate the typhoid bacillus? He had seen a patient from Cuba with symptoms like those of Dr. Musser's patient, whose blood gave a perfect Widal reaction. The blood of another patient with similar symptoms failed to give the reaction.

DR. HUNTER, of Minneapolis, had seen two cases of dysentery, in one of which the ameba coli was found and in the other of which no ameba were found. The symptoms were similar to those of Dr. Musser's patient.

DR. WOODHULL, of the United States Army, said that it was the policy of the army surgeons to return dysenteric patients to the United States as soon as possible, because they did not convalesce rapidly in the Philippines.

DR. MURPHY, of Missouri, had seen three cases of

amebic dysentery in patients who had not been away from the United States.

DR. VICTOR C. VAUGHAN, of Ann Arbor, had studied cases of dysentery bacteriologically, and had only found the bacillus coli communis, although these studies were made when technic was not as exact as at present. In the camps in the Southern States during the Spanish War there were cases of dysentery characterized by the passage of fresh blood. The number of chronic cases, however, was small. During the Santiago campaign, the dysenteric patients did not pass fresh blood. These cases were apparently benefited by strychnine hypodermically.

DR. WILSON, of Pennsylvania, had seen two cases in soldiers of the Tenth Pennsylvania Volunteers. The patients did not pass blood and did not have fever. The disease in one lasted for six months.

DR. FLEXNER said that the epidemics in jails and hospitals may be identical with the disease that he had seen in Manila. It is important that in every epidemic now, no matter how small, bacteriologic examination should be made and the agglutinating properties of the blood be studied. He offered to give cultures of the bacillus of Shiga to any one who was interested in the work. The organism looks very much like the bacillus typhosus. There is no reason why typhoid fever and dysentery might not exist at the same time. There is undoubtedly more than one kind of tropical dysentery. In the type of the disease under discussion liver complications are uncommon, while they are very common in the amebic form. The bacillus coli communis can do damage to the intestines, but it is probably not responsible for epidemics of dysentery.

DR. MÜSSER said that the cases of tropical dysentery under his care were afebrile.

DR. J. C. WILSON, of Philadelphia, read a paper entitled

SERUM THERAPY IN CROUPOUS PNEUMONIA.

Croupous pneumonia is due to infection with the pneumococcus through the respiratory tract. Toxins may enter the circulation and produce a septicemia. The sera produced up to the present are anti-infectious, although it is hoped by Dr. Macfarland that in time a serum will be found that will benefit the symptoms. In the German Hospital, in Philadelphia, the antipneumococcal serum was used in 18 cases of croupous pneumonia, but it was not used to the exclusion of other treatment. The injections were given in the majority of instances immediately after admission to the ward. There were two women and 16 men in whom the treatment by injections of serum was used. They varied in age from fifteen to forty-eight years. They were admitted to the ward from the first to the sixth day of the disease. The temperatures ranged from 101.2° to 105°; the pulse-rate varied between 90 and 128. Albumin was present in 15 cases, casts in nine, and blood in one. There was leucocytosis in 13 cases. The pneumococcus was found in 15 of the cases. The serum, which varied between seven and fifty-three days in age, was given hypodermically over periods varying from six hours to eight days. Total doses of from 22 cubic centimetres to 460 cubic centimetres were given. The effects seemed to be better when a recent serum was used. After the injections the temperature became

lower, the pulse slower, the pain less, and the patient felt better. Four of the patients died. Deferescence occurred by crisis or by rapid lysis. The duration of the attack did not seem to be lessened or the defervescence hastened. In a series of 20 cases treated at the Pennsylvania Hospital at the same time without serum four died.

DR. A. O. J. KELLY, of Philadelphia, reported the case of a man, an alcoholic, age thirty-five years, who was admitted on the fourth day of an attack of pneumonia of the right lower lobe. On the day after admission the left lower lobe became consolidated, and 20 cubic centimetres of antipneumonic serum were given every three hours for seven doses. The leucocytes were at first diminished, but later increased. The autopsy confirmed the clinical findings. The serum was of no avail in this case.

DR. ROCHESTER, of Buffalo, gave serum from a blister on a patient that was convalescent from pneumonia to a patient ill with the disease. There was improvement for twenty-four hours. He thinks that the evidence points to the future development of a therapeutic agent of value.

DR. NEWTON, of Montclair, N. J., asked for the details of preparation of the serum.

DR. JOSEPH MACFARLAND, of Philadelphia, said that he regretted that up to the present time there is no method of measuring the strength of the serum. The serum is prepared by administering live cultures of the pneumococcus to horses. The organism is difficult to grow, and the measure of the toxin is not accurate. The organism is kept virulent by growing it alternately on artificial culture media and in the rabbit. The nature of the serum is uncertain; it may be antitoxic or it may be antimicrobial, possibly the latter. It is probable that the serum may be used for other micro-organisms than the pneumococcus. He believes that the use of serum from convalescents is unreliable. It is possible that the serum should be injected into the blood-vessels in order to produce the desired result.

DR. W. BLAIR STEWART, of Atlantic City, N. J., read a paper entitled

THE INFLUENCE OF SEA-AIR AND SEA-WATER ON DISEASE.

The purest air is on the sea. The presence of iodine is doubtful, but ozone is surely present. Atlantic City is on an island of pure sand, five miles from the mainland and twenty miles from tidewater. The Gulf Stream makes a difference of from 10° to 20° in the temperature as compared with other places in the country. The great effects of the air are seen on the nervous system and on the digestion. The author spoke of the class of patients that are benefited by residence in such a place. Salt-water baths are in reality medicated baths and should only be used in an intelligent manner, and, for patients, under the direction of a physician. He spoke of the physiologic effects of surf-bathing. The least exhausting form is to lie in the water between the shore and the point of breaking of the waves. A person should leave the bath when the exhilaration is at its height. Surf-baths should be taken three hours after eating, and a meal should not follow until reaction is complete. Warm salt-water baths should be taken in a warm room and should not last longer than ten minutes.

SECOND DAY.

DR. T. J. HAPPEL, of Trenton, Tenn., read a paper entitled

PSEUDO(?) OR MODIFIED(?) SMALL-POX.

The paper was based on the personal observation of 200 cases and on the inspection of 100 additional cases as county health officer. In the first cases seen none of the patients had been vaccinated. The premonitory symptoms of backache, headache and fever were present; but as soon as the eruption appeared the fever disappeared and the patients felt perfectly well except for some slight discomfort caused by the presence of the eruption, which in some of the cases was confluent in character. All patients that were exposed were vaccinated; but only two escaped the infection. Patients that were vaccinated in childhood also contracted the disease. The pustular stage of true small-pox was absent; there was no itching; there were no crusts, no scars, and no mortality. The author considered the disease not to be true small-pox.

DR. JAMES J. WALSH, of New York, called attention to the fact that Senator and his pupils believed in the existence of a disease that is intermediate between varicella and variola. He thought that these cases might correspond to such an intermediate stage.

DR. JAMES, of Missouri, had seen similar cases, but in them he was able to demonstrate the efficiency of vaccination in preventing the contraction of the infection.

DR. CHAPMAN, of Ohio, said that he had seen the disease. According to his experience, the majority of the patients were adults and the majority had been vaccinated during childhood, but not since. He does not think the disease is varicella and is of the opinion that, unless vaccination is systematically carried out, the country will experience a severe epidemic of small-pox.

DR. CORLETT, of Ohio, believes that chicken-pox and small-pox are distinct diseases and that there is no intermediate stage.

DR. WOODWORTH, of Ohio, said that vaccination protected in the cases seen by him. He called attention to the fact that cases of small-pox following vaccination often resemble varicella.

DR. STEWART, of Philadelphia, said that he considered that the cases reported by Dr. Happel were not cases of small-pox, nor were they cases of chicken-pox; but that they should be classed as some form of vesicular exanthem.

DR. HAPPEL said in closing that none of the cases presented the typical appearance of small-pox. He wished to go on record as a thorough believer in the efficiency of vaccination as a preventive measure against small-pox.

DR. EUGENE WADDIN, of the United States Marine-Hospital Service, read a paper on

YELLOW FEVER, ITS NATURE AND CAUSES.

He believes that the bacillus icteroides is the cause of yellow fever. The infection takes place through the respiratory tract and secondary infection may then soon arise. The toxin produced by the growth of the bacillus has a marked potency and a preventive serum is probably possible. The bacillus icteroides was present in 85.7 per cent. of autopsy cases. The bacillus produced the disease in the lower animals.

The bacillus X of Sternberg and the bacillus icteroides are distinct micro-organisms; the former being, probably, a member of the colon group. The domestic animals may be a factor in the spread of the disease, since it has been carried spontaneously from inoculated to non-inoculated animals. The bacillus icteroides is an artificially pathogenic organism; it is profoundly influenced by temperatures at or below the frost-mark, and at such temperatures loses its toxic, septic and specific properties. This explains the cessation of the disease on the appearance of frost. The disease is air-borne, it first attacks the respiratory tract and the resulting intoxication produces the first symptoms. The organism may then pass into the circulation and develop its septicity. The fulminating cases are sterile because the bacillus has not passed into the blood. The guinea-pig is resistant to the infection, but other rodents, particularly rats, are susceptible. These animals may be active in the propagation of the disease.

DR. FLEXNER, of Philadelphia, said that while the facts expressed in the paper seem to be well authenticated, before they can be accepted as undoubted they must be confirmed by future observations. The propagation of the disease by the lower animals is at present merely a hypothesis. Animal experiments do not actually reproduce the normal conditions pertaining to an infectious disease, because the animals are overwhelmed by huge doses of the organisms. The effect of the natural method of spread of the disease should be studied on the lower animals.

DR. WADDIN said that in his work the animals had been infected by the insufflation of lycopodium powder containing small quantities of bouillon culture of the organism, so that the conditions were as near normal as possible. Animals in an adjoining room to the one in which the insufflation experiments had been made took the infection and died, the organisms having undoubtedly reached them through the air. In answer to Dr. Gerry, of Boston, he said that one attack of yellow fever does not necessarily protect against a second attack of the disease. Undoubted instances of second attacks of yellow fever are on record.

DR. WILLIAM OSLER, of Baltimore, offered a resolution of regret for the death of Dr. James T. Whitaker, of Cincinnati, which was adopted.

The following papers were read by title: "Prolonged Fevers of Obscure Origin," Dr. Robert B. Preble, of Chicago; "Some Interesting Cases of Infectious Diseases," Dr. DeLancey Rochester, of Buffalo, N. Y.; "Certain Clinical Features of Influenza Recently Epidemic," Dr. H. S. Anders, of Philadelphia; "Influenza with Four Distinct Pneumonic Attacks Accompanied by Otitis Media Purulenta, Cerebral Hyperemia, Colitis, Marasmus, Recovery," Dr. Julius Ullman, of Buffalo, N. Y.; "Observations on Direct Antiseptic Treatment of Infectious Diseases," Dr. C. am Ende, of New York City.

THIRD DAY.

A paper by DR. JESSE W. LAZEAR, of the United States Army, entitled

PATHOLOGY OF MALARIAL FEVERS; STRUCTURE OF THE PARASITES AND CHANGES IN THE TISSUES,

was read by the Secretary, DR. FUTCHER. The author described the method of making cover-slip

preparations of the blood for the study of the malarial organisms. He then proceeded to describe the microscopic appearances of the tertian, quartan, and estivo-autumnal parasites throughout their cycles of development. In the latter type of organism there is a sexual development; the male form is furnished with a flagellum, while the female form is devoid of any such appendage. Observers have seen the male form penetrate the female parasite.

DR. W. S. THAYER, of Baltimore, Md., read a paper entitled

ETIOLOGY OF MALARIA WITH SPECIAL REFERENCE TO MOSQUITOES.

The author read a summary of the recent work dealing with the mosquito as an agent in the transmission of malaria. This work shows that the mosquito is able to remove the parasite from the human body, that the parasites develop by sexual methods in the stomach wall of this host, that thence, passing into the venomosalivary gland, the parasite, in the form of sporozoids, may be inoculated into uninfected individuals and produce the disease. These results have been confirmed by the author and his associates in Baltimore. The parasite undergoes an asexual cycle of development in the human body and a sexual cycle in the body of the mosquito of the genus anopheles. The author thinks that the investigations will finally show that the mosquito bites are the only means by which the disease can be transmitted. Investigations seem to show that mosquitoes are always present in a malarial district, or else the cases occurring in such a district are imported. Further, the observations seem to show that the mosquito acquires the parasite only from man. The early spring cases are all relapses, which decrease in number in June, and the new cases begin in July, when the anopheles begin to bite. Prophylaxis requires that patients be isolated under mosquito netting and that the mosquito larvæ be killed.

DR. L. O. HOWARD, of the United States Department of Agriculture, gave a lantern demonstration of

STRUCTURAL AND OTHER DIFFERENCES BETWEEN THE SEVERAL MOSQUITOES OF NORTH AMERICA.

The slides shown illustrated the life history of the genus culex, the life history of the genus anopheles and the biologic difference between the two genera. The eggs of the culex are deposited in a raft-shaped clump, while those of the anopheles are distinct. The larva of anopheles is dark, while that of culex is light. The respiratory siphon of the anopheles is short, while that of culex is long. The larva of culex has a big head and a small body, while that of anopheles has a small head in proportion to the size of the body. The anopheles larva feeds at the surface of the water, while the larva of culex feeds on the bottom, coming to the top of the water periodically to breathe. The note of culex is high pitched, while that of anopheles is about four tones lower. The genera megarinus and psorofora should be investigated.

(To be continued.)

CANCER IN GERMANY. — Drs. von Leyden and Kirchner are presidents, and George Meyer secretary of a committee for collective investigation of cancer in Germany.

THE BOSTON Medical and Surgical Journal.

THURSDAY, JUNE 14, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE MASSACHUSETTS MEDICAL SOCIETY.

THE one hundred and nineteenth annual meeting of the Massachusetts Medical Society has just been held. This meeting, like its predecessors, has brought together practitioners from every section of the State, who, no doubt, have imbibed certain added knowledge from contact with their fellows and from attendance at the section meetings, and more important than this, have renewed old acquaintanceship, and deepened, to a certain extent, the social relationships which, in the activity of practice, are apt to languish. For after all, while we make a bold front to present at our annual medical gatherings certain of the results of the progress of medicine, it is not to be denied that the predominating attraction is the social element, accompanied by the relaxation and professional companionship which is the just reward for a year of work. This is as it should be.

However valuable papers may be enshrined in a volume of *Proceedings*, it is not to be expected that they should awaken an extreme degree of enthusiasm on an exceedingly hot day, as days are apt to be in June, particularly when those same papers are later to be published in full. This portends no lack of scientific enthusiasm, but simply a weakness of human nature which demands recognition and respect. This general fact has been more and more realized by the Committee of Arrangements of the Massachusetts Medical Society, with the gratifying result that the programme of the meetings grows simpler year by year rather than more complex, in spite of the ever-widening range of possible subjects for discussion. For example, this year there were presented at the various sections but three general topics — pneumonia, the diseases of joints, and a discussion of uterine displacements, with but two added communications. There is not the slightest doubt that this method is a good one, and one designed to give the maximum of instruction with the minimum of intellectual effort on the part of the listeners. A few subjects discussed thoroughly and from various points of view is much to be preferred to the superficial rela-

tion of personal experiences, to which the medical meeting, without strict watchfulness, is apt to degenerate. The success of this latest meeting of the Massachusetts Medical Society and the evident interest taken in the scientific communications is sufficient proof of the correctness of our position. Dr. Wm. H. Welch's Shattuck Lecture on "Diseases Caused by *Bacillus Aërogenes Capsulatus*" was peculiarly timely because of the recent interest aroused in this subject in Boston, through the researches of Thorndike and others. The Annual Discourse, delivered by Dr. A. T. Cabot, was an able and fitting literary termination to a century of usefulness and progress.

THE DEATH-RATE OF CHICAGO.

RECENT quotations from certain statements in the monthly bulletin of the Health Commissioner of Chicago, in regard to the death-rate of that city, which have very much the usual Western flavor and can hardly be regarded as reliable, have attracted our attention. The following fallacies in the Chicago figures are worthy of notice:

(1) All death-rates depend upon two factors, the number of the population and the number of deaths occurring in such population in a given time or period. An error in either produces an error in the result. Now, the number of the population is obtained at the taking of a census and the liability of error increases greatly in proportion to the time which has elapsed since the taking of the census. In this instance eight years had elapsed since the taking of the census, and the growth of all Western cities has been exceedingly irregular in intercensal periods. Very little reliance can be placed in any local census made by the school or police or other local officials.

(2) The average age at death is not an index of sanitary conditions, but depends chiefly upon the age distribution of the population, and the fact that the average age of decedents has doubled in Chicago is not necessarily an indication of increased length of life. To illustrate: The average age at death in a certain infant asylum is two years and six months; that of a neighboring old ladies' home is seventy-five years. We are not, therefore, to infer that the health of the old ladies' home is thirty times as good as that of the infant asylum. This, to be sure, is an exaggerated instance, but the illustration applies equally well to cities and towns. In the two towns of Yarmouth and Winthrop in Massachusetts, each situated in healthy locations on the seacoast, the average age at death in 1885 was respectively sixty-seven years and six months, and seventeen years and four months. This cannot be interpreted as meaning that the sanitary condition of Yarmouth was fourfold better than that of Winthrop. The explanation, as in the other instance, is that Yarmouth, like most of the Cape Cod towns, has a scarcity of young children, while Winthrop has a corresponding dearth of old people. Almost any populous Western city has an unusually large proportion of young and healthy

people between the ages of fifteen and thirty years, an age at which the death-rate is very low, not over seven or eight per thousand. Hence it is that in England, when comparing death-rates, the custom has arisen of correcting them, and of referring them to a standard population, such as that of the country at large, or to that of some unusually healthy country like Sweden, which has always had a low death-rate. There is, therefore, a manifest fallacy in comparing the death-rate of Chicago with that of any foreign country, without making the proper correction due to the difference in the constitution of the population.

(3) The health commissioner has adopted an expedient which among sanitary authorities can hardly be considered as a fair method of representation, that of comparing extremes instead of means. The year 1872, as is well known, was throughout the United States the most unhealthy year of the last half century. In every large city where records were kept the death-rate was at its maximum. Almost every known infectious disease seemed to run riot in that year, while, on the other hand, 1898 was a year of unusual health, the death-rate throughout the country being exceptionally low. The only fair method of comparison would have been to compare the means of two five- or ten-year periods, as, for example, 1871 to 1875 with 1891 to 1895, or 1894 to 1898.

AMERICAN MEDICAL ASSOCIATION.

THE last meeting of this growing Association has just been held under more favorable weather conditions than are ordinarily to be expected at this time of year. The gathering was an enthusiastic one, as attested by the fact that upwards of 2,000 members were present. Corresponding with this attendance was a programme which has rarely been equalled in the number and variety of communications presented. Of quantity, therefore, there was certainly no lack, but we are inclined to feel that in these days of excessive literary zeal in medical writing a certain censorship, tending to an improvement of the quality and the arrangement of the subject matter, would not be amiss. Sporadic papers on such occasions are of comparatively small value, and serve rather as a personal advertisement than as a substantial addition to medical progress. It is to be hoped that this representative Association will make a virtue of necessity and bring its programmes in the future within reasonable limits. Science would not suffer, and the responsibilities placed upon the broad shoulders of the medical editor would be visibly lightened. We are, therefore, quite in accord with our contemporary, the *Philadelphia Medical Journal*, when it comments editorially on the recent meeting: "There was the same plethora of papers offered, again proving how necessary it is that the officers of sections should weed and choose and limit according to their judgment and conscience, and regardless of personal influences."

MEDICAL NOTES.

INTERNATIONAL MEDICAL CONGRESS.—At the request of Henry B. Jacobs, M.D., Secretary, American National Committee of the International Medical Congress, the following official statement is made: According to instructions from Dr. A. Chauffard, Secretary-General of the Thirteenth International Medical Congress, no subscriptions to the Congress will be received after the 15th of July, and the name of no subscriber will appear in the official programme whose subscription is not received before the 15th of June. The publications of the Congress will consist of seventeen volumes, one of which will be sent gratuitously to each subscriber; that is, the volume containing the papers of the section under which he has inscribed himself. The other sixteen volumes may be purchased at a price of four francs per volume, or forty-five francs for the series.

PHILIPPINE ASSOCIATION OF ACTING ASSISTANT SURGEONS, UNITED STATES ARMY.—The first annual meeting and dinner of the Philippine Association of Acting Assistant Surgeons was held in Manila, May 3d. The Association was formed April 28, 1900, on board the United States Army transport *Grant*, on which seventeen of the members of the Society came over to the Philippines to care for sick and wounded soldiers. The following were elected officers of the Association: President, H. W. Beal; Vice-President, H. Morell; Corresponding Secretary, R. M. English; Recorder, H. M. Stromberger. It is the intention of the Association to enroll as members all the acting assistant surgeons in the Philippine Islands and hold a meeting and banquet on "Dewey Day" (May 1st) every year in the future.

PRIVILEGES FOR MEMBERS OF THE INTERNATIONAL CONGRESS.—The following special privileges are to be accorded to the members of the Congress: The right to participate in the proceedings of all the sections; invitation to all festivities; entrance free of charge to the Exposition during the session of the Congress, August 2d to 9th; a badge engraved for the Congress by M. Vernon; reduction in railway and other fares; facilities for securing lodgings.

CHOLERA IN BOMBAY.—A serious epidemic of cholera is reported from the northern districts of Bombay. The sufferers from famine fall an easy prey to this disease. The Government has made a special appropriation of £1,000 for immediate cremation of the dead.

DEATHS ABROAD.—The following deaths of distinguished physicians are announced: Dr. A. Milne Edwards, Paris; Dr. Apostoli, Paris; George Viner Ellis, F.R.C.S., London.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, June 13, 1900, there were reported to the Board of Health of Boston, the following

cases of acute infectious diseases: diphtheria 61, scarlatina 34, measles 89, typhoid fever 16.

MORTALITY REPORT OF BOSTON.—The number of deaths reported to the Board of Health for the week ending June 9th was 215, as against 208 the corresponding week last year, showing an increase of 7 deaths, and making the death-rate for the week 20.2. The deaths from consumption were 25; pneumonia, 27; whooping cough, 1; heart disease, 22; bronchitis, 6; marasmus, 7. There were 8 deaths from violent causes. The number of children who died under one year was 35; under five years, 67; persons more than sixty years, 40; deaths in public institutions, 63.

APPOINTMENTS AT THE HARVARD MEDICAL SCHOOL.—Franz Pfaff, M.D., has been appointed assistant professor of pharmacology and therapeutics for five years. Dr. F. H. Davenport has been reappointed assistant professor of gynecology.

PRESIDENT OF THE MASSACHUSETTS MEDICAL SOCIETY.—Dr. F. W. Draper, of Boston, has been elected President of the Massachusetts Medical Society.

DIPHTHERIA IN WATERTOWN, MASS.—Several new cases have recently been reported to the Watertown Board of Health.

NEW YORK.

STATISTICS OF WOUNDS IN WAR.—In a paper read by Capt. W. C. Borden, U. S. A., on the last day of the recent meeting of the Association of Military Surgeons, on "The Mortality of War Wounds, with Tentative Conclusions Relative to Modern Weapons and Surgical Methods," the following statistics were given: In the American Civil War out of every 100 persons struck by a bullet 15 per cent. died on the field of battle; in the Russo-Turkish War, 21 per cent.; in the Spanish-American War, 17 per cent. Of the 100, 40 received wounds of the head, 29 wounds of the abdomen, 26 wounds of the chest, and three wounds of the extremities. Of the men wounded and carried from the field of battle during the Civil War, 10.9 per cent. died; in the Spanish-American War, seven per cent.; in the Boer War, four and a half per cent.; in the Philippine War, six per cent. Having given the statistics of wounds in different parts of the body in the several wars mentioned, Dr. Borden stated that the data he had collected showed that so far as the modern armament in death-dealing weapons is concerned, the modern weapon seems to be as destructive as those of earlier years, as regards wounds in the head, chest and abdomen, on the field of battle. The fact that there was a smaller percentage of deaths from wounds in other portions of the body showed the improvement in surgery and the care of the wounded. In the Boer War two-thirds of the British soldiers who were wounded and attended in the hospitals were able to return to the field. The reason for this was not so much the lessening of the destructive power of the rifle as the great progress made in surgery and hospital care.

DESTRUCTION OF GARBAGE.—Capt. F. M. Gibson, Deputy Commissioner of Street Cleaning, has advertised for proposals for the erection of a plant, or plants, for the destruction of the city garbage, to replace the works on Barren Island, which, under an act passed by the last Legislature, must be removed within a year. Among those desirous to undertake the work, it is said, is the Horsfal Company, an English corporation, which cremates the garbage of Liverpool, Leeds and a number of other British cities. In the meanwhile, the department has been notified by the present contractors that they purpose testing the constitutionality of the new law.

BIOLOGICAL LABORATORY FOR VASSAR COLLEGE.—Announcement has been made of the completion of the fund of \$50,000 for the construction and equipment of a biological laboratory at Vassar College. Over a year ago a friend of the College residing in New England, whose name was not made public, offered to subscribe \$25,000 for this purpose, on condition that the additional \$25,000 required could be raised. The hope was expressed that all the money might come from New England, and it is said that the entire sum has been secured through the efforts of the Boston branch of the Vassar Alumnae.

COMMENCEMENT, MEDICAL DEPARTMENT OF CORNELL UNIVERSITY.—The annual commencement of the Medical Department of Cornell University was held at Carnegie Music Hall on June 6th. There were fifty-three graduates, twenty-one of whom were women. On the roll of honor, which comprised ten names, there was one woman. President Schurman announced that of the entire number of graduates thirty-four have already received appointments in hospitals in New York and adjoining cities. The address to the graduating class was made by the Rev. Dr. Vanderwater.

APPOINTMENTS AT THE COLLEGE OF PHYSICIANS AND SURGEONS.—At a meeting of the Trustees of Columbia University, held June 4th, the following appointments in the Medical Department (the College of Physicians and Surgeons) were announced: Dr. Frank Hartley, professor of clinical surgery and instructor in operative surgery; Dr. Francis H. Markoe, professor of clinical surgery at the New York Hospital; Dr. Bern B. Gallaudet, demonstrator of anatomy; Drs. Robert A. Budington and Nathan W. Greene, assistant demonstrators in anatomy.

REGULATIONS REGARDING TUBERCULOSIS IN NEW JERSEY.—The Board of Health of Trenton, N. J., with the backing of the State Board, has recently adopted an amendment to the Health Code, placing consumption among the contagious and infectious diseases. It provides fines and imprisonment for physicians who fail to report cases of consumption within thirty days after they are diagnosed. Hospitals are not exempted from the general provisions.

COMMENCEMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.—At the sixty-eighth annual

commencement of the University of the City of New York, which was held at the Metropolitan Opera House on June 7th, there were thirty-eight graduates in the Medical Department (University and Bellevue Hospital and Medical College), and eight graduates in the Department of Veterinary Surgery.

COMMITTEE OF ONE HUNDRED ON INDIA FAMINE RELIEF.—A committee of one hundred representative citizens of New York, under the chairmanship of Wm. E. Dodge, has recently been formed to the end of sending relief for India famine sufferers. The committee will constantly study the conditions of the famine itself, and make every effort to choose the best method of relief.

ARMY NOTE.

INVESTIGATION OF DISEASE BY ARMY MEDICAL OFFICERS.—A board of medical officers has been appointed to meet at Camp Columbia, Quemados, Cuba, for the purpose of pursuing scientific investigations with reference to the infectious diseases prevalent on the island of Cuba. The board will act under instructions from the Surgeon-General of the Army. The detail for the board consists of Major Walter Reid, Surgeon U. S. A., and Acting Assistant Surgeons James Carroll, Aristides Agramonte and Jesse W. Lazear. It is understood that the board will chiefly devote attention to the investigation of yellow fever. Dr. Agramonte has been studying this disease in Havana for the past eighteen months, while Major Reid and Dr. Carroll, at the Army Medical Museum in Washington, have been engaged in an exhaustive study of Sanarelli's bacillus and serum, the results of which have already been made public. The work of the board will be done in the army laboratory at Quemados. As mentioned in a previous issue, the systematic investigation of disease by army medical officers in Cuba, Puerto Rico and the Philippines has already been of great value to medical science. From the organized investigations now going on, much may be expected.

Miscellany.

HORSEFLESH AS A FOOD.

In view of the fact that horseflesh is being used more and more as a food in Germany, and through force of necessity, as in the South African War, must at times be eaten in lieu of other meat, it becomes a matter of importance to determine its effects upon the body. This Professor Pflüger has done, his results being published in the *Archiv für Physiologie*, and abstracted in a recent number of the *Lancet*. The experiments went to show that the known deleterious effect of horseflesh, characterized chiefly by excessive diarrhea, is due to a toxin, probably consisting of neurin or some modification of that poisonous agent.

The paper concludes with some suggestions for cooks in beleaguered garrisons who are reduced to horseflesh as food, which, coming from the pen of one of the most distinguished living physiologists, deserve consideration. In one mode of dressing the horseflesh is converted into a pulp, and for every two pounds about three-quarters of an ounce of ox fat or mutton fat taken from the region of the kidneys is served up with a sauce of meal as a hash. Another is to cut it into collops, boil it in water, throw away the broth, and serve it with a fat sauce. Beer, wine, tea or coffee may be taken with it. A third is to convert it into a pulp, add a tenth of its weight of rice and a fortieth of its weight of fat, and cook by steaming; or, lastly, it may be beaten up with plenty of fat and eaten with an oily sauce.

Obituary.

PAUL GIBIER, M.D.

DR. PAUL GIBIER, of New York, died June 9th, from injuries inflicted by an accident. He was born in France in 1851, and was at one time a pupil of Pasteur. In 1888 he was commissioned by the French Government to make an investigation of yellow fever, in Havana and Florida, and on his way back to Paris, while in New York, conceived the idea of establishing an institute in the latter city for the treatment of hydrophobia. With this work he was closely identified until his death.

Correspondence.

PRELIMINARY REPORT ON INVESTIGATIONS IN THE BACTERIOLOGY OF SCARLET FEVER IN THE SCARLET-FEVER WARDS OF THE CHILDREN'S HOSPITAL, BERLIN.

BERLIN, May 18, 1900.

MR. EDITOR:—The work described below is according to plans I formed some eighteen months ago, at which time I lacked proper opportunities for carrying them out. Under strict aseptic precautions I have lately collected, through a canula into sterile test tubes, hydrocele fluid from a healthy child of nine months who has never had any of the contagious diseases or even been vaccinated. Specimens of this material remained sterile after a number of days at body temperature. Into this media I made inoculations from the blood of several patients in the early eruptive stage of scarlet fever, observing rigid asepsis. Cultures were similarly prepared on coagulated ascitic fluid, bouillon, agar-agar and milk. All were kept at body temperature for about thirty-six hours. Examination then showed no development in any but the hydrocele fluid, in which appeared a feeble growth of a capsulated diplococcus in pure culture. It grew thus from the blood of each case, and while probably the same organism often described in connection with scarlet fever as the diplococcus pneumoniae cruposæ, it may be but a variety of that germ. On re-inoculation of this into agar-agar, gelatine, blood serum and hydrocele fluid, a luxuriant growth now appeared in each within twenty-four hours. In the latter media the bacteria developed very rarely in anything but pairs. The ends of these oval cocci always pointed away from each other, and unstained preparations seemed to show dark granules in the protoplasm. The growths on the blood serum and agar appeared as frosty, granular, grayish-white streaks limited to the path of the inoculating needle. The stab culture in gelatine was similar and

no liquefaction attended it. Cover-slips prepared from these took the methylene blue stain irregularly. No change in reaction accompanied the growth on the media.

On investigating as to why I did not succeed in inoculating the artificial media from the patient's blood, and why the original cultures in hydrocele fluid were hindered in developing, my experiments showed a reactive power in the blood of scarlet-fever patients against this diplococcus. I found that in hanging-drop preparations from the second generation in hydrocele fluid the organisms when placed simply in normal salt solution remained scattered throughout the droplet in pairs and kept their slight motility for hours. A similar drop in salt solution to which some blood from a patient convalescent from this fever was added gave quite a different appearance after some minutes. The bacteria were then found only at the edge of the drop, had become quiet and often appeared in groups. However, when hanging-drop preparations were treated simply with blood from a child which has never had scarlet fever the cocci gave the same appearance as when only in normal salt solution.

From a culture of the streptococcus which I prepared on blood serum from the throat of one of the patients (as I did not meet with it in the several cultures from the blood) I inoculated a colony into the hydrocele fluid and also into the latter media after coagulation. No growth developed in the former and only three or four colonies in the latter, but numerous colonies of streptococci were found after I caused the diplococcus to grow on the media. From the heart blood of one of the cases which proved fatal I did not succeed in growing the diplococcus.

My experiments as to the power existing in the blood of convalescents from scarlet fever to hinder the growth of the diplococcus when already developing on media are not yet complete. The inability to gather sufficient supply of suitable hydrocele fluid while at work in the contagious wards has as yet prevented my carrying the investigation out on a more extensive scale or to definite conclusions. Up to this time I have not experimented with hydrocele fluid in the other contagious diseases, nor can I say how the germs mentioned will act on the hydrocele fluid from those children believed to be immune to scarlet fever.

I injected half a cubic centimetre of the vigorous growth in hydrocele fluid into the peritoneal cavity of a kitten and no symptoms whatever followed.

The results of my examinations thus far would seem to justify the following inferences:

- (1) The early presence of this diplococcus in the blood of many if not all scarlet-fever patients, and the absence in the blood at this time of the streptococcus.
- (2) That hydrocele fluid from a child who has not had a contagious disease may possess qualities better suited for investigating that disease than the artificial media or serum changed by heat.
- (3) That the blood of those who have been infected with this diplococcus a short time shows a reactive power against it.
- (4) That the doings of this "happy pair" seem to open the way for the serpent of streptococcus to bring evil into the Eden of childhood.

Very truly yours,

W. F. DOOLITTLE, M.D.,

of Cleveland, Ohio.

FOREIGN BODY IN THE RECTUM.

WINCHENDON, MASS., June 4, 1900.

MR. EDITOR:—A man, age sixty, recently consulted me at my office for what he termed "a little trouble with his rectum." On enquiring the nature of the trouble, he said he thought there was a "small vial" in it. He said he had inserted it about thirty-six hours previously; had consulted his doctor at home, who did not examine him but gave a cathartic. On examination I found what seemed to be a bottle of considerable size, well inside the sphincter, with the neck down. It was firmly impacted and I was

soon convinced that its removal would be a matter of difficulty. He was having a good deal of pain and the abdomen was considerably distended and tympanitic. With the assistance of Dr. Thorning, he was thoroughly anesthetized and by grasping the neck of the bottle with two pairs of heavy tooth forceps, having the jaws well guarded with compresses, after a difficult and disagreeable labor we succeeded in delivering the vial. It proved to be a round bottle, fortunately of very heavy glass, and with quite a rim at the neck which afforded an excellent hold for the forceps. It was of the following dimensions: Length five and one half inches, circumference of neck five and one fourth inches, of shoulder eight and one fourth inches, of base six and three-fourths inches.

By diligent questioning, I obtained the following scanty history. Of vigorous physique, he had always enjoyed excellent health, and had for many years been employed in a shop. Was married, and till within a year or two his relations with his wife had been pleasant, but for a year or two they had occupied separate beds, and his wife had accused him of improper relations with other women. Admitted that he was quite amorous, and that he had on one or two previous occasions introduced something into his rectum.

Very truly yours,
J. G. HENRY, M.D.

Newburyport . . .	15,036	6	1	33.33	—	—	—	—	
Melrose . . .	14,721	4	1	—	—	—	—	—	

Deaths reported 907; under five years of age 308; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 220, acute lung diseases 128, consumption 105, diphtheria and croup 27, diarrheal diseases 24, measles 12, scarlet fever 10, cerebrospinal meningitis 10, whooping-cough 9, typhoid fever 7, erysipelas 5.

From scarlet fever Boston 8, Washington, Worcester and Lawrence 1 each. From cerebrospinal meningitis Quincy and

Marlboro 2 each, Boston, Baltimore, Worcester, Cambridge, Lynn and Gloucester 1 each. From whooping-cough Boston 3, Baltimore and Salem 2 each, Washington and Providence 1 each. From typhoid fever Washington 2, Boston, Baltimore, Providence, Lawrence and Newburyport 1 each. From erysipelas Boston, Baltimore, Washington, Somerville and Lawrence 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending May 26th, the death-rate was 18.4. Deaths reported 4,098; acute diseases of the respiratory organs (London) 296, measles 127, whooping-cough 126, diphtheria 81, diarrhea 39, fever 34, scarlet fever 34, small-pox (Liverpool) 2.

The death-rates ranged from 12.3 in Croydon to 27.4 in Liverpool: Birmingham 20.1, Bradford 16.1, Cardiff 12.6, Gateshead 18.6, Hull 21.2, Leeds 22.1, London 16.4, Manchester 25.5, Nottingham 17.0, Portsmouth 16.0, Salford 23.8, Sheffield 19.4, Swansea 15.8, West Ham 13.4.

METEOROLOGICAL RECORD

SOCIETY NOTICES.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.—The tenth annual meeting of this Association will be held September 25, 26 and 27, 1900, at the Academy of Medicine, New York City.

MAINE MEDICAL ASSOCIATION.—The forty-eighth annual meeting of the Association will be held in Portland, Me., June 13, 14 and 15, 1900.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the Chicago Pathological Society, from May, 1897, to June, 1899. Vol. III. 1900.

Normal Histology. By Edward K. Dunham, Ph.B., M.D., Professor of General Pathology, Bacteriology, etc. Second edition, illustrated. Philadelphia: Lea Brothers & Co. 1900.

Contributions to the Science of Medicine. Dedicated by his pupils to William Henry Welch on the Twenty-fifth Anniversary of his Doctorate. Baltimore: The Johns Hopkins Press. 1900.

Transactions of the New York State Medical Association for the Year 1899. Vol. XVI. Edited for the Association by M. C. O'Brien, M.D., of New York County. New York City. 1900.

Verhandlungen des Vereins für innere Medizin zu Berlin. Herausgegeben von dem Vorstande des Vereins, Jahrgang XIX, 1899-1900. Sonderabdruck aus der "Deutschen medicinischen Wochenschrift," Jahrgang, 1899-1900. Berlin. 1900.

A Manual of Obstetrics. By A. F. A. King, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children in Medical Department of Columbia University, etc. Eighth edition, revised and enlarged, illustrated. Philadelphia and New York: Lea Brothers & Co. 1900.

The Management of Large Congenital Exomphalos; Infantile. The Therapy of Feminine Hernia in the Adult. On Radical or Tentative Treatment of Piles. Hemorrhage and Circulatory Disturbances in Complicated Fracture. By Thomas H. Manley, M.D., New York. Reprints. 1889-1900.

A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., B.Sc. Illustrated. Eighth edition. Philadelphia and New York: Lea Brothers & Co. 1900.

Address.

REALISM IN MEDICINE.¹

BY A. T. CABOT, A.M., M.D., BOSTON,
Surgeon to the Massachusetts General Hospital.

(Concluded from No. 24, p. 618.)

I HAVE presented to you this brief and incomplete sketch of the great movement of medicine under the guidance of realism, to show how it has steadily proceeded along a path without a break, or rather the progress has been more like that of an army penetrating an enemy's country, where different columns, mutually supporting each other, advance along parallel lines, meeting success now here, now there.

Cellular pathology put us in a position to appreciate and understand the action of germs, and the work in bacteriology opened ways in which the student of the cell could make still further conquests.

I have not tried to do more than point out the grand strategy of the forward movement and the important places that have been taken. Many of the lesser achievements in this advance have, however, been essential to the success of the greater.

Physiology, physiological chemistry, pathology, bacteriology, embryology, anatomy, clinical medicine and surgery, have all, within their own fields of action kept abreast of the general movement. Men trained in science, skilled investigators, have occupied the firing line, constantly pushing forward, and as fast as they have gained new territory the practitioners of medicine have moved in like settlers and made it their own.

After this hasty review of the general course of medicine in this century, it should be of especial interest to us to study the part which America has played in promoting and in keeping step with the advances that have been made.

At the beginning of the century the main idea that an American student had in entering upon the study of medicine was to learn what he could of the care and treatment of the sick, with so much understanding of anatomy, physiology and pathology as could be made of service in his practical work. The teaching in the scientific branches of medicine was, as I have said, very meagre in this country, so that a young man, wishing to be thoroughly abreast of the times, was forced to seek instruction in the laboratories of Europe. The result of this was that a well-trained American physician had usually passed two years abroad acquainting himself with the methods of the best teachers of the world.

The lack of opportunity at home, forcing men to travel, had its partial recompense. For the young American, travelling from teacher to teacher, going for each part of his education to the place where that was best taught, learned to look at things in a broader way than would have been the case had he found all that he required in one school.

This increased breadth of view was at once reflected in the medical practice of the men so trained, and long before American physicians began to take their proper place as scientific investigators, they developed in their ranks some of the best practitioners in the world.

Many men came back from their foreign travel filled with a desire for research; but the absence of

laboratories and the need for self support stunted their aspirations in such directions. It was not until the last quarter of the century that the use of laboratories became so manifest that they began to spring up and to receive adequate support in this country. I cannot, even in so condensed a review of this movement, forbear to speak of the pioneer work done at the Johns Hopkins Hospital under the inspiring lead of our guest, Prof. William H. Welch. The wise provisions of that foundation gave the Johns Hopkins Medical Faculty the almost unique opportunity of putting their school on the right line from the start. And, thanks to the wisdom and energy of Professor Welch and his co-workers, the scientific investigation of disease at once took its proper place in that institution. Since that time the constant help that laboratory investigation gives to the clinical study of disease has appealed so strongly to the practical American mind that pathological laboratories have sprung up in every direction and are still constantly on the increase. These have been of the greatest value in raising the scientific quality of the work in many of our communities. Such laboratories have given men inclined to research opportunity for pursuing their studies, and have also enabled many clinical workers to acquire a knowledge and facility in scientific methods. This training has been of great service in their practice. They have gained a clearer understanding of morbid processes and have come to have a personal acquaintance with the germs against which they are constantly waging war. When a man thus trained speaks of a bacillus, he has in his mind a distinct picture of its appearance and its characteristics. He knows where to look for it and what effects to expect. If it is a pneumococcus he watches the serous membranes and early detects its migration to them. His horizon has become wider and his vision more acute.

With the appearance of laboratories the need of endowments for pathological and other scientific work has been brought home to our people. Practical business men see that the researches in the higher branches of medicine bear tangible and most valuable results; that by them the health of the community is improved and protected. They are thus encouraged to invest in a movement which has such evident good effects in the present and that holds forth still brighter promises for the future. Considerable sums of money have been drawn into these enterprises and have already done much good. They have, however, been but as a drop in the bucket which we wish to see filled. This work, by its interest attracts the best minds and the world should discharge its proper obligation to them and should see that they are adequately cared for.

The administration of laboratories and the prosecution of complicated investigations is expensive.

At present I see no direction in which charity to the human race can better expend itself, with full assurance of lasting good, than in assisting the prosecution of such studies, whose benefits are shared by all peoples and go down to remotest posterity.

The perfecting of a system under which the scientific investigation of disease may flourish should be the constant aim of all American physicians. The profession of this Commonwealth have already taken steps in this direction, of which mention may be here appropriate. A quarter of a century ago we had at the Harvard Medical School, a chemical laboratory, a

¹ The Annual Discourse read before the Massachusetts Medical Society, June 13, 1900.

physiological laboratory, a dissecting-room and a small pathological laboratory. Students had fairly good opportunities for the study of chemistry and anatomy, but they had no regular laboratory instruction in either physiology or pathology. Both of these important branches were taught by lectures to large classes in which each individual had but little personal contact with the professor, or with the phenomena described. The pathological instruction up to that time and till a considerably later period, was given by men who depended on clinical practice for their support and gave what time they could spare from this to their own scientific studies and to the instruction of the students.

It would take too long to describe in any detail the gradual changes by which this condition of things grew and expanded into that which exists to-day; but a statement of the present provisions for research and teaching in the Harvard School will give an idea of the rapidity with which this movement has advanced.

The physiological laboratory, with a professor, an associate professor and a greatly increased corps of teachers, is now thrown open to the students, who receive personal instruction in small classes. There is a laboratory for embryology and histology, where the development and the finer anatomy of the tissues is taught to small classes by the professor, the assistant professor and other assistants.

There is a good-sized pathological laboratory under the direction of a professor who gives his whole time to study and teaching, and he has in addition to this the control of the clinical laboratory at the City Hospital, which is under the supervision of the assistant professor.

The clinical laboratory at the Massachusetts Hospital is also available for teaching purposes, and being under the direction of one of the instructors in pathology, makes very substantial contribution to the opportunities that students have in this branch.

Surgical pathology has a special demonstrator and the curator of the anatomical museum, having control of the surgical material obtained at the Massachusetts Hospital, is able to give special instruction in it. In the new buildings now nearing completion, he will have a large room devoted to his department and will have ample accommodation for small classes in this specialty. The surgical department, too, have taken steps towards the establishment of a special laboratory in the Medical School for surgical pathology.

Even this list does not complete the recital of what the Harvard Medical School is doing for pathology, for at the Bussey Building in West Roxbury the professor of comparative pathology has his laboratory and is constantly at work on the pathological questions suggested by the diseases of animals and has done much in tracing out their connections with human diseases. The limitations of the laboratory space at his disposal prevents his accommodating students, but his own original researches are making constant valuable contributions to our knowledge of microbic diseases.

In addition to these laboratories and teachers devoted to the study of pathology, the medical school has also a large and well equipped laboratory devoted to bacteriology, and a professor with a corps of assistants devoted to the study of the life history of microorganisms. Besides the instruction and research work done there, great assistance is rendered to private

practitioners by the systematic examination of material submitted. Thus this department acts in a measure as a clinical laboratory for the profession outside of the hospitals.

A considerable enlargement of the chemical laboratory and its staff, the establishment of a laboratory for physiological chemistry under able direction, a laboratory of pharmacology and a laboratory of hygiene, with an assistant professor, who, besides his research and teaching, gives aid to practitioners by examinations made for them, complete this rehearsal of the present provisions and opportunities for scientific training.

Certainly the contrast between the conditions of twenty-five years ago and those of to-day indicates that our medical teachers are fully awake to and mindful of the demands of modern science. Indeed, despite all the recent improvements that I have imperfectly recounted, the College is, at this moment, considering a plan for the very great enlargement of the Medical School accommodations. They are driven to this by the need for still more laboratory space to meet the requirements of modern medical education.

I have selected the Harvard Medical School to serve as an illustration of the recent advances in American methods of study, because it is the institution with which we are most familiar. Similar changes have been going on in greater or less degree in all our centres of medical study, and as a result of this awakening of interest in scientific investigation and teaching, we have already reached the point where it is no longer necessary for American practitioners to go abroad to complete their training in the higher branches of medicine. Ample opportunities now exist in this country for the attainment of an education wholly up to the modern requirements of practice.

It is still wise for a man who can spare the time to travel and learn what he can of other points of view and methods of work. I am inclined to think that the time is near, if not already here, when our foreign *confrères* might learn something by coming to this country.

An acquaintance with the literature of a subject does not widen a man's field of view in the way that an acquaintance with the makers of that literature does.

To return from this digression and to continue our consideration of home matters, we find that this movement towards scientific and accurate methods is not confined to the teachers of medicine. If the time served, it would be a congenial task to say a few words of deserved praise of our boards of health.

The executives of State and city have been fortunate in selecting competent, sagacious men to guide the public in matters of sanitation. We are not surprised, therefore, to find that they have been fully alive to the forward movement in medicine, and have established laboratories for the study of sanitary questions. Here are made the many tests necessary in the selection of cases for isolation. Antitoxin is here carefully prepared for distribution, and all possible aid is given to practitioners in the application of laboratory methods to the study of their cases.

We are thus entering the twentieth century with an enthusiasm and a promise for the future which are well justified by what has already been accomplished.

We have many unfinished tasks on our hands. Important principles have been established in the nine-

teenth century the detail of which remains to be worked out.

There are many infectious diseases and others believed to be parasitic in origin, of which the microbial causes remain to be discovered.

Our knowledge of the action of microbes in the body and of their effects upon the tissues is in its infancy.

What we know of the action of the tissues in protecting themselves from the micro-organisms and their products is as nothing to what remains to be known.

Efficient autitoxic sera are as yet few, but the list is slowly growing.

These are all questions which bear directly on the successful treatment of disease. We wish, however, to aim higher than this and to learn how to prevent disease.

Our experience with small-pox and diphtheria shows that for some diseases, at least, the body may be made resistant by producing alterations in its fluids or tissues. Lister has shown us, too, how other diseases may be prevented by intercepting the microbes and preventing their entrance into the body. This is comparatively easy in surgery, where we have full control of the conditions; can we not protect the body from other infections? Our methods of disinfection of dwellings and public places are constantly improving, but they are still lamentably inadequate. Our boards of health have accomplished something by the isolation of cases of infectious disease and by the extensive use of disinfectants to cleanse the habitations of the sick. The street cars are adorned with signs warning against expectoration, in the hope of thus limiting the spread of tuberculosis, the germs of which are contained so abundantly in the sputa of those afflicted.

May we not hope that further knowledge of the life history of micro-organisms and a more widely spread habit of seeking them out may make their destruction more generally attempted and more thorough?

If every public hall and school-room could be safely and quickly disinfected during the night hours while it is empty, is there any doubt that the public health would be greatly benefited thereby? Sanitary engineering may make this possible, in which case every enlightened community will make it obligatory. Unfortunately, there is a force constantly contending against the efforts of our sanitarians and this is the very steady increase in the numbers and consequent crowding of our populations. For germs flourish in a crowd.

It is to be hoped that the efficiency of our methods of sanitation will be so greatly added to in the near future as to enable us to meet and overcome these increasing difficulties.

There is another nut that the nineteenth century leaves for the twentieth century to crack, if it can. It is the question of the cause and nature of malignant growths. With all the knowledge of them that we have gained through cellular pathology and embryology, we are still left much in the dark with regard to their causation. Bearing considerable resemblance, as some of them do, to processes that are known to have a microbial cause, it is natural that attempts should have been made to convict them of a parasitic origin. Without going into the arguments or a minute consideration of the evidence advanced, I think

that I shall be in accord with the best present opinion if I bring in a verdict of "not proven."

Diseases of this sort, especially the carcinomata, are apparently on the increase. So prevalent are they and so much to be dreaded that were it possible to choose in advance the next great medical achievement, the world's vote would probably be for the discovery of a cure for cancer.

It will then, perhaps, be interesting for you to know that provisions have been recently made in this community looking to systematic research into the cancer question, and I am sure you will be glad to hear what steps are being already taken in this direction. Last year a sum of money was put at the disposal of Harvard College for the investigation of this question. The donor, Mrs. Caroline Brewer Croft, left by will, \$100,000 for this purpose, and after deducting the exceedingly liberal legacy tax which England exacts, a still considerable sum is left for the furtherance of the wishes of the testatrix. The income of this fund, with some substantial additional gifts obtained by the professor of surgery for the same object, are now available for these researches. The investigations under the direction of a committee appointed by the corporation of the college have been put in charge of the department of surgery, and the instructor in surgical pathology has been selected to especially devote himself to a study of the pathological side of the subject. The co-operation of the laboratories of the Boston City Hospital and of the Massachusetts General Hospital has been obtained, and workers in these laboratories have been selected to devote their time to this object. All of these men are in close touch with each other and will have the control of a large amount of material.

At first it is proposed to examine the present theories of cancer production. The question of the relation of germs or parasites to these growths will receive minute and exhaustive attention. Incidental to this examination, the inoculability and infectiousness of malignant growths will be studied.

Besides this study of the pathological side of the subject, attention will be given to the general question of whether the impression that malignant growths are on the increase is well founded. Statistics are already being collected with a view to getting information upon this point as well as ascertaining the conditions of life which favor the development of these neoplasms, and it is hoped that by a long persistent effort in this direction, light may be thrown on the etiological side of the question.

Something may also be hoped from a patient investigation of remedial agents. In syphilis and in some skin affections we have new growths of tissue which are caused to disappear by the constitutional use of drugs. The effect of arsenic in so-called sarcoma of the skin, and the fact that this same drug has, in some cases, effected or seemed to effect the disappearance of a sarcoma which had invaded the lymph glands, offers some encouragement in this direction.

Such is the beginning of this enterprise. The funds are barely sufficient for a good start, but for so good an object it is to be hoped that others will be forthcoming. In the neighboring State of New York a liberal appropriation has been made by the Legislature for similar researches. So much earnest effort cannot be without avail, and it is satisfactory to us all to feel that America is lending her hand to the investiga-

tion of this burning question. Whatever comes of it we may be sure the labor will not be wasted.

Most of us here are practitioners of medicine, men so occupied in the care of the sick that but little strength or time is left for the pursuit of purely scientific studies. Are we then mere spectators of this forward movement? I do not think so; and I wish to close this rather rambling discourse by pointing out a few of the ways in which the busy profession at large may substantially assist their brethren who are devoting themselves to research.

The mere moral support of feeling that the profession are backing them up and are appreciative of their labors and quick to profit by them is of great importance to the investigators.

The intelligence of the audience has a stimulating effect upon the teacher, and if we take an active interest in this work and keep ourselves informed of the steps gained, we shall lend the encouragement of our interest to the men working in laboratories. We shall, at the same time, fit ourselves to properly judge new ideas and shall be stimulated to accurately observe and record phenomena which pass under our eyes. It must act as an incentive to the men who are working out the higher problems of medicine to feel that any hint they are able to obtain will be at once made of practical value, or will at least be fairly tested and its value determined.

A profession thus made up of men who are in the habit of applying all known scientific methods to the study of their cases and who demand that every patient shall have the advantage of as minute an investigation as is possible, will keep the scientists supplied with material for their studies and by bringing them in contact with patients will make them in a measure sharers in the emoluments of practice.

This last consideration is no small matter, for in this country where government does not support its investigators, they must be provided for in other ways. The medical colleges supply places and salaries to a certain number, but there are many men of scientific bent who are unable to follow their inclinations because they must be sure of adequate support for themselves and families. If an enlightened profession demands the services of such men, we may be sure the supply will equal the demand. The army of investigators will not lack recruits. Many a good man will be enabled to spend his life in congenial research instead of seeking his livelihood in the routine of practice, for which perhaps he is ill fitted.

Do not understand me to disparage the practice of healing the sick or to imply that any other pursuit is higher. I only wish to point out that a man loving the laboratory may if driven into general practice prove to be a square peg in a round hole.

Lastly, it is important that the profession at large, who come in close contact with the people, should keep the community informed of the importance and magnitude of scientific work. In this way only can the proper interest be aroused and necessary endowment and support be obtained.

These are a few of the many duties devolving upon us as we enter the twentieth century. We are in the middle of the stream of medical progress and the current shows no sign of slowing. Let us do our utmost to ensure that it flows on with increasing tide and that there are no back eddies or slack water on the American side.

Original Articles.

CLOSING STATEMENT FOR THE REMONSTRANTS TO THE MASSACHUSETTS HOUSE BILL NO. 917, ENTITLED "AN ACT FOR THE FURTHER PREVENTION OF CRUELTY TO ANIMALS," BEFORE THE JOINT COMMITTEE ON PROBATE AND INSOLVENCY, MARCH 15, 1900.

BY HAROLD C. ERNST, A.M., M.D., BOSTON,
Professor of Bacteriology in the Harvard Medical School; President of the Boston Society of Medical Sciences.

(Concluded from No. 24, p. 622.)

THE Committee must remember that this bill is not aimed alone at the studies of normal and abnormal processes in the physiological laboratories, but at all inoculation experiments as well, and that these may last over a series of days, weeks or sometimes months. These inoculation experiments include all studies upon the etiology (causation) of the infectious diseases, and cannot be studied in the time that an animal will survive under ether or chloroform. Upon these experiments are based practically all the advances that have been made in sanitation of the infectious diseases, much of their treatment and the great triumphs of modern surgery in the way of safe operative procedures unattended with the risks of blood-poisoning and pus formation. Perhaps the best examples of the results obtained are the disappearance of hospital gangrene, that curse of the hospitals of the Civil War, and of puerperal fever, the fear at one time of every mother in childbirth. I believe it to be true that these two infectious processes have so completely disappeared that it is now not possible to give instruction in either of them, by actual demonstration, to the students of medicine of the day. Tuberculosis, another great curse, perhaps the greatest, of civilized communities is disappearing — without question as the result of the knowledge gained in regard to its infectious nature within the past thirty-five years by direct experimentation upon animals.

The provisions of the bill are summarized as follows:

(a) "The Secretary of State shall have power to grant and revoke licenses, and (b) all places where experiments are performed shall be registered and a detailed report of every experiment shall be transmitted to the Secretary of State." The Secretary is ready to appear before you and give you his feeling in regard to this provision; its irksome nature, in bearing heavily upon the energies of those whose time may be better occupied than in clerical work, is so manifest that it seems hardly necessary to lay stress upon it.

(c) "All persons licensed to experiment upon living animals must be vouched for by competent medical authorities." The bill itself specifies that the application for license must be signed by three physicians duly licensed to practise, and actually engaged in practising medicine in the State of Massachusetts, and also by a professor of physiology, medicine, anatomy, medical jurisprudence, *materia medica* or surgery, leaving it out of the power of any professor of pathology, bacteriology or hygiene to have any voice in the procuring of licenses for the workers in his special department. I fancy that the heads of such departments as these, and of biology in general, or the many departments of that study, would protest most vigorously against this absurd discrimination.

(d) "The authorized agents of humane societies in Massachusetts shall be permitted to visit any registered place at any time and without previous notice." The bill says "of any society for the prevention of cruelty to animals in the State of Massachusetts." So far as we know, this places the power of inspection in the hands of the only two societies organized for the purpose of the prevention of cruelty to animals now existing in the State — the Massachusetts Society for the Prevention of Cruelty to Animals, and the Animal Rescue League. The president of the latter has already refused to sign the petition for this bill, and no representative of the former has appeared here in its support. If this were allowed, what sort of reports would be forthcoming? Can it be expected that they would be such as would tend to allay public suspicion, or rather reports in which the inspector would be put to his utmost endeavors to detect for his employers some sort of sensational incident, some sort of impression which could be used either in their weekly paper or in the daily press, to promote the objects of the society? There could not possibly be a more ill-advised or dangerous method of inspecting this work, and we object fundamentally to anything of the sort.

These objections would hold against the New England Antivivisection Society, but that their treasurer — the only officer we have seen — has stated that the Society is "not to prosecute, but to disseminate a knowledge on vivisection." It is hardly possible that such important matters could be put in the charge of a body that conducts its avowed work as loosely as has been shown to be the case with this one.

We are told that there is a large number of people demanding this legislation, and that there are many ready to appear in its favor. As a matter of fact, the petitioners have been represented at these hearings by their counsel, and by three witnesses only, whose testimony may be summarized about as follows:

The first witness for the bill was Herbert D. Ward, but such a witness is hardly worth attention, for how can a man be worth belief who will allow himself to make the statement which closed his testimony: "I do not consider it necessary to go into a laboratory in order to find out what is going on there?"

If this is what the petitioners want, to be allowed to judge of what goes on at any given time by what has gone on in some other place at some other time, it would hardly have been necessary for the remonstrants to have taken up the time of the Committee in listening to them.

This witness brought forward certain cases of the effects of vivisection upon the "finer feelings"; this at Cornell and at Matteawan. We have not attempted to find out the state of the case at Cornell, but if it is the same as at Matteawan, it would hardly be necessary.

The witness stated: "At Matteawan, a public school teacher dissected a cat. The animal was not under extreme anesthesia, the feelings only partly dead, and the parents of the children of that school made such a fuss that the teacher was obliged to withdraw."

One of the students at the Harvard Medical School heard this testimony given, and as he was born in Matteawan, and knew something of the place, was sufficiently interested to make some inquiries on this matter. I beg to present to you the following letters in regard to the Matteawan matter, brought forward

by this person — permit me to remind you — as an authentic instance of the effect of vivisection (the dissection of *living* animals) on the pupils:

BOSTON, MASS., March 5, 1890.

SUPERINTENDENT OF SCHOOLS, MATTEAWAN, N. Y.,

Dear Sir: — At a hearing before the Massachusetts Legislature on a bill "For the further prevention of cruelty to animals in Massachusetts," introduced by the New England Antivivisection Society, I was surprised to hear the following statements made: "At Matteawan a public school teacher dissected a cat; the animal was not under extreme anesthesia, the feelings only partly dead." The last time that I was at home I heard of this case, but if my memory serves me the cat was dead. I should be very much obliged if you will write me a brief statement of the facts.

Yours truly,

WALTER R. BRINCKERHOFF.

MATTEAWAN, N. Y., March 6, 1890.

WALTER R. BRINCKERHOFF,

Dear Sir: — Three years ago a cat was dissected before a class of High School pupils in Matteawan. The cat was *completely and thoroughly dead* before it was taken to the class-room.

Very truly,

G. R. MILLER.

BOSTON, March 8, 1890.

MR. G. R. MILLER,

Dear Sir: — Your letter about the Matteawan cat case received. Do you know of any other occurrence that could have given rise to the statements that I quoted in my last letter?

Thanking you for prompt answer to my letter, I remain

Yours truly,

WALTER R. BRINCKERHOFF.

MATTEAWAN, N. Y., March 9, 1890.

MR. WALTER R. BRINCKERHOFF,

Dear Sir: — No dissection of a cat or of any other animal has ever taken place in the schools of Matteawan, except in the one case referred to.

It has always been our custom to bring before our classes some parts or organs of animals for the inspection of the class. This is a common practice in schools. The parts usually taken before the class are those that can be commonly obtained at any meat market.

There is only one case, aside from the one cited, from which any idea such as stated in your first letter could be obtained. It was as follows: One year after the dissection in the school, the teacher of science dissected a cat at her own home and brought the vital organs before her class in school on the following day. These are the plain facts. Any other statements are either distortions or falsehoods.

Appreciating your interest in the case, and hoping to learn the results of your efforts, I remain

Very truly,

G. R. MILLER.

Following this witness, whose testimony was closed by the remarkable statement given above, that he did not need to be an eye-witness to know what was going on, came the treasurer of the New England Antivivisection Society, J. M. Greene, the only officer of the Society we have yet seen. The testimony of this witness has been shown to be inaccurate by many of the gentlemen who have appeared here to remonstrate against the proposed legislation, but I should be glad to add something to that testimony. He begins by saying that he has no personal knowledge of experimental laboratories, but goes on to say that personal evidence is impossible. This has been shown not to be the case to any properly qualified person. The wit-

ness made the same charges of cruelty in regard to the experiments on animals that have been flung about so freely in this and other antivivisection agitations. Now cruelty in law means an act inflicting severe pain and done with wilfulness and malice. I can assure the witness that the remonstrants listened with much interest to hear the specific instances of cruelty that he would support with evidence, but none were forthcoming, and perhaps the Committee will remember that when Dr. Porter asked this witness whether the experiments he referred to of Dr. Porter's were meant by him (the witness) to be specific instances of cruelty, and whether the witness so charged, the answer of the witness to this specific question was not secured. I wish to point out that such a specific answer in regard to a specific case would be a more serious matter than general statements. This witness repeated the old charge that animals are not anesthetized, which has been sufficiently answered already, and reiterates the old assertion that chloral is in no sense an anesthetic. Anesthetics and narcotics both attain the desired end, the doing away with the sensibility to pain; chloral will do this as effectively as ether, as has been stated many times.

That I have not said this first is evidenced by the following from *Anesthesia*:⁷ "I trust that I may be pardoned if I pause here for a moment to correct a misconception which does not exist among well-informed medical men, least of all among practitioners of medicine, but which plays a considerable part in antivivisection literature. I refer to the distinction there made between the use of anesthetics and that of narcotics for the purpose of rendering animals insensible to pain. So far as the point in question is involved, this distinction is ridiculous, and seems to be based upon a misunderstanding of some old physiological experiments. For prolonged experiments, it is often advantageous to place the animal in the sleep induced by morphine or chloral, instead of that of ether or chloroform. These drugs are administered in much larger doses and often in different ways than is customary in human beings. That under these circumstances the animal is rendered insensible to pain is a fact the knowledge of which might have been gained from ordinary medical experience."

The witnesses' more general statements that vivisection is of slight use, or that the medical profession should not be allowed to control it, would seem to have been sufficiently answered. Certainly in the last case,—an unscientific body of ill-informed agents are not the persons to entrust its management to. The witness's further assertions that the present laws do not cover the case, that the advance of medicine of late years is not real, that serum medication has failed, and that the study of bacteriology has done nothing have been considered by other speakers or myself.

So, too, after what has been said, it seems hardly necessary to refer again to his statements in regard to the antitoxin of diphtheria, but it would really seem to be advisable for the witness to take some other than the *Medical Brief* for his authority before making the statement that it is the carbolic acid in the diphtheria antitoxin that does the benefit, when this is a statement that he could have at any time known to be untrue so far as this State is concerned, by a

simple inquiry, which would have told him that no carbolic acid has ever been used in such antitoxin, made either by the Boston Board of Health or the State Board. Such inquiries might also have kept him from the insult offered to the State Board of Health in the implication that their efforts to secure a cheap and reliable product of this material were due to their desire to be on the side of the latest fad.

In other words, this witness takes the very easy ground that when his opponents bring forward evidence that is not to be pushed out of sight or disproved, the only answer that is to be made is a charge of false witness, which may be a temporarily happy frame of mind, but is an exceedingly dangerous one.

Finally, gentlemen of the Committee, we come to the testimony of the last *successful* witness for the supporters of the bill, A. Westcott, a professional agitator according to his own admission; one who has been for eight years doing nothing but getting up such evidence as he could on the subject of vivisection, under salary all the time; a non-resident, not a citizen of this Commonwealth or country, and not even a man with a scientific training; one who calls Charcot a brain surgeon. It was no evidence that this witness offered, but an oration that was evidently well in hand until the Committee itself felt it necessary to disturb its smooth-flowing sentences, that withal sounded strange and somewhat uncouth to our unaccustomed ears. This witness asserted that nine-tenths of the experiments were made in a spirit of "curiosity." A closer acquaintance with the definitions of the word would assure him that one of them is as follows: "The desire to see or learn something that is new, strange, or unknown;" so that after all he came nearer the truth than perhaps he intended, that the desire of all experimentation in a new field is to see or learn something new, strange, or unknown, but of value to the human race.

To such a witness it would do no good to say that anesthetics (or narcotics) are usually used in experimentation on animals, as has been here testified, nor would it be of value to refute his statement that the facts learned have no bearing in man, but it will be of value to remind the Committee that this is not the case, and that many processes are the same in man and some of the lower animals, or very similar, so that close analogies can be readily drawn by the study of these processes in animals. Does not the witness know of, or does he mean to deny, the transmission of various infectious diseases from animals to man or to each other. What about rabies, by the bite of a dog (usually); diphtheria, from pet animals; tuberculosis, in cattle; plague, by rats and other house vermin and insects, flies, etc.; anthrax (in man called malignant pustule, woolsorter's disease, and so on); glanders, in the groom from an infected horse; actinomycosis, from infected grain, and possibly meat and milk; malaria, undoubtedly carried by mosquitoes; typhoid, by flies at Chickamanga, and hog cholera, foot and mouth disease, bacillus typhi murium and the experiments in Thessaly? Of course if all these great epochal studies are to be called "nothing," then "nothing" is of value to some of us, but argument is useless.

The object of the petitioners is said by this witness to be not to retard "science" but to eliminate barbarities, so that then the experimenter may devote

⁷ Welch, p. 66.

himself to "true science," whatever they may mean by that. I would again call the attention of the witness to the definition of words, and inform him that (1) "science" means knowledge, comprehension, or understanding of facts or principles, and (2) knowledge gained by systematic observation, experiment and reasoning. I regret I cannot trust his judgment to answer the question, but perhaps the Committee will tell us what higher or truer science there is than that which benefits the human race.

I should like to bring to the attention of the Committee an editorial from the *Boston Herald* of Thursday, March 8, 1900, the authorship of which is entirely unknown to me, and from which I will quote the last paragraph: "We must take the universe as we find it. It is one in which life is constantly destroyed, doubtless for the benefit of other lives. As the highest type of the animal species, we at least need not be consciously cruel, but we should be blind to the teachings of nature and invite race destruction if we did not seek to strengthen our species by endeavoring in every way to provide for it safeguards against the ravages of the lower types of life."

I wish before closing, gentlemen, to contrast the character of the evidence brought forward, and by whom presented. On the one hand the three individuals whose testimony for the bill I have just spoken of; on the other, against the bill, the words of experts, actually engaged in the work of which they speak, of practitioners of medicine using the results of that work, of the greatest educational force this country has known, of the clergy, both from the general point of view, and from the results seen in their own daily life, and of members of the community who have experienced the benefits of the results of animal experimentation, and also knew what was being done for them. It seems to us that we are justified in our protest against this bill as unnecessary and unjust.

I thank you, gentlemen, for the courtesy you have extended to me.

(In opposition to this bill there appeared: Dr. H. P. Bowditch, professor of physiology in the Harvard Medical School; Dr. W. T. Sedgwick, professor of biology in the Massachusetts Institute of Technology; Dr. W. T. Porter, associate professor of physiology in the Harvard Medical School; Dr. Theobald Smith, professor of comparative pathology in the Harvard Medical School; Dr. W. T. Councilman, professor of pathological anatomy in the Harvard Medical School; Dr. John H. McCollom, superintendent of the South Department of the Boston City Hospital; Mr. and Mrs. Arthur Astor Carey, the Rev. A. A. Berle, A. Parker Browne, Esq., to relate personal experiences; Dr. J. C. Warren, professor of surgery in the Harvard Medical School; Dr. H. L. Burrell, assistant professor of clinical surgery in the Harvard Medical School; Dr. James J. Putnam, professor of diseases of the nervous system in the Harvard Medical School; Charles W. Eliot, President of Harvard University; William Lawrence, Bishop of Massachusetts; Professor Wilcox, of Wellesley College; Prof. J. S. Kingsley, of Tufts College.)

AN AUTOMOBILE AMBULANCE. — The new automobile ambulance of St. Vincent's Hospital, New York, the first of its kind in the city, made its first regular trip on June 13th. It cost \$3,000, and is the gift of Mr. Edward Kelly.

THE LAW OF DYING DECLARATIONS.¹

BY M. J. RUGHRICE, ESQ., BOSTON.

THE rules of evidence relating to the competency of statements of dying persons are a branch of the law with which physicians are frequently called upon to deal. A brief recital of some phases of this branch of the law, the scope of which has recently been extended by statutory enactment, is here attempted.

It is a general rule of law that statements made by third persons are not admissible in evidence, but are within the class of hearsay evidence, and are usually excluded. To the rule excluding hearsay evidence there are some exceptions; among them are dying declarations. Dying declarations are statements of material facts concerning the cause and circumstances of a homicide made by the victim, under the solemn conviction of impending death.

There are certain other declarations of dying persons which may not be admissible under the dying declaration rule, but which may be competent as part of the *res gestæ* (which are the circumstances of the transaction) on the ground of their natural, contemporaneous and explanatory connection with the main transaction. To be admissible under the latter rule, the declarations must be so nearly contemporaneous with the main fact as to be part of the *res gestæ*, but need not have been made under a conviction of impending death. On the other hand, to be admissible under the dying declaration rule, the declaration need not be part of the *res gestæ*, but must have been made in the consciousness and expectation of immediately approaching death.

Certain declarations made in the presence of the defendant are also competent for the purpose of showing defendant's response, when charged with causing the injury done to the deceased; the admissibility of this class of evidence depends upon the conduct, presence and response of the defendant. It is not necessary to the admissibility of dying declarations that the defendant should be present when they are made. Confessions, admissions and declarations are words frequently used interchangeably, but are each technical terms of distinct significance. A confession is a statement by a person of his agency or participation in a crime. An admission is an acknowledgment by a party to a suit of the truth of some incidental fact or facts. Confessions and admissions are made by parties to the indictment or suit; declarations are made by third parties.

An examination of the law of personal statements generally would involve a broad inquiry of no special interest from a medico-legal standpoint and will not here be attempted; but that branch of this law which relates to dying declarations is alone considered.

A fuller statement of the rule relating to dying declarations than the one hereinbefore given is this: Where a defendant is on trial for homicide, the declaration of the person whom he is charged with having killed, if made while *in extremis* and under the solemnity of a conviction that he was at the point of death, and relating to matters of fact concerning the homicide which passed under his own observation, may be given in evidence.

The reason for the rule excepting dying declarations from the rule against hearsay evidence is that the

¹ Read before the Massachusetts Medico-Legal Society, February 7, 1900.

solemnity of the circumstances under which such declarations are made, naturally constitutes a guarantee of their truth equal to that which is afforded by the customary oath.

The further reason for the rule is in the necessity of the case; the victim of the homicide having passed away, and as there may be no other witness to the transaction, in order that the malefactor may not go unpunished, the strongest reasons of public policy require the admission of this testimony.² It was objected that the admission of this testimony contravened the constitutional provision that the accused should be confronted by his witnesses face to face, but Chief Justice Shaw declared that dying declarations are admissible notwithstanding the Twelfth Article of the Declaration of Rights, that every subject shall have the right to meet the witnesses against him face to face, and this rule has been affirmed so often that the question is no longer open.³

In order that a dying declaration may be given in evidence the following conditions must be shown: That the declarant must have been conscious of impending death; that death must have occurred; that the statement must relate to the crime and be a description of the crime itself, and its manner of commission and of the person who committed it.

Even if the death was impending, if the declarant did not so believe, the declaration would not be competent; all hope of recovery must have been abandoned, and the declarant must be without hope or expectation of recovery.⁴

It is not necessary that declarant should be actually breathing his last; even though he lived some time, the declaration is competent if made under a sense of impending death.

It has been held that statements made by the deceased while he yet entertained hopes of recovery are admissible if they were reaffirmed by him after he lost all hope.

FORM AND MANNER OF GIVING DECLARATIONS.

The form of the declaration is immaterial; it may be made orally or in writing. It is not necessary that a declaration should be expressed in words; it may be communicated by signs. It was said by Chief Justice Shaw, in *Commonwealth v. Casey* cited above, that "If the injured party had but the action of a single finger, and with that finger pointed to the words 'yes' and 'no,' in answer to questions, in such a manner as to render it probable that she understood, and was at the same time conscious that she could not recover, then it is admissible evidence."⁵

It will be sufficient if the declaration is taken down in writing by a bystander, and the writing then read over to the deceased, who assents to its terms and affixes his signature. But it is not essential that it be taken down in writing or that it be signed, but it will be useful so to do to preserve the evidence.

If the statement is carefully drawn and is a fair recital of the declarant's statement, it is not fatal to its competency if the exact words of the account of the case are not used. The declaration is admissible even if brought out by means of questions. It is not necessary that the declarant should be sworn. Dying declarations are admissible in favor of the accused as

well as in favor of the Commonwealth.⁵ But in each case the declarant must be the person who was the victim of the homicide.

CASES IN WHICH DYING DECLARATIONS ARE ADMISSIBLE.

They are admissible only in cases of homicide, and in such additional cases as have been provided for by statute.⁶ By statute, abortion cases have been included.⁷ Dying declarations are admissible only where the death of the declarant is the subject of the inquiry; they are not admissible to prove any other death. On an indictment for murder it is not competent to introduce the statements of another person that he killed the deceased.⁸ Defendant in a case tried in New York offered to introduce a letter which might be regarded as containing a confession of another person that he had committed the murder; the evidence was excluded.⁹

Where three persons are jointly indicted for murder, and one of them is tried separately, it is not competent for him to give in evidence a conversation between the other two when they were alone, inculcating themselves, and exculpating him from all participation in the crime.¹⁰

On an indictment for an assault with intent to murder, it was held that although the accused might exculpate himself by showing that another was guilty, yet this rule goes no farther in favor of the accused than to allow him to show another's guilt by some appropriate evidence directly connecting that person with the *corpus delicti*. Therefore mere disconnected threats and declarations of third persons are inadmissible.¹¹

Where the defence of a criminal charge is that a third person committed the offence, the confession of such third person, made after the offence and not part of the *res gestæ* is not admissible in evidence.¹²

The testimony of the declarant may be discredited as that of a witness taking the witness stand and testifying. It may be shown that the declarant was not mentally capable of making a statement, that his reputation for truth was bad. The statement of the dying person must be of matter competent; it must not be merely an expression of opinion, it must be a statement of facts which could be testified to if the declarant lived and was a witness at the trial.

It is competent for the defendant to introduce testimony to show that the deceased has made contradictory statements, and it is competent for the government to introduce testimony corroborative of the dying declaration.

In passing upon the weight to be given to dying declarations the jury have a right to consider all the circumstances under which it was made, and all the conditions by which the dying person was surrounded, and the state of mind of declarant, as shown by all that was said and done. Conduct, deportment, condition, all should be noted by the person who is to be a witness. Declarant's conduct in saying farewell to his relatives, in making such provision as is made by persons about to die; if the declarant is a Catholic, if

³ *Commonwealth v. Casey*, 12 Cushing, 246.

⁴ *Commonwealth v. Bishop*, 165 Mass., 148.

he receives extremeunction, this is of importance as indicating the state of mind. It will be found a most useful practical rule in these cases first to ascertain the state of mind of the dying person, and after that an expression by him that he has no hope of recovery, then to listen to a recital of the story of the crime.

It is because of a failure to proceed in this way that physicians frequently obtain an account of a crime which cannot be used in evidence, and it is more often because of inadvertence than want of knowledge; but the result is equally disastrous so far as a successful prosecution is concerned. Particularly is this true in abortion cases, in many of which, apart from the evidence obtained at the autopsy, there is no testimony save the dying statement of the person operated upon, which by reason of the carelessness or ignorance of the person hearing the statement is worthless as evidence.

Another form of declaration of deceased persons made competent evidence by a recent statute which will be likely to call physicians into court to some extent hereafter is the law passed in 1898, Chapter 535 of Massachusetts Laws; this will be used in civil cases only; it is entitled, "An Act Relative to the Declarations of Deceased Persons." It reads: "No declaration of a deceased person shall be excluded as evidence on the ground of its being hearsay, if it appears to the satisfaction of the judge to have been made in good faith before the beginning of the suit and upon the personal knowledge of the declarant."

In closing this paper it is proper, perhaps, to say that in speaking on the occasional failure of some person to comply with the exact legal requirement of the particular situation, it is with no desire to criticise, but on the contrary with a full recognition of the aid received from physicians and also of the fact that in most instances every requirement of the rules of evidence is complied with. The abortionist, the poisoner and the murderer would often have very little to fear from the best efforts of lawyers seeking to prevent crime were it not for the skill, the watchfulness and the fearlessness of the trained minds which trace the evidence of subtle poison or the course of the murderer's bullet. Without this assistance, in many instances the law would be helpless, and the fact that detection is made certain by the attainments of these scientific men restrains the criminal by bringing close to him the certainty of detection.

A CASE OF EXTRA-UTERINE PREGNANCY.¹

BY FRANK HOLYOKE, M.D., HOLYOKE, MASS.

ON December 5th, at 2 A. M., I was summoned from police headquarters to view the dead body of a woman who, though unmarried, called herself Mrs. Eugene S., of Boston. She had been visiting a friend in Holyoke for the previous three days. Her history and habits for the past sixteen years had not been a credit to her sex. The friend whom she was visiting stated that the deceased had visited her on the 6th of last July and again on the 15th of September, on each occasion complaining of considerable abdominal pain. On this her last visit, she reached her friend's house December 1st, at 11.20 P. M. On the second day she went out in the morning and did not return until

evening; on the third she lay down most of the day, and on the fourth she went out after dinner and came back at 4 P. M., complaining of terribly severe pain in the belly. At 8 o'clock she began to grow weak, very restless and pale, calling for water continually. She was conscious until near the end; refusing to see the priest or physician. She died at 1.15 A. M., three-quarters of an hour before I viewed the body. The body was still warm. There was at this time no rigor mortis.

On making a vaginal examination I was unable to reach the os, but through the anterior vaginal wall, which protruded forcibly into the vagina, I could very readily feel ballottement of a floating body of a size which would indicate that she was at least five months pregnant. The posterior cul-de-sac bulged prominently as though filled with fluid. There was no trace of blood in the vagina nor history of hemorrhage. Through the very thick abdominal wall a tumor could be felt rising from the pelvic cavity as high as the umbilicus.

The body was removed to an undertaker's ware-room, where, nine hours and a quarter after death, the autopsy was made. The body was that of a woman thirty-six years of age, weighing about one hundred and sixty pounds; the skin surface was pale; there was marked absence of livid spots; the belly was much distended. The abdominal walls were very fatty. Large, black, tarry clots covered the omentum, and the abdominal cavity was filled with clots and serum. Beneath the omentum there was found what looked, at first sight, like a large, ruptured ovarian cyst with a very vascular wall, to which the omentum and intestines were extensively and firmly adherent. This cyst lay between the folds of the right broad ligament. It reached as high as the umbilicus. The cyst wall was ruptured in the upper anterior part.

The uterus was pressed high up out of the pelvic cavity to the left, which accounts for my inability to find the os by vaginal examination before the autopsy. This abnormal position of the uterus was produced by the combined pressure of extravasated blood in the posterior cul-de-sac and the forcible bulging of the tumor anteriorly. I doubt if the uterus was so hard to reach prior to the rupture. The uterus was six inches long, the cervix softened and filled with mucus. The body of the uterus was soft and thickened proportionately to its size, though the enlargement was more in the long axis. The lining of the uterus was softened and very pale.

The tumor was ruptured at the site of the placenta. In breaking up adhesions the sac wall tore readily, showing, beneath, the amnion, unbroken and adherent throughout to its covering, which was composed of the anterior and posterior layers of the broad ligament; the pregnancy being tubal in origin, and primary rupture having occurred in the early months. The amnion contained a six months fetus, lying transversely with its breech toward the right ilium.

I could find no hematoma or other evidence of earlier hemorrhage, though such probably took place to some degree at the time of the primary rupture of the tube into the broad ligament; in such a case the hemorrhage is usually less than when it occurs in the abdominal cavity, and the fetus is more likely to live and to continue developing until destroyed by secondary hemorrhage into the placenta, or into the general peritoneal cavity by a secondary rupture of the sac.

¹ Read before the Massachusetts Medico-Legal Society, February 7, 1900.

The pelvis of the right kidney was very much distended, as was also the ureter, and this was caused by pressure of the tumor and its firm adhesions. The lungs were perfectly healthy. The gall-bladder contained one calculus. All other organs of the body showed a tendency to fatty degeneration.

She had been treated last September for what was pronounced as rheumatism in the right buttock and thigh, which, however, was probably a mistaken diagnosis, as her regular physician tells me that she had never suffered with rheumatism before. But many of these cases of extra-uterine pregnancy complain of intense pain following along the course of the sacral-plexus distribution.

With apology, I add to my report of this case a few notes from some of the latest literature on the subject, which, being of interest to me, will, I hope, not weary my listeners; for, with the exception of appendicitis, nothing seems to have interested the surgeon and gynecologist more than this subject during the past few years; and while they are discussing the treatment and proper time for operation it behooves us to consider the subject from its medico-legal side, if in a hasty review of a few of the peculiar anomalies which interest us, we can find some facts or theories to work from which may increase the importance of this subject in forensic medicine.

Most writers believe that it has been proved that the normal place of impregnation is in the tube. How much, then, may we be helped by a review of the supposed causes of the occurrence of tubal pregnancy? Some authors think that the larger percentage of these cases occurs among the lower classes, attributed chiefly to their malnutrition; while others believe that the hard work or straining at heavy lifting is a chief cause of arresting the ovum in the Fallopian tube. But we read that other possible causes are fright or shock; and that catarrhal or other inflammatory diseases of the tube, or any diminution of its lining epithelium, or any mechanical obstruction in the nature of new growths within the tube, or pressure from abdominal or pelvic tumors, have also been demonstrated as causes of the arrest of the ovum in the tube.

Dr. T. A. Stoddard,² however, presents the history of a few cases to illustrate what he considers a plausible theory, that the large majority of cases of tubal pregnancy, if not all, are impregnated just prior to a menstrual period.

It has been considered that, as a rule, tubal pregnancy follows a sterility of some years, but to this rule there are many exceptions. It occurs both in multiparæ and in those who have never given birth, and with many complications.

We find, for example, cases of tubal pregnancy occurring two or three times in the same individual. Tubal twin gestation has also been reported. A number of cases have been collected of ovarian or tubal pregnancy together with normal uterine pregnancy; "the mother, in one case, being delivered at full term of two healthy, well-developed children."³

In fact, extra-uterine fetation carried to maturity is not exceptional, and laparotomies performed near the end of gestation with living extra-uterine child are no longer rare, but "the fruit is not only short-lived but deficient in development,"⁴ both physical and mental."

I would say that if our old and beloved instructor in anatomy were among us, Dr. Oliver Wendell Holmes, he might explain a reason for this deficient development of these record-breakers of our genealogical tree, for I well remember in one of his lectures, in referring to the calibre of the Fallopian tube, he straightened himself up to his full height, which was indeed majestic, when he spoke with emphasis, and looking very seriously at the class said: "Just here, gentlemen, I want you to understand that not one of you is any better than I am, for we have all passed through the sixteenth of an inch."

The diagnosis is often very difficult, but has been made before operation as early as the second week, although for a diagnosis to be made before the fourth or fifth week is very unusual, even for the most expert gynecologist. Primary rupture occurs more often within the first three months, most frequently in the second and third. However, it may take place in any month.

Cessation of menstruation is not always a symptom of extra-uterine pregnancy; but the menstrual irregularities may induce us to suspect the possibility of its existence. In case of rupture and the throwing off of the decidua from the uterus, we have symptoms which closely resemble a miscarriage. It is advisable that the physician examine the patient with the possibility of finding a tubal pregnancy. In a case of hematocele this also becomes our duty. Hemorrhage may occur by rupture of distended vessels upon the surface of the sac.

This completes the few points which occur to me as of special interest to the medical examiner in connection with a report of the specimen. But I ask myself of what immediate value, medico-legally, is the autopsy of a case where the history and view, together with external and vaginal examination, all point to rupture of an ectopic sac, unless we may thereby help to solve some question connected with the administration of justice? May we not expect to discover approximately at what time she conceived? Can we not help to prove or disprove an attempted abortion? Or may we not be the means of freeing a fellow-practitioner from suspicion of malpractice, as did Dr. Flavian Krug in an interesting case where the physician in charge was believed to have given poison by mistake; the death of the patient from rupture of the sac unfortunately following his hypodermic almost instantly?

Such and possibly other questions may arise in a given case. But the most valuable notes on this specimen you will now have the pleasure of listening to from Dr. F. W. Whitney, who has carefully examined and prepared it for the Warren Museum, as a peculiarly interesting addition to the study of this subject.

ANATOMICAL REPORT BY DR. W. F. WHITNEY.

The specimen consists of the uterus and adnexa. The uterus is enlarged, the extreme length 14 centimetres. The wall is thickened, the cervical portion measures one centimetre, the fundus measures three and a half centimetres, and the breadth of the fundus is eight centimetres. The interior of the uterus is lined with a soft, slightly shaggy and irregular membrane varying in thickness from two to four millimetres and was somewhat folded. The cervix is dilated and filled with tough mucus, the glands about the orifice being large and distended with the same material.

¹ American Gynecological and Obstetrical Journal, January, 1897.

² H. Ludwig: Wien. klin. Wochenschr., July 2, 1896.

³ L. E. Frankenthal: American Gynecological and Obstetrical Journal, September, 1896.

On the left side the ovary and tube are normal. On the right side the tube is normal for a distance of a few centimetres and then is lost on the surface of a sac 21½ centimetres in diameter.

There are no adhesions between the uterus and the tumor, which is cystic in character and lies between the folds of the broad ligament. On the upper part the covering is more or less torn and reveals a shaggy mass which is divided into two parts—one measuring about seven centimetres, in which is a considerable hemorrhage; and the other about five centimetres in diameter, which is pale and bloodless. This shaggy coat is partly lifted up and reveals a fetus of apparently about the sixth month, lying in an unruptured amniotic sac. The fluid surrounding the fetus is of a dark bluish-red color. No ovary could be detected on this side.

The diagnosis is a retroperitoneal pregnancy originating in the tube, and apparently about the sixth month. A decidua was present in the uterus.

THE MARKS PRODUCED BY PISTOL SHOTS.¹

BY G. DE N. HOUGH, M.D., NEW BEDFORD, MASS.

THE object of this research was to ascertain what inferences could be drawn as to calibre of weapon and distance from which it had been fired from the marks produced on the skin or clothing.

The material used was as follows: One .22-calibre revolver of unknown make capable of using either long or short cartridges. With this I used Winchester Co.'s .22 short cartridge containing 3 grains of powder and 30 grains of bullet; the same make smokeless cartridge containing 1½ grains powder and 30 grains bullet; the Union Metallic Cartridge Co.'s .22 short and .22 long cartridge whose exact contents of powder and bullet I was unable to learn. All .22 cartridges are rim fire, and it is not probable that the Union Co.'s differs much in charge from the Winchester's. Judging from the mark, however, the former uses a coarser grained powder. In .32 calibre I had several pistols: (1) A Young America, double action, centre fire, with a 2-inch barrel firing a short .32 U. M. C. Co.'s cartridge with 10 grains of powder and 88 grains of bullet; (2) Hopkins & Allen's Mfg. Co.'s Dictator, single action, rim fire, 3-inch barrel, with a Winchester .32 short cartridge, containing 9 grains of powder and 82 grains of bullet; (3) Hopkins & Allen Co.'s X. L., double action, rim fire, 3-inch barrel, with Winchester .32 short, containing 9 grains of powder and 82 grains of bullet, and U. M. C. Co.'s .32 long, containing probably 13 grains of powder and 90 grains of bullet (this is what their long centre fire, .32 and W. Co.'s long rim fire .32 contain); (4) Iver-Johnson Arms & Cycle Works, double action, tip up, automatic ejector, centre fire, 3-inch barrel, with U. M. C. Co.'s .32 short, containing 10 grains of powder and 88 grains of bullet, and also with the U. M. C. Co.'s .32 short smokeless, containing about 4 grains of powder and 90 grains of bullet. In .38 calibre I had: (1) American Bull-dog, double action centre fire, 2½-inch barrel with U. M. C. Co.'s short .38, containing 15 grains powder and 146 grains bullet; (2) a Belgian imitation of Smith and Wesson's Automatic Ejector, double action, 3½-inch

barrel, with same cartridge as in previous pistol, also with the .38 central fire S. & W. cartridge of the United States Co., of Lowell; (3) a Colt's single action, 7½-inch barrel with U. M. C. Co.'s .38 long Colt's, centre-fire cartridge, containing 18 grains of powder and 150 of bullet. I had finally an old-fashioned Derringer of .41 calibre and 2½-inch barrel requiring a .41 short, rim-fire cartridge. I had great difficulty in obtaining ammunition for this pistol, and that which I did get was without label on the box, so I cannot tell by whom it was made. The W. Co.'s cartridge of this size contains 13 grains powder and 130 of bullet. It is probable that the cartridges I obtained contain about the same charge. I regret very much that I was unable to procure any pistols of larger calibre and that my outfit was so limited, and I wish to point out here, once for all, that my conclusions are based on experiments with the above-mentioned weapons and ammunition, and refer only to the marks produced by them. Whether any modification of my conclusions will be rendered necessary by experiments with other calibres and ammunition, I of course cannot say.

Method of experimentation.—I had an apparatus constructed which would enable me to measure the distance of the muzzle of the pistol from the target within one-eighth of an inch and at the same time hold the pistol securely while not preventing the recoil or the upward jump of the muzzle at the instant of firing. As targets, I used a variety of things—various sorts of leather, cloth and paper. Whatever material I used, the character of the mark was the same. I used white blotting paper most extensively because the mark could more easily be seen, and because it was my opinion that powder grains would embed themselves in it about as easily as in the human skin. Now while the character of the mark is the same, its appearance varies much with the different materials, so that, given a powder mark on a piece of clothing, I should consider it extremely advisable to confirm one's opinion as to the weapon and the range by actual experiment with similar pieces of cloth.

Results.—The same pistol at the same range with similar ammunition produces the same mark. The mark consists of (1) the bullet hole; (2) the burn; (3) the smut; (4) the tattoo. Beyond a certain distance, a pistol mark consists only of the bullet hole. This distance depends upon the calibre of the weapon and the size of the powder charge. Thus for a .38 long Colt, central fire, which is loaded with 18 grains of powder and 150 grains of lead, fired from a Colt's revolver of 7½-inch length of barrel, I could get no mark except the bullet hole at a distance of anything over 11 feet. As we approach the target, the tattoo begins to develop. This consists of unburned powder grains and droplets of the grease with which the bullet is lubricated. With the pistol and ammunition above mentioned the tattoo is well defined at a range of 7 feet, but the individual grains are widely scattered. Further diminution of the range results in a condensation of the tattoo, the individual grains getting closer together, the whole mark covering a smaller area, and there being a larger and larger number of the grains close to the bullet hole. It occurred to me to count the grains in the marks by means of the device which I now show you. In general it is undoubtedly true that there are more grains

¹ Read before the Massachusetts Medico-Legal Society, February 7, 1900.

between the centre and the 1-inch circle than between the 1-inch circle and 2-inch circle, and more between the 1-inch and 2-inch than between the 2-inch and 3-inch, and so forth. The progressive condensation at progressively shorter ranges is still more strongly brought out by counting the number of grains in equal areas, situated half an inch, an inch, etc., from the centre.

I hoped that the numbers found might enable one to determine definitely the distance at which the shot had been fired, but the variation in size of the grains is too great and there are other difficulties which seem to me insurmountable at present. Arriving at a certain distance, which with the pistol and ammunition above mentioned is 15 to 18 inches, the aggregation of powder grains immediately about the bullet hole has become so dense that the mark has a distinct black spot at its centre which I call the *smut*. At the same time the burn becomes visible. Continuing to diminish the range the smut and burn become larger and larger and the visible tattoo smaller and smaller, until finally there is nothing but the smut and burn to be seen. At the same time the form of the mark becomes more and more perfectly circular, until with the muzzle of the weapon in actual contact with the target we have nothing but a round black mark.

As long as we use ordinary powder, this is the series of changes which the mark undergoes, no matter what the weapon or ammunition may be. The variable parts of the mark (smut, burn and tattoo) are produced by that portion of the powder charge which is not completely burned and one would naturally expect that with any one pistol the size of the mark would depend upon the quantity of powder in the charge and that the distance at which a certain kind of mark is produced would depend upon the same element. This is not true, however, as is shown by a comparison of the series of marks produced by short and long .22 or .32 cartridges; at any rate when the difference between the charges is as little as in these instances no difference in the mark is manifest.

In the case of the long and short .22, there is a difference of 40 per cent. in the respective charges of powder and in the case of the .32 the difference is 44 per cent.

The difference in the mark produced by pistols of different calibre is very noticeable, the size of the mark increasing with increase of calibre and the range at which the different elements of the mark are developed differing considerably. With pistols of the same calibre but different length of barrel different marks are produced at the same distances but the differences are by no means as great as one would suppose, as may be seen by a comparison of the marks produced by the .38 Colt with 7½-inch barrel with those of a .38 American Bull-dog with 2½-inch barrel.

There are about 12 different calibres in use, varying from .22 up to .50. Some of these, namely, .22, .32 and .38 can be obtained in almost any city or town, the others, except by accident, only in large cities unless they are specially ordered. The possibility, however, of one of these unusual calibres being used in any case can never be excluded and neither can we say beforehand that an assailant may not have somehow come into possession of one of the many forms of obsolete muzzle-loading pistols, though the latter can hardly be found, that is, if you want one, except in a museum.

I regret to say that it is not possible to determine with absolute accuracy, from the mark alone, what was the calibre of the weapon used or the distance from which it was fired. Still these points can be determined within certain limits, the calibre from the size of the mark and the distance from its character. In my experiments, if the mark is wholly a smut, with no tattoo zone, the shot was fired at a distance of not over 6 inches. If the mark consists of a tattoo with a distinct smut at the centre, then the distance at which the shot was fired was not over 2 feet. If the mark consists of the bullet hole alone, then the range was not less than 4 to 6 feet if a .22 calibre was used, 7 to 9 feet if a .32, and 9 to 12 feet if a .38 or 41.

For practical purposes one must have a library of experimentally produced marks as standards, and by comparison of the mark actually found with these standards, helped in some cases by a little additional experimenting, a sufficiently close approximation to the calibre and range of the weapon used can ordinarily be made.

Reports of Societies.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

JULIAN A. MEAD, M.D., SECRETARY.

THE Society met in Boston, February 7, 1900, with a full attendance of members, and the President, Dr. B. H. HARTWELL, in the chair.

After the transaction of routine business, M. J. SUGHRUE, ESQ., of Boston, read a paper on

THE LAW OF DYING DECLARATIONS.¹

DR. WHITNEY: I should like to ask if in the case of a dying declaration which has been made before the person admits his belief that he is in this extreme condition, he then reaffirms the story, after his conviction is expressed, would this be sufficient?

MR. SUGHRUE: Quite so; if the reaffirmation is made with sufficient distinctness, and it is a part of the statement. The danger is in the strict requirement to conform to the rule of law. The objecting lawyer might say that the reaffirmation did not reaffirm that the statement was sufficiently covered: but that would never occur when the sequence follows, as suggested in the paper; it would be perfectly good, if complete, under the rule of law.

DR. MEAD: I should like to ask if it adds strength to the declaration to have the defendant at the bedside when the declaration is taken.

MR. SUGHRUE: Not to the declaration; but it makes it not only a declaration, but another kind of evidence. It is very frequently the case that when the defendant is present, and a statement is made inculcating him, he makes some answer that is apart from the dying declaration; it then becomes subject to the ordinary rule of evidence, and competent to be used against him.

DR. MEAD: Is it advisable to have the defendant there?

MR. SUGHRUE: It would be a question of expediency rather than otherwise, having in mind the temperament of the person whose declaration was sought.

¹ See page 653 of the Journal.

Dr. Hough: I would like to ask if it is extremely unusual to find that a dying declaration is false?

Mr. SUGHRUE: I think that it is. More can be said in favor of it than of any kind of testimony. It is argued that here is a person who has every reason to tell the truth; who is beyond any expectation of any interest to serve him; who is, ordinarily, under religious injunction to tell the truth, and whose condition is the best safeguard of the truth itself; and I think that it is generally accepted by juries as the very best kind of evidence and as being much more infallible than any other.

Dr. Hough: I would like to mention a case that has come under my observation. An injured man, being informed by a physician that he was surely about to die, having received extreme unction, he being a Catholic, in the presence of the priest and the attending physician, and in the presence of the defendant, whom he identified, told an absolutely false story of the crime. The hearing in the district court found the defendant to be unimpeachable, and the testimony went to show that the homicide was in self-defence, and the defendant was not even brought before a grand jury, the evidence was so strong in his favor.

Dr. BUCK: I would like to add another case—a case of abortion, where the victim fully expected death and received extreme unction, and her dying declaration was taken down. She did recover, however, but that declaration was false. The case was never brought before the court, yet, if it had been, if the victim had died, and there had been occasion, the declaration would have been found false.

I should also like to ask whether it is advisable to multiply the witnesses, whether it would be well to have more than the physician, or more than two witnesses, when a dying declaration is made.

Mr. SUGHRUE: I should say have no additional witnesses usually. If the statements are taken down in writing, it would be well to have any number of witnesses to testify to the fact that these were the statements made. If the statements were not written, if the declarations were oral, every witness would remember the facts somewhat differently from every other, either adding something to, or taking something from, the statement itself, and in that case it would not be advisable to have a number present. Two are quite enough, and in many cases two witnesses are one too many in an oral declaration. But if the statement is taken down in writing, then simply multiply the number present to give evidence to the fact that the statement was made.

Dr. BUCK: Is it better to have the declaration written and signed?

Mr. SUGHRUE: It adds something to your testimony. You have then the material fact, something besides the recollection of the witnesses; you have the material fact in writing.

Dr. BUCK: I should like to ask another question. Is it essential that a physician should receive this statement in order that he may testify as to the certainty of death in the mind of the person, or would a layman's opinion be sufficient?

Mr. SUGHRUE: That is purely a practical question. The testimony coming from a physician, if the physician had stated to the declarant his opinion as to death and received a response, would come more fittingly and more convincingly from him than from a layman. There would be no difference in the testimony except

for that reason, that the declarant would be more apt to have that sort of a conversation with a medical man.

Dr. PERKINS: I have a case now coming up which I expect to be thrown out through a failure in the dying declaration. The trouble with it is that when we come to look it over carefully in different parts of the statement, the declarant has apparently contradicted herself; it is not of much importance in itself, and only a small part of the declaration; but the fact that she contradicted herself was thought an important matter, and the court might properly throw the case out before it comes to grand jury.

Mr. SUGHRUE: I do not think that it would be thrown out. The fact that parts of the statement are contradictory would affect the story, but not the competence of the declarant.

Dr. PERKINS: The contradiction was only a small part of the statement. The case was one where a man was arrested for killing his wife, and she said in her declaration that he threw an oil stove at her, and later she stated that as she stooped to pick it up he kicked it at her. This contradiction was not noticed at first, but appeared afterwards when it was read over, and we expected that the declaration would be thrown out.

Mr. SUGHRUE: Perhaps as important a thing as I can say in conclusion is this. It is, unfortunately, frequently the case that a physician will hear the story of the dying person, and get a full recital of the case, of the crime and of the criminal, and then will ask the person if he is conscious that he cannot recover, and if he says that he is conscious, and makes no further statement, but rests there, that declaration cannot be used. That is a condition with which prosecuting officers are confronted. Physicians should remember that it is extremely important that they should first obtain from the declarant the conviction on his part that there is no hope of recovery, and then obtain the recital; then there is no trouble when the evidence comes in, otherwise it is of no importance, and the testimony can never be used.

Dr. G. DE N. HOUGH read a paper entitled

THE MARKS PRODUCED BY PISTOL SHOTS.²

Dr. DRAPER said that he deemed it very important in making experimental shots in preparation for a homicide trial that the same weapon should be used as was used in the homicide, and that ammunition of identical kind and calibre with those which the accused had employed should be taken. In cases where a defendant's liberty or life is at issue, the expert should avoid guessing as well as dogmatism in his opinions and the nearer a medical witness can come in his experiments to the same conditions as those of the crime the more trustworthy his conclusions will be. Observations like those reported by the reader have a distinct value, but they suffer an obvious loss in trustworthiness as data because an attempt is made to establish a standard by means of shots from revolvers chosen for the purpose without reference to those used in the crime itself. Better evidence would seem to be afforded by photographs of the bullet wound found upon the victim of the crime; such photographic representations tell their own story much more graphically than could be accomplished in any other way.

Dr. HOUGH: I want to state that the object of my

² See page 657 of the Journal.

investigation was to discover what, if anything, we could tell from the mark; if we have the weapon that was used, it simplifies the problem very much indeed. I think that if we have the weapon and know the ammunition that was used, we can say that the problem is practically no problem; and I stated in my paper that marks produced on different sorts of material are different in appearance, although the same in character, and I further stated that it was extremely advisable in experiments in any given case that the same material be used on which the mark has been made. I quite agree with Dr. Draper in what he says. I simply wish to call attention to the fact that I was aware of these objections he makes, and I thought that I brought that out strong in my paper, though not strong enough apparently. I would not for a moment go into court and testify as to the calibre and distance at which a weapon was fired, with nothing to guide me except these things, unless I made considerable reservation. But you can see from these papers how the difference in the mark is produced at a small difference in range, and I think that it is important, and that it shows us that we can tell very closely, if we take sufficient pains, the calibre and distance from which a weapon was fired by the mark found.

DR. MEAD: I think that the legal profession are fully aware of the importance of having the same powder and the same material in experimenting. In a case in which I was interested, the man being killed, Attorney-General Knowlton insisted that the experiments with the revolver be made on a leather jacket, same as the one worn by the dead man; not the same jacket, but another one similar, and they took this pains to get it. The police failed to get this leather jacket at one of the city stables, where it was thought that the men all wore leather jackets, for it was found that they were all using canvas. A man was then posted on the old Mill Dam Road, and stopped somewhere from twenty to thirty milkmen, until he found two leather jackets that were like the one the deceased had worn when he was shot, and he spent all night getting that jacket to bring it out to Watertown to me to make experiments in the morning. And that taught me a lesson of the importance of getting the same material, if these experiments are made; and I think it is one of the lessons to carry away from the reading—to experiment with the same powder and same weapon, and to make the experiment as near as possible on the same material as that of the homicidal act.

MR. SUGRUE: This has all been very interesting to me. It seems to me that the prosecuting officer could, and would, receive very great assistance from such experiments as have been made here. The difficulty that has been suggested in reference to experiments upon the same coat or upon the same substance is ordinarily one that is not of great importance, because it is not competent to introduce evidence of experiments. The court will not permit you to make experiments in court, and the only use of such experiment as this is as illustrations. The expert comes in and states his opinion, and the importance of his opinion depends upon that upon which it is based, and the danger of such testimony is that if it is not accurate, if the expert can be attacked, if there is a wide range between the experiments, and if it is shown that it is not exact and that his testimony is based upon a

foundation that is not very secure, it is very bad. But I can conceive that such experiments as have been made here would be of very great value in a trial for homicide by shooting or intent to murder; if it can be said, within given limits, that certain things mean certain other things, it is going to be of very great importance, and I can conceive that this would result from such experiments as Dr. Hough has made, and would be of very great importance in the trial of cases.

DR. PERKINS: In the case that I reported at the last meeting something came up in regard to the mark made by the shot which did not play any important part, but was of some interest. The woman shot at had on a blanket wrapper, and as I was not certain in regard to the distance at which the weapon was held, I made experiments. I obtained material the same as that worn in the blanket wrapper, by going to several of the wholesale houses; I also used the same revolver, although I could not get the same ammunition, and I found by the burns that the revolver had to be within twelve inches of the burned blanket wrapper. But another thing in regard to these burns which I found out was the care which should be taken in preserving the material burned. In that case I transferred the garment to the police, and as it was some distance to the station, the man took it to his home; when he got it again, he found that the servants had carefully washed it, and as a result the evidence of the burn had been destroyed. As this was an insanity case, it made no difference, but in another case it might be of great importance.

DR. HOUGH: I want to speak of a case where this was of some importance. The weapon and ammunition were unknown, and from the mark, I told the officers that it had probably been made with a .32-calibre, and the distance, as I figured it, had probably been not more than two inches. The man pleaded guilty when the case came into court. But the officers found the pistol which he might have used, and the ammunition which he might have used, and which they believed he did use, and it was found they corresponded with my suggestion.

Another point which I did not mention, because it did not amount to anything, was, I was in hopes that marks in cloth, for instance, that of a black coat, might be brought out by the x-ray photograph, but the cross light coming through carbon prevented satisfactory results.

DR. FRANK HOLYOKE reported

A CASE OF EXTRA-UTERINE PREGNANCY.³

THE MASSACHUSETTS MEDICAL SOCIETY.
COUNCILLORS' MEETING.

THE annual meeting was held at Mechanics Building, Boston, on Tuesday, June 12, 1900.

The meeting was called to order at 5 p. m. by the President, Dr. Edwin B. Harvey. One hundred and twelve Councillors were present.

The Secretary read the names of 160 Fellows admitted since the last annual meeting, and of 29 whose deaths had been recorded.

It was voted, on recommendation of the Committee on Membership and Finance, that \$3,500 of the sur-

³ See page 655 of the Journal.

plus in the treasury be distributed among the district societies.

The Committee on Publications reported that Dr. William F. Whitney, of Boston, has been appointed to deliver the Shattuck Lecture at the annual meeting of the Society in 1901.

The Committee on Nominations reported, and the following were chosen officers of the Society for the ensuing year: President, Dr. Frank W. Draper, of Boston; Vice-President, Dr. William W. Eaton, of Danvers; Treasurer, Dr. Edward M. Buckingham, of Boston; Corresponding Secretary, Dr. Charles W. Swan, of Brookline; Recording Secretary, Dr. Francis W. Goss, of Roxbury; Librarian, Dr. Edwin H. Brigham, of Brookline. Dr. Charles F. Folsom, of Boston, was chosen orator of the annual meeting of the Society in 1901.

Voted, That the next annual meeting of the Society be held in Boston on the second Wednesday in June, 1901.

The following standing committees were appointed:

On Arrangements.—Drs. M. Storer, S. Crowell, W. H. Prescott, F. G. Balch, J. C. Hubbard, Farrar Cobb.

On Publications.—Drs. O. F. Wadsworth, G. B. Shattuck, H. L. Burrell.

On Membership and Finances.—Drs. E. G. Cutler, L. R. Stone, F. W. Goss, W. Ela, C. M. Green.

To Procure Scientific Papers.—Drs. H. L. Burrell, A. K. Stone, F. H. Thompson, G. de N. Hough, H. W. Van Allen.

On Ethics and Discipline.—Drs. G. E. Francis, F. C. Shattuck, C. G. Carleton, E. Cowles, J. F. A. Adams.

On Medical Diplomas.—Drs. H. E. Marion, E. N. Whittier, O. F. Rogers.

On State and National Legislation.—Drs. F. W. Draper, H. P. Bowditch, S. D. Presbrey, S. W. Abbott, B. H. Hartwell.

ANNUAL DINNER.

The annual dinner of the Society was held at one o'clock, June 13th, DR. EDWIN B. HARVEY, the President, presiding.

The literary exercises were opened by prayer by the REV. DR. E. L. CLARK. In his introductory remarks the President spoke of the prosperity of the Society at large and the success of the meeting just terminated. After formally committing the conduct of the Society to the newly elected officers, he introduced as the first speaker Dr. W. H. WELCH, of Johns Hopkins University.

Dr. WELCH referred felicitously to his Shattuck Lecture, which had concerned itself with gas sepsis, and expressed the hope that his remarks might not be a psychological variety thereof. Speaking on the toast of the "Medical Profession," he felt that he had never before been in the presence of a body of men where such a theme should inspire better thoughts, that high medical ideals had always prevailed in Massachusetts and that it had offered more contributions to medical science than any other section of the country. The expectation which he had formed of standing in the presence of exceptionally intelligent men had been more than met, as he faced his audience. He felt that the medicine of to-day offers intellectual pleasures as never before; it now has all the attraction of a natural science, such as before belonged only to

physics, geology and kindred subjects. The same intellectual pleasure is now to be had, whether study is conducted in the laboratory or at the bedside, and the term "scientific" is to be applied to the one no more than to the other. There is a growing solidarity of all workers in medicine, and the one aim of prevention and cure of disease is common to the laboratory workers and to those engaged in the practice of medicine. However seemingly remote the problems of the pathologist and bacteriologist may appear, the fact remains that all knowledge, however gained, must finally be of practical use, and the distinction at times made between the laboratory and the practical man is wholly false. Dr. Welch, in concluding his remarks, thanked the Society for the cordial reception accorded him, and brought the greetings of the Medical and Chirurgical Faculty of Maryland, which is one of the oldest State societies in the country. He felt that the bond of sympathy between the States of Massachusetts and Maryland was continually growing closer.

DR. HARVEY, introducing the next speaker, ATTORNEY-GENERAL HOSEA M. KNOWLTON, spoke of the age of the Massachusetts Medical Society and of its relations during the nearly one and a quarter centuries of its existence to the Commonwealth. Attorney-General Knowlton spoke at considerable length; he said in part: There is a definite relationship between the Commonwealth and the medical profession which it is my desire in part to elucidate. The medical profession is a company of artists, and by an artist I mean a man who knows how to do something useful to mankind better than the ordinary man. Physicians live to educate themselves and to benefit the world by their education. In general the government of the Commonwealth has in common with you a desire to protect its citizens from imposture, quackery and swindling. This is a ground of agreement. A difference is that the Commonwealth is not intolerant. It was founded on the principle of tolerance, that every man could do, say and think what he pleased. You have at times wanted to interfere with that doctrine; you may have attempted to regulate the practice of medicine by legislation. The Commonwealth cannot do that; it permits entire liberty of action to its citizens; it has not the right to prevent a man from employing any means of cure he may choose, but we have required that a man shall know something about this frame of ours before he calls himself "doctor." The less you undertake to regulate private conduct the better off you will be.

The time, however, is not far off when parents even should not be allowed to substitute humbug for medical science in the treatment of minors. In the second place, while any man may do as he pleases as concerns himself, no man has a right to communicate disease. Things are settled in the law; our work is finite; yours to a certain extent is infinite. Appreciate the fact that no one knows everything; that every sect has given you something. Let false dogmas expose themselves.

Mr. Knowlton concluded his remarks by a humorous allusion to Christian Science, which he had been reading and trying to understand, but without success. He felt that medicine as practised by its devoted students the world over was the true "Christian Science."

DR. HARVEY then introduced MR. HENRY L. HIGGINSON, "whom if we have not met we all know."

Mr. Higginson eulogized the medical profession and saw great hope for the future in the broader education which it would be the function of the physician to inculcate among the people.

The Graduate Glee Club, under the leadership of Dr. Richard C. Cabot, rendered a number of admirable songs during the course of the dinner.

AMERICAN ORTHOPEDIC ASSOCIATION.

FOURTEENTH ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY 1, 2 AND 3, 1900, HARRY M. SHERMAN, M.D., OF SAN FRANCISCO, PRESIDENT.

(Concluded from No. 24, p. 631.)

SECOND DAY.

THE RECUMBENT KYPHOTONE, AND A SIMPLE DEVICE FOR APPLYING PLASTER JACKETS FOR THE CORRECTION OF THE DEFORMITY OF POTT'S DISEASE.

DR. R. TUNSTALL TAYLOR, of Baltimore, exhibited both of these devices.

FORCIBLE CORRECTION OF SPINAL CURVATURE FOLLOWED BY PARALYSIS.

DR. H. AUGUSTUS WILSON, of Philadelphia, reported this case. The kyphosis had been noted only a few weeks before coming under observation, and there was good reason for believing that it was of very recent development. Two attempts to reduce the deformity forcibly under profound anesthesia had resulted in an audible snap but in only slight improvement in the deformity. The operation had been followed by fever, lasting two weeks, and by sloughing of the soft parts. At the end of nine weeks the patient had been able to move around feebly, but had returned in forty days with an almost complete spastic paraplegia.

DR. A. M. PHELPS remarked that this case seemed to be a typical one of pressure myelitis from invasion of the cord, the forcible correction having nothing to do with the paralysis.

DR. RIDLON concurred in this opinion.

DR. R. W. LOVETT, commenting upon the brace presented by Dr. Dane, said that this apparatus was interesting in that it aimed to produce torsion. His own studies in lateral curvature had taught him that it was important to throw the weight backward on the articular processes, though not necessarily by producing lordosis. The problem was to determine in just what position of the spine the weight could be thus thrown on the articular processes to the best advantage.

DR. PHELPS said that it was only when the spine was bent backward considerably that any pressure is made on the articular processes, and that if there was any lateral deviation present, the application of an anteroposterior brace would aggravate this.

DR. LOVETT contended that this statement was erroneous, because experiment had shown that the articular processes come in contact at a point about fifteen degrees in front of the erect position.

A CASE OF SCORBUTIC SPINE.

DR. JOHN RIDLON, of Chicago, reported an interesting case of this kind in an infant of one year. The

symptoms had developed so suddenly as to lead to the belief that the knee had been injured. The child was large and fat, with a rough and muddy skin. The spine was arched forward and rigid. The gums were dusky. Dr. Ridlon had ordered the child fed on unsterilized milk, raw meat and orange juice, and in two weeks the boy was well. In making the diagnosis one was called upon to differentiate scorbutus from rheumatism of the acute articular variety, infantile paralysis and rickets. In rickets the onset was gradual, and the spine was bent backward or laterally, and did not become stiff and painful without evidence of the disease.

DR. R. H. SAYRE said that he had put these children on a pillow with a shirt-board inside of it, and had then bandaged the child to the pillow. In addition, the diet had been appropriately regulated. All these scorbutic children that he had seen had been fed on sterilized milk or on some patent infant food.

DR. HOFFMAN spoke of a case of scorbutic spine that he had seen in a child of fourteen months. The kyphosis had been sharper than ordinarily seen in rickets. The infant had made a satisfactory recovery on a recumbency splint, being wet-nursed and fed with orange juice.

DR. HENRY LING TAYLOR, of New York, said that he had reported to this Association one of the earliest cases noted in this country. In these cases there was not true paralysis, but the limbs were kept quiet because motion caused extreme pain.

DR. STEWART L. MCCURDY, of Pittsburg, said that he had seen and reported several such cases. In none of them had there been bleeding from the gums. The absence of pain, fever and fretfulness enabled one to differentiate between scorbutus and rickets.

DR. R. H. SAYRE did not see how the paralysis in his case could be looked upon as only apparent, for when pins had been stuck into the feet, the child had made no effort to retract the part, and when the limbs had been lifted, they had fallen as though lifeless. He was inclined to believe that acute rickets was as good a term as scurvy.

DR. TAYLOR thought it unfortunate to confuse rickets and scurvy. Several cases had been recently reported in which there had been absolutely no rickets.

KNEE-JOINT SURGERY FOR OTHER THAN TUBERCULAR PROCESSES.

DR. JOEL E. GOLDTHWAIT, of Boston, read a paper with this title. The paper was based on a study of 27 patients and 33 operations. One of these operations had been for the removal of loose pieces of cartilage from the knee-joint in a woman of sixty-five. Another case was an irreducible dislocation of the patella of many years' duration. Eight of the operations had been because of the presence of loose cartilages. Apparently a relaxed condition of the joint had favored the crushing and tearing of the inner edge of the cartilage. The point usually contused was the inner thin edge. The best treatment was the removal of the cartilage, and this method had the advantage of extending only over a period of three weeks. There was danger of over-treatment. Where there were marked fringes, they should be removed, as they usually act as foreign bodies, excite frequent attacks of synovitis, and in course of time large coagula form in the joint.

DR. W. R. TOWNSEND cited as an instance of the importance of early exploratory incision a case in which two well-known surgeons had confirmed his diagnosis of tubercular disease of the knee, and yet exploratory incision had proved the true condition to be sarcoma.

DR. GOLDTHWAIT said that the object of his paper was to remove the dread of many surgeons have of invading the knee-joint. He believed it was just as safe to enter the knee as the peritoneal cavity. In the cartilage cases he had made use of a straight incision, about one inch and a half long, inside of the patellar tendon. For exploration of the joint he made an incision, three inches long, on either side of the knee, and about one inch outside of the patella. He sutured the capsule separately when closing the wound.

THE TREATMENT OF VERTEBRAL TUBERCULOSIS WITH REFERENCE TO THE FORCIBLE CORRECTION OF THE DEFORMITY.

DR. JOHN RIDLON opened this discussion. In the past three years he had straightened two cases of rheumatoid stiffening of the spine, and had operated upon eight lateral curvatures under ether, and more than 35 cases of Pott's disease. In the worst cases that he had treated he had gained at first one and one-fourth inches in height, and at the second attempt, three-fourths of an inch. In all of the cases of lateral curvature almost all that had been gained had been subsequently lost; hence he no longer favored straightening such cases under ether. In a case of rachitic curvature he had gained nothing by the method. He had operated upon both old and recent cases of Pott's disease, and those with and without abscess. There had been two fatalities. One of these, a case whose previous and personal history had not been sufficiently studied, died of tuberculosis two months after operation. The other fatal case was one having an abscess at the time of operation. The child had done well for six or eight months; then two or three abscesses had developed, and death had finally taken place as a result of the exhaustion consequent upon the prolonged suppuration. The operation seemed to him a reasonably safe one if done with proper care. In many cases he had used almost no pressure with his hands; in other cases the force had been very considerable, and exceptionally he had made use of as much force as he could exert with both hands. There had always been some crunching of the bones. In none had paralysis subsequently developed, while some, paraplegic at the time of the forcible correction, had improved as regards the paralysis. In the earlier cases he had hung his patients up by the heels; later he had tried supporting the head and pelvis, with the face down, while the plaster was applied. More recently he had made use of the Goldthwait frame, and had since then never included the head in the plaster. The shortest case had been four weeks in bed; the longest case had been in bed for about one year. His aim had been to keep them in bed for six or eight months, allowing them to lie on the face, back or side. In a few instances there had been no return of the deformity; about half a dozen had gone for a year without support or return of the deformity. In the majority of cases he had succeeded in keeping the deformity reduced to about half of what it had been before the operation.

DR. GOLDTHWAIT said that in the past two years or more it had been a common practice at the Children's Hospital in Boston to apply an apparatus in the hyperextended position, for the most part without ether. He then exhibited a number of tracings that had been taken during the period in which the hyperextension treatment had been in use. They showed, in general, that the deformity had not increased, though in some instances there had been an increase in the compensatory curve. As a result of the work of the last two years he would hesitate to forcibly correct any spinal deformity resulting from tuberculosis unless it was associated with a paraplegia that had resisted other methods of treatment. He did not think the mortality had been materially increased by the use of forcible correction.

DR. W. R. TOWNSEND said that he had predicted that this treatment would ordinarily be followed by a recurrence of the deformity. There had been no deaths from forcible correction in the Hospital for Ruptured and Crippled. There the Goldthwait frame was employed without anesthesia.

DR. DE FOREST WILLARD, of Philadelphia, said that this treatment had always seemed to him illogical and unsurgical, and consequently he had only made use of it in one case of total paralysis, which was at the time in a desperate state. The child had been able to walk about quite well at the end of six months. In a few selected old paraplegics this operation seemed to him justifiable.

DR. R. H. SAYRE said he believed many cases of severe lateral curvature could be benefited by great force applied under anesthesia.

DR. T. HALSTED MYERS, of New York, said that his experience with forcible correction had been limited to four cases, but in all these it had been unfortunate.

DR. GALLOWAY said that while he had always regarded forcible correction as unscientific, he had held it in reserve for the first case of Pott's paraplegia incurable by other methods. Such a case had not yet presented itself.

DR. MCCURDY said he was accustomed to classify these cases into three groups, namely: (1) Old cases which require an anesthetic and considerable force for correction; (2) cases of paraplegia in which forcible correction may be beneficial, and (3) cases under active treatment in which there is a beginning kyphosis which gradual but forcible correction seems to improve.

DR. WEIGEL thought the reports just presented indicated that the mechanical support used after the forcible correction had been inefficient.

DR. R. TUNSTALL TAYLOR, of Baltimore, had not been favorably impressed with his trial of the method, and he was of the opinion that the older mechanical methods were safer and more accurate.

DR. HOFFMANN said that great stress had been laid upon the use of forcible correction in cases of Pott's paralysis, yet he had never seen a case of this kind that had not recovered if the spine had been rigidly immobilized and the patient kept on the back.

DR. JOHN L. PORTER, of Chicago, said that from his observation of Dr. Ridlon's cases he felt positive that fully 50 per cent. of those straightened under anesthesia continued to show an improvement in the deformity.

DR. RIDLON said that he would certainly try to

straighten every paraplegic case. Since seeing Dr. Goldthwait's tracings he had formed a better opinion of the value of the correction method with the aid of anesthesia.

DR. GOLDTHWAIT remarked that he had purposely not brought tracings of the cases treated under anesthesia because they were not better than those already exhibited. He was not in favor of using much traction or other force in securing correction.

THIRD DAY.

BRACE FOR LATERAL CURVATURE OF THE SPINE.

DR. GWILYM G. DAVIS, of Philadelphia, exhibited a new lateral curvature brace having a hip band and both anterior and posterior uprights. A shoulder piece encircles the high shoulder. From the posterior upright a band passes over the lump and underneath the arm of the affected side. The two points of support are on the arm above and the hip below.

DR. R. H. SAYRE was of the opinion that if the pressure were made on the large side, as it would be with this brace, the peak of the arch would become more arched.

DR. WEIGEL remarked that simply keeping the high shoulder down could have no special corrective influence on the deformity.

DR. DAVIS replied that he believed that the brace exerted a twisting force as well as a direct pressure.

RETARDATION OF GROWTH AS A CAUSE OF SHORTENING AFTER COXITIS.

DR. HENRY LING TAYLOR, of New York, read a paper on this subject. He said that measurements of some 30 cases of long-standing coxitis in children had shown that the tibia and foot of the affected side, as well as the femur, were considerably shorter than on the sound side. A comparison of a group of 10 cases of old unilateral poliomyelitis with a similar group of hip cases showed about the same amount of bone shortening. Retardation of growth was also found in the affections of childhood which disable one limb, and somewhat in proportion to the amount and duration of the disability and restraint imposed.

DEVELOPMENTAL SHORTENING IN TUBERCULAR BONE DISEASE.

DR. STEWART L. MCCURDY, of Pittsburg, presented in this paper several cases going to confirm some of the statements made in the paper just preceding.

DR. R. H. SAYRE said that in cases in which apparatus had been removed from one limb a considerable time before removal from the other he had noted the greater growth in the limb first liberated.

DR. GOLDTHWAIT said that by measurements and skiagraphs he had demonstrated in a series of hip-joint cases under treatment that the shortening took place below the knee.

DR. GIBNEY said that in tubercular disease of the knee the limb actually lengthens. Some of the dry cases which go on so well at first sometimes show after a few years a sudden and alarming degree of shortening.

DR. H. AUGUSTUS WILSON, of Philadelphia, said that according to Dr. Hurd's observations in China, after the use of the muscles of the feet in Chinese women had been partially restored there is evidence of increase in the diameter and length of the bones.

DR. PHELPS thought the shrinkage of the muscles was largely owing to a neurotic influence.

DR. NEWTON M. SHAFFER, of New York, said that where the nervous phenomena are most marked the shortening is apt to be proportionately great.

REPORT OF SOME STUDIES UPON THE ARTICULATIONS OF THE FOOT.

DR. JOHN DANE, of Boston, presented this report, illustrating, by means of anatomical specimens, the more common anomalies of articulation.

OBSERVATION ON CERTAIN PAINFUL AFFECTIONS OF THE FEET.

DR. LOUIS A. WEIGEL, of Rochester, made some remarks on this subject, illustrating them freely with skiagraphs.

INVESTIGATIONS AS TO THE TREATMENT OF FLAT-FOOT.

DR. E. H. BRADFORD, of Boston, sent a communication on this subject, but was unable to be present to read it.

A CASE OF CONGENITAL DISLOCATION OF THE WRIST.

DR. PHILIP HOFFMANN, of St. Louis, reported this case, and DR. GIBNEY then showed a second example of this dislocation, occurring in the person of one of the audience.

A CASE OF CONGENITAL DISLOCATION OF THE SHOULDER.

DR. JOHN L. PORTER, of Chicago, read the report of this case by invitation.

DR. PHELPS said that he had had eight cases of this dislocation, and had operated on four of them. In the latter he had invariably found fracture of the posterior border of the glenoid cavity. He now believed that the cause of the condition was always trauma.

DR. GIBNEY remarked that many of these cases were classified in the neurological clinics as examples of Erb's paralysis.

RAPID OSTEOCLASIS FOR THE CORRECTION OF RHACHITIC DEFORMITIES OF THE LEGS.

DR. WALLACE BLANCHARD, of Chicago, advocated in this paper a method of osteoclasia occupying not over eight seconds. The advantage claimed was that when operating so rapidly the circulation of the part was not impaired, and, as compared with supracondyloid osteotomy, the limb was increased in length instead of shortened. After the osteoclasia he exaggerates the correction of the curve. A long experience with the Grattan osteoclast in its original form had led him to think very highly of this instrument, which did not slip or cause splintering.

DR. T. HALSTED MYERS said that he had employed osteoclasia a good deal in the New York Foundling Hospital, and had found that if the pressure bar were applied on the inner side the bone could be fractured much more easily than if applied on the outer side.

AN OPERATION FOR UNUNITED INTRACAPSULAR FRACTURE OF THE HIP.

DR. GWILYM G. DAVIS, of Philadelphia, described in this paper a method of uniting the fracture by the insertion of ivory pins through an anterior incision after having freshened the edges of the fragments.

The following officers were elected: President, Dr.

Arthur J. Gillette, of St. Paul; First Vice-President, Dr. B. McKenzie, of Toronto; Second Vice-President, Dr. Louis A. Weigel, of Rochester; Treasurer, Dr. E. G. Brackett, of Boston; Secretary, Dr. John Ridlon, of Chicago.

The next annual meeting will be held at Niagara Falls, in May, 1901.

AMERICAN MEDICAL ASSOCIATION.

FIFTY-FIRST ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., JUNE 5-8, 1900.

SECTION ON SURGERY AND ANATOMY.

(Continued from No. 24, p. 637.)

THIRD DAY.

THE TREATMENT OF HERNIA IN CHILDREN,

by A. J. OCHSNER, of Chicago. He gave as predisposing factors of hernia the existence of the opening of the inguinal canal, weakness of the abdominal wall and hereditary tendency; the influence of a long mesentery is of doubtful importance. Among the exciting causes increased intra-abdominal pressure is of great importance; this may be partly due to indigestion and distention of the intestines with gas as a result of improper feeding; the digestive trouble often causes the child to cry, thus aggravating the condition; pressure may also be increased by straining at stool as a result of constipation, straining because of phimosis, and as a result of coughing. These conditions are much more common among the poor; the children are usually badly nourished, and their tissues abnormally lax and soft. In children, if the hernial sac is kept empty, and the abdominal pressure is removed, the majority are cured spontaneously. To keep the hernial sac empty, put the child in bed with the foot of the bed elevated. Remove digestive disturbances by careful attention to diet, and treat constipation, phimosis, coughing or other causes of intra-abdominal pressure. The child is thus relieved of its discomfort, is contented and sleeps most of the time. In this way the majority of cases of hernia can be cured. Operation is indicated if the hernia becomes strangulated, in case of irreducible hernia which becomes adherent to the sac, if the hernial opening is large and it cannot be retained with a truss, and if accompanied by hydrocele. The operation consists in dissecting out the sac, ligating it, and cutting it away, after which the stump is allowed to retract into the abdomen, and the opening is simply sutured.

TREATMENT OF VENTRAL HERNIA.

Dr. M. M. JOHNSON, of Hartford, Conn., believes that ventral hernia occurs in nearly 10 per cent. of cases after abdominal operations. Factors influential in its causation are drainage and granulating wounds, stitch abscesses, division of the motor nerves, lowered vitality and hereditary diseases. Dr. Johnson described his method of operating, in which he uses buried kangaroo-tendon sutures with quilled stay sutures of silver wire. He reported two bad cases in which he had operated successfully.

CURE OF INGUINAL HERNIA IN THE MALE.

Dr. H. O. MARCY, of Boston, said it is scarcely ten years since the radical cure for hernia has become a

recognized operation. The various methods of operating need not be considered in detail, but only the essential points of any successful operation. In most hernias except the inguinal variety there is a simple opening, and its closure will give rise to cure of the hernia. The essential point of difference in inguinal hernia is produced by the passage of the cord through the inguinal canal. Under normal conditions Marcy does not believe that a funnel-shaped process of the peritoneum such as is described by many writers exists. Sufficient attention has not been called to the importance of closure of the internal ring in the cure of hernia. Operations in which the cord is passed directly through the abdominal wall and transplanted under the skin are not followed by the best results, as the obliquity of the inguinal canal is a natural protection against protrusion of the abdominal contents. Among the essentials of successful operation were mentioned free, careful dissection, proper disposition of the hernial contents, careful attention to asepsis, the use of buried animal sutures, closure of the wound without drainage, and sealing the wound without further dressing.

Dr. W. B. DEGARMO, of New York, considers some defect of the abdominal wall the most important predisposing cause of hernia, while constipation is considered the most important exciting cause. He hesitates to operate upon children under five years old, for he believes that 95 per cent. of them can be cured by the use of a truss. He does not endorse the plan of treatment by putting the child in bed, for this prevents its development. The method of operating first described by Marcy and now generally known as Bassini's method he considers the best.

Dr. FERGUSON, of Chicago, considers deficiency of the internal oblique muscle at Poupart's ligament the most important etiological factor in inguinal hernia. The honor of proposing the method for the cure of inguinal hernia belongs to Marcy.

Dr. MAYO, of Rochester, Minn., believes that the majority of hernias occurring in children can be cured by the method suggested by Ochsner. The most important factor which tends to give permanent cure in operations by Bassini's method is the fact that the scar tissue is divided into two lines, the first line protected by Poupart's ligament, the second by the thick abdominal muscles. Scar tissue is always weak and this division is consequently of great value.

Dr. OCHSNER said that Dr. DeGarmo's objection to his method of treatment in bed does not hold, as it is continued only six weeks.

Dr. MARCY said that ventral hernia may usually be avoided. He has not had a single hernia in non-suppurative cases after over 1,000 abdominal operations.

Dr. W. L. WILLS, of Los Angeles, Cal., read a paper on

EXTERNAL DRAINAGE OF SUPERFICIAL LUNG CAVITIES, WITH REPORT OF TWO SUCCESSFUL CASES.

It is difficult to explain why suppurating tuberculous cavities of the lung are allowed to go on to infect the other lung and to produce pyemic conditions, when surgeons would feel justified in operating for such suppuration in any other part of the body. Wills advocates external drainage in such cases, but finds it difficult to get the consent of patients to the operation. He reported the case of a man of forty-five,

who had been losing strength and weight and who had all signs of a tuberculous cavity of the lower part of the left lung. Tubercle bacilli and elastic fibres had been found in the sputum. Under medical treatment he improved, and refused operation, but returned and consented to operation after his condition became much worse, three months later. An incision was made in the anterior axillary line and the seventh rib was resected; no pus was found in the pleural cavity, but a drainage tube was inserted. A gush of pus came, nine days later, simultaneously from the trachea and the wound. After this the temperature fell to normal, and there was free, foul discharge. The patient left the hospital with several discharging sinuses, and when seen about a year later, his sinuses had closed, he had gained seventy-five pounds in weight and was working hard. Special attention was called to the fact that strong solutions of mercuric chloride were used for irrigation without poisonous effect, and these were thought to have had something to do with the cure. [Wills has evidently lost sight of the fact that absorption does not take place from granulating surfaces, such as the walls of abscess cavities.] A second operation was reported, which was performed by a colleague of the speaker. A slight-built, emaciated man with signs of tuberculous cavity was subjected to resection of the rib, and three days later free discharge appeared and the temperature fell to normal. After eight days the patient left for home much improved in health. Both patients took the anesthetic very poorly.

Dr. MURPHY, of Chicago: If no adhesions of the pleura to the chest wall are present there is danger in opening the thorax. Puncture with a needle, admitting air, is not dangerous, and the air will produce compression of the lung and evacuation of the abscess cavity through the bronchi. If adhesions exist the lung should be directly incised instead of being opened with canterly.

Dr. WILLS, in closing, mentioned the advantages of California climate for such patients, and the importance of getting them out into the air soon after operation.

SURGICAL ERRORS OF SKIAGRAPHY.

Dr. CARL BECK, of New York, reported a case of fracture of the tibia, showing the necessity of two or more skiagraphs in the diagnosis of fractures. In this case of oblique fracture it was impossible to see any break by a skiagraph taken in the frontal plane, but it was clearly seen in one taken from one side. Unless the normal epiphyses are understood they may be taken for fracture, as may also the os intermedium pedis. Several skiagraphs were exhibited.

DIAGNOSIS OF CALCULOUS DISEASE OF KIDNEY, URETERS AND BLADDER BY THE X-RAYS.

Dr. C. L. LEONARD, of Philadelphia, read this paper. If skilfully used the diagnosis by the x-rays is absolutely accurate. He reports 20 cases in which the diagnosis of calculus was confirmed by operation, necropsy, or passage of the stone. Not only is positive diagnosis possible but a negative diagnosis may be made, thus avoiding unnecessary operation. The x-ray diagnosis is preferable to exploratory operation. Errors are only possible from faulty technic or lack of skill in reading the negatives.

TREATMENT OF INJURIES OF THE URETER.

Dr. B. B. DAVIS, of Omaha, Neb., described a method of ureteral anastomosis which he employed in uniting the ureter in a case in which it was divided while removing an intraligamentous cyst. The lower end of the duct was split for about one centimetre, threaded needles were passed through the walls of the upper end, then through the lower end, and on drawing on the sutures the upper end was drawn down and invaginated into the lower end. Later examinations proved that the ureter remained patulous. This method is quicker, simpler and sacrifices less tissue than that of Van Hook.

Dr. KELLY, of Baltimore, commended Leonard's work with the x-rays; in several cases in which he had been unable to locate ureteral stone with wax-tipped bougies, a diagnosis was made by Leonard with the x-rays. He briefly described his method of end-to-end anastomosis of the ureter with a guide, and reported a case in which he freed the bladder from its attachments and sutured it to the psoas muscle in order to get it high enough to anastomose with a short ureter.

Dr. BEVAN, of Chicago, mentioned a case in which two stones in the pelvis of the kidney and one in the kidney substance were located by the x-rays. The third stone was found only after some needling, and would not have been discovered had it not been previously located by the x-rays. He considers the x-rays a most valuable means of diagnosis.

Dr. BOVÉE, of Washington, D. C., considers anastomosis usually the best method of dealing with a severed ureter. Implantation into the bowel is the next best procedure. Over eighty operations of this kind have been reported with a large number of successes. He believes that the dangers of ureteral anastomosis have been overestimated; the function of the ureter is usually completely restored. Out of 21 cases thus far reported an unfavorable result followed in but one case.

Dr. GOODHUE, of Dayton, O., reports a case of ureteral anastomosis by Van Hook's method.

Dr. WINSLOW, of Baltimore, reported having operated on a case several years ago, by a method similar to that described by Davis.

Dr. BECK, in closing, expressed his belief that the importance of a negative x-ray diagnosis is not sufficiently appreciated. To make such a diagnosis three or four skiagraphs are necessary.

Dr. McARTHUR, of Chicago, called attention to the different intensity of shadows produced by calculi of various chemical compositions.

Dr. SUMMERS, of Omaha, Neb., mentioned a case in which he found double ureter present at the time of operation.

Dr. CARPENTER, of San Francisco, in removing an intraligamentous cyst cut out a section about two inches long from the ureter; he performed implantation into the bladder and showed a button, devised on the plan of Murphy's button, which had been devised for such operations.

Dr. LEONARD, in closing, emphasized the importance of using a low vacuum tube in diagnosing renal calculi by means of the x-rays, and the necessity for skilful technique.

Dr. DAVIS, in closing, called attention to the fact that the ureter is apt to be divided in severe, long

operations and hence the necessity for a rapid method of repair such as he had described; the operation could be performed in five minutes.

DR. MORGAN VANCE, of Louisville, Ky., read a paper entitled

EXSTROPHY OF THE BLADDER, WITH EXHIBITION OF A CASE.

A boy of seventeen came under observation for exstrophy of the bladder and hypospadias with all the disagreeable consequences. Operation was performed by sliding triangular flaps from the iliac region without inverting the skin, and after seven operations at different times extending over a period of two years a successful result was obtained. The patient was present for examination.

DR. DE FOREST WILLARD, of Philadelphia, considered the result in this case one of the most admirable he had ever seen. In most cases success is not obtained even after repeated operations. If the skin is turned in, concretions form and give rise to pain and discomfort, sometimes making it necessary to reopen the bladder. He believes that the most satisfactory treatment in these cases is to transplant the ureters into the colon above the sigmoid flexure, thus preventing incontinence of urine. It is best to remove a section of bladder wall with the ends of the ureters, for in this way the best possible valve is obtained.

DR. KELLY, of Baltimore, agreed with Willard that transplanting the ureters into the bowel was the most successful operation. In one case he loosened the sacro-iliac joint as had been done by Trendelenburg to aid in approximation. Vance's operation had the advantage of giving a functioning penis.

DR. MEANS, of Columbus, has a case similar to Vance's under treatment.

DR. HERZEL, of Chicago, has been favorably impressed with the operation of anastomosing the intestine and bladder in such cases.

DR. EASTMAN, of Indianapolis, Ind., mentioned a case in which he did nephrectomy on one side and sutured the ureter into the groove of a hypospadiac penis on the other for the relief of exstrophy. The patient is still in excellent health.

DR. SUMMERS, of Omaha, Neb., mentioned a case occurring in a female in which he performed anastomosis between bladder and vagina, thus obtaining a narrower opening from which to collect the urine.

DR. VANCE, in closing, expressed his belief that the case presented was as bad as any case could be and that a similar result could be obtained in any case by perseverance and boldness in dragging on the tissues.

SURGICAL ASEPSIS OF THE URETHRA AND BLADDER.

DR. FERD C. VALENTINE, of New York, read this paper. Attention was called to the difficulties of obtaining anything like a sterile condition of the urinary tract; urinary diluents, antiseptic drugs taken internally and injections with the piston-syringe are evanescent in their effects and give only an approach to asepsis. Valentine demonstrated an apparatus which he devised seven years ago for copious flushing of the urethra. During that time he has invariably practised such irrigation before and after all instrumentation of the urethra and he has not had a single case of urethral fever. He advises auto-irrigation by the use of the apparatus also in cases of gonorrhoea in which the patient cannot visit the physician regularly and for

those obliged to use the catheter themselves for enlarged prostate, etc.

THE TREATMENT OF PROSTATIC HYPERTROPHY.

DR. PARKER SYMS, of New York, described the pathologic conditions found in these cases and the well-known series of symptoms produced. For the operative relief of this condition, Bottini's operation and prostatectomy are the only procedures which merit discussion. The former operation he has not performed, but he thinks favorably of it; the latter operation he considers one of the greatest achievements of modern surgery. The death-rate has been high, not because of the dangers of operation, but because operation was left as a last resort and undertaken when the patient was unfit for any operation. Operation, to be successful, should be undertaken before the appearance of pain, infection and cystitis. It should not be undertaken on men with atheromatous arteries, unfit for any operation. He advises the perineal operation without suprapubic incision, and he showed a bulb which he has devised which can be introduced into the bladder in a collapsed condition and then filled with air to force the prostate down, so that it is readily accessible for operation.

DR. C. C. THAYER, of Clifton Springs, N. Y., commended Valentine's apparatus, but believed a fountain-syringe might be substituted for it. Local applications offer the best hope in the treatment of urethral affections.

DR. GLENN, of Alabama, believes that Valentine is over-enthusiastic in using irrigation, and that it is unnecessary except when there is urethral discharge.

DR. YOUNG, of Baltimore, has performed the Bottini operation successfully in several cases and considers it a very valuable method.

DR. CHISMORE, of San Francisco: The method of complete enucleation of the prostate commends itself to him as a great advance in the treatment of prostatic hypertrophy.

DR. BECK, of New York, agrees with Valentine that irrigation is advisable in all cases of instrumentation of the urethra.

DR. ROBBINS, of Detroit, considers urotropin the only internal urinary antiseptic of any value, and considers copious irrigation a valuable procedure.

DR. EASTMAN, of Indianapolis, credits Valentine with the introduction of Janet's irrigation method in America. He believes that a large piston-syringe is more easily sterilized, more convenient, and in skilful hands may be more accurately used than the fountain-syringe.

DR. BULLITT, of Louisville, Ky., considers Valentine's apparatus unnecessarily complicated; the shield is an advantage. It is impossible to gauge pressure by the piston-syringe and it is not easily sterilized.

DR. GRAY, of Jersey City, thinks more favorably of prostatectomy than of Bottini's operation.

DR. GUTERAS, of New York, believes that irrigating the urethra and bladder always improves their condition. Auto-irrigation should not be advised if there is any obstruction, and irrigation should always be discontinued as soon as there is any discomfort felt. An enlarged prostate should not be enucleated if there is pyelonephritis or arterial disease. The Bottini operation is suited to cases in which there is not great enlargement and in which the obstruction is mainly caused by the middle lobe. The mortality has been

placed too high by some writers; in the hands of skilled operators it should not be over five per cent., while the mortality of enucleation is never less than 20 per cent.

(To be continued.)

SECTION ON THE PRACTICE OF MEDICINE.

(Continued from No. 24, p. 641.)

DR. A. E. WOLDERT, of Philadelphia, read a paper entitled

INOCULATION OF MALARIAL FEVER THROUGH THE AGENCY OF THE MOSQUITO, WITH SOME SECTIONS AND DISSECTIONS OF THE MOSQUITO. ETIOLOGY OF MALARIAL FEVER AND SOME OBSERVATIONS MADE IN THE SOUTH SEVERAL YEARS AGO.

The paper dealt with the varieties and the anatomy of mosquitoes. Among the agents for destroying mosquito larvæ it was found that a solution of tobacco in kerosene oil was the most efficient.

A paper by DR. CHARLES F. CRAIG, of the United States Army, entitled

SOME TYPICAL CASES OF ESTIVO-AUTUMNAL AND TERTIAN MALARIAL FEVERS, WITH A STUDY OF THE PARASITES OBSERVED IN THE BLOOD,

was read by the Secretary of the Section, DR. FUTCHER. The paper described the symptoms, temperature curves, and course of cases of quotidian and of tertian estivo-autumnal malaria. Small doses of quinine will cause the temperature curve and the symptoms to become so changed that the disease cannot be recognized as malaria. The infection by two forms of parasite will also produce abnormal temperature curves. The paper described the differences in the microscopic appearances of the two forms of parasite.

A paper by DR. GOLTMAN, of Memphis, Tenn.,

EXPERIENCES WITH SOME OF THE PERNICIOUS FORMS OF MALARIA,

was read by title.

DR. FRANK A. JONES, of Memphis, Tenn., read a paper entitled

CLINICAL OBSERVATIONS IN MALARIA.

In the Mississippi swamps the doctor frequently sees cases of malaria that are chronic from the start. When the patient who has this form of malaria goes to a non-malarial district chills will develop in from twenty-four to forty-eight hours. A patient coming from a non-malarial into a malarial district often puts on fat and suffers from boils in winter, which the author thinks is due to the malarial poison. In the swampy regions pneumonia is common and the attacks are irregular and fatal. Cases of pernicious malaria are common. The negro seems to be immune to malarial paroxysms. Hemoglobinuria is the end product of neglected malaria; it is more frequent after the occurrence of the first frost, and at that season of the year it is more fatal than at other seasons. In cases of hemoglobinuria paresis of the bowels is common. Quinine is dangerous in such attacks. The author believes that attacks of true splenic leukemia are due to malaria.

DR. WM. BRITT BURNS, of Deckerville, Ark., read a paper entitled

MALARIAL HEMOGLOBINURIA.

The author has found estivo-autumnal parasites in the blood in all cases of malarial hemoglobinuria that he has seen, 16 in number. He is an advocate of the use of quinine in the disease. He has seen it in full-blooded negroes.

In the discussion that followed the reading of these papers, DR. WILLIAM KRAUSS, of Memphis, Tenn., said that in his opinion hemoglobinuria following malaria is a syndrome if not a distinct disease, and that it is not a mere symptom. The condition is not a toxic one. There must be some substance in the blood that allows quinine to produce the condition, since that drug sometimes will, and again will fail to, produce it. The attack of hemoglobinuria usually kills the parasites in the blood, which accounts for the fact that they are seldom found. There has never been a malarial toxin described. The determining factors in the production of the condition are: (1) Neglect of an old malaria; (2) the superposition of a new attack of the disease; (3) some indiscretion; (4) constipation and hepatic stasis; and (5) change to a non-malarial climate. The speaker had never found the parasite in the tissues of a patient dead of the disease.

DR. THAYER, of Baltimore, said that Romanowsky's stain is an important advance in clinical hematology. He has not been able to find a quotidian estivo-autumnal parasite. Nephritis and pneumonia are common in malarial negro patients. In some cases of malarial hemoglobinuria quinine does harm, while in other cases it does good. A rule is suggested for the administration of the drug: when the parasite is found active in the blood of the sick patient, give quinine; when the plasmodium is not found, do not give it.

DR. WESLEY, of Chicago, said that he had seen chronic malaria in the negro soldiers who had returned from Santiago.

DR. DAVIS, of Chicago, asked whether the anopheles migrated. If this insect does not migrate, how can the disappearance of the disease and its reappearance in a given locality be accounted for?

In answer to this question DR. HOWARD said that there was no evidence that the anopheles migrated by itself, but that it was frequently carried from place to place in public conveyances. Finding a suitable place for breeding in a new locality it would then become a resident. The anopheles has been found from 1,500 to 2,000 feet above the level of the sea.

DR. ROBERT B. PREBLE, of Chicago, read a paper entitled

PROLONGED FEVERS OF OBSCURE ORIGIN.

The author is of the opinion that many continued fevers are manifestations of sepsis and that they may be due to the pus cocci, the pneumococcus, the gonococcus, or the bacillus pyocyaneus. The cases may be either systemic or focal. They may be classed as cardiac, pulmonary, gastro-intestinal, hepatic, renal, osteo-arthritis, hemolytic and nervous. The author then gave a description of the symptoms of the various forms of the cases as classified above. Such cases were formerly diagnosed typhoid fever or typho-malaria. The differential diagnosis is best made by blood examination. He believes that the cases of so-called malignant endocarditis may be a manifestation of sepsis. Many of the joint diseases that are now

diagnosed as rheumatic and the condition known as peliosis rheumatica are probably also septic manifestations. The treatment should be symptomatic and supporting.

DR. ROBERTS, of Syracuse, asked whether the reader would exclude typhoid fever if the Widal and the diazo reactions were absent?

DR. BISHOP, of New York City, said that he was of the opinion that some of these obscure cases might be atypical cases of typhoid fever. If they were it would be possible to determine definitely by resort to serum diagnosis.

DR. DAVIS, of Chicago, advised those that had to do with all forms of febrile disease to watch for endocarditis, especially in these atypical septic conditions. Many cases of malignant endocarditis have not been such from the start, but are instances of endocarditis engrafted upon some septic disease.

DR. PREBLE said that he would not make a diagnosis on the presence or absence of the Widal reaction alone. A large number of these cases recover. He would not exclude the terms rheumatism, purpura, etc. from the nomenclature, but would instruct students that these conditions are probably not entities but symptoms of septic conditions.

DR. KRAUSS, of Memphis, Tenn., and DR. FAVILL, of Chicago, also took part in the discussion.

PATHOLOGY OF RHEUMATISM.

DR. DAVID RIESMAN, of Philadelphia, says that the facts pointing to the infectious origin of the disease are: (1) The fever; (2) the chill; (3) the occasional epidemic outbreaks; (4) the seasonal and climatic influence; (5) the character of the complications, which are those of the infectious diseases; (6) a demonstrable portal of entry for the virus in many cases, such as the tonsils, otitis media, operation in the nose, felon, furuncles, fistula in ano and vaccination; (7) the occurrence of acute endocarditis; and (8) the direct transmission of the disease from the mother to the fetus. Bacteriologic examinations seem to lead to the conclusion that acute polyarthritis is an entity caused by a single agent as yet to be discovered. The anaërobic bacillus of Achalmé seems to be the most promising of the organisms yet isolated from the diseased tissues. The joint changes found in the patients dead of acute articular rheumatism resemble those seen in other acute infectious processes. The early changes in the heart valves, according to the investigations of Achalmé, are swelling and edema with the occurrence of mast cells in the tissue of the valve.

RHEUMATISM AND THE PREVENTION OF HEART COMPLICATIONS.

DR. JAMES J. WALSH, of New York City, thinks rheumatism includes a series of closely allied processes. It is possible that the acid reaction of the blood is a protective process on the part of nature. The disease is one of low mortality. The use of the salicylates has reduced the severity of the symptoms, but does not seem to lessen the frequency of the occurrence of heart complications. The salicylates are not specifics, and the German school holds that antipyrin lessens the frequency of the heart complications. Rest is the most important element both in the prevention and in the treatment of the cardiac complications. Potassium iodide has some influence for good

on the valvular lesions in their incipency. Endocarditis is one of the essential elements of the condition, not a true complication.

THE RELATIONS OF CHOREA AND RHEUMATISM.

DR. CHARLES W. BERR, of Philadelphia, read this paper. There is frequently a history of rheumatism in cases of chorea. More frequently there is a history of joint or of general pain. Rarely chorea occurs during an attack of acute rheumatism. Children who have had chorea are more apt, in adult life, to have acute rheumatic fever than those that have not had chorea. At autopsy in subjects dead of chorea the one lesion that is invariably found is valvulitis. Rheumatic angina frequently precedes chorea. The coincidence of the diseases is not so frequent as to justify saying that chorea is a rheumatic disease. Rheumatic affections may possibly predispose to chorea.

HEART IN RHEUMATISM.

DR. DELANCY ROCHESTER, of Buffalo, thinks rheumatism is undoubtedly an acute infectious process. Endocarditis is seen in 60 per cent. and pericarditis in 10 per cent. of all cases. Myocarditis occurs in all cases of pericarditis, often in cases of endocarditis, and is sometimes found to exist alone. In myocarditis complicating rheumatic affections the papillary muscles are the first structures to become involved. The soft systolic murmur heard at the apex and over the body of the ventricle and not transmitted very far toward the axilla is probably due to the involvement of the muscular papillares. The occurrence of endocarditis or of pericarditis is no contraindication to the salicylic-acid treatment.

PATHOGENESIS AND CLINICAL FEATURES OF ARTHRITIS DEFORMANS.

DR. A. O. J. KELLY, of Philadelphia, said the disease presents joint, muscle and constitutional lesions. The nervous and the bacterial theories are the most important and reasonable yet advanced to account for the symptoms, but neither entirely covers the case, although it is probable there is a germ of truth in each. Arthritis deformans is an infectious trophoneurosis. The bacteria, which probably possess a selective tendency to affect certain joints, become lodged there, producing local lesions and elaborating toxins that are taken up by the blood and produce the other symptoms of the disease. The acute cases of the disease are decidedly infectious in type clinically.

DR. F. A. PACKARD, of Philadelphia, said that rheumatism now covers many diagnostic sins, just as dropsy did at one time. Rheumatism is not a local disease. Arthritis, endocarditis, etc., are not rheumatism. Acute articular rheumatism is a well-defined series of signs and symptoms produced by an unknown etiologic factor, with a great tendency to attack the serous membranes, notably the endocardium. Arthritic diseases may be classified as (1) acute articular rheumatism; (2) acute infectious arthritis, seen in gonorrhœa and in scarlet fever; (3) chronic infective arthritis, seen in children; (4) rheumatoid arthritis; (5) the spinal arthropathies, and (6) the arthritis of gout. The endocarditis that presents growing pains in the history should not be called rheumatic endocarditis. The term rheumatic pleurisy is a mistake, since the condition is not always rheumatic. Rheumatism is not a nervous disease. The lactic-acid theory is not

tenable. Articular rheumatism is an infectious process that may be caused by one of various microorganisms entering the system, often from the throat.

Dr. JOHN H. MUSSER, of Philadelphia, said that acute articular rheumatism is undoubtedly an infectious process. Many joint cases are of toxic origin. In many cases skin lesions, which may be of gastrointestinal toxic origin, are associated with joint lesions.

Dr. J. M. ANDERS, of Philadelphia, said acute articular rheumatism is not an arthritic disease; it is unquestionably infectious. The cardiac complications are always infectious and will be found to be due to a toxin. Chorea and rheumatism are not etiologically related. The endocarditis of chorea is not necessarily rheumatic endocarditis. It is going too far to think that all murmurs in chorea are organic; they may be functional. If in the course of chorea a murmur develops accompanied by fever, he would say that that murmur was organic. Rheumatism is a febrile disease. Cases of secondary acute articular rheumatism are rare, and if such cases do occur, the primary affection should be carefully noted. The differentiation of acute articular rheumatism and osteomyelitis is important. To prevent the cardiac complications, he combines the salicylic acid and the alkaline treatments.

CHARLES G. STOCKTON, of Buffalo, considered acute articular rheumatism to be an infection. The infectious neurotrophic theory of arthritis deformans is very reasonable. There are undoubtedly inherent conditions in certain individuals that invite the localization of the disease process.

Dr. L. F. BISHOP, of New York City, believes that there is a disorder of the chemistry of the body, a disorder of the processes of nutrition, as well as an infectious aspect in the development of joint diseases. We obtain better results by classifying these diseases according to this system: (1) Infectious arthritis, as acute articular rheumatism; (2) arthritis due to chemic changes, as gouty; and (3) arthritis due to nutritional changes, as arthritis deformans. These three classes of changes may exist in the body coincidentally. Chorea has been too definitely defined; chorea major is a different disease from Sydenham's chorea. Very few of the murmurs of the cases of chorea that he has seen are organic. Chorea may be complicated by infectious processes and it is these cases with the infectious element that develop cardiac lesions.

Dr. H. B. FAVILL, of Chicago, said acute articular rheumatism has both a toxic and an infectious side. The confusion of classification is due to the endeavor to group different conditions under one head.

Dr. BURNIE, of Maryland, said that, in his experience, no drug had any influence on the course of acute articular rheumatism. Rest in bed, hygiene and nursing are the best methods for the prevention of cardiac complications. Potassium iodide and iron are useful.

Dr. McCASKEY, of Fort Wayne, Ind., considered rheumatoid arthritis to be a toxemia of unknown origin, possibly from the gastro-intestinal tract. He has used potassium iodide by cataphoresis with satisfactory symptomatic results. It may be more proper to use some antiseptic solution by cataphoresis.

Dr. S. SOLIS-COHEN, of Philadelphia, said acute cases of rheumatoid arthritis affect the large joints, while the chronic cases affect the small ones. In the

latter group of cases the joints may be spindle-shaped, or they may present lateral deformity. The infectious element is more probable in the acute than in the chronic forms. The definition advanced by Dr. Kelly would better be that the disease is a toxic trophoneurosis. The tincture of ferric chloride in arthritic cases may be combined with salicylic-acid preparations, and seems to prevent heart complications. Alkaline treatment is also valuable.

Dr. DAVID REISMAN said that he had used extension in rheumatoid arthritis to prevent the occurrence of deformity in the large joints. In acute articular rheumatism he uses a combination of salicylates and alkalies; gives a milk diet with lemonade, and has the patient sleep between blankets.

Dr. J. J. WALSH said that if the bacillus of rheumatism should be found to be aerobic, after passing through the lungs it would be more virulent, and thus the frequency of left-sided heart disease in the condition might be explained. He believes that in complicated cases the following is the course of events, — rheumatism first, then chorea from a lessened blood supply to the brain, then rheumatism again.

Dr. ROCHESTER said that the patient should be kept in bed for from six to eight weeks in every case. The bowels should be kept freely open by the use of rochelle salt. Large doses of sodium salicylate, frequently repeated, should be employed; 30 grains every three hours for three days has failed, in his hands, to produce a deleterious influence on the heart. Iron is of great importance in the treatment of the accompanying anemia. He advises the use of 30 minims of the tincture of ferric chloride or 15 grains of the pyrophosphate. He believes that no treatment by drugs will prevent the occurrence of cardiac complications. Strychnine is of great value.

Dr. KELLY referred to the use of superheated dry air during a long period of time as being beneficial in cases of rheumatoid arthritis. He thinks strontium salicylate better than sodium salicylate because it is less likely to upset the stomach. Pure salicylic acid is also a convenient and satisfactory form in which to administer the remedy.

A CASE OF MALIGNANT ENDOCARDITIS WITH RECOVERY.

Dr. N. S. DAVIS, JR., of Chicago, read this paper. The patient was a locomotive fireman, age twenty-five. The condition was at first diagnosed gastro-enteritis, then typhoid fever, and later malignant endocarditis. The latter diagnosis was made on account of the persistent cardiac murmur, the absence of the plasmodium malariae, the absence of the Widal reaction, the septic type of the fever with chills and sweats. The chronic gastritis may have been the portal of entrance for the infection. The diazo reaction was present. The author cited recorded cases of recovery from the disease.

(To be continued.)

APPOINTMENTS AT THE UNIVERSITY OF PENNSYLVANIA. — The following appointments have recently been made: Dr. J. William White, Rhea Barton Professor of Surgery; Drs. Edward Martin and C. H. Frazier, clinical professors of surgery; Dr. R. M. Pearce, of Boston, demonstrator of pathology; Drs. W. F. Hendrickson and F. H. Howard, assistant demonstrators of pathology.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 21, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

THREE NOTABLE VOLUMES.

MEDICAL teaching in America up to within a few years has occupied relatively so subordinate a place as compared with medical practice that few men of eminence are remembered because they have been primarily great teachers. It is one of the best possible signs of the times that a change in this respect is everywhere observable. We are coming to see that the teaching of medicine is as worthy a profession as teaching Latin or Greek or science in any of its special departments. The result of this changed attitude is that the medical teacher as an individual is coming more and more into prominence, because he is a teacher and not because he is successful merely on the practical side of his profession. Teaching in medicine, as in everything else, must be an end in itself, and not merely a means, if the dignity of medical instruction is to be maintained and enlarged. In certain sections of the country, at least, this fact is being clearly recognized, with the natural result that medical education is rapidly progressing toward that position of respect to which it should long ago have been elevated.

Germany, on the contrary, is a country where the teacher in medicine, as in other branches of learning, has for many years been accorded the greatest measure of respect. This has led to the public recognition of his services on the part of his students and colleagues in the so-called "jubilees," functions of much solemnity as well as hilarity. That this particular form of recognition could ever be transferred from German to American soil is doubtful, and even were it possible it is extremely questionable whether it would be desirable. The spirit, however, which animates such gatherings up to a pitch often of extreme enthusiasm, as in the "Fest Kommers" given Helmholtz and Virchow some years ago, is quite possible of reproduction here. If we have the men capable of calling out the enthusiasm of their colleagues, the particular form which that enthusiasm takes is a matter of small consequence.

It seems to us, therefore, of no little interest that very recently two men in America should so have impressed themselves upon their time and generation that almost simultaneously their student and associates should have planned to recognize publicly their services to the cause of medical progress. We refer, of course, to Prof. Wm. H. Welch, of Baltimore, and Prof. Abraham Jacobi, of New York, two men who in very different ways will stand pre-eminent in the history of American medicine. Dr. Welch typifies the teacher, a man whose devotion to the study of the problems of disease, both by his own researches and indirectly through his pupils, has done much to deepen our conceptions of the true significance of medical teaching. The recognition of this work has recently appeared in a memorial volume published by his students, which bears on its title-page the following words: "Contributions to the Science of Medicine, dedicated by his pupils to William Henry Welch, on the twenty-fifth anniversary of his Doctorate." There is no preface or introductory note; no doubt, a designed omission. The volume contains thirty-eight articles, by forty contributors, Dr. Welch's former and present pupils, on various subjects connected mainly with pathological anatomy, filling, with the index, 1,066 pages. Many of the papers are of great scientific value and none are trivial. The general appearance and workmanship of the book are quite beyond criticism. It is profusely illustrated, largely with heliotype plates, and, as its frontispiece, has an admirable heliotype of Dr. Welch. Perfect as the volume is as a specimen of the bookmaker's art, it goes without saying that its chief interest lies in the fact that it represents the influence of one man on the professional life of his time, and stands unique in America as a public recognition of the debt which students owe to a great teacher.

Almost coincidently with the formal exercises attending the presentation of this volume to Dr. Welch in Baltimore, a similar ceremony was taking place in New York in commemoration of the seventieth anniversary of the birth of Dr. Abraham Jacobi. We have, in a previous issue, referred at length to the complimentary dinner given Dr. Jacobi, and to the exercises of that occasion. As a more permanent memorial of the appreciation in which Dr. Jacobi is held by his colleagues a "Festschrift" has been prepared, somewhat less elaborate than the volume to Dr. Welch, but of hardly less interest. This volume was presented to Dr. Jacobi at the dinner given in his honor, May 7th. It contains papers from the pens of fifty contributors both in America and Europe, men eminent not only in pediatrics, but also in other departments of medical investigation. In a short preface the outline of Dr. Jacobi's eventful professional and political life is given, which is epitomized in the following words, which we quote: "Dr. Jacobi's fame does not rest alone upon his greatness as a teacher and writer. He has taken an active interest in all that is best in medicine and has, withal, been an active and public-spirited citizen. As author, practitioner, hospi-

tal physician and society worker, he has ever been in the harness. In all these various departments of professional endeavor, he has been a leader and has never been content to be a servile follower."

Within a few days still a third volume has come to our hands, which, while not precisely in the same category as those just mentioned, deserves much more than a passing notice. It is a volume of contributions from the William Pepper Laboratory of Clinical Medicine, University of Pennsylvania, in memoriam of the late William Pepper. The volume is in admirable taste, entirely in accord with the dignity of the object for which it is designed, and contains a number of papers of great scientific value.

The custom which has this year been so auspiciously inaugurated of recognizing in such substantial and appropriate ways the services of our distinguished medical men, we sincerely hope may continue to grow into a fixed custom of the country. Such recognition, always bestowed with care, can have no other effect than to elevate the dignity of the profession of medicine, by granting such honors where they justly belong, to those men only who have done their share in materially advancing the cause of medical education and research.

ALCOHOL IN THE TROPICS.

A STATEMENT recently made by a writer in one of our contemporaries¹ to the effect that the use of alcohol is a physiological requirement in the tropics appears to have attracted considerable attention in the lay press — far more than would seem to be warranted by the circumstances. No fact has been more definitely settled through the efforts of the white race to colonize the tropics than that the use of alcohol, always undesirable, is here a source of positive danger. Medical men of ability and long residence in hot climates are well agreed upon this point. This fact is so well known to the laity that much of the interest attaching to the statement mentioned above — outside of the opposition at once excited among the temperance element — is undoubtedly due to the audacity of the proposition to brush aside the results gained by bitter experience during the past centuries.

The writer above referred to makes little effort to sustain his views by the opinions of others, and it is more than doubtful if he could find scientific support for the attitude taken. He does, however, make the claim that "Experience has demonstrated that in a hot climate the moderate use of intoxicating drink is essential to health and efficiency." To this claim we take decided issue.

Beginning with the admirably conducted expedition against the Ashantis in 1873, the British soldier has rarely been allowed the ration of spirits when on campaign in the tropics to which he is entitled on field service in temperate climates. This deprivation was the result of earnest representations on the part

of observing officers, both line and medical; and the reports of the medical officers accompanying subsequent expeditions have been uniformly enthusiastic in favor of the substitution of tea for alcoholics. Their reports are, however, expressions of opinion merely, and it is extremely interesting to see how the position assumed by them is fortified by figures. The British army is stationed at points all over the world in the temperate zone and in the tropics. The medical statistics of the British Army are presumably accurate and the use of alcoholics by the British soldier, as he changes from station to station, is presumably the same. According to the article above referred to, the amount of drunkenness, death and constant inefficiency in the British Army due to the use of alcohol should be greater in the temperate zone than in the tropics. On referring to the British Army Medical Department Report for 1897 it is seen that quite the opposite is the case. The figures given for alcoholism and its results in this report are as follows:

Place.	Year 1897. Ratio per 1,000 strength.			Decade 1887-96. Ratio per 1,000 strength		
	Admissions to Hospital.	Deaths.	Constantly non-effec- tive.	Admissions to Hospital.	Deaths.	Constantly non-effec- tive.
England	1.7	.01	.06	2.3	.04	.08
Scotland	1.9	.04	.05	2.8		.06
Ireland	1.4	.04	.05	2.0	.02	.06
Canada	3.7		.07	3.2		.09
South Africa4		.03	3.0	.03	.08
Gibraltar	8.9		.37	5.0	.02	.18
Bermuda	11.2		.30	9.1		.29
West Indies	15.6	.74	.32	7.8	.08	.19
Mauritius	14.5		1.82	20.0		1.20
Ceylon	4.5		.12	4.8	.08	.17
China	6.4		.34	3.2	.15	.16
Straits Settle- ments	3.0		.07	6.2	.08	.27
India	5.2	.03	.22	7.4	.07	.24

On averaging these figures together it is seen that for the five stations in the temperate zone — England, Scotland, Ireland, Canada and South Africa — the ratio of admissions for alcoholism in 1897, per one thousand strength, was 1.8; the death-rate from alcoholism was .018 and the constant inefficiency from the same cause was .052. For the stations in hot and tropical climates — Gibraltar, Bermuda, West Indies, Mauritius, Ceylon, China, India and Straits Settlements — the admission rate for alcoholism during the same year was 8.68 per thousand and the death-rate from the same cause was .09 and the constant non-efficiency was .445. For the decade 1887-96 the rates per thousand were: For cold climates 2.64, .016 and .072; for hot climates 7.93, .06 and .337. These results are extremely interesting, since they show that not only do four times as many British soldiers enter hospitals in the tropics for alcoholism as do in temperate climates, but also that the death-rate from alcoholism is more than four times as high in hot climates as in the temperate zone.

Full data as to the relative influence of alcohol in producing inefficiency among United States troops

¹ Philadelphia Medical Journal, April 7, 1900.

servicing in the tropics and at home stations are not as yet available; but the report of the Surgeon-General of the United States Army for 1899, which mentions deaths alone, shows that during the period May, 1898, to June, 1899, inclusive, the death-rate from alcoholism was .14 per thousand among troops serving in the United States and .296 for troops serving in Cuba, Puerto Rico and the Islands of the Pacific — or more than twice as large in the tropics as in temperate regions.

If it be objected that soldiers actually drink less in the tropics, then the above figures for the troops of Great Britain and the United States should obviously be increased to correspond with the deficiency in the alcohol used; if the soldier is said to drink more liquor in the tropics than in a cool climate, the evil results of such excessive drinking are shown by the above figures. In either instance the claim that the use of alcohol is desirable in the tropics is refuted beyond the possibility of discussion. In the light of such figures it is apparent that if the claim above mentioned possesses any value it is merely such as might attach to the personal opinion of a single observer.

It is furthermore to be borne in mind that under conditions of physical discomfort such as must prevail in the tropics, moderation in the use of alcohol is a matter of extreme difficulty. It is easy to conceive that a man temperate in a more northern region might easily fall into habits of extreme intemperance in the tropics, were he permitted to take the first step.

ADJUSTABLE SCHOOL FURNITURE.

At a meeting of the Boston Society for Medical Improvement held April 2d, the subject for consideration was, "The Proper Seating of School Children." The subject aroused an active discussion, and led to the appointment of a committee, consisting of Drs. John G. Blake, Chairman; Edward M. Hartwell, Wm. M. Couant, Myles Standish and Robert W. Lovett, to investigate and report upon the subject of adjustable school furniture. The following propositions were suggested by this committee and submitted to the Boston School Board:

(a) That it is desirable to have all the new school buildings provided with the most approved form of adjustable school furniture.

(b) That such children as are now in schools supplied with fixed furniture who are found, upon medical examination, to require adjustable furniture, shall be supplied with such desks and seats.

(c) That when it is necessary to replace the worn-out furniture of fixed pattern in the old schoolhouses it shall be done by adjustable furniture.

After careful examination of the seats submitted by the various manufacturers, which we believe comprised the best to be obtained, and comparison of the different varieties of seats, the Committee are unanimously of the opinion that the Miller chair combines more completely the

desirable features of a scientifically constructed chair than do any of the others.

With regard to the desk, the Committee are also unanimously of the opinion that the Boston School Desk with top adjustable for distances and height, made by the Chandler Company, possesses advantages for reading and writing not equalled by any other desk submitted to the Committee. Your Committee feel that the additional cost of eighty-five cents more for seat and desk combined, of the pattern mentioned above, is not worth taking into account in considering the great benefits which the pupils would derive from the use of these forms of school furniture. The small increase in the cost of the seat, fifty cents, is made possible by Professor Miller's refusal to patent his chair, for which he deserves and should receive the commendation of all school authorities as well as of the medical profession.

The Committee earnestly hope that the school authorities will give earnest, immediate and, if possible, favorable consideration to these recommendations.

The foregoing recommendations were referred to a sub-committee of the School Board on hygiene and physical training, which has recently reported on the matter. We quote the report in part, signed by S. H. Calderwood, Chairman:

The Committee on Hygiene and Physical Training, to whom was referred, May 22d, a communication from Dr. John G. Blake, chairman of a committee appointed by the Boston Society for Medical Improvement on the subject of adjustable school furniture, report that they have granted a hearing upon this matter, and have very carefully considered the recommendations and views expressed by those present, many of whom have devoted much time and thought to the question of providing scientifically constructed furniture for the use of school children. Your Committee believe that the time has arrived for the general adoption in the public schools in Boston of the most approved form of adjustable furniture, and that the old-style furniture of fixed pattern that is now in use should be gradually displaced as opportunity serves and means permit. Your Committee have also considered this matter in conjunction with the Committee on Schoolhouses and the joint Committee have given expression to their conclusions by recommending the passage of an order presented at this meeting of the Board. Your Committee desire to express their indebtedness to the Boston Society for Medical Improvement for its interest in this important matter and return their thanks for the valuable suggestions and recommendations which it has submitted.

It is much to be hoped that this most recent effort at reform may show some definite result in the near future. The matter was vigorously agitated a number of years ago by the medical profession without noticeable effect: in fact it is hard to see how physicians can do more than they have already done in impressing the importance of proper school furniture. The accomplishment of any far-reaching reform must naturally rest with the school authorities. The plan of a gradual substitution of new chairs of improved type as the need of them arises would certainly do much toward reducing the expense of such an innovation, and at the same time would gradually lead to the proper seating of all school children.

MEDICAL NOTES.

MEETING OF ASSOCIATION OF AMERICAN MEDICAL COLLEGES. — The Association of American Medical Colleges had an interesting and profitable meeting at Atlantic City, June 4th and 5th, at which several educational papers were read and vigorously discussed. Fifty-six colleges were represented. Such amendments as would exclude "Sun-down" medical colleges were adopted to take effect in July, 1901. Dr. Albert R. Baker, of Cleveland, was elected President; Thos. H. Hawkins, of Denver, First Vice-President; W. H. Earles, of Milwaukee, Second Vice-President. Drs. Parks Ritchie, W. W. Keen and J. M. Dodson were added to the Judicial Council. The Cooper Medical College, of San Francisco, the Medical Department of the University of Kansas and the American Medical Missionary College, of Chicago, were elected to membership. A committee was appointed at the request of the Federation of State Examining Boards to co-operate with a similar committee appointed by them to consider common interests. This committee consisted of Drs. W. J. Holland, Dudley S. Reynolds, Wm. E. Quine, W. J. Means and Parks Ritchie. The papers and proceedings of the Association are published in the *Bulletin of the American Academy of Medicine*.

DENTISTS AT THE INTERNATIONAL MEDICAL CONGRESS. — In response to numerous requests, the Executive Committee of the Thirteenth International Medical Congress has decided that dentists who are not doctors of medicine, but who have a State diploma either French or foreign, may be registered as members of the Congress in the Section on Stomatology. Names should be sent to the officers of the Congress, 21 Rue de l'École de Médecine, Paris.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 20, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 71, scarlatina 24, measles 121, typhoid fever 24.

BOSTON SOCIETY OF MEDICAL SCIENCES. — At the request of the President of the Massachusetts Medical Society, a meeting of the Society of Medical Sciences was held at the Harvard Medical School, on Tuesday, June 12, 1900, in connection with the Massachusetts Medical Society. Papers were read as follows: Dr. W. H. Robey, "Methods of Staining Flagella"; Dr. Franz Pfaff and Mr. Vejux-Tyrode, "On the Influence of Defibrination on the Secretion of the Kidney"; Dr. Eugene L. Opie (Johns Hopkins Hospital), "Pathological Changes Affecting the Islands of Langerhans"; Dr. Charles Harrington, "The Action of Drinking Water on Metals"; Mr. Ernest L. Walker, "A New Method for Distinguishing Human from other Mammalian Blood, in Medicolegal Cases."

LONG ISLAND TRAINING SCHOOL FOR NURSES. — The second class of nurses from the training school at

the Long Island Hospital, Boston Harbor, was graduated June 11th, with appropriate exercises. Remarks were made by the Chairman of the Board of Trustees and members of the visiting staff.

DEATH OF TWO PHYSICIANS FROM SEPTICEMIA. — It is reported that Dr. Elbridge K. Leonard, of Rockville, Conn., and Dr. Melancthon Storrs, of Hartford, have both died of septicemia resulting from infection at an operation on abscess of the liver.

NEW YORK.

MORTALITY STATISTICS. — The reports of the Bureau of Vital Statistics for the month of May show a gratifying decrease in the mortality of the city. For the four weeks ending June 2d, the mortality represents an annual death-rate of 18.83, against 22.87 for four weeks in April. This is still somewhat higher than the death-rate for the corresponding four weeks in 1899, but it is noticeable that the rate for the week ending June 2d is lower than that for the corresponding week of last year; the figures being respectively 16.63 and 17.67. This is the first time since the beginning of the present year that the death-rate has been lower than at the same period of 1899. The greatest reduction is in pneumonia, the weekly average of deaths from which was 215, against 359 for four weeks in April. The weekly average of deaths from influenza, aside from pneumonia, declined from 36.75 to 7.5; scarlet fever, from 16.75 to 11.5; measles, from 26.75 to 18.75; whooping cough, from 18.5 to 14.5; bronchitis, from 58 to 35.25, and pulmonary tuberculosis, from 193 to 174.5. It will be seen, however, that pneumonia is still causing considerably more deaths than phthisis. There is but little change in the mortality from diphtheria and from typhoid fever, the latter being, as usual, very small. There was one death from small-pox in April, as there was in May.

STATE HOSPITAL FOR CRIPPLED AND DEFORMED CHILDREN. — At a meeting of the Board of Managers of the New York State Hospital for the Care of Crippled and Deformed Children, created by the last Legislature, which was held at the residence of the President, Bishop Potter, on June 14th, the Committee on Site reported that it had leased a house and grounds at Tarrytown, on the Hudson, and that the changes required for equipping the premises for hospital use would be completed early in the autumn. The following were elected members of the consulting medical board: Drs. Francis Delafield, Robert F. Weir, N. Gilman Thompson, Joseph D. Bryant, Lewis A. Stimson, A. Alexander Smith and Reginald H. Sayre, of New York; Roswell Park, of Buffalo, and L. A. Weigel of Rochester.

COMMENCEMENT AT COLUMBIA UNIVERSITY. — At the one hundred and forty-sixth annual commencement of Columbia University, which was held on June 13th, the degree of M.D. was conferred upon 167 graduates, the largest class ever graduated from the College of Physicians and Surgeons. The degree of LL.D. was con-

ferred on Prof. Abraham Jacobi. The Stevens Triennial Prize for the best essay showing results of original research was awarded to Dr. James D. Voorhees, the Alumni Association Prize to Dr. David Boyaird, Jr., and the Alonzo Clark Scholarship to promote the discovery of new facts in medical science to Dr. Augustus J. Lartigau.

SMALL-POX IN COLUMBIA COUNTY.—An outbreak of small-pox has occurred among 500 negroes employed in brickyards at Stockport, Columbia County, and on June 15th it became necessary to call out the Hudson Company of militia to aid in enforcing the quarantine regulations of the State Board of Health against a number of laborers who refused to be vaccinated.

NEW COTTAGE HOSPITAL FOR INFANTS.—The corner-stone of the new cottage hospital for very ill infants, in connection with the Seaside Hospital of St. John's Guild at New Dorp, Staten Island, which is to be the gift of Mrs. Frederic Lewis, was laid on June 12th. One of the addresses on the occasion was made by Dr. Abraham Jacobi.

DEATH FROM CHLOROFORM ANESTHESIA.—It is reported from New York that a patient about to be operated upon for appendicitis died during the administration of the anesthetic, which was chloroform. The heart had shown no abnormality preceding the anesthesia.

Correspondence.

LITHIASIS PREPUTIALIS.

BOSTON, MASS., June 3, 1900.

MR. EDITOR:—In the *Allg. Wiener medicinische Zeitung*, September 12, 1899, is reported a case of lithiasis preputialis, first published in *La Grèce Médicale*, No. 7, 1899.

The case is communicated by Dr. Alex. Louis, of Velezza, Macedonia. I have made a translation of the article, and wish to add a similar case observed by myself. The case of Dr. Louis is as follows:

Lithiasis of the prepuce is extremely rare, and even in medical works only few cases are recorded. M. G., age forty-five years, is the father of three children. He concealed his condition from motives of false modesty, until his sufferings became so great that this was no longer possible, and forced him to seek medical aid. The condition had lasted seven years. At first the pain was slight, but has continually increased to the present time. After some hesitation he allowed an examination, in which the following condition was disclosed: The prepuce had externally the form of a pear, and the entire penis that of a clock pendulum. The circumference was 25 centimetres. The organ was painful to the touch, the feeling to the finger being that of a bag full of sand. From the preputial orifice issued a constant flow of a mucopurulent fluid of fetid ammoniacal odor. The urethral orifice was red, and barely visible at the bottom of the preputial opening. A sound introduced beneath the prepuce at once came in contact with a large deposit of stones, which it was impossible to remove on account of the phimosis. The prepuce was incised to the extent of four centimetres, and the stones removed and the glans and prepuce carefully cleansed. The glans was deeply indented from the pressure of the

calculi. Healing was rapid and complete. The number of stones, not reckoning the sandy detritus, was 119, of which 30 reached the size and diameter of a pea, the others diminishing to that of a grapeseed. It is of interest to note that the patient during the whole time of his disease fulfilled his marital duties until very shortly before the operation, when the increasing pain prevented coitus.

My own case: A. B. age twenty-two years, single, of neurotic ancestry on mother's side, and presenting certain stigmata of degeneration, consulted me on account of a condition which troubled and puzzled him. He has always led a strictly moral life. At the age of eighteen, he was placed in an asylum on account of an onset of *folie de doute* accompanying, or closely following, puberty. He recovered after some months and has since attended to business in a large commercial firm. After much hesitation and with great mental perturbation he told me his trouble and consented to an examination. There was extreme phimosis of a greatly elongated prepuce. It was quite impossible to retract the foreskin to such a degree as to expose any part of the glans penis. The entire organ was small in relation to the development of the patient, and its proximal portion presented nothing peculiar. Its distal portion, however, was greatly enlarged, elongated and pendulous, presenting roughly the appearance of a small pear, over which the prepuce was tightly extended, and at the end of which it was so contracted as to form only a narrow purse-like opening, perhaps half an inch in length. The opening was directed to one side, and on urination the stream was discharged at an angle from the penis, soiling the clothing of the patient. The swelling was very hard, unyielding, and pressure upon it caused much pain. A greenish, puriform discharge constantly issued from the opening, which was excoriated and painful. The discharge was ammoniacal and very offensive in odor. No cause could be assigned for the condition. The effect upon the patient was most depressing and was rapidly inducing threatening mental symptoms, similar to those for which he had been previously under my care. Operation was advised, and at once accepted by the patient. The prepuce was laid open upon a director, and disclosed a perfect collar around the base of the glans, filling the sulcus, except at the location of the frenum, and prolonged upon the surface of the glans toward the meatus. This calcareous collar was perfect at the time of operation, but was unfortunately broken in removal. A suitable portion of the stretched and redundant prepuce was removed on either side, the flaps sutured, and treated with antiseptic lotions. Healing was quite uneventful and perfect.

The rarity of this condition leads me to desire that this case should be placed on record.

Yours respectfully,

ALBERT N. BLODGETT, M.D.

THE RECENT MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

BOSTON, June 14, 1900.

MR. EDITOR:—The annual meeting of the Massachusetts Medical Society which this day marked the end of another year in the history of this ancient and honorable association will certainly take rank as one of the grandest and most successful events in the history of this Society. I think that the Society has never been so fully represented on such an occasion, and the quality of the work done has seldom been equalled. The provisions for the comfort and convenience of the members were ample, and though there was an unexpected increase in the number of those present at the banquet, all were amply cared for. I think the Society has been extremely fortunate in the selection of its Executive Committee, to whose efforts the excellent arrangements were due, and who have labored assiduously to ensure the successful accomplishment of their undertaking. The annual dinner was an especially attractive

feature, when more than a thousand members were assembled at table, and all were served with promptness and ease. It is easy to find fault upon an occasion of this kind, and to some extent this may be justified at times, but the arrangements for the meeting just ended were so judiciously made, and so perfectly carried out, that the thanks of the Society are certainly due to the committee in charge, for their unwearied and painstaking efforts.

Yours truly,
X. Y. Z.

EXPERIENCE WITH TUBERCULIN.

POMONA, CAL., June 7, 1900.

MR. EDITOR:—On June 23, 1898, I reported in your JOURNAL the use of Koch's new tuberculin on two consumptives. The conclusion drawn from its use was that the patients were benefited by it. About a year after its first use I again used it on these same patients with as near as may be the same results; their weight, strength and appetite were all increased. Subsequent events have, however, shown that they were not cured by it.

Truly yours,
C. D. NELSON, M.D.

RECENT DEATH.

WILLIAM PIERSON, M.D., one of the most prominent physicians of New Jersey, died at his home in Orange, on June 12th. He was born in Orange in 1832, and was the eldest son of the late Dr. Wm. Pierson. He was graduated from the Medical Department of the University of City of New York in 1852. He was one of the founders of the New Jersey State Medical Society and for thirty years its secretary. Later he became its vice-president, and at its annual meeting held at Atlantic City the week before his death, he was elected president of the Society.

A STUDY OF TWENTY-FOUR CASES OF TYPHOID FEVER WITH SYMPTOMS OF PERITONEAL INFECTION; LAPAROTOMY.¹

SUMMARY.—SEVENTEEN CASES OF PERFORATION OF INTESTINE; TWO CASES OF PREPERFORATIVE NECROTIC AREAS; ONE CASE OF RUPTURED MESENTERIC GLAND; THREE CASES CAUSE OF SYMPTOMS UNDETERMINED, DIAGNOSIS NOT CONFIRMED.

GROUPING AND ANALYSIS OF CASES;

GENERAL CONCLUSIONS; DETAILED REPORT OF CASES.

REPORTED BY GEORGE B. SHATTUCK, M.D., J. COLLINS WARREN, M.D., FARRAR COBB, M.D.,

Committee of the Boston Society for Medical Improvement.

THE whole number of cases studied by this Committee is 27, all coming in the years between 1895 and 1900; 9 cases from the Massachusetts General Hospital; 16 cases from the Boston City Hospital; 1 case from St. Elizabeth's Hospital, and 1 case from the Boston Children's Hospital.

In the year 1895 there are 3 cases, but only one of them will bear analysis as a case of genuine typhoid fever; 1 case in 1896, 4 cases in 1897, 5 cases in 1898, and 14 cases in 1899.

This is a striking illustration of the increase in the operative tendency. The data from which this analytical report has been made are the complete medical, surgical and post-mortem records of the several hospitals, together with the summarized statements and opinions sent in by the physicians and surgeons in attendance. From this available material a concise view of each case has been made with reference to all the important points bearing in any way on the diagnosis and treatment of peritoneal infection in typhoid fever.

The Committee would deprecate its critical comments of to-day being interpreted as fault-finding with the practice of earlier years; neither does the Committee forget that the ideal is not always, or under all conditions, to be realized in practice. Doubtless a nearer approach to the ideal should be aimed at and would now be possible than is found in most of the cases here reported. And the Committee is still further quite aware that the ideal itself—for example, in regard to such a matter as the value and application of the white blood count—is subject to further changes; the value of pain as a warning symptom also merits further study.

Of the 27 cases A, B and C must be thrown out of our consideration, because of no proof that they were genuine cases of typhoid. Cases B and C were both cases of advanced general peritonitis when first seen, and in both of them there was no proof that typhoid was the origin of the peritonitis.

Case A was brought to the City Hospital in a moribund condition, and showed general peritonitis at the operation. Cultures from the interior of the gall-bladder showed the presence of the bacillus typhosus. This, however, cannot be accepted as conclusive proof that the case was one of typhoid peritonitis. Cultures from the peritoneal fluid showed only the staphylococcus albus. It is an accepted fact that typhoid bacilli can and do remain active in the gall-bladder for

months and years after an attack of typhoid fever. For example, Miller² has reported a case in which the bacillus typhosus was found in the gall-bladder seven years after an attack of typhoid fever. There is no proof, therefore, that the peritonitis in Case A might not have been of other origin than typhoid fever, and, therefore, it cannot be included in our list of cases for study. This series, then, embraces 24 cases, which are all undeniable cases of typhoid; there can be no controversy on this point.

Eighteen cases had a positive Widal serum reaction in addition to the evidence furnished by the clinical course of the case and the positive pathological evidence furnished by the operation or post-mortem examination. In 3 cases the Widal test was not made; in 3 cases the Widal test was negative. Two of the cases in which it was not made occurred in the years 1895 and 1896, a period of time before the use of the test.

Of the 6 cases in which the Widal test was not made or was negative there can be no doubt of the diagnosis of typhoid, because of the findings at the operation or the post-mortem which fully corroborated the clinical diagnosis. In 2 of the cases in which the Widal test was not made the diazo test was positive.

All of the 24 cases had symptoms upon which a diagnosis of intestinal perforation was made and for which an operation was performed.

Three of the cases (XXII, XXIII and XXIV) presented symptoms strongly suggestive of intra-abdominal infection, and accordingly were operated upon with a diagnosis of intestinal perforation, but at the operation no positive cause for the symptoms was found. Two cases recovered from this exploratory operation, and 1 died. These cases are of the greatest importance from the diagnostic point of view, and will be considered carefully when the subject of "Symptoms and Diagnosis" is taken up.

Case XIX had characteristic symptoms of acute sudden peritoneal infection, and operation discovered a general septic peritonitis, but did not determine the cause; therefore this case should not be classed with those in which the cause of the peritonitis is certain, although it certainly seems rational, on considering the history and the symptoms and the fact that several different thin places in the intestinal wall were found at operation, to consider it a case of perforation.

In Cases II and XVI the classic severe symptoms of perforation were simulated, but operation discovered the cause of the symptoms to be a general septic peritonitis originating in damaged and necrosed areas of peritoneum over the bases of one or more typhoid ulcers. These cases might be called cases of progressive peritoneal infection from threatened perforation.

In Case XXI the symptoms amply justified the diagnosis of intestinal perforation, but operation proved that the symptoms, which were identical with the usually accepted symptoms of perforation of the bowel, were due to a general septic peritonitis arising from a ruptured mesenteric gland.

So that out of the 24 cases of true typhoid only 17 were cases of peritoneal infection from actual perforation of the intestinal wall. Two cases were of general infection from threatened perforations or areas of necrotic peritoneum; 1 case of general infection from

¹ Report presented at a meeting of the Boston Society for Medical Improvement, April 16, 1900.

² Johns Hopkins Hospital Bulletin, May, 1898.

a ruptured mesenteric gland; 1 case of general infection from an unknown cause, presumably intestinal perforation; 3 cases had no certain cause for the symptoms which demanded operative interference.

Since it will be shown that in many cases no differentiation between the usually accepted symptoms of actual perforation and the symptoms of general septic peritonitis can be made, this series of 24 cases gives us, for further study, 21 cases of grave peritoneal infection in typhoid fever and 3 cases of mistaken diagnosis, but with symptoms of peritoneal infection.

Diagnostically and from the point of view of treatment all of these cases should go in under the head of acute peritoneal infection in the course of typhoid fever. It may be well, however, to analyze the two groups of cases separately, dividing the perforations from the other cases.

Of the 24 cases presenting acute abdominal symptoms, with or without discoverable cause, 18 were males and 6 were females. Of the 18 males 15 were under thirty years; 1 was forty-five years; 1 was thirty-eight years; 1 was thirty-two years; 14 cases were between the years of nineteen and thirty and 1 case was sixteen years. Of the females, 6 in number, 4 were between twenty and twenty-six years, 1 was forty years and 1 was sixteen years.

The total number of cases shows, therefore, that acute abdominal infection occurs most often in young adults between the ages of eighteen and thirty years; that it is most frequent in men; that it is rare in children. It is noteworthy that 2 of the cases presenting acute abdominal symptoms without discoverable cause occurred in young women, aged twenty and sixteen years, respectively.

These facts in regard to age and sex are in general accord with the investigations of Dr. R. H. Fitz and others, although the percentage of those under thirty years of age happens to be somewhat larger than in Dr. Fitz's tables.³

As to the question of typhoid perforation in children under twelve years of age, we have been able to find but 4 cases of operation for perforation in children under that age in all the cases reported in literature.

Cushing:⁴ Boy, nine years old, on which case 3 laparotomies were done; the case recovered. Three cases are given in Keen's⁵ tables of cases of operation for typhoid perforation.

All the cases but one were white in color. This proportion of blacks to whites would very likely be different in other parts of the country, where the proportion of the colored population to the white is greater.

In 18 of the 24 cases the clinical nature and course of the typhoid was mild, and in 15 of these 18 mild cases perforation or general septic peritonitis was present. The 3 cases which presented symptoms without certain cause were mild cases.

One case, XVII, was a "walking typhoid"; 6 cases, II, VI, VIII, XII, XIV and XX, were severely sick typhoids. All of these 6 cases had general septic peritonitis from actual or threatened perforation, and all died.

These facts are in accord with the hitherto accepted knowledge that intestinal perforation in typhoid fre-

quently occurs in those cases of a mild type, or, in other words, there is no relation between the severity of the course of the fever and the likelihood of intestinal perforation.

The difficulty of the diagnosis of the peritoneal infection in cases of the severe type will be touched upon later.

The sudden fulminating symptoms in the severely sick cases will be found in the majority of instances to be due to a general septic peritonitis, which was often unsuspected and had slowly progressed. On the other hand, a sudden, acute onset in the mild type more often meant sudden intestinal perforation with extravasation. In certain of the severely sick cases in this series it would seem as if a diagnosis of the onset of the peritoneal infection was practically impossible.

The organic complications were very few: Three cases had mitral regurgitation amply compensated; 1 case in which operation discovered no cause for the symptoms had an especially feeble heart, with mitral regurgitation, yet this case recovered from the exploration; in 9 cases intestinal hemorrhages are noted; in 2 cases it occurred three weeks before the severe symptoms of perforation appeared; in 2 cases it occurred forty-eight hours before the severe abdominal symptoms, but there was a distinctly comfortable period between the occurrence of these hemorrhages and the sudden onset of abdominal pain. In 3 cases intestinal hemorrhages preceded and coincided with the beginning of peritoneal infection. Case XIX had daily intestinal hemorrhages for three days before sudden abdominal symptoms. Case XII had a severe hemorrhage five days before the symptoms for which operation was done; but this case was so sick and stupid as to justify the supposition that perforation probably took place long before the foul and evidently long-established general peritonitis was diagnosed. Case VI had two severe hemorrhages just preceding and coincident with the perforation. In 2 cases intestinal hemorrhages are noted after the operation. In Case I a severe hemorrhage five days after the operation was undoubtedly the cause of death.

Intestinal hemorrhage, inasmuch as it must come through extensive ulceration of the intestinal wall, and since this may mean proximity to the peritoneal coat of the intestine, must be to a large extent a danger signal of perforation. The occurrence of intestinal hemorrhages, therefore, should properly demand a close watch for the symptoms of beginning peritoneal infection, frequent examination of the abdomen to detect tenderness or abnormal rigidity and muscular spasm, associated with frequent leucocyte counts. The occurrence of acute abdominal pain following and coincident with intestinal hemorrhage should lead to the suspicion of peritoneal infection.

THE WEEK IN THE DISEASE IN WHICH PERITONEAL INFECTION TOOK PLACE.

Of the cases in which perforation and general peritonitis existed the acute abdominal symptoms appeared at the following times: In 5 cases at the end of the second or first of the third week; 8 cases at the end of the third week; 1 case during the fourth week; 4 cases during the fifth week; 1 case during the sixth week; 1 case during the ninth week; 1 case during the eleventh week in a relapse.

Of the cases operated upon under a mistaken diag-

⁵ Surgical Complications and Sequels of Typhoid Fever.

nosis I was in the fourth week, I in the fifth week and I in the sixth week. The diagnostic symptoms of intestinal perforation in typhoid as they are usually understood, namely, sudden abdominal pain, fall of temperature, collapse, general abdominal rigidity and tenderness, with or without vomiting, anxious facies, coming on without warning, do not present themselves as a complete picture in any one of this series of cases. The majority of the cases show records of definite warning symptoms, or, in other words, present evidences of a gradual onset of peritoneal infection.

It is, in fact, rational to conclude from a study of the symptoms in these cases, together with the findings at operation, that the severe symptoms corresponding to the ordinary text-book picture of intestinal perforation in typhoid were, in the majority of cases, caused by the general septic peritonitis resulting from a perforation or a threatened perforation, the occurrence of which (the perforation or local area of infection) was indicated more or less plainly by symptoms of less severity, which antedated the severe or so-called diagnostic symptoms by a definite number of hours.

If it is one thing to operate for intestinal perforation, and a decidedly different thing to operate for a septic peritonitis resulting from a perforation, the fact should be thoroughly understood that the severe and usual diagnostic symptoms in this class of cases meant that septic peritonitis had already existed for some time, and that the perforation took place at a previous time and was evidenced by milder and more localized symptoms. It is a fact that in the majority of these cases definite premonitory symptoms are recorded at a time more or less remote from the severe symptoms which first led to the diagnosis, and for which the physician called the surgeon in consultation.

Seven cases of the 21 in which operation found cause for the symptoms, namely, I to VII, inclusive, presented a sudden, acute picture of grave abdominal infection without *any* premonitory symptoms. Of these 7 cases 5 (I, III, IV, V and VII) were mild typhoids, whose general and mental condition was favorable to the noting of abdominal pain. Two cases (II and VI) were very sick, stupid and semi-conscious; a class of cases in which the occurrence of considerable localized abdominal pain might not be noted. In Case II the symptoms, sudden though they were, were due to a general peritonitis from the damaged peritoneum over the base of one or more ulcers, and not due to a sudden perforation. In Case VI the sudden symptoms were caused by the presence of a general peritonitis which had extended from a localized abscess originating from the intestinal perforation which at its appearance had given no symptoms, so that of the 7 cases which presented fulminating symptoms and which most closely conformed to the hitherto established idea of the symptoms of intestinal perforation only 5 proved to be due to *actual sudden perforation*, while 1 was not a case of perforation at all, and in the other the perforation and progress of the localized peritonitis with abscess formation did not cause any symptoms.

The sudden onset in these 7 cases presents a different picture in the 5 cases in which the symptoms were proved to be due to actual perforation. In these cases we have the symptoms of sudden severe pain

coming on without warning, more or less localized in the right iliac region, accompanied by localized muscle spasm and tenderness, with the varying amount of shock. In the 2 cases in which the symptoms were due to general peritonitis, we have a picture suggesting general peritonitis, marked collapse, great distention, and general tenderness and rigidity. It might be concluded from a study of these 7 cases that in mild typhoids the appearance of sudden severe abdominal symptoms without any previous abdominal pain or tenderness may most often mean sudden intestinal perforation with extravasation into the general peritoneal cavity, and that the symptoms may vary, the chief symptoms being sudden pain, tenderness and muscular spasm localized, attended with more or less marked shock; but in very sick and lethargic cases the appearance of severe abdominal symptoms without warning most often means the presence of general septic peritonitis originating in some one of the possible sources of peritonitis in typhoid, the gradual onset of which it has been impossible to diagnose because of the sick and stupid condition of the patient.

It has been stated that in the above 7 cases there were no warning symptoms. By this is meant direct abdominal symptoms — pain, tenderness and muscular spasm. It should be stated, for the sake of completeness, that 3 cases had one or more intestinal hemorrhages on the two days preceding the acute abdominal symptoms. One case had several hard chills without hemorrhage during the twenty-four hours preceding the onset of the peritoneal symptoms. The occurrence of chills as a symptom of peritoneal infection in typhoid is probably rare. It can only be a symptom leading to suspicion of infection when it is unassociated with hemorrhage.

J. F. R. Gairdner⁶ states that rigor as an initial symptom of peritoneal infection in typhoid is uncommon. He noted it in only 2 cases out of 47 studied by him. It is noteworthy that in 1 of his cases and in the case of Jenner the peritonitis ushered in by rigors was due to the rupture of a softened mesenteric gland. In Case XXI, the only case of our series of peritonitis from the same cause, no chill occurred. In the absence of intestinal hemorrhage to account for rigors it might not be irrational to suppose that it might occasionally be present in the early stages of peritoneal infection.

In those 3 cases in which no cause for the symptoms was found at operation the onset of the same was gradual. These cases will be referred to again in the subject headed "Symptoms and Diagnosis."

We have 14 cases, namely, Cases VIII to XXI, inclusive, with more or less gradual onset of the abdominal symptoms. Eleven of these are cases of intestinal perforation and resultant general septic peritonitis; 2 are cases of general peritonitis without perforation; 1 a case of general septic peritonitis of unknown origin, though probably due to a perforation.

One of the perforative cases (Case XVII) was a "walking typhoid," and had probably had general peritonitis for at least thirty-six hours before entering the Massachusetts General Hospital.

In all of these 14 cases *distinct warning symptoms* antedated equally distinct severe and diagnostic symptoms. The milder symptoms, which we must conclude marked the beginning of the peritoneal infection, were chiefly various degrees of abdominal pain and

⁶ Glasgow Medical Journal, 1897, vol. xlvii, p. 103.

tenderness, either localized or general, complained of by the patient. All of these 14 cases were mild types except 4. In only 1 of the 14 cases was any complaint recorded of abdominal pain until the complaint ushering in the severe symptoms, and in the single exception to this the complaint of abdominal pain antedated the actual perforation by some weeks.

In 4 cases abdominal distention throughout the course of the fever is noted. In 9 cases there is no record of any abdominal complaint or abnormality until the peritoneal infection was under way. In every one of these cases recorded *complaint by the patient of abdominal pain* was followed by peritoneal infection. The severe symptoms followed these warning symptoms at various intervals in every case, and there can be little doubt that the severe symptoms, when they appeared, meant that the peritoneal infection had become general and alarming.

An analysis of these premonitory symptoms shows that in 6 cases the pain complained of was general abdominal pain; in 3 cases localized in the left iliac region; in 4 cases in the right iliac region; in 1 case in the lower abdomen; in 1 case general abdominal pain, and also pain in the rectum and bladder; in 1 case the pain began in the epigastrium and later became marked in the right iliac region. It is much to be regretted that the importance of this abdominal pain was apparently not appreciated, as shown by the case records.

In 3 cases *comparatively* complete physical examination is recorded as made at the time. In no case was there a record of as careful an examination of the patient in every detail as the importance of the symptoms demanded, so that our knowledge of the accompanying conditions of tenderness, muscular spasm, leucocytosis, pulse and temperature is insufficient.

In 2 cases the complaint of pain was preceded by vomiting. In only 2 cases was the record of a leucocyte count made, and in these cases it appears that the blood count was only done once. As will be shown under the head of "Leucocytosis as a Symptom," an isolated blood count is of little or no value. In 1 case general abdominal tenderness and rigidity were noted, and in 2 cases there was general tenderness. In 4 cases there is no record of any physical examination, but a record *that morphine was given*. In 3 cases it is noted that the pulse and temperature were rising. This warning abdominal pain preceded the severe symptoms by hours and days; it appeared in 1 case sixty hours before; 1 case forty-eight hours before; 1 case twenty-four hours before (Case XVII); 4 cases twelve to fifteen hours before; 4 cases eight hours before; 3 cases three to five hours before. It is noteworthy that the 2 cases in which no actual perforation but general peritonitis from other causes existed had equally marked advanced pain.

Cases XVI and XXI, where the severe symptoms followed just as in the cases of perforation, point plainly to the reasoning that the early pain in these cases was due to local peritoneal infection, and that the severe symptoms were due to the establishment of a general infection.

The severe abdominal symptoms in every case determined the diagnosis and the decision to operate. In general these symptoms were those of general septic peritonitis, namely, general abdominal pain, severe; general tenderness and rigidity, with distention, collapse, poor pulse and anxious facies.

In only 3 of the cases was there any vomiting. The classical sudden fall of temperature is not present in many of the cases. The temperature fell somewhat in a few cases. In 2 cases it fell to normal, and began at once to rise; in 1 case it fell to and remained subnormal; in 3 cases a slight drop of temperature is noted; in 6 cases there was no fall of temperature, and in 3 cases it is recorded as rising.

In 8 cases a leucocyte count was taken at a time corresponding to these severe symptoms; in 4 cases it showed leucocytosis; in 4 cases it showed no leucocytosis. The leucocyte counts are, however, of only relative value, as will be considered later under the heading of "Leucocytosis as a Symptom."

In only 2 cases was a record of obliterated liver dulness made.

The constant symptoms in every case are abdominal pain, general tenderness and rigidity, with distention, associated with collapse and rapid, feeble pulse.

A comparison of the severe abdominal symptoms in the two classes of cases—the 7 cases where warning symptoms were not present and the 14 cases with warning symptoms—shows *distinct differences* in the severe symptoms in those in which the sudden intestinal perforation and extravasation came on without warning. As has been stated, the severe pain, more or less localized, with shock and muscular spasm and tenderness, characterized the first set of cases, and the shock varied in the different cases. In 1 case the pulse was not over 100. There was no vomiting, no general abdominal tenderness or rigidity, and no distention in any case.

Contrasted with this first set of cases, the severe symptoms in the second set present a much graver picture. It is noteworthy that in the 2 cases in the first set, in which general peritonitis was the cause of the symptoms and not intestinal perforation, the picture corresponds to the severe picture in the second class of cases.

It should be noted that if the signs of actual perforation with extravasation are local to a great extent, as in the 5 cases of our first set, a careful examination of all cases at the warning complaint of pain might in many of them give us definite diagnostic signs, as in Case III, for example.

A comparison of these two sets of cases—the 7 with sudden symptoms without perforation and the 14 cases with severe symptoms following premonitory pain—bears out the point that in most of them no positive diagnosis of perforation was made, but only a diagnosis of the general peritonitis resulting from the perforation.

THE TIME OF OPERATION AFTER SYMPTOMS APPEARED.

In the 7 cases with no warning symptoms operation was done within twelve hours in every case; 1 case within an hour and a half; 3 cases within four hours; 1 case within seven hours; 1 case within eight hours; 1 case within twelve hours.

At the operation general septic peritonitis was not evident to the eye in Cases I, III and VII. In Case V it is noted as just beginning and not far advanced. In Case IV the perforation was protected by weak adhesions, and no general infection had taken place up to the date of operation. In Cases II and VI general peritonitis was farther advanced and was evidently the cause of the sudden symptoms, so that only 5

macroscopical signs of general peritonitis. Case I lived nearly a week, and died from intestinal hemorrhage, and the autopsy showed no general peritonitis. Cases III and VII both died within sixty hours, one with the symptoms of general peritonitis and the other without such symptoms. There were, however, no bacteriological studies of the peritoneal infection in these 3 cases at the time of operation. Two of the cases may very probably have died from a virulent infection, which did not cause any visible signs.

Vincent⁹ experimentally has called attention to the fact that a streptococcus peritoneal infection in typhoid is usually a fatal complication. Vincent's studies have been corroborated by Flexner and Fraenkel.¹⁰ Cushing¹¹ reports a case in which operation was done within an hour or two after perforation, and at the operation no visible signs of general peritonitis were present. Cultures and cover-slip preparations from the fecal fluid pouring out of the perforation in the intestinal wall showed large quantities of streptococci, and the case died of streptococcus peritonitis.

It is perfectly within reasonable bounds to believe that one or more of the supposedly favorable cases in our series may have had a streptococcus infection. Certainly we have no evidence to the contrary.

Cases II and V show a beginning general peritonitis, as evidenced by gas and serous fluid free in the abdominal cavity, but indicated no injection of the peritoneal coat of the intestines. Both of these cases, so far as the macroscopical appearance went, seemed favorable, yet both died. Cultures taken in Case V showed a pure infection of the bacillus typhosus.

Case IV had no general peritonitis, as has been stated. Case XVI was one of general peritonitis arising from the same cause as in Case II, namely, damaged peritoneum; yet in Case XVI peritonitis was much more extensive macroscopically than in Case II, being evidenced by seroturbid fluid with fibrin flakes and with green fibrin patches on the intestines. Case XVI recovered; Case II died. Although Case II was a more severe typhoid, presumably the general peritonitis in one case was caused by a virulent infection, and in the other by a non-virulent; yet no bacteriological proof is available in either case.

General septic peritonitis in typhoid arising from threatened intestinal perforation from the necrosed and damaged areas of peritoneum over the base of ulcers must be accepted as a not very uncommon occurrence. J. F. R. Gairdner¹² has reported 5 such cases.

To sum up in regard to our first class of cases, namely, 7 with sudden onset of symptoms, 3 had no general peritonitis evident to the eye; 1 case had limiting adhesions around the perforation, with no general peritonitis; 2 cases had slight evidence of general peritonitis. These are all of them the most favorable cases for operation, for it must be said of them that operation was actually directed against the infecting cause and not against the resulting general infection. The bacteriology was studied in only one of these cases, and in this one a pure culture of the typhoid bacillus was found.

It is a fact that the typhoid bacillus has been very rarely found in the peritonitis of typhoid fever, possibly because, through delayed operation, cultures

have not been taken until the typhoid bacillus was overgrown.

It is possible, and probable, that the others of these early and seemingly favorable cases for operation may have had a general virulent infection either with typhoid bacilli or streptococci. It is past controversy that fatal peritoneal infection can have taken place without causing visible macroscopical signs at operation or autopsy. Of the 14 cases of gradual onset or with early warning symptoms, in every one visible peritonitis was found at operation, and in the majority of cases it was evidently of comparatively long standing.

Comparing the two sets of cases, namely, the 7 cases with sudden onset and the 14 with gradual onset, we find that in operations done on the cases of sudden perforation within one to eight hours after the first symptoms there was found no general peritonitis, but at most a very slight beginning peritonitis; but operation done on those of gradual onset, within one to eight hours after the severe or diagnostic symptoms, found extensive general peritonitis—so extensive that in several cases the operator noted that this peritonitis must have existed many hours longer than the symptoms would lead one to suppose. The conclusion is plain that in these cases the perforation or the beginning peritoneal infection took place at a time more or less remote from the severe and diagnostic symptoms.

These 14 cases are cases of operation for general peritonitis which had existed for a longer or shorter time—in 1 case originating in a ruptured mesenteric gland; in another, threatened perforation; in 1 from an unknown cause; in 11 from intestinal perforation.

The prevailing type of peritonitis noted was the seropurulent, with fibrin flakes in the turbid fluid and adherent fibrin patches on the intestine. Nine cases are noted that had feces or fluid fecal matter in the intestinal cavity or fluid with a fecal odor. All of these cases were intestinal perforations. Two cases of intestinal perforation note a cloudy, turbid fluid without fecal odor.

Case XXI was a case of general seropurulent peritonitis originating in a ruptured mesenteric gland. Cultures showed this to be a pure infection of bacillus typhosus. In Case XVII punctate hemorrhages on the intestinal wall are noted, and brownish fluid in the peritoneal cavity without odor.

It is greatly to be regretted that in only 4 of these 14 cases were any bacterial cultures taken, and in certain of these the question arises as to their value, because of our incomplete knowledge as to how they were taken and because of incomplete reports of the differentiation of the various bacteria found. Flexner¹³ and Cushing¹⁴ dwell upon the necessity of making cover-slip preparations as well as plate cultures at the operation from the abdominal contents in cases of peritonitis, because of the well-known fact that the bacillus coli communis overgrows the other organisms in the mixed infection. Cushing says: "Undoubtedly the colon bacilli, being more in evidence, were frequently held responsible for peritoneal infection due to more virulent but culturally less active organisms."

Case XIV is recorded as showing an infection with colon bacilli and "other varieties of bacteria." Case

¹⁴ Philadelphia Medical Journal, March 3, 1900.

XX is recorded as having turbid peritoneal fluid with fibrin flakes, infection with colon bacilli. Case XXI, resulting from a ruptured mesenteric gland, gave a pure culture of bacillus typhosus. Case XV is reported to have been a specially foul-appearing general peritonitis, in which the infection was colon bacilli, and "many others not differentiated." The 2 cases (Cases V and XXI) in which the peritonitis was found to be due to a pure infection of bacillus typhosus died—1 within twelve hours and 1 on the fourth day.

The finding of the bacillus typhosus as the infecting organism in cases of peritonitis is exceedingly rare. At most, but 5 cases, including the 2 cases reported in this series, have been published. It may be suspected, reasoning from the evidence furnished by Case V and Case XXI, that when it does occur it is probably virulent and fatal.

DIAGNOSIS.

The diagnosis of the peritoneal infection within a sufficiently reasonable time from its beginning is a question of the greatest importance to physicians and surgeons. So far, our study of these cases has shown us that the diagnosis in 14 cases out of 24 was apparently made later than it might have been, and in 7 cases only once was it made as soon as possible, and that in 3 cases a mistaken diagnosis was made.

It seems fair to suppose that the majority of cases of intestinal perforation present a slow intestinal infection or a gradual onset, or that actual perforation may take place without fulminating symptoms. Cushing has referred to what he calls a "preperforative stage," or a "pre-extravasation stage," and has attributed the early complaints of pain to a slight involvement of the serosa and possibly to omental adhesions. He understands by his "preperforative stage" the "whole period between the first involvement of the serosa, with the formation of customary adhesions at this point, until these adhesions (which may for a time constitute the floor of the ulcer after the serosa has given way) have themselves become broken down, and general peritonitis has taken place." This condition of things is well illustrated in our Case IV, which is a typical case of pre-extravasation, because of delicate protecting adhesions.

It would seem, however, from a study of our cases, that the formation of protecting adhesions in perforation or threatened perforation of the ileum is exceedingly rare. Monard and Van Verts¹⁵ state that in their study of this condition, adhesions, however slight, almost never occur when the perforation is situated in the ileum, and they further state that peritoneal infection is not always a rapid fulminating affair: that it may occur slowly from what they call "propagation"—that is, migration of the bacteria through the necrosed and damaged intestinal coats—and that this form of infection is no less worthy of consideration than the rapid infection from sudden intestinal rupture and extravasation of intestinal contents.

Intestinal ulcers certainly may have a preperforative stage, and by this we mean a stage of local peritoneal infection and bacterial involvement of the peritoneal coat—whether or not adhesions exist. This local infection may cause general infection without adhesion formation and without perforation. The

pre-extravasation stage properly means a period of time after local peritonitis has taken place in which there is no extravasation of intestinal contents, either because of the necrosed portion of the intestinal wall remaining in place without dropping out, as in Case XVI or in Case II of our series, or because of adhesions, as in Case IV of our series. Local infection of the peritoneum causes pain of greater or less severity. This pain may not be appreciated and complained of in very sick and stupid typhoids, but in mild cases may be just as prominent a feature as the pain from the local peritoneal infection of appendicitis before perforation has taken place.

Our series of cases shows that this early pain was absent in only 7 cases out of 21; 5 of these 7 cases were mild cases, in which sudden rupture of the serosa and extravasation took place; 2 cases with equally sudden symptoms had a septic peritonitis already under way, which cases were so sick and stupid that it was impossible to diagnose the beginning of the general infection.

Fourteen cases, as has been seen, had early warning pain, earlier by a definite number of hours than the severe symptoms, and all these cases were found to be far advanced in general peritonitis at the time of operation. These early symptoms undoubtedly meant beginning peritoneal infection, as is shown by the after development, and the severe symptoms meant general septic peritonitis then existing. Whether these early symptoms meant a necrosed serosa without perforation, or a pin-point perforation protected or not protected by delicate adhesions, it is positive that general septic peritoneal infection started at a time coincident with these early symptoms and not coincident with these severe ones.

It must be admitted that these 14 cases had advanced general peritonitis at the time of operation; that they had signs and symptoms antedating the symptoms of peritonitis; that the severe symptoms in the cases of actual perforation differed in no way from the severe symptoms in the cases of general peritonitis from other causes of infection; and if this statement is true, then the diagnosis of these cases should have been made before these severe symptoms set in, and, therefore, a decision as to what symptoms are of importance in making a sufficiently early diagnosis of peritoneal infection in these cases is of the utmost necessity.

From a study of these cases and also of the cases reported by Cushing it would seem that complaints of abdominal pain in any typhoid case, especially if localized, and especially in cases of mild type, should be regarded as serious danger signals. We have already seen that in our sick and septic cases the condition of the patient may be such that moderate pain may not be noted, and that therefore a complaint of abdominal pain on the part of such a sick case may mean an established general peritonitis. (See Cases II and VI.)

In the mild cases of typhoid complaint of abdominal pain should lead to a strong suspicion of beginning peritoneal infection through a preperforative stage, or of a slow peritoneal infection through perforation, with or without temporary adhesions; or of a beginning infection from some other source than the intestine, as in Case XXI. This plan may vary in severity and locality. It is most frequent in the right iliac region, and is most often associated with

¹⁵ Revue de Chirurgie, 1897, p. 169.

localized tenderness and spasm. To confirm the suspicion of beginning peritoneal infection a leucocytosis, steadily rising, during a few hourly counts, at least, should accompany this pain. Vomiting is rare. The temperature generally rises and the pulse also.

It cannot be too strongly emphasized that abdominal pain, especially if localized, complained of by the patient in the mild or moderately severe typhoids, is not a frequent occurrence unless it means peritoneal infection, localized or general. By pain we do not mean the discomfort or uneasiness accompanying meteorism or distention by gas.

We have made a study, bearing upon this point, of 70 cases of typhoid fever at the Massachusetts General Hospital occurring in the last two years, and have found, according to the records, that in the majority of cases of the mild and moderately severe typhoid no genuine abdominal pain whatever was complained of, even in the presence of distention, diarrhea and hemorrhage. Seventy cases: 20 severe typhoids and 50 mild; 7 cases died. In only 8 cases was any abdominal pain recorded as a complaint (11.4 per cent.), and 4 of these cases died (1 case with probable certain perforation or peritonitis, 1 of pneumonia, and 2 cases with suspicious symptoms of peritonitis). The other 4 cases had slight and transient abdominal pain, and recovered. Abdominal distention of more or less extent was noted in 10 cases, without any pain. Intestinal hemorrhages are noted in 8 cases, but pain accompanied these in only 1 case. Diarrhea is recorded as marked in 3 cases, but in only 1 was any pain, and in this slight.

With reference to this same point the records of the Boston City Hospital have been gone over for a year. Pain is recorded as complained of in 22 cases out of a total of 160 cases; of these 22 cases 5 are included among those operated on, which leaves 17 cases with pain, or about 10.6 per cent. of the total.

Localized muscular spasm and localized tenderness are diagnostic signs of the utmost importance associated with pain and leucocytosis.

The question as to whether the site of the perforation or the region of the beginning peritoneal infection materially affects the prognosis both of unoperated and operated cases is one that needs discussion. The fact that the appendix may be the seat of the typhoid perforation was first noted by Dr. R. H. Fitz, and the relation of this fact to the prognosis in cases of typhoid perforation was thus stated by him: "The probability of its occurrence (perforative appendicitis) furnishes the best solution to the prognosis of intestinal perforation in the latter disease (typhoid fever). Most cases of recovery from symptoms of perforation of the bowel in typhoid fever are those in which an attack of appendicitis is most closely simulated, while the fatal cases of perforation of the bowel in typhoid fever are, in the great majority of instances, those in which other parts of the bowel than the appendix are the seat of the perforation."

This set of cases does not furnish any case in which the perforation was appendicular. Fitz found this variety of perforation in 2 per cent. of 167 cases. In a series of cases operated upon—that is, our own set, 24; Cushing's, 8, and Finney's, 3; 35 in all—no instance occurs. Gairdner's¹⁶ 47 cases included only one of *perforated appendix*. Perforation in the appendix can only have a more favorable prognosis

because of its occurrence in a fixed portion of the bowel in a remote region where the chances of the peritoneal infection being shut up by protecting and life-saving adhesions prevail.

It is certainly misleading to state that most cases of recovery from symptoms of perforation are those in which an attack of appendicitis is closely simulated, because—as can be plainly seen from a study of our list of cases—many of them had beginning symptoms which suggested appendicitis, and yet the perforation was in the ileum, and the peritoneal infection became general and fatal. It is imperative that we should not be prevailed upon to wait operation in the hope that the perforation may be in the appendix, considering that the chance of localizing the infection by delay offers more hope to the patient than speedy operation, because the attack began with right iliac pain and tenderness and muscular spasm. The better teaching is that perforation of the appendix may occur in typhoid, although *rarely*; that when it does occur the infection may be localized, as in any cases of perforating appendicitis; but the great majority of cases of perforation of the bowel in typhoid fever may simulate an acute appendicitis.

A study of our whole list of 27 cases shows the following: Eleven cases had initial symptoms referred to the right iliac region, with one or more of the symptoms of localized pain, tenderness and spasm. Any one of these cases might have been suspected as the appendicular variety, and delay counselled because of the apparent localization of the signs; but 9 cases were perforations of the ileum, followed in all but 1 by general infection, and 2 had no cause for symptoms. In only 3 cases pain and tenderness, etc., were initial in the left iliac region. One was a case of general peritonitis from a suppurating gland, and the other 2 cases were very sick cases, in which the peritonitis had become extensive and general before any symptoms were noted. In 7 cases the pain and tenderness with rigidity were general. In 1 case locality of pain is not given. Therefore, we may conclude that the majority of cases of perforation have initial symptoms referred to the right iliac region; that in a very small percentage of all such cases is the perforation in the appendix; that general abdominal pain and symptoms, or symptoms and signs referred to the left side, point to the existence of a general peritonitis, the onset of which has been gradual and not definitely noted.

LEUCOCYTOSIS AS A DIAGNOSTIC SYMPTOM.

A careful comparative white blood count at frequent intervals in the presence of abdominal pain in typhoid may furnish the most valuable evidence of beginning peritoneal infection. A full and complete knowledge of leucocytosis in typhoid peritonitis has not been reached. Thayer, in 1892, first showed that in typhoid fever the white blood corpuscles are less than normal, or, in other words, that a condition of hypoleucocytosis exists, and that the smallest number of leucocytes is usually found at a period of time corresponding to the height of the fever. Cabot, in 1897, reiterated these facts and pointed out that a low leucocyte count in typhoid meant freedom from septic complications. Our study of 70 typhoid cases at the Massachusetts General Hospital is merely corroborative of the statements of Cabot and Thayer. The majority of cases at entrance had a hypoleucocytosis

¹⁶ Glasgow Medical Journal, 1897, vol. xlvii.

of about 4,000; the lowest count in an uncomplicated case was 1,800. Septic complications, as phlebitis and otitis media, caused a leucocytosis. In nearly all the cases, however, only one white count—the one at entrance—is recorded; and even when this early count was high—over 9,000—no other record is available. Certainly more frequent counts should be made in the future. The fact that leucocytosis in typhoid means inflammatory complications in the majority of instances, and that leucocytosis was present in peritoneal infection, was noted by Cabot (1897); and Finney, in his paper on "Typhoid Perforation" (1897), considered the most important symptoms of perforating typhoid ulcer to be "marked increase in the number of white blood corpuscles in association with continued abdominal pain." It does not appear that a full realization of the importance of a falling leucocyte count or the absence of leucocytosis in general peritoneal infection is held by a majority of medical men. Cabot stated that certain cases of general peritonitis would show no leucocytosis because of their being too sick to react against the infection.

Cushing, in his two papers on this subject, seems to have most carefully studied leucocytosis as a symptom, and his work strongly suggests that a white blood count, steadily rising from the first complaint of abdominal pain (which is confessedly the first warning of local or general infection), with certain fluctuations, reaches a maximum point, and then as steadily falls. This he aptly calls the wave of leucocytosis, and raises the question as to whether a falling count or an absence of leucocytosis (other symptoms being present) may not be diagnostic of a well-established general septic peritonitis. He considered it rational to suppose that the enormous migration of leucocytes to enter into the seropurulent exudation was a sufficient reason for the falling or deficient white blood count in general peritonitis. This point is a very important one to settle, for diagnostic reasons. Cushing's conclusions from a careful study of leucocytosis in his cases are here given:

"If this septic complication, namely, complication causing leucocytosis, is a peritonitis which remains localized, associated possibly with a preperforative stage of ulceration or with a circumscribed, slowly forming peritonitis after a perforation, it may be and usually is signalized by an increase of leucocytes in the peripheral circulation. If, however, a general septic peritonitis follows, the leucocytosis may be transitory and overlooked, as it disappears concomitantly with the great outpouring of leucocytes into the general peritoneal cavity.

"In order that the white blood count be of any diagnostic value whatever in the presence of abdominal symptoms it is essential that, for the purpose of comparison, previous counts have been made. An individual count at such a critical time may be misleading—in the first place, because a condition of hypoleucocytosis often is a characteristic of the fever, and a count comparatively within normal limits, of from 8,000 to 10,000, may actually represent a double increase in the number. Secondly, because by a single count the transient wave of leucocytosis may entirely escape notice.

"The flood-tide of this increase is a transient affair, lasting but a few hours in some cases, and may in consequence entirely escape observation, since there

ordinarily is a following rapid diminution in number, corresponding to the spread of peritoneal infection. In some instances, when the process for the time remains localized, and in cases in which the preperforative stage exists, the leucocytosis may be of longer duration, the condition being analogous to that associated with acute appendicitis (typhoid or otherwise) before perforative peritonitis has occurred. Suppurative complications of typhoid, here or in other situations where they remain localized processes, have ordinarily a persisting leucocytosis, as is well known."

These conclusions of Cushing are reinforced by careful observations, and seem to give the best interpretation of leucocytosis in this class of cases. Whether absence of leucocytosis in the face of symptoms of peritonitis means well-advanced general peritonitis in every case has not been proven absolutely. Certainly one sure thing is that a single isolated blood count on the appearance of abdominal symptoms may be of little or no value. In one of Cushing's cases of perforation an hourly blood count showed that the white corpuscles rose in two hours from 4,800 to 10,400, and in an hour and a half later dropped to 7,000. In another of Cushing's cases of intestinal perforation a drop of 20,000 in three hours after the probable time of perforation is noted. The appearance of leucocytosis in the presence of abdominal pain may, however, be misleading as a diagnostic symptom of peritoneal infection.

As is well known, the existence of a septic focus, an abscess, or a septic phlebitis elsewhere might furnish cause for the leucocytosis coincident with abdominal symptoms. One or more cases have been reported in which the symptoms of peritoneal infection, including leucocytosis, led to an exploratory laparotomy, with negative findings. Cushing has had such a case. Case XXIII in our series is also such a one. Finney has been led to an exploratory laparotomy in which the symptoms suggesting intestinal perforation, including a leucocytosis, were probably due to an iliac thrombophlebitis. This case recovered. It has been found by Cushing that a post-operative leucocytosis occurs after all abdominal operations.

With these facts and theories in mind as representing the latest opinions in regard to leucocytosis as a symptom, reference to our series of cases with a view to find corroboration of these facts furnishes very little of value because of the lack of comparative counts. In almost all of the cases only one blood count was made.

To take our cases in detail, the leucocyte count is only recorded in 11 cases of the 21 in which perforation or peritonitis was found. In the first set of cases, namely, those without warning symptoms, the leucocyte count is recorded in 4 cases. In Case IV (the case of perforation protected by local adhesions) a leucocytosis of 14,300 was found at an unknown number of hours after the onset of abdominal symptoms. No other count is recorded. In Case V one count at the onset of symptoms showed 6,000; no other count. Case VI showed a leucocytosis of 13,200. This case was one in which perforation and localized abscess formation took place without any diagnostic symptoms at a time probably remotely preceding the severe symptoms which demanded operation. Occasional comparative leucocyte counts as a matter of medical routine might have led to the suspicion of a septic complication. Case VII showed a white count of 8,600 at the onset

of the symptoms; no other count is recorded. The other 3 cases of our first set have no record of any leucocyte count.

Taking our second set of cases, namely the 14 in which premonitory symptoms existed, as we have seen, it would have been of the *greatest importance diagnostically* to have known what the white blood count had been for several days before the symptoms, and also to have known what the white blood count at early intervals after the occurrence of abdominal pain was; yet in only 2 cases was there any leucocyte count taken at this time, and then only one isolated count in each case is recorded.

Case XVI had a white blood count of 6,900 two days before he complained of abdominal pain; at the first complaint of pain a count of 8,000. Then no further leucocyte count was taken for twenty-four hours; but when severe symptoms (which meant general peritonitis) set in a white count equalled 17,200. Certainly in this case frequent and comparative blood counts might have contributed much to our knowledge of a rising and falling count. Case XV, seen after the warning complaint of pain, had a white blood count of 31,000. Twenty-four hours after, when general peritonitis had set in, the white count had dropped to 23,000 and 17,000. Only these three counts are recorded.

It is much to be regretted that in this series of cases in which 14 had premonitory symptoms, such slight knowledge in regard to the diagnostic value of the white blood count is available. In Case XIV the blood count at the time of the first abdominal symptoms showed 10,000 whites, but no other count was taken. Six cases of the 14 record no blood count at the occurrence of either mild or severe symptoms. In 6 cases the only blood count was made when severe symptoms appeared. In Case XII, a case of extensive peritonitis at operation, the white cells were 3,800. In Case XIII, also a case of extensive peritonitis, the white cells were 5,400. In Case VIII, also a case of general peritonitis, the white cells were 7,300. In Case II they were 8,000 just before operation.

Here are 4 cases in which an isolated blood count, taken when peritonitis had become general, showed no leucocytosis. Whether a previous leucocytosis had existed, and whether the absence of leucocytosis in the presence of general peritonitis is a diagnostic sign, cannot be determined because of the absence of comparative counts in all of these cases.

Case IX had a leucocytosis of 16,000 after general peritonitis was evident. Ten days before the count was 14,000. No interval counts are recorded.

Case X had a white count of 14,000 with the symptoms of general peritonitis. At entrance to the hospital, ten days before, his white count was 6,500. No other counts are noted.

It is not possible to establish anything new and valuable in regard to leucocytosis as a symptom from the study of these cases, because of the lack of sufficient data. The one conclusion is that the leucocyte counts in typhoid cases should be sufficiently frequent to be of comparative value; that any complaint of abdominal pain or the appearance of abdominal symptoms demand frequent counts.

The question of diagnosis and the relative value of abdominal symptoms and leucocytosis as deciding for operation is illustrated in a negative way in Cases

XXII, XXIII and XXIV. Cases XXII and XXIII were mild or moderately severe typhoids, practically convalescent in the fourth and sixth weeks of the disease. Case XXII had no leucocyte count, and it seems questionable whether it would be justifiable to operate upon a case with such abdominal symptoms without the corroborative evidence of a leucocyte count. It has been done, however, in other cases (the case reported by Herrington and Bowlby¹⁷). Case XXIII had practically the same abdominal signs and symptoms as Case XXII, except that there is no record of the temperature at this time, which in Case XXII was rising from a normal curve, and Case XXIII had also a leucocytosis of 12,000 one hour before the operation. While this leucocytosis is not large, the white count had risen from 9,000 twelve hours before the operation. Neither of these 2 cases seems to have been very sick or to have had any great amount of shock. Case XXIV seems to have been a case of typhoid septicemia, in which no certain cause for the abdominal symptoms was found. No leucocyte count and no bacteriological cultures are recorded in this case. Probably he died from typhoid fever, although the presence of a green, necrotic fibrin patch found on a loop of the intestines at the operation leaves room for the thought that the abdominal symptoms and death may have been caused by a virulent peritoneal infection.

RESULTS.

Of the 21 cases in which the local or general peritoneal infection was found at operation 3 cases recovered absolutely — that is, 14.3 per cent. recovered. In Case IV — a case of operation in the pre-extravasation stage — it is noted by Dr. F. S. Watson that the protecting adhesions were very slight and delicate, and that in Dr. Watson's opinion they would not have long resisted fecal extravasation.

The 2 other cases which completely recovered are Cases XVI and XVII, both cases of general septic peritonitis. Together with Abbe's¹⁸ case they prove that it is not impossible to save cases of general peritonitis in typhoid fever. The bacterial infection, however, in both of these cases, as well as in the case of Abbe's, was not determined.

Case I properly should be classed as a recovery from an operation for intestinal perforation in typhoid, for death occurred from intestinal hemorrhage five days after the operation, and the autopsy showed the suture tight and no general peritonitis. If this case can be classed as a recovery, we have four recoveries from operation from acute peritoneal infection in typhoid, or 19 per cent.

Case IX cannot be considered as recovering, but it is a case of death caused by giving way of the intestinal sutures put in at the first operation.

Taking our 24 cases of typhoid fever which were operated on, 21 with abdominal infection and 3 with no infection found at operation, we have 6 cases of recovery from laparotomy in typhoid fever, or 25 per cent.

Cases XXII and XXIII are noteworthy as showing that the mere abdominal operation in a slight or moderately severe typhoid is not a very fatal thing when no peritoneal infection is present. Case XXIII was also not a very favorable subject for any opera-

¹⁷ Medico-Chirurgical Transactions, London, vol. lxxx, p. 127.

¹⁸ Medical Record, 1895, vol. xlvii, p. 1.

tion, because of cardiac and renal complications, yet both these cases made uneventful recoveries from the operation. In Case XXII an appendectomy was done for an old chronic process in the appendix. In Case XXIII the operation was simply exploratory. Two of Cushing's reported cases further show that an exploratory laparotomy or a simple appendectomy in a mild or moderate typhoid is usually well borne. We have seen that the 5 cases (Cases I, III, IV, V and VII) were especially favorable cases for operation. Three of these died, and they were all cases that could have stood laparotomy just as well as Case XXII or Case XXIII had it not been for the peritoneal infection, the nature of which was undetermined in 2 cases and found to be the bacillus typhosus in 1. These 3 fatal favorable cases point to the fact that a fatal peritonitis may set in within from one to two hours after perforation. Of these 3 cases Case III died on the third day, Case V on the fourth day and Case VII on the second day.

Of the 14 cases in our second set, in all of which operation found more or less extensive peritonitis, and in regard to which it may be said that the operation was directed against the peritonitis primarily, 12 died; 1 lived eight days and died from secondary extravasation. All the others died within fifty hours after the operation; 2 within six hours, 7 within thirty-six hours, and 1 on the operating-table.

If we grant, for the sake of argument, that the sick typhoids, 6 in number, might have died from their typhoidal condition complicated by an abdominal operation, even if peritonitis had not been present, we still have 8 mild cases in which the cause of death was probably a peritoneal infection, and not the operation itself.

Calculating statistics of the operative treatment of general peritonitis from any cause is foolish business. The chances for success in such treatment depend on so many factors: the amount and virulence of the infection, the condition and resisting powers of the patient, the differing operative technique of different men, the time of operation, the kind and amount of anesthetic used, etc. In trying to find out why some of these cases lived and some died it would be well to take only the 15 mild cases, throwing out for the time being the 6 severely sick typhoids as doubtful cases for standing the shock of the abdominal operation, leaving ourselves 15 mild typhoids for consideration. Of these, 5 had perforation without any warning symptoms, and were operated upon very speedily thereafter; 2 recovered, 1 because the operation was done in the pre-extravasation stage—a rare event; 3 died from peritoneal infection from the intestinal extravasation, although no macroscopical signs—or, at most, slight signs—of general peritonitis were present at the operation. Ten of these mild cases had general septic peritonitis at the time of operation; 2 recovered.

When we consider the reasons for the recovery of 2 of these cases and the death of 8 we are brought face to face again with insufficient recorded data. The time of operation is recorded in only 3 of the fatal cases: 1 case, thirty minutes; 1 case, thirty-five minutes; 1 case, one and a half hours.

The time of operation in the cases that recovered is not noted. The kind of bacterial infection in the cases that recovered is unknown. In 1 case that died it was an infection of bacillus typhosus; in 1 case infection of the colon bacillus and other doubtful bacteria.

Ether was the anesthetic in every case; but the amount given, and the time the patient was kept under it, and the effect on the pulse are in no case recorded.

Cushing has enthusiastically endorsed the use of cocaine anesthesia in exploratory laparotomies in acute abdominal infection in typhoid. He has not, however, proved in his article that the majority of his cases were any better off than the cases operated upon under ether. It is not the feeling of this Committee that operation under cocaine anesthesia is advisable in cases of mild typhoid whose general condition of mind and body is fairly good, because rationally the shock to the mental and physical organism from an abdominal operation, with all its attendant manipulation, to a conscious patient must be greater than the judicious administration of ether. In certain cases of advanced peritonitis in which the patient is sick or nearly moribund, stupid and unintelligent, the use of local anesthesia may be advantageous.

Irrigation of the peritoneal cavity with hot salt solution or hot sterile water was practised in every case of general peritonitis but 1, namely, Case XVI. In this case careful wiping out of the cavity with gauze was done. Drainage with gauze or with tube and gauze was used in every case but 2, both of which died. It does not appear from available data that these variations in technique affected the result. The surgical opinion is practically unanimous the world over, that the operation for septic peritonitis must include free incisions, careful cleaning of the abdominal cavity by wiping, irrigation and free drainage.

It is impossible to work out by percentages the chances of recovery in cases of intestinal perforation and peritoneal infection in typhoid fever. It is a question of peritoneal infection (kind, amount and virulence), together with the condition and resisting powers of the patient, who has already contended with another disease. It is not the mere fact of operating in these cases that kills them, and it cannot be said that the typhoidal condition forbids an operation. It has been shown that a majority of the cases of perforation and infection are mild typhoids, and it has also been shown that abdominal operation in the absence of infection is not necessarily fatal, but, on the contrary, is well borne. The peritoneal infection is the thing that kills in the majority of cases.

A peritonitis from a perforation of the intestine in typhoid may be caused by virulent or non-virulent organisms just as in any other perforation of the bowel. Most of the typhoid perforations operated upon in this series of cases and all cases hitherto published have had a general peritonitis that would kill a majority of the men who had contracted it from other causes than typhoid, namely, perforated appendix or wounds. General peritonitis of the intestinal variety in a strong man, without typhoid fever, is a very fatal affair, and the chances of a recovery from operation in any case cannot be established by statistics except in a general way.

CONCLUSIONS.

This series, unfortunately, leaves much to be desired in the way of accurate and carefully reported study of many of the cases in the light of the most recent experience; but from the foregoing analysis of the material we can definitely conclude that:

(1) In many very sick typhoids perforation or

peritoneal infection cannot be diagnosed until the results are already widespread and of fatal extent. The chances of a fatal issue from an abdominal operation in such cases are overwhelming.

(2) In mild typhoids of fair general condition an abdominal operation is readily borne, provided no peritoneal infection is present.

(3) A small number of mild typhoids may have sudden perforation with free extravasation. In these the symptoms are fulminant, but localized to a great extent, and in these

(4) Operation must be done at once, for general infection may become past relief in from one to five hours, and walling off of the perforation by protecting adhesions is so rare as not to be counted upon.

(5) In the majority of mild cases, beginning infection (whether from perforation or not) is marked by comparatively slight symptoms—local pain, tenderness, spasm and leucocytosis. The severe following symptoms mean general peritonitis.

(6) These warning symptoms demand serious consideration and study, but in many cases are either not rightly understood or not acted upon.

(7) Complaint of abdominal pain in a case of typhoid should always lead to a suspicion of beginning peritoneal infection.

(8) Frequent leucocyte counts are needed in every case of typhoid. In the presence of abdominal pain an hourly count is necessary.

(9) Pain associated with local tenderness and muscular spasm and a rising white blood count points in most cases to an operation; in all cases to a surgical consultation.

(10) In not a few of this series of cases operation was imperative a varying number of hours before it was done.

If it can be appreciated that the severe symptoms more often mean general peritonitis, it must be understood that the milder and earlier symptoms are the important ones.

REPORT OF CASES.

CASE I. Seelcy, male, age thirty-two years, white. Drs. Bowditch and Thorndike, Boston City Hospital, September, 1899. Sudden perforation. Operation within three hours from first symptoms. No general peritonitis. Death five days after from intestinal hemorrhage. Uneventful until the sudden abdominal symptoms. Mild course. Widal positive. Diazo (?). No complications. No abdominal complaints. Not a sick man. End of sixth week, forty-second day, operation. Ether. Time not known. Incision, right iliac. Irrigation. Gauze drainage. Sudden intense abdominal pain, not localized. Marked shock. Pulse 150. Temperature 102.6°. No leucocyte count recorded. No fall of temperature. No vomiting. Operation three hours after. No general peritonitis. Intestinal contents in abdominal cavity; fluid fecal matter. Perforation in ileum, two feet from cecum. Closed with silk. No cultures. Excellent result for five days. Operation for the perforation successful. Five days after, excessive intestinal hemorrhage causing death. The autopsy showed that the operation was a success. No general peritonitis. The suture was intact and protected by adherent intestines with slight local peritonitis, from which the colon bacillus and staphylococcus albus were grown. Cultures from rest of abdominal cavity negative.

CASE II. Bowler, male, age twenty-five years, negro. Drs. G. B. Shattuck and F. B. Lund. Boston City Hospital, October, 1899. A case of general septic peritonitis from necrosed patches of peritoneum, *without perforation*. Symptoms of perforation, however. Moribund at opera-

tion. Death. Severe course. Widal positive. Diazo (?). Abdominal pain constant. Fourth week, twenty-second day. Operation. Ether. Time (?). Incision, right iliac. Irrigation and drainage. Very sick case. Temperature high. Delirious. Abdominal pain and tympanites at frequent intervals. Two intestinal hemorrhages before operation (two days before). Sudden chill, shock, collapse, rising temperature and pulse. Distention. No vomiting. Operated on seven hours after, when in moribund condition. No leucocyte count. No perforation. Two necrosed patches in wall of ileum over ulcers. General peritonitis. No cultures made. Gas and serous fluid escaped. Intestines clean and not injected. Several necrotic areas. Necrosed places, inverted with silk. Death in eighteen hours. Cause, peritoneal infection and typhoidal state. Compare this case to Case XVI. This case had sudden severe symptoms from peritonitis without perforation. An unfavorable case from all points of view. Peritoneal infection from necrosed patches, probably virulent, whereas in Scappacci's case infection from necrosed patches probably non-purulent, with the abdominal pain and distention marked. Specially associated with hemorrhages. Careful white blood count at frequent intervals might have been suggestive.

CASE III. McCann, male, age thirty years, white. Dr. F. C. Shattuck and Dr. Warren. Massachusetts General Hospital, January, 1899. Sudden perforation without warning. Operation within two hours. Death in three days. Mild course. Widal positive. Diazo positive. Bronchitis. No abdominal complaints. Fifth week, thirtieth day, incision, right iliac. Irrigation. Drainage, gauze. Ether. Time of operation (?). Mild fever complicated by hemorrhagic bronchitis. Intestinal hemorrhage two days before perforation. No warning. Patient comfortable, when sudden sharp pain in right iliac region with great tenderness and muscular spasm. No white count at this time. White count two days before 3,800. White count at entrance, ten days earlier, 10,000. No vomiting. Temperature subnormal, but began soon to rise. Pulse below 100. Operation one and a half hours after. Perforation in ileum, site not mentioned. No general peritonitis. Some free fluid. No bacteriology. Death on third day, in sixty hours, with symptoms of general peritonitis. No autopsy.

CASE IV. Scott, male, age twenty-eight years, white. Drs. Withington and Watson. August and September, 1895. Perforation. Localized peritonitis. Operation in pre-extravasation stage. Recovery. Mild course. No Widal test made. Diazo positive. Rose spots. Eleventh week in a relapse. Operation. Ether. Time (?). Incision right iliac over induration. No irrigation. No drainage. Long course, one or two relapses. No special complications. Twenty-three days before perforation, two or three hemorrhages. No abdominal pain recorded, but some tympanites. Without warning sudden severe pain in right iliac region at 2 A. M. Temperature did not fall, but rose. Pain steadily worse. Pulse rapid and weak. Some cyanosis and prostration. Muscle spasm on right side of abdomen. Dulness and indurated feeling to right of umbilicus, "size of hand." No distention. No vomiting. "The symptoms of local pain and rigidity increased while patient's general condition improved." Leucocytosis 14,350. Operation twelve hours after first pain. A loop of ileum adherent to parietal peritoneum around a perforation size of a dime; well-defined area of local peritonitis. Limiting adhesions delicate. "Every probability that these adhesions would not have resisted fecal extravasation long and that a general peritonitis would have resulted if case was left to itself." (Watson.) Perforation closed. Recovery uneventful. No cultures.

CASE V. Dolan, female, age twenty-five years, white. Drs. George B. Shattuck and Lund. Boston City Hospital, November, 1899. Perforation. Beginning general infection with typhoid bacillus. No definite warning symptoms. Death. Mild course. Widal positive. No complications. No abdominal complaints. In second week, twelfth day. Operation. Ether. Time, thirty min-

utes. Incision, median. Irrigation. Drainage. Uneventful till twenty-six hours before operation, then hard chill (no other record at this time). Next A. M. (twelve hours after) several chills. Twenty-two hours after first chill and four hours before operation abdominal pain above pubes. Tenderness and spasm (more on right). Temperature fell to 98°, but rose at once. No distention. Pulse 120. No vomiting. Nausea. Leucocyte count, recorded as taken when pain complained of, 6,000. No other count. Perforation eight inches from cecum in ileum. Gas and turbid fluid in general abdominal cavity. General peritonitis not far advanced. Infection, pure typhoid bacillus. Perforation closed with silk, also two thin places enfolded. Death on fourth day, with symptoms of general peritonitis. Perforated coil of intestine was lying low down in pelvis. (Note locality of pain above pubes.) Perforation probably when pain was first noted. Operation reasonably soon. Typhoid infection, probably a virulent one. The general peritonitis was not far advanced at operation, yet was undeniably a general infection.

CASE VI. Devlin, male, age twenty-four years, white. Drs. F. H. Williams and Munro. Boston City Hospital, November, 1899. Perforation and local abscess formation, with no diagnostic symptoms, followed by general peritonitis with severe symptoms. Death. Severe course. Widal negative. Rose spots. Large spleen. No complications. In fourth week, twenty-sixth day, operation. Ether. Time (?). Incision, right iliac. Irrigation. Drainage. Case stupid and sick. Fever high. No abdominal complaints till special ones. Two severe intestinal hemorrhages on day before in A. M. and P. M., accompanied by hard chill and collapse. Very near death at this time. Unconscious twenty-four hours after this. Abdominal pain. Tenderness, mainly right iliac. Distention. Rigidity. No vomiting. Leucocytes 13,200. Temperature (?). Operation twenty-eight hours after hemorrhage. Operation four hours after pain, etc. General peritonitis with cloudy fluid; pus and feces in left pelvis free. In right iliac region an abscess cavity walled off by fairly strong adhesions, filled with pus, blood and feces; large ragged hole in ileum near cecum. No cultures recorded. Perforation closed. Death in forty-eight hours from general peritonitis. No autopsy. This case was one of perforation and forming of a walled-off abscess with no symptoms complained of by a very stupid, sick man. Time of extension to a general peritoneal infection doubtful. No cultures from general peritoneal fluid, as well as from local abscess, were taken.

CASE VII. Marchiono, male, age thirty years, white. Drs. Henry Jackson and Munro. Boston City Hospital, July, 1898. Perforation. Sudden onset. Peritoneal infection not known. Quick operation. Death. Mild case. Widal positive. Diazo (?). No complications. No abdominal complaints. In third week, twentieth day, operation. Ether. Time, one-half hour. Incision, right iliac. Irrigation. Drainage. Ten A. M. pain complained of in abdomen, with no special tenderness, nothing localized. No spasm. Leucocyte count then 8,640, not taken again (?); 1.30 P. M. severe pain and chill, collapse. Abdomen everywhere tender and rigid, but especially on right side. Fall of temperature recorded to 98°, rising soon to 105°. No vomiting. Operation eight hours after first pain, five hours after collapse. One perforation in ileum ten inches from cecum. No free fluid. "No extensive signs of peritonitis." Perforation closed. No cultures recorded. Death in forty-eight hours without symptoms of peritonitis. Partial autopsy through wound. Slight microscopic signs of general peritonitis, but no bacteriology. Cause of death (?). Infection not known. In this case quick operation after first symptoms. Beginning peritonitis.

CASE VIII. Schick, male, age sixteen years, white. Dr. Gannett and Dr. Mixter. Massachusetts General Hospital, August, 1897. Case of perforation. Symptoms of peritonitis. Perforation probably took place some hours before first symptoms. Death. Severe course. Widal positive. Diazo positive. End of third week, twen-

ty-first day, operation. Ether. Time (?). Incision, median. Irrigation. Drainage, gauze. Albumin, a trace in urine. Mitral regurgitation. Compensated. White count on entrance 4,000. High temperature and great abdominal distention all the time in the hospital, but no pain till August 20th (the day before severe symptoms) — that is, twenty hours before operation sharp pain in the left iliac region. No white count. Temperature falling gradually to 99.4° the following evening. No record of close watch of case. Next A. M. severe symptoms. Very great pain. Great distention, "board-like abdomen, most tenderness left iliac," bad pulse, anxious facies, no vomiting. White count 7,300. Perforation eight inches from cecum in ileum. Virulent general peritonitis, pus and feces. Intestines covered with fibrin. No cultures. "Peritonitis of longer standing than twenty hours." Death in fifty hours. Peritonitis, spreading from a local area of infection or from perforation which took place without being noted. Small leucocyte count, possibly due to extensive purulent peritonitis. No comparative counts except one at entrance.

CASE IX. Hanahan, male, age twenty-seven years, white. Drs. Fitz and Beach. Massachusetts General Hospital, November, 1897. Perforation. General peritonitis. Operation. "Second perforation" or giving way of sutured area eight days after second operation. Death. Mild course. Widal positive. Diazo positive. First of third week, operation. Ether. Time, thirty minutes. Incision, median. Irrigation. No drainage. Slight bronchitis. Trace of albumin and hyaline and granular casts in the urine. Nothing pointing to the abdomen save a little distention. No intestinal hemorrhages till after the first operation. December 6th, distention and tenderness to the right of the umbilicus. Temperature rising, pulse steady, no white count then. Leucocytosis at entrance, November 27th, 14,100; November 29th, 14,200; December 8th, 16,000. December 7th, tenderness increasing and temperature rising. No white count. December 8th, gradually falling temperature and great increase in tenderness and distention of abdomen. Liver dullness obliterated. White count 16,000. General tenderness, pulse 130, temperature 104°. No vomiting. No complaint of pain. Operation next day (December 9th), about sixty hours after first warnings and after twenty-four hours after symptoms of general peritonitis. The infection was a slowly spreading one; the severe symptoms on December 8th were probably due to the general peritonitis. The condition on December 6th and 7th strongly suggests a pre-extravasation stage, but comparative blood counts are not recorded. Operation would certainly would have been justified by these symptoms of peritonitis fully fifteen hours before it was actually performed. Perforation one-eighth inch in diameter, one inch from cecum in ileum (Beach). Closed. Foul gas and fecal fluid in belly. Yellow fibrin on intestines. No bacteriology. Did well after operation save for the continuation of typhoid temperature, averaging 102°, and three or four moderate intestinal hemorrhages. Some distention. Eight days after first operation pain all over belly, followed in three hours by collapse. Second operation found large necrotic area and ragged hole in the cecum which was, for a great space around ulcer, soft and gangrenous — "shows patches of necrosis." Peritoneal cavity contained much dark fluid, feces and blood. Died five hours after. Autopsy: Much foul fluid in the peritoneal cavity. Many ulcers in last three feet of ileum and in ascending colon. In cecum large necrotic areas, two small perforations, and two ragged large openings. In ileum no ulcer through to peritoneal coat, and no sutures found. Although this case has been considered a case of second perforation after recovery from the first perforation, the facts do not permit this view of it. The first perforation was said to be one inch from the cecum; the second operation and the autopsy found great necrotic softening and ragged holes in the cecum, and the autopsy found no ulcers in the ileum which were through to the peritoneal coat, and no trace of the silk sutures. The localities are practically coincident. It seems just to add that the case did well after the first operation until the

extensive necrotic changes in the cecum involving the sutured area caused giving way of sutures and second extravasation. Certainly eight days is too short a time in which a sutured ulcer could heal and vanish, and the silk sutures would not have disappeared.

CASE X. Hoyt, male, age nineteen years, white. Drs. F. C. Shattuck and C. B. Porter. Massachusetts General Hospital, October, 1896. Perforation. General peritonitis. No full study of early and warning symptoms recorded. Death. Mild course. No Widal test made. Diazo. No complications. No abdominal complaints. Thirteenth day, last of second week, operation. Ether. Time (?). Incision, median. No irrigation. Wiping. Gauze drains. No hemorrhages. Uneventful till October 26th. Pain in abdomen growing steadily worse. No collapse, no fall in temperature then. Pain steadily increasing. Legs drawn up. No records of any examination for spasm, etc., but records of morphine given. No white count. Eight hours after pain first noted symptoms of general peritonitis. Pulse 112, sweating, temperature down somewhat, pinched face, belly rigid, tenderness general. Liver dulness not obscured. No vomiting. White count 14,700. Operation eleven hours after first symptoms. Perforation in ileum "near cecum." This is called in record "a sloughing area from which gas was escaping, but no fecal matter." General peritonitis, seroturbid fluid of fecal odor. No bacteriology. Perforation infolded with two rows of sutures. Death in thirty-six hours after great distention with obstinate vomiting. The autopsy raises a speculation as to the cause of death — whether due to obstruction from too much infolding of intestines by the two rows of sutures. The lumen of intestine at the point of suture admitted the little finger-tip, but was obstructed by a hard, impacted mass of feces. Whites at entrance 6500. Eight hours after first pain 14,700.

CASE XI. Bresnahan, female, age forty years, white. Dr. C. A. Porter and Dr. Thompson. St. Elizabeth's Hospital, August, 1899. Perforation. Definite early symptoms, which were not considered important. Operation six hours after severe symptoms. Death. Mild type and course. No Widal test made. No diazo. Rose spots, etc. No complications. No abdominal complaints. In third week, operation. Ether. Thirty-five minutes. Incision, right. No second incision. Irrigation. Drained with gauze. Uneventful case. No intestinal hemorrhages. Twenty hours before operation, pain in abdomen with some tenderness. No white count. No examination through the day. Six and one-half hours before operation pain severe, pulse 135. Three and one-half hours before operation — that is, sixteen and one-half hours after first complaint of pain — symptoms of collapse (general peritonitis). Temperature 106°. Muscle spasm and tenderness in right iliac region. No vomiting. Leucocytes 8,000. One perforation six inches from cecum in ileum. V-shaped resection, silk sutures, one thin plate inverted. General peritonitis. Free fluid of fecal odor. Injected intestines, with fibrin flakes. No cultures taken. Infection unknown. Death thirty-seven hours after. Partial autopsy through wound. Existence of other perforations unknown. Cause of death, peritoneal infection. Beginning infection probably when first pain, twenty hours before operation. No importance attached to early symptoms. Severe symptoms due to general peritoneal infection.

CASE XII. McDonald, female, age twenty-six years, white. Drs. Buckingham and Munro. Boston City Hospital, September, 1899. Case of perforation with excessive general peritonitis. Perforation and peritonitis much earlier than diagnosed. No symptoms save of general peritonitis. Death. Severe course. Widal positive. Diazo (?). No complications. No abdominal complaint. First of fifth week, thirtieth day, operation. Ether. Time of operation (?). Incision (?). Entered the Boston City Hospital in the fourth week. Two intestinal hemorrhages five days before "perforation." After these very sick, stupid. Pulse and temperature high. Some abdominal distention. No abdominal pain until the morning of September 18th, then pain and tenderness, requiring mor-

phine. Four hours after this great distention, general tenderness, chill, collapse, poor pulse, temperature fell to normal, but began at once to rise. No vomiting. Leucocytes 3,800 (note, general peritonitis with excess of fluid). No other count recorded, and no time of this given. Operation six hours after pain, two after collapse. Case "moribund" at operation. Perforation site not recorded. "Excessive general peritonitis, evidently of long standing; appearance of intestines and abdominal cavity showed general peritonitis of much longer standing than six hours" (Munro). No bacteriology. Death on operating table. No post-mortem. This case was "stupid" and sick, and illustrates that perforation and general peritonitis may be gradual, and in a sick and stupid patient unnoticed until extreme septic infection.

CASE XIII. Starnar, male, age twenty-five years, white. Drs. Gannett and C. B. Porter. Massachusetts General Hospital, October, 1899. Perforation gradual. General peritonitis of long duration. No very definite diagnostic symptoms. Death in two hours. Mild case. Widal positive. Diazo positive. No complications. First of fourth week or end of third, operation. Ether. Time, one and one-half hours. Incision, median. Irrigation. No drainage. In the hospital ten days before operation. Abdomen distended most of the time, but no pain. Patient dull and stupid. Temperature high, pulse good. Four A. M. intense pain, abdominal distention. No examination. Eight A. M., September 13th, sudden vomiting. No pain complained of, but abdomen much distended and knees drawn up, face anxious, general rigidity, abdominal and general tenderness. No fall of temperature recorded. White count, 8.30 A. M., 5,400; 10 A. M., 4,400; 2 P. M., 6,300. Operation twelve hours after first pain. General peritonitis, cloudy fluid, gas in large amounts. Intestines much injected, distended, covered with fibrin. Perforation just above ileocecal valve in ileum, "pin-head," closed. No culture. "Condition on leaving table very bad." Death in two hours. No autopsy.

CASE XIV. McKenna, male, age thirty-eight years, white. Drs. George B. Shattuck and F. B. Lund. Boston City Hospital, December, 1898. Perforation. General peritonitis. Definite warning symptoms. Death. Severe course. Widal positive. Diazo (?). No complications. No abdominal complaints. End of third week, twenty-first day. Ether. Time (?). First incision in right iliac, second in left. Irrigation. Drainage, gauze and tubes. Seven P. M. of the day before operation general abdominal pain, also pain in rectum and bladder. General abdominal tenderness and rigidity. No change in pulse and temperature. Leucocyte count 10,000. Query as to why this was not repeated. No record of any observation of case till next day. The next morning (twelve hours after warning) symptoms of peritonitis recorded, namely, distention, anxious facies, vomiting, no fall of temperature, pulse rising to 120. Operation fifteen hours after first symptom. Perforation in ileum one foot from cecum. Closed. Seropurulent general peritonitis, pus and feces, fibrin. Infection, colon bacillus and other bacteria. Death in forty-two hours. Autopsy showed general peritonitis. No other perforations. Beginning of infection when first pain, fifteen hours before operation. Definite warning. No record of case for twelve hours. Leucocyte count day before, when suggestive symptoms appeared.

CASE XV. Mahr, male, age thirty years, white. Drs. Bowditch and Watson. Boston City Hospital, February, 1898. Perforations. General peritonitis. Early symptoms definite. Operation delayed forty-eight hours. Death. Mild course. No Widal. No diazo. Post-mortem proof. End of third week, operation. Ether. Time (?). Incision, median, and two counter incisions in flanks. Irrigation. Drainage tubes and gauze. No special complications. Temperature normal for two days. No abdominal complaints till last. September 15th, A. M., vomited and complained of sudden pain, first in epigastrium, then all over abdomen and shooting into testicle. Tenderness in abdomen general but most marked in right lower region and in epigastrium. "Shock not marked." Temperature

rose from normal to 102°. Pulse 150. In a few hours rigidity of abdomen and tympanites. Leucocytes on September 15th, 31,550; next day, 17,000 to 23,000 (September 16th). In spite of these marked warning symptoms no operation for forty-eight hours. Then symptoms of fatal peritonitis, case nearly moribund, temperature subnormal, cold extremities, marked prostration, cyanosis, marked distention and rigidity. Operation found perforation in ileum near cecum, size of "split pea." Found general peritonitis, pus, fecal fluid, dirty-gray lymph, coils adherent, pelvis full of turbid fluid, perforated coil fastened in abdominal wound. Infection, colon bacillus and great variety of other bacteria (?). Death in six hours. Autopsy: Numerous typhoid ulcers in lower ileum. A second perforation (pin-point) close to valve. General peritonitis. A repeated white count in this might have contributed much to the knowledge of a falling count in peritonitis.

CASE XVI. Scappacci, male, age nineteen years, white. Drs. Cutler and Elliot. Massachusetts General Hospital, June, 1899. General peritoneal infection from a necrosed and gangrenous patch over an ulcer. Threatened perforation. Definite warning symptoms of infection. Recovered. Mild course. Widal positive. No complications. No abdominal complaints. Last of second week, operation. Ether. Time (?). Incision, median. No irrigation, but wiping. Gauze drainage. Uneventful till June 4th, then pain in lower abdomen with general tenderness. Leucocytes June 2d, 6,900; June 4th, 8,000. No complaints or examination recorded for June 5th. June 6th, severe pain, abdomen tender and rigid, but more on right side; tympany, anxious facies, pulse 120, fall of temperature. Leucocytes 12,200. No vomiting. Operation two days after first abdominal pain. Four hours after, symptoms severe. Four feet from cecum a necrotic patch of peritonem, the base of intestinal ulcer. General peritonitis, seroturbid, purulent fluid and fibrin flakes. Intestines injected, with green fibrin patches occasional. No cultures. Patch inverted. Recovery after relapse of typhoid. Infection not determined. A case of perineal infection from ulcer not yet perforated. Symptoms of perforation all present. Infection probably non-virulent (?). Compare Case XXI.

CASE XVII. Bloom, male, age forty-five years, white. Dr. Brooks. Massachusetts General Hospital, September, 1898. Extensive general peritonitis from perforation in walking typhoid. Infection not determined. Recovery. Widal positive. Ambulatory case. In second week, operation. Ether. Time (?). Incision, right iliac. Irrigation. Drainage, gauze. Case of typhoid as shown by Widal and by finding of typical ulcer indurations in ileum. Had been sick for a week or ten days, with pains in abdomen. Up and about out of bed most of time (walking typhoid). Brought to accident-room 3 A. M. in bad condition. Temperature 103.4°, pulse 134, respiration 60. History of pain in region of appendix, severe for two days, with nausea. Operation found brown, purulent fluid in general peritoneal cavity, with no odor; portions of small intestine covered with hemorrhagic spots, "size head of tack." Perforation found one foot from cecum. "Indurated area, size of quarter, in centre of which pin-point opening." The appendix removed, incidentally, for old thickening. No active process in it. Perforation took place two days at least (?) before entrance. No white count. Recovered. No return of typhoid state, though Widal positive after operation. Discharged, well, in six weeks. No bacteriology.

CASE XVIII. McCarron, male, age thirty years, white. Drs. Bowditch and Thorndike. Boston City Hospital, October, 1899. Perforation. Beginning general peritonitis. Operation eight hours after first symptoms. Death. Mild course. Widal positive. Diazo (?). No abdominal complaints. In the fifth week, thirty-third day, operation. Ether. Time (?). Incision, right iliac. Irrigation. Drainage, tubes and gauze. Cardiac murmur, systolic, not affecting compensation. No other complications. Early warning symptoms: 2 A. M., sudden, sharp pain in right iliac

region. No fall of temperature, good pulse. Vomited. No blood count in this case. Seven A. M. (five hours after) severe symptoms. General severe abdominal pain and rigidity, especially right iliac. Pulse 120. Vomiting. Operation eight hours after first pain. Operation three hours after severe symptoms. Perforation in ileum three feet from cecum. Perforation closed with silk. Straw-colored fluid and fecal matter in abdominal cavity. Intestines injected and fibrin flaked — that is, beginning general peritonitis. No cultures recorded. Death eighteen hours after. No autopsy. This case perforated eight hours before operation, when pain noted. If the case had been carefully watched with hourly blood counts between the hours of 2 A. M. and 7 A. M. operation possibly could have been decided on three or four hours sooner. Severe symptoms at 7 A. M. due to general spreading infection.

CASE XIX. Ellam, female, age twenty-one years, white. Drs. Townsend and Burrell. Children's Hospital, October, 1899. General peritonitis. No perforation found. Symptoms of perforation or of peritonitis. Warning pain sudden and not reported. Death. Moderately severe. Widal positive. No complications. No abdominal complaints. Fifth week, thirtieth day, incision, right iliac region. Irrigation. Gauze and tube drainage. Intestinal hemorrhages daily from three days preceding severe symptoms. No abdominal pain with them. Sudden sharp abdominal pain in the middle of the night; no examination. At 9 A. M. (eight hours after) severe pain, abdominal tenderness and resistance, marked in right upper quadrant, slight distention. No leucocyte count recorded. No vomiting. Pulse 130. No fall in temperature noted, but rise to 104° at 9 A. M. May have fallen in the night. Operation eleven and one-half hours after pain. General peritonitis. Injected fibrin flaked intestines. No perforation found. "Thin place," but not necrosed; turned in. "Condition forbade search" for cause of peritonitis. No bacteriology. Death in twelve hours. No autopsy. This case could have been operated sooner. Severe symptoms came suddenly and were not reported for seven or eight hours.

CASE XX. Buckley, male, age thirty-four years, white. Drs. Jackson and Munro. Boston City Hospital, September, 1899. Signs suggestive of perforation in third week. Very sick after this. Perforations in ninth week. General peritonitis. Early warning symptoms. Death. Severe course. No Widal. No diazo. Rose spots. Cardiac enlargement. Systolic murmur. In ninth week, fifty-ninth day, operation. Ether. Time (?). Two incisions, first median; second right flank. Irrigation. Drainage, gauze and tube. In the third week, while pulse and temperature were high, sudden fall of temperature. Collapsed. Distended abdomen. Operation advised and refused. Leucocyte count then 6,800. No other count recorded. From this attack very sick until ninth week. Abdomen distended. Pulse and temperature high. One small intestinal hemorrhage in fourth week. Twenty-four hours before operation abdominal pain, especially on left side. Pulse and temperature rising still higher. Twelve to fifteen hours after pain general and severe. Vomiting. Temperature subnormal. Two perforations in ileum three inches apart (where?). Also in ileum (site?). "Recent scar, possibly healed perforation of third week." Perforations closed. General peritonitis, cloudy fluid with fibrin flakes. Infection, colon bacillus. Death ten days after. No autopsy. A frequent leucocyte count would have been very valuable.

CASE XXI. Powell, male, age twenty-seven years, white. Drs. Ames and Munro. Boston City Hospital, September, 1899. No perforation. General peritonitis from ruptured mesenteric glands. Symptoms of perforation exactly simulated. Infection, pure typhoid bacillus. Death. Mild course. Widal positive. Diazo (?). No complications. No abdominal complaints. Last of third week, twenty-first day, operation. Ether. Time (?). Incision, median. Irrigation. Drainage. Pain, abdominal, more on left side at 11 P. M. This required morphine. No further record till 7.30 A. M. (eight and one-half hours later), when collapse, anxious facies, tympanites, general

abdominal tenderness, and rigidity. Temperature rising. (Temperature had been normal for twenty-four hours.) No vomiting. No leucocyte count. Operation twelve hours after pain. No perforations. Two suspicious thin places of inflamed peritoneum over ulcers. Seropurulent general peritonitis. Infection, pure typhoid bacillus. Death in twelve hours. Autopsy: No perforations. General peritonitis from two softened and ruptured mesenteric glands. This case strongly suggests the idea that symptoms of general peritonitis are identical with the "supposed symptoms" of perforation, and suggests the virulence of bacillus typhosus in peritonitis.

CASE XXII. Sawyer, female, age sixteen years, white. Drs. G. B. Shattuck and Watson. Boston City Hospital, December, 1897. No perforation. Nothing to account for symptoms of infection. Leucocyte count not taken. Recovered. Mild course. Widal positive. Diazo (?). No complications. No abdominal complaints. In sixth week, thirty-sixth day, operation. Ether. Time (?). Incision, right iliac. No irrigation. No drainage. Uneventful case. Temperature falling steadily. At no time especially sick. The afternoon before operation, severe abdominal pain and tenderness in right iliac. Temperature rising to 104°. Pain local in "lower abdomen," gradually increasing, not sudden. Next morning pain and tenderness general, but more on right side. Temperature 102°, pulse 128. No vomiting. Abdominal muscles rigid. No distention. No leucocyte count. "Absence of marked shock." Operation seventeen to eighteen hours after first symptoms. No perforations. No peritonitis. Appendix not actively inflamed, but bound by old adhesions; removed. Recovery uneventful. Important case from diagnostic side. Pain, tenderness, rigidity, rise in temperature and pulse. No great shock. No vomiting. The leucocyte count is all important, but is not recorded.

CASE XXIII. Eagles, female, age twenty years, white. Drs. Vickery and Mixer. Massachusetts General Hospital, August, 1898. No perforation found at operation. No cause for symptoms of perforation, which were definite. Recovered. Moderately severe. Widal positive. Complications, cardiac and renal. Abdominal complaints frequent. Fourth week, operation. Ether. Time (?). Incision. No irrigation. No drainage. Moderately severe case. Complicated by mitral regurgitation, with poor compensation and by acute renal congestion. Both cardiac and renal complications improved in hospital. Frequent complaints of moderate abdominal pain, which was due to retention of urine and relieved by catheter. Probably cystitis. Temperature lower and sitting up in bed in fourth week, when pain in abdomen complained of; white count at this time 9,200. Leucocyte count at entrance 4,200; twelve hours before operation 9,200, when pain first complained of; one hour before operation 12,000. Twelve hours before operation, pain, abdominal tenderness and spasm, mainly on the right side; slight distention; pulse 118. Temperature (?) No vomiting. Operation twenty-four hours after pain first noted. Nothing found. Recovery. Symptoms of gradual perforation, including some leucocytosis. No marked shock recorded. Query as to how to account for leucocyte count. Compare this case with Sawyer, Case XXII. Same symptoms, but in Sawyer's case no leucocyte count. The comparative value of leucocyte count in this case is questionable.

CASE XXIV. Seile, male, age twenty-seven years, white. Dr. Balch. Massachusetts General Hospital, September, 1897. Symptoms of peritonitis of gradual onset. Operation found necrosed patch, but no microscopic general peritonitis. No leucocyte count. No cultures. Death. Mild course. Widal positive. No complications. Fifth week, operation. Ether. Time (?). Incision, median. Irrigation. No drainage. Slight intestinal hemorrhages at intervals for three weeks before operation. Ten days before, abdominal distention, but no pain or rigidity. Temperature rising. Distention only transient, none two days before operation. September 25th, at noon, pulse 140; some sweating in the afternoon. Pain below and to left of umbilicus. Abdomen distended (spasm,

vomiting and white count not recorded). (Temperature not recorded.) September 26th, picture of peritonitis, anxious face, pain, restlessness. Liver dullness obliterated. Operation twenty-four hours after first symptoms. No perforation, one Peyer's patch, one and one-half feet from cecum, threatening perforation, with fibrin area on intestine, "green, necrotic area," this inverted. No extravasation in peritoneal cavity. No bacteriology. Death in ten hours. Autopsy showed no general peritonitis. Only local necrotic patch. Death from typhoid.

CASE A. Eladed, male, age fifteen years, white. Drs. Bowditch and Munro. 1899. Case of general peritonitis. No perforations. Gall-bladder infected with typhoid bacilli. Cause of peritonitis unknown. Sick case. Widal negative. Diazo negative. Large spleen. Sick for four weeks. Came into hospital with general peritonitis. "Nearly moribund at entrance" (Bowditch). Delirious; distended belly; distended, rigid muscles; temperature 104°; pulse 120. Leucocytes 5,200 (note, purulent peritonitis of long standing). No symptoms of perforation. At operation for general peritonitis no perforations found. Gall-bladder opened, but no evidence of origin of peritonitis. Cultures of free peritoneal fluid, staphylococcus albus. Cultures from gall-bladder, bacillus typhosus. Exploration only half satisfactory (Munro). No anatomical evidence of typhoid found. Death in twenty-four hours. No autopsy. No conclusive proof that this was a case of general peritonitis during typhoid. Moribund case of general peritonitis, cause of which doubtful. Should not be counted with other cases.

CASE B. Collins, male, age twenty-five years, white. Drs. Jackson and Gavin. Boston City Hospital, September, 1895. Case of general peritonitis. No evidence of typhoid fever. No Widal. No rose spots. No spleen. Case of no value. This case had general peritonitis, was operated on and died. No reason to call it typhoid. No post-mortem. Leucocytes 32,000 before operation.

CASE C. James, male, age (?). Dr. Munro. Boston City Hospital, 1895. Case of general peritonitis. No evidence of typhoid or of perforation. Case of no value. Case entered the Boston City Hospital with general peritonitis. Operated on and died. No cause for peritonitis found. No autopsy.

SEPARATION OF THE EPIPHYSIS OF THE OLECRANON.

BY F. J. COTTON, M.D., BOSTON.

SEPARATION of the epiphysis of the olecranon is classified as one of the rarest of the epiphyseal separations. Poland, in his recent book, gives no instance of this separation save as a complication of other injuries of the elbow, unless one accepts a doubtful case by Bryant, and a case of Hamilton's where he produced the injury by forced flexion in attempting to reduce an old dislocation of the elbow. Nor has the writer, in a short search of the literature, found any case recorded where this separation occurred without other injury.

There is experimental evidence enough (Poland, Gueretin and Salmon) to show the possibility and ease of separating this epiphysis, but curiously enough, all the experimenters seem to have used forced hyperextension to produce it. Muscular action in resisting flexion, the apparent cause in the following cases, cannot, of course, readily be imitated on the cadaver.

Both the cases here reported came under the care of the writer while he was acting out-patient surgeon to the City Hospital.

The first case was in a naval apprentice, a lad of sixteen years. He gave a history of having had a fall on the hand without any blow on the elbow.

This fall had been followed by marked disability of the arm, and Dr. Saunders, the ship surgeon, recognizing an injury to the olecranon, had put the arm up on a straight splint.

When the boy was referred to the hospital, about two months later, he was still wearing a short splint. The arm showed no disturbance in the relation of the bony landmarks, save a loss of prominence of the tip of the olecranon. On careful palpation a fragment could be felt just above what seemed to be the end of the ulna; this was, as nearly as could be estimated, one-half to three-fourths inch in either diameter, and not over one-fourth to one-third inch in thickness, perhaps less. It was freely movable over a short range laterally but not movable, to an appreciable extent, vertically. The displacement was upward and forward, the interval of separation about one-third inch. A skiagraph was taken, and showed above the outline of the olecranon an outline evidently representing the cap of the separated epiphysis, displaced upward and for-

FIG. 1. (a) Posterior line of olecranon epiphysis.

ward. The gap we should expect to see left in the place of the epiphysis is not obvious in the skiagraph, but on palpation, comparing the two arms at a like angle of flexion, the shortening of the olecranon was very definite, though not great.

The comparatively slight showing of the shadow of the epiphysis, despite the patient's age (sixteen years), will be referred to later.

When first seen the elbow could be flexed only about 20 degrees. There was no sign of union of the epiphysis to the ulnar shaft, but on the other hand there was in flexion no apparent tendency of the triceps to cause further separation. A week later the fragment was less movable. Massage was then begun. After another week or ten days fibrous union of the fragment to the olecranon could be clearly made out; the interval of separation was now one-third to one-half inch. The joint was freely movable from an angle of 135 degrees to one of 170 degrees (that is, within 10 degrees of the straight line). The arm

was still kept on a short obtuse-angled splint and massaged regularly three times a week, with very gentle passive motion.

At the end of six weeks, union of the fragment being firm, the splint was omitted and the arm simply put in a sling so as to allow of partial flexion. Flexion of about 60 degrees was then possible, and the range of motion was slowly but steadily increasing. The arm was painless and was already useful to some extent. From this point on the patient was not seen again, but he is said to have shipped later on a merchant liner, so presumably the arm is doing good service.¹

The second case was in a boy of eleven years. Here again there was a definite history of a fall on the hand without direct violence to the elbow. The patient had been dressed in the accident-room soon after the injury and came in wearing a splint which fixed the arm at a very obtuse angle. There was at this time some swelling and a slight ecchymosis on the outer side of the arm above the elbow. The bony landmarks of the elbow were in normal relation, but on careful palpation a small mass was to be felt, apparently about one-half inch in diameter either way, and about one-quarter inch in thickness vertically. This was separated from the ulna by an interval of not over one-eighth inch; the slight displacement was upward and forward. The fragment was loose and could readily be rocked under the fingers, but was movable only from side to side, and that very slightly. On attempted flexion there was only a very slight increase in the distance of the separation.

The x-ray taken in this case shows a distinct and typical nucleus of ossification at the site of the epiphysis; the displacement is not notable in this view; the ossified bone is intact.

The arm was put up on a splint at an angle of 15 or 20 degrees less than full extension.

Three weeks later the fragment was still movable, but there was no tendency to an increase of the interval of separation; massage and cautious passive motion were begun. Five days later motion was possible from an angle of 135 degrees to within 10 degrees of full extension. A month from the time of the injury the splint was omitted. There was then a possible flexion of only 40 degrees and the fragment was not yet firmly fixed in place on the ulna, but there was no increase of the separation interval.

Three months from the date of the accident the elbow was examined again. The epiphysis was then very slightly displaced forward and was no longer movable. The motions of the elbow were all normal save for a 10- or 15-degree limitation of extreme flexion. There was no pain and the joint was functionally perfect.

It would seem that both these cases were separations of the olecranon epiphysis from muscular action alone. The insertion of the triceps is largely on the epiphysis, but it is undoubtedly due to the fact that the insertion and the tendinous expansions run beyond the epiphyseal line that there was no more considerable separation in these cases; evidently the triceps fibres running beyond the epiphyseal junction withstood the strain after the junction itself had given way. The same thing may occur, according to Stimson, in

¹ Since the above was written the patient was seen again. Function is normal, deformity trifling. Flexion still about 20 degrees, extension 25 degrees short of normal, but still improving.

fractures of the olecranon from muscular violence. In a younger child, where the epiphysis is relatively larger, this safeguard against separation would probably not hold good, but, on the other hand, in such young children sufficiently vigorous muscular action to wrench off the epiphysis in this way would hardly be possible.

Why the separation of this epiphysis should not occur clinically as a result of violent hyperextension, in the way that it has been produced experimentally, is not clear; perhaps the cases are not recognized, though this seems hardly likely.

In regard to treatment in these cases probably the second, rather than the first of the two reported, approximates the period of fixation and the treatment which should ordinarily suffice for good results, though some allowance would have to be made for the difference in age of the patients. At all events, given a short interval of separation, six or seven weeks, at most, of fixation in partial extension with

scale at the posterior angle of the olecranon. No. 457, age seventeen years, partly united, seems to show a similar line of junction, and in still another (an unnumbered specimen without data, but apparently from a child of about nine or ten years) the same form of epiphysis is to be seen; the epiphysis is thicker, but the line of junction runs upward and forward and none of the articular surface is formed by the epiphysis.

It would seem, then, that there is more than one form for this epiphysis. The first of the foregoing cases seems, from the evidence of the skiagraph and the examination, to represent this thinner, scale-like form of epiphysis just described, while the second presents the more usual form, an epiphysis of some thickness with a centre of ossification of some considerable size.

As to the clinical importance of these separations of the olecranon epiphysis, it seems noteworthy only that the separation may occur without other injury, apparently from muscular action; that little reaction in the joint results from the injury; that the separated epiphysis does not tend to become widely separated, and that union with the shaft and entire restoration of function are to be aimed at, seemingly with some confidence of success.

New Instrument.

A MODIFICATION OF THE SPHYGMOGRAPH.¹

BY ROBERT T. EDES, M.D., BOSTON.

THE sphygmograph is an instrument which, I believe, has never been held in high respect by the physiologists. It is unnecessary to analyze all its defects and inaccuracies in the various forms in which it has appeared. This has been very thoroughly done by Baumgarten in "Wood's Reference Handbook." But notwithstanding these it has always had a certain attraction for the clinician because it gives a record more compact and less subject to personal error, if not more delicate, than even the well-trained finger. It is useless to expect from it pathognomonic indications of valvular disease, but, with care, it can be made to show certain conditions of the blood pressure that are, if not more easily detectable, at least more easily demonstrable in this way and which are very useful in studying and recording diseases, disorders and the action of remedies, especially such as involve the vasomotor system.

A clinical sphygmograph must be convenient and not require a tedious adjustment of pads, straps and support, and it is this virtue which has made the "Pond" instrument, when used without the arm rest, so popular in this country. But it is defective in the following points. The resistance to the tension of the artery should be, so far as possible, by a spring and not by weight, because the error due to *vis inertiae* is less, and also because unless the instrument is held exactly upright, which is not always easy at the bedside, the levers are not working at all times under the same conditions. The spring should be a metal one. Rubber springs are constantly changing by time and readjustment. The pressure used

¹ Read in abstract at the Association of American Physicians, May 3, 1900.

FIG. 2. (a) Epiphysis of olecranon; (b) of capitellum; (c) of trochlea; (d) of radial head.

massage, followed by cautious passive and active motion, would seem to be the indication. In the second case consolidation began early and it was possible to shorten the period of treatment.

One point in relation to the diagnosis of such cases, especially by means of the skiagraph, should be brought out, and that is the different forms presented by the olecranon epiphysis in different individuals. According to Poland, the epiphysis at ten years includes about a third of the olecranon, at fourteen and one-half years it is about three-eighths inch in vertical diameter, and at fifteen years it includes one-third of the articular surface and but one-fourth inch of the posterior surface. This does not seem to apply to all cases. There is, for instance, one specimen in the Warren Museum (No. 537, age fifteen years) which corresponds to this description, as do others (553, 334 and an unnumbered specimen) of seven, eight and ten years, but in specimen No. 417, age eighteen, the epiphysis, still distinct, is not much more than a

should be simply the pressure of the pad on the artery, or as nearly so as possible and not the pressure of the base of the instrument on the adjacent tissues. Of course no sphygmograph to be used on the human subject can be free from the modifying effects of the tissues superjacent to the artery which may, equally of course, vary a good deal with the elasticity of the skin and the amount of connective tissue present. The base of the "Pond" is so broad that when the little metal disk within the rubber cap is pressed down on to the radial, the graduation on its stem indicates not the pressure over the artery but that of the metal cap upon the edge of the radius, the flexor carpi radialis, or both. It is also very desirable that the tracing should itself be a record of the pressure at which it is made. This roughly made instrument indicates, I think, how some of these defects can be remedied.

Some years ago I made and published a short account of a sphygmograph with a single lever, in which the tracing taken, which of course was only slightly multiplied, could be further enlarged by the use of a cylindrical lens.² As one might say, the amplification usually accomplished by a second lever is here done by a beam of light. The objection to this was that the tracing could not be used for demonstration without the lens and could not easily be recorded for convenient use. This slightly magnified tracing, however (only two and a half or three times), when taken on the same slip with the usual more highly magnified one is useful for comparison with it. It throws out a certain amount of instrumental error dependent on looseness of joints and on acquired velocity of the most rapidly moving parts. A too delicate action of rapidly moving levers carries the writing point beyond its proper mark in each direction. A very beautifully constructed instrument shown me some years ago by Dr. Hopkins, of Buffalo, was open to this objection in the highest degree and gave tracings which indicated an amplitude of movement considerably beyond that of the arterial wall. Elasticity and want of rigidity in the levers have very much the same effect. If a very long lever multiplying the necessary number of times (say twenty) could be made absolutely rigid and extremely light, then a sphygmograph of only one lever, but using a slip of paper wide enough to register all pressures, would be the ideal.

In the modification which I now present I have endeavored to combine these essential points: magnification sufficient to be read without a glass, the easy and convenient applicability of the "Pond," the observation and recording of actual pressure over the artery alone, and the diminution of some instrumental errors. It consists of a bent lever of which one end rests on the artery and the other carries a writing needle. It

is held by a spiral spring. Pressure upon the artery is made and changed simply by the amount of force employed by the hand which holds the instrument, the pressure upon the other tissues of the wrist having no effect upon the tracing except through the lever. The sphygmograph is held between the thumb and first two fingers, the other two or edge of the hand supporting themselves on the wrist. This slightly magnified trace indicates by its position on the slip the amount of pressure on the end of the lever placed upon the artery; and the amount of movement is sufficient to allow the amplitude of the wave to be estimated, and the best pressure for development to be selected. It can be made more distinct by the use of the cylindrical glass. The range of pressures with the spring now on the instrument, on a slip of the usual width, is from 75 to 250 grammes. The second lever, multiplying considerably more, does not have a fixed connection with the first, but by means of a notched arm is attached to it when the degree of pressure at which the tracing is to be taken has been determined. The pressure can be varied a little even after the two levers are connected, without throwing the writing point off the smoked slip. We have, then, on the slip two tracings, one magnified three times, showing exactly the pressure and the amplitude at that pressure and free from exaggeration; and the second corresponding to the only one given by the usual form of sphygmograph which brings out the milder peculiarities of the pulse wave.

As I am now presenting this combination rather as a suggestion than as a finished instrument, I can speak of some points which might be improved in the hands of a better workman than I am. I overheard a hardware salesman say with considerable emphasis to a customer who thought he could buy a spring to suit him ready made, "Making a spring is an art." It is one which I do not possess either in theory or practice. Although the spiral spring which I have here covers, I think, most ordinary ranges of pressure, yet I presume it would be possible to temper a steel

² Journal American Medical Association.

spring so as to do much better and make a paper of the ordinary width record a range from nearer zero to a considerably higher point than this. But that which I found most difficult to arrange satisfactorily looks at first sight so exceedingly simple that it seems almost silly to speak of it; that is, the catch between the two levers, which should be very light, very easy and quick of adjustment, without any slip, and on the other hand without friction or stiffness.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting Monday, April 16, 1900, Dr. E. H. BRADFORD in the chair.

DR. G. B. SHATTUCK presented a paper entitled

A STUDY OF TWENTY-FOUR CASES OF TYPHOID FEVER WITH SYMPTOMS OF PERITONEAL INFECTION; LAPAROTOMY.¹

Before the presentation of the report itself I will make in behalf of the Committee a very brief statement. This is a report upon the cases and such discussion as there was at a preceding meeting of this Society. I would like to say that a great deal of labor has been expended upon the report. The report itself is divided into two parts: The concise presentation of each case, which is the result of as careful an investigation of each case as it was possible to make; this is preceded by an analysis of the cases from different points of view and the general remarks and conclusions which the Committee derive therefrom. I do not know whether all the gentlemen who have submitted cases will agree with all our statements in regard to the cases themselves, or whether they will agree with regard to all our conclusions, but whether they agree or do not agree, whether they should be right and we should be wrong, it will not be because we have not given the utmost pains and taken much time in order to be right. The general results may be summed up in a word as far as we draw conclusions from these cases, that they point to the importance of an early diagnosis, and we state what considerations we think are especially important in order that this early diagnosis may be made; especial stress is laid upon the recognition of *pain*—not mere discomfort—and upon the question of the use of the white blood count and its proper use in aiding in this early diagnosis. Then the other point around which the conclusions turn is the character of the infection, which undoubtedly varies in different cases, and emphasis is laid upon the point that the perforation is one thing and the later peritoneal infection is another thing. These should be kept distinct. As I have said, a great deal of work has been expended upon the report; much of this work has been done by Dr. Farrar Cobb, and the Committee desire that he should read the paper.

DR. FITZ: It seems to me the Committee deserve the highest credit for the work they have done and the thoroughness with which the results have been

prepared and the force and vigor with which they have been presented. Certainly the paper is the most intelligent, careful and comprehensive consideration of the subject that I know of. The Committee wish the paper to be criticised, but it is impossible for any attempt to be made to carefully criticise it at such short notice. One simply admires and that is about all there is to be said. The one general thought that came to my mind as the paper was being read was that what was needed in the first instance was control with a larger series of cases than is here collected. For instance, with reference to the question of pain, it may be that the next 100 cases, more or less, will show a still higher percentage of pain, proving to be insignificant so far as its relation to perforation is concerned.

The next thought that occurred to me was that the report suggested very emphatically the kind of work that had to be done, and that so far as hopefulness from the experience of the past is concerned, we were not after all very much better off with regard to the results of operation in this most modern time than we have been for some time previous, and that in cases even with no evidence of peritonitis and with appearances at the time of the operation suggesting that a favorable result was likely to follow, it is evident that the prognosis must still be held in abeyance and the probability is that the patient will die whatever is done for him.

There is only one word I have to say in what might be called self-defence and that is with reference to the question of the prognosis being the more favorable the more the condition resembles that of appendicitis. It was not my thought in making that observation to suggest that cases of appendicitis were common in typhoid fever. The point was that the simulation of appendicitis meant a more circumscribed peritonitis and the more circumscribed the inflammatory process at the time of the operation the more likely the latter was to prove successful. This statement was based on an analysis of operations done years before and seemed to be confirmed by evidence collected at the time, but I do not undertake at present to defend very warmly a paper written seven or eight years ago upon a subject which is so rapidly growing in interest, and in which experience is constantly increasing.

DR. MUNRO: I have nothing special to say except to heartily endorse everything that I could grasp in hearing the paper read to-night. It establishes a much better basis for the treatment of these cases than we have had heretofore. I am sure, in the cases I have watched in my own practice and in the practice of others, that one finds as serious a condition from necrosis without actual perforation as from actual perforation. In almost all the cases that came under my own care I found by careful questioning that there had been antedating symptoms of a preperforative stage which had escaped the observation of the medical house officer. This was so fixed in my mind that I had previously spoken of it to several of my colleagues. As to the question of an anesthetic, I am positive that Cushing, of Baltimore, lays too much stress on the value of cocaine. I am positive as I can be of anything in surgery that ether properly given, given certainly as we give it at the City Hospital, in the cases of typhoid perforation that have not developed acute general peritonitis, does no harm, and that the operation can be done more rapidly and safely

¹ See page 677 of the Journal.

than under local anesthesia. I lost, to be sure, one case on the table where the patient vomited into her own trachea, an unpardonable accident. It was, however, a case of operation in collapse and was offered only as a last resort. Setting aside those severe cases as you set aside the severe cases of strangulated hernia or general peritonitis from other causes, I am sure that ether is harmless in early cases of perforation or in the preperforative stage. The operation also, I believe, is well borne except in cases of acute general purulent peritonitis. There is practically no shock, when the operation is done in twenty to thirty minutes, certainly not shock enough to warrant delay or hesitation. When, on the other hand, the abdomen is the seat of an acute purulent peritonitis, any operation is serious or fatal, and it is to avoid operating at this stage that we must use every available means, not least of which is the light given us by this invaluable paper read to-night.

DR. ELLIOT: I think this most admirable paper deserves some discussion. The thing that has occurred to me in listening to the paper is that a very sharp line is drawn between the operations that were done for the perforation itself and those done for the septic general peritonitis. It seems to me that while theoretically that may be a good point to make, practically the vast majority of operations must be done for a more or less extensive septic peritonitis. A few years ago there was a great deal of talk about whether an appendix had been perforated or not, but after we had had a little more experience, we found it did not make any difference whether it was perforated or not; there was apt to be septic peritonitis around the appendix before it was perforated. It seems to me these preperforative cases of ulcer suggest the key to the situation. The report would maintain this point by saying that in certain cases the ulcer sloughs out suddenly and leaves a hole, but the chance of successfully closing such a hole would be very rare indeed. We know that actual fecal extravasation is very fatal in spite of early operations. I think, as is maintained in the latter part of the paper, we must watch for beginning septic peritonitis. That is the only chance we have for saving these cases. Such a peritonitis as comes just before the ulcer perforates, or from an ulcer partly closed by adhesions, will give a fair chance for operation. And apropos of the leucocytosis, although I should not like to give or assume to have an opinion on leucocytosis above scientific men, yet I think this account of these cases is a pretty strong argument against leucocytosis being of any great value in operating. In the first place, the only man who has a theory which would account for the varying leucocytosis is Cushing, and Cushing and Finney have both done operations, according to this account, on the basis that leucocytosis was a diagnostic symptom where they found no perforation. That in itself is a pretty severe setback for the leucocytosis theory. Then, in the reader's cases where the leucocytosis was given there appears to be no certainty that the white corpuscles are increased. At a meeting of the Surgical Section we went over all the cases of peritonitis in which the leucocytosis was given in the hospital records. In half the cases there was leucocytosis and in half the cases there was not leucocytosis, and the same variation appears in this report. I think at present it is clear we cannot be guided by leucocytosis in the least in operating for general peri-

tonitis. It was said at that meeting that it is a great comfort if you are going to do an operation for general peritonitis to find there is a leucocytosis. It may be, but the crucial test is, would you operate if everything else was even; if you were in great doubt, would you let a leucocytosis lead you into an operation? I think I am not prepared to operate on a blood count from the evidence as given in the report before us.

DR. BEACH: I am grateful for the report of the Committee and appreciative of the formulae which the conclusions give as a working basis for future reference and operations. Upon the question of anesthesia, my conviction remains in favor of the advantages supplied by the judicious administration of ether, in the avoidance of shock and mental disturbance.

It is inevitable that some patients while conscious should suffer permanent damage from the unavoidable routine of an abdominal section, and true that others could be indifferent to it, although the pain in both classes should be wholly controlled by local anesthesia.

In patients whose vital forces have been already lowered by continued fever, hemorrhage or beginning peritonitis the question of adding the uncertain degree of nervous tension and excitement commonly associated with a considerable operation without anesthesia becomes serious and deserves careful consideration.

After-treatment.—For my own part, the results in these cases are so dependent upon the general treatment to which they are subject after any operation, that I hoped for its discussion in the masterly report of the Committee. It is not difficult to understand, however, that this side of the investigation could be better left for the accumulation of additional and important evidence, necessary for the establishment of safe and reliable methods.

Meantime the surgeon must admit that abdominal section will be required in cases, without the preparation by catharsis commonly employed before laparotomies. After operation, where the intestine is softened and much inflamed, the usual measures may provoke increased perforation and hemorrhage. On the other hand, an expectant treatment may be followed by intestinal obstruction, great distention with rupture of sutured ulcerations and fecal vomiting. The requirements of individual cases will modify more or less diet and remedies in satisfactory use at the time of operation.

DR. SHATTUCK: It seems to me the report covers one of the points made by Dr. Elliot. I think the report acknowledges a similarity of symptoms and conditions between the cases in which necrotic areas exist which are those of the preperforative stage and the cases of actual perforation with larger or less destruction of tissue.

As to the question of leucocytosis, the Committee thought it was extremely desirable to find something which would ameliorate the difficulties of the physician in making an early diagnosis. The surgeons say: "We have done our best. If you cannot turn these cases in to us more promptly or in better condition, you can hardly ask more of us than you do now," and that is about what you come up against in considering this question. It was the extreme desire of the Committee to find something which would alleviate the hard position of what the report would call the diagnosing physician, and it was in hopes merely that the study of leucocytosis might offer some such help that the Committee went into it as much as they have. I think

that our position in regard to it is carefully guarded. We think that due justice has not been done in the past to its possibilities of usefulness; the future may change the views which are at present propounded, but these at least deserve more careful and extended application to practice. The indications of pain as a warning, especially in conjunction with spasm and tenderness and the white count, merit more careful attention.

DR. ELLIOT: My remarks were simply directed to the regrets expressed that we could not get at the ulcer when it first perforated and that we had to operate with peritonitis, and it seemed to me that such would always be the case. And also the report deplors that we had not more data on leucocytosis. It seems to me it was pretty well proven that leucocytosis is not of any very great value in these cases.

AMERICAN MEDICAL ASSOCIATION.

FIFTY-FIRST ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., JUNE 5-8, 1900.

SECTION ON SURGERY AND ANATOMY.

(Continued from No. 25, p. 668.)

FOURTH DAY.

THE TREATMENT OF TUBERCULOSIS OF THE KNEE-JOINT.

DR. WISNER TOWNSEND, of New York, read this paper. The treatment of tuberculosis should be both constitutional and local. The former is too generally neglected; it should consist in careful attention to diet, the use of creosote and general tonics, out-of-door life, and careful attention to the general health. Rest is indicated if the exercise gives no benefit. In the local treatment the joint should be protected from every slight jar. This is best accomplished by the use of the Thomas knee-splint with a high-soled shoe for the opposite side. Plaster of Paris or silicate of soda may be sometimes used. In any measures to overcome deformity, force should be avoided. Excision in children should not be performed if any other treatment can be substituted on account of the interference with the normal growth of the limb; in adults excision should be performed in the majority of cases. Complicating abscesses should be evacuated and sinuses dissected out or treated by stimulating injections. The limb should be given complete protection for at least two years.

DR. OCHSNER, of Chicago, considers constitutional treatment of great importance. After operating on patients who come from a part of Chicago known as "Little Hell," if they return to that section of the city to live the disease often recurs in some part of the body, while if their residence is changed to "Lake View," another part of the city, which is high and dry, though also inhabited by working people, the patient usually recovers permanently.

DR. BULLITT, of Louisville, Ky., believes that protective treatment gives better results than operations in these cases.

DR. SULLIVAN, of Chicago, emphasized the importance of early diagnosis. If an early diagnosis is made and suitable general and local treatment instituted, excision will be required in but few cases.

FRACTURES OF THE PATELLA,

by DR. J. M. BARTON, of Philadelphia. The results of the methods of treatment of fracture of the patella which have been in vogue in the past are far from satisfactory, and surgeons now generally prefer to operate in case of this injury. Operation is usually deferred to the tenth day after injury on account of the lessened danger of infection, and it may well be undertaken much later. The prepatellar tissues generally get interposed between the bony fragments and it is this that gives rise to non-union. Asepsis is the point of greatest importance in successful operation; after opening the joint the prepatellar tissues are removed from between the bony fragments, clots are removed and the joint cavity is irrigated with sterile water, never with an antiseptic solution. The fragments are then united with silver wire, drainage is inserted for twenty-four hours, and a fixation dressing is applied. Rapid bony union follows.

UNREDUCED AND IRREDUCIBLE DISLOCATIONS.

DR. ARTHUR D. BEVAN, of Chicago, based his paper on three dislocations of the elbow-joint, one dislocation of the ulna at the wrist, one dorsal dislocation of the hip-joint, and three others not operated upon, and one dislocation of the astragalus. In two of the cases of backward dislocation of the elbow a fragment of bone was found in the joint, which prevented reduction. In the third case no such bony fragment was found. From his observation of these cases Bevan concludes that operation for reduction of irreducible dislocations of the elbow-joint are justifiable if carried out aseptically; there is generally a fragment of bone in the joint. He prefers double lateral incisions with no drainage; he dresses in a semiflexed position and uses passive motion early. The mortality is less than five per cent. In some very old cases it is possibly best to remove the lower end of the humerus. Within the past year, Bevan has had five cases of irreducible dislocations of the hip under observation; three of these were accompanied with fracture of the edge of the acetabulum. He considers the avoidance of drainage very important, and in one case he got union by first intention. In another case an engineer was thrown from his cab, injuring his ankle; the astragalus was twisted to an angle of ninety degrees, and remained so for three weeks; operation was performed, and a useful joint resulted. Points especially emphasized were: The necessity for the use of the x-rays in diagnosis, the frequency of accompanying fracture, and the importance of not using drainage.

DR. McLEAN, of Detroit, called attention to the great changes which had been recently made in our methods of treating fractures and dislocations. It is a matter of small importance whether a fracture or dislocation is compound or not as long as the wound of operation is aseptic.

DR. BLAKE, of Baltimore, agrees with Barton as to the necessity for perfect asepsis in operations for suture of the patella. He prefers not to use drainage and not to use the finger in the wound.

DR. TINKER, of Philadelphia, called attention to the aluminium bronze as a material for wiring the patella. This was introduced by German operators, and is now in almost universal use in Germany instead of silver wire. The advantage of this material is that it is gradually absorbed, the aluminium being acted upon

by the normal body fluids. It is composed of aluminium with a small proportion of copper to give it sufficient tensile strength. X-ray pictures have shown that the wire remains for at least a year, but German operators claim that it is eventually absorbed.

DR. OCHSNER, of Chicago, prefers to operate immediately, as the patient thus avoids loss of time. He prefers a transverse incision, and uses chromicized gut as a suture material. The patients are able to walk about three weeks after operation.

DR. MEANS, of Columbus, O., has operated upon nine cases of fracture of the patella by wiring and has had complete recoveries in all of them.

DR. WINSLOW, of Baltimore, has found it necessary to divide the triceps tendon in several cases in order to reduce dislocation of the elbow-joint; perhaps this might be avoided by using double lateral incisions, as Bevan suggested.

DR. HART, of China, has performed a number of operations for wiring the patella and for reducing dislocations. He described the difficulties encountered in restraining the unintelligent Chinese patients.

DR. MCFARLAND, of Pittsburg, does not agree that all cases of fracture of the patella should be treated by wiring.

DR. BARTON, in closing, stated that as he wears rubber gloves there can be no great disadvantage in introducing the finger into the wound. He prefers to use non-absorbable suture material, for in many cases the joint is used before complete bony union has occurred.

DR. BEVAN, in closing, stated that he does not usually advise operation for fracture of the patella, for he has obtained good results without it. In two cases treated by conservative methods the x-rays demonstrated that bony union had occurred with a functionally perfect result. He has seen one death and several cases of sepsis following this operation, and believes that no man in general practice should open any joint.

TETANUS TREATED WITH ANTITETANIC SERUM.

DR. J. D. BLAKE, of Baltimore, believes that the essentials in the treatment of tetanus are seeing patients early and using the serum freely. He has treated five consecutive cases with but one death, much better results than he formerly obtained by other methods of treatment. The amount of serum used was 50, 60 and 70 centimetres in the cases which recovered, and 40 centimetres in a case that died. The specific organism was found in but two cases.

DR. WHITMORE, of New York, mentioned nine cases which were treated at the Roosevelt Hospital by trephining and injecting the serum, with seven deaths.

DR. BLAKE, in closing, expressed his belief that the unfavorable results are usually due to the fact that the serum is not used early enough.

GROWTHS IN THE FRONTAL SINUS,

by DR. W. D. HAMILTON, of Columbus, O. The diagnosis of these cases is difficult and usually impossible until late; a mortality of 33 per cent has been given. Dr. Hamilton reported two cases of osteoma, which he removed from the frontal sinuses. In one case the bony growth removed weighed four and one-half ounces, and was exceedingly dense. The second osteoma was considerably softer and was complicated by extensive empyema.

DR. DAWBARN, of New York, advises the use of a round sewing needle, as an aid in the early diagnosis of bony growths. Malignant disease causes softening and decalcification, and in these cases the needle can be pushed in easily, which is not the case in ordinary bone tissue. It is best not to crush through the septum into the sinuses for drainage; by curving a probe a drainage tube can be inserted through the natural passages.

INJURIES OF THE SKULL AND ITS CONTENTS.

DR. W. H. EARLES, of Milwaukee, quoted Sir Ashley Cooper that "no injury to the skull is too slight to be despised or too severe to be despaired of." He believes that intervention is more frequently indicated than is generally believed in the cases of fracture of the skull, and specially if there is laceration of the soft tissues and the depression, operation is justifiable.

LAMINECTOMY FOR DISEASES AND INJURIES OF THE SPINAL CORD.

DR. SAMUEL LLOYD, of New York, reports 15 cases in which he has operated for paraplegia resulting from Pott's disease of the spine. In all, 118 operations have been performed. Operation of itself is not so dangerous, but death usually results later from the tuberculous process. In advanced cases operation is of little advantage unless the abscess is located posteriorly. Non-operative treatment should be thoroughly tried, and if not successful, operation should be performed early without waiting for ascending or descending myelitis. Pressure is usually caused by tuberculous debris. Operations in the lower part of the spine show the most favorable results. Chipault has collected 22 laminectomies for tumors, with 16 recoveries. Permanent cure is generally not to be expected, because the growths are usually malignant. In case of fracture there is no hope if the function of the cord is destroyed by pulpification. Obliteration of the deep reflexes generally contraindicates operation. We should wait until shock is passed and then operate if there is not complete destruction; if hemorrhage is producing extension of the symptoms; if there is improvement at first and the symptoms become worse later; or if there is full recovery, with paraplegia and symptoms developing later, probably from the formation of callus. The mortality of operation is now about 50 per cent., but we should give the patients what little chance there is of recovery.

DR. DAWBARN, of New York City, had no criticism to make, but only desired to emphasize the importance of early operation. He mentioned the case of a girl who fell from a window, breaking her back; two hours later operation was performed and a spicule of bone was removed, which was sticking into the cord from in front. Terrific hemorrhage was controlled by gauze packing, and good recovery resulted; he urges that these cases are in the same category as fracture of the skull, and we should not wait for operation.

DR. HOUGH, of New Bedford, Mass., reported a case in which he removed the laminae of the sixth and seventh cerebral vertebrae for injury. A slight paralysis of the right arm persists, otherwise recovery is perfect.

DR. LLOYD, in closing, emphasized the importance of early operation. We should not cease removing bone until the cord pulsates; if the dura is cyanotic

from the presence of blood clot it should be opened and evacuated.

OPERATIONS FOR INJURIES OF THE MEDIAN AND ULNAR NERVES.

Dr. B. B. EADS, of Chicago, reported one case in which he operated to free the ulnar nerves from a cicatrix and four cases in which he performed nerve suture. The results of these operations are encouraging.

RESULT OF SURGERY IN THE AGED.

Dr. J. P. TUTTLE, of New York, read this paper. Old people stand operations better than is generally supposed; Dr. Tuttle has operated on 133 patients over sixty years of age; the average age was sixty-nine. There were only three deaths, all following operations for hernia; two resulted from pneumonia and in the third case operation was performed by mistake on a patient with contracted kidney. Most of the operations were major ones; 38 of them were for hernias, 36 for hemorrhoids. Ether was used as an anesthetic in the majority of cases, chloroform was used in 13 cases and cocaine in 30 cases. Albumin in the urine is not a contraindication to operation unless there be fatty or epithelial casts. Celerity in operating is important; the mortality is less than three per cent.

Dr. DAWBARN, of New York, believes that the greatest danger is from sepsis in such operations. Old people do not fight suppurative processes well.

Dr. HART, of China, finds that a man of seventy-five in China is as old as a man of ninety-five in America. The lower classes of Chinese stand operations well, probably as a result of their simple methods of living; aristocrats do not bear operation well.

Dr. TUTTLE, in closing, stated that he agreed with Dr. Dawbarn's suggestion that the old do not bear suppurative processes well; in his cases those which suppurated required a long time for recovery.

Dr. C. VAN ZWALENBERG, of Riverside, Cal., read a paper entitled

SARCOMA OF THE INTESTINES.

Of 13,000 necropsies at the German University of Prague during fifteen years there were only 13 cases of sarcoma of the intestine, showing that the condition is relatively very rare. He reports a case in a boy of five, both of whose parents had died from carcinoma. There was a history of abdominal injury followed by declining health with no discernible cause but digestive symptoms. A rapidly growing tumor was soon felt in the abdomen; a grave prognosis was given, but exploratory operation was advised. On opening the abdomen two growths were found involving ileum and colon near the ileocecal valve; there was intussusception of three or four inches of intestine. The ascending colon, which was affected, and a part of the ileum were excised and end-to-end anastomosis by Murphy's button was performed; after twenty-four hours the patient's condition was good, and now six months later he is well and has gained seventeen pounds. A microscopic examination proved the growth a round-celled sarcoma. Dr. Zwahlenberg has tabulated 15 cases, all he was able to find in literature. Of these cases of intestinal sarcoma, 10 affected the small intestine; nine patients were males and five females; the ages ranged from one and a half to fifty-one years; he finds that stenosis of the intestine, which is com-

monly reported as a symptom of the affection, is rarely present; on the contrary there is general dilatation; the diagnosis is difficult and resection is the only proper treatment.

THE ADVANTAGES OF RETAINED CATHETER.

Dr. J. R. EASTMAN, of Indianapolis, Ind., finds retained catheter often the best method of dealing with cases of retention of urine, particularly if the urethra is sensitive. He advises using a large soft-rubber catheter, which is retained with remarkable tolerance. In one case of traumatic stricture of thirteen years' standing with urinary fistula the catheter was retained without disturbance; the fistula healed permanently in twelve days; in another case the catheter was retained seventeen days; in a third case of perineal fistula it was retained sixty-five days with occasional removal and cleansing. The dangers of cystitis from retained catheter have been much overestimated.

Dr. E. W. HOLMES, of Philadelphia, agrees with Dr. Eastman as to the value of retained catheter. He reported a case of suprapubic cystotomy for the removal of vesical calculus in which a soft catheter was retained for twenty-one days.

Dr. LORD, of Omaha, Neb., believes that the retained catheter is contraindicated in case infective processes are present.

Dr. GUTERAS, of New York, always uses the retained catheter for a few days after external urethrotomy if the urethra is tortuous. He has used the catheter in such cases as long as two weeks. It may be used with advantage in case of spasmodic stricture, acute prostatitis, or seminal vesiculitis; it is also useful in cases in which the patient is being broken into catheter life if there is spasm of the urethra with resulting trauma on passing the catheter, but in these cases the catheter may be plugged until there is a feeling of distention of the bladder. He has also used retained catheter in severe febrile conditions.

Dr. EASTMAN, in closing, noted that it is often easy to pass a large catheter in cases where it is impossible to pass a small one.

NEPHRO-URETEROCYSTEOTOMY.

Dr. HOWARD A. KELLY, of Baltimore, reports a case of tuberculosis of the left kidney, ureter and the adjacent portion of the bladder, in which he removed kidney, ureter and the diseased part of the bladder wall; the specimen was demonstrated. The operation was performed through two incisions; one in the loin, the other median. The patient made a good recovery from the operation, but from a mistake of a house physician in charge, the bladder became distended and ruptured, causing fatal peritonitis. Dr. Kelly believes that it is possible to do far more extensive operations for tuberculous processes than has been supposed; removal of the entire disease is essential.

Dr. E. W. HOLMES, of Philadelphia, gave an abstract of a paper on the

ANATOMY OF HANGING,

which was reported in full to the Section on Neurology and Medical Jurisprudence.

Dr. McLEAN, of Detroit, expressed the belief that from a humanitarian standpoint we are not justified in executing fellow human beings, no matter what their crime may have been.

(To be continued).

Recent Literature.

The Diseases of Children, Medical and Surgical. By HENRY ASHBY, M.D. (Lond.), F.R.C.P., Physician to the General Hospital for Sick Children, Manchester; Lecturer and Examiner in Diseases of Children in the Victoria University; Lecturer in Physiology in the Owens College and in the Liverpool School of Medicine, and G. A. WRIGHT, B.A. and M.B. (Oxon.), F.R.C.S. (Eng.), Assistant Surgeon to the Manchester Royal Infirmary, and Surgeon to the Children's Hospital; Lecturer on Practical Surgery in the Owens College. Fourth edition. Edited for American students by WILLIAM PERRY NORTHROP, A.M., M.D., Professor of Pediatrics, the University and Bellevue Hospital Medical College; Attending Physician New York Foundling, William Parker and Presbyterian Hospitals. London and Bombay: Longmans, Green & Co. 1900.

This now deservedly well-known work on children has, in its fourth edition, added to its text about 60 pages; 25 new photographs and 14 plates have also been added. The surgical part of the work has been made still more attractive by a number of excellent skiagrams. It would seem that in the differential diagnosis of meningitis mention should at least be made of lumbar puncture, but we fail to find such mention anywhere. It would seem that the Widal reaction should deserve more than the very incomplete reference which is made to it. The American editor, Dr. William P. Northrop, has thought best to leave the body of the book intact, stating that the same disease differs but little in its course in America and England. He, therefore, notes such differences in theory and in treatment as would seem to bring the book into accord with the present American practice. He has done this by means of the appendix, carefully referring supplementary matter to its proper connection in the main work by page reference and by additions to the index. The formula on page 865 have been entirely rewritten to conform to the United States Pharmacopœia.

Our Baby. For Mothers and Nurses. By MRS. LANGTON HEWER, diplomée Obstetrical Society. London: late hospital ward sister; author of "Antiseptics: a Hand-Book for Nurses." Sixth edition, revised. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. 1899.

Although this book has been carefully written it might be one which would do a great deal of harm in the hands of an inexperienced person. Thus it is manifest that the treatment of diarrhea and vomiting should not be placed in the hands of a nurse or mother, nor should such drugs as calomel and bromide of potash be ordered by any one but a physician. These are only instances of what may be met with throughout the whole book.

FOREST SANATORIUMS FOR THE TUBERCULOUS.—According to the *Philadelphia Medical Journal*, the Commissioner of Forestry of Pennsylvania is in favor of throwing open to consumptives the forest lands owned by the State. They are the property of the people and were pledged to the maintenance of public health.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 28, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE SCIENTIFIC PHYSICIAN.

THE development of medicine in America has been erratic in many respects, but in none more so than in the peculiar stress laid from time to time on certain phases of progress. Without entering into details regarding this sufficiently self-evident fact, it is clear that the present wave of enthusiasm is concerning itself with what is popularly known as "scientific research." This is due, no doubt, in great measure to natural and inevitable tendencies, and also to the influence of certain men of strong intellect and fixed convictions, who have consistently maintained that the laboratory side of medical science must be cultivated as a foundation for the whole superstructure of more or less empirical clinical facts. As we have repeatedly found occasion to say in these columns, this tendency, which is now definitely materialized in the form of innumerable laboratories, stands as the most important advance of the past few years. Upon its continuance and growth must depend the future of medicine as a science worthy of cultivation by intelligent men. This general proposition has been discussed at length by Dr. A. T. Cabot in his annual address before the Massachusetts Medical Society, recently published in this JOURNAL.

It is of interest to an unprejudiced onlooker to observe the effect of this zeal for accurate observation and experiment on the practice of medicine at large. In the first place, it has unquestionably tended toward the establishment of more systematic methods throughout the whole field of medical practice. Each and every man who now practises medicine is feeling the effects of the general movement, however far removed he may be from the centres of laboratory research, and however little he may himself have employed so-called laboratory methods. In the second place, and it is to this that we desire to call special attention, the laboratory, and particularly the use of the word "scientific" in a narrow sense as applied to laboratory work, has done much to arouse prejudice and establish false standards. By degrees there has grown up a distinction, which is now heard on every hand, be-

tween what is termed "scientific medicine," and "practical medicine," naturally with the implication that practical medicine as personified in the practitioner is not scientific. In other words "scientific" as popularly used in medical writing and discourse demands a laboratory and the accessories which a laboratory implies, whereas the man who is examining his patients from day to day in most painstaking and accurate fashion is looked upon perhaps as a faithful and conscientious practitioner, but not as a scientific investigator. So deeply has the laboratory impressed itself upon the uncritical thought of the time, that he who often aimlessly looks through a microscope, or with narrow vision describes a lesion, is placed upon a pedestal as a man of "scientific" tendencies, while his colleague who faithfully describes a symptom is denied any such distinction.

The reason for this anomalous state of affairs is certainly not far to seek. It lies in the fact that accuracy and hence knowledge have, in great measure, come by way of the laboratory. The insistence on the necessity of exact observation and description has certainly not had its origin with any one set of investigators in the general field of medicine. The laboratory worker deals with problems of the most complex sort, and on the other hand with facts which may be easily and accurately described. His claim to distinction as a scientific man does not, however, lie in his description of isolated facts, but wholly upon his attitude toward the problems, the solution of which depends upon the proper interpretation of those facts. Certainly nothing is simpler than to go into a laboratory and to describe at any length what one sees under a microscope. This is, however, not science, however often the results may masquerade as such, nor does the mere accomplishment of such work constitute a scientific man. But to go into a laboratory, to study facts laboriously, and then to appreciate clearly the meaning of those facts for the sum total of knowledge and to make generalizations therefrom is, properly speaking, "scientific." Men who do this are rare, whether within or without laboratories. When we turn to the great mass of empirical facts which constitute the body of what we speak of as clinical medicine we see why progress has been slow. Until the laboratory came to the rescue there was no adequate standard of classification; the facts themselves were extremely difficult of interpretation, and in consequence a certain superficiality of observation was developed, which is still the bane of much of the work on the observation of clinical phenomena. This the laboratory, with its peculiar methods, has certainly gone far to rectify, and the natural result has been that in the popular mind all that is accurate and "scientific" has come to be regarded as a product of laboratory methods. Hence has arisen the unfortunate distinction, which has at times created a certain amount of personal feeling between men equally earnest in the pursuit of truth, between "scientific" and "practical" medicine. Clearly the difficulty is one

of words merely, arising from a too narrow conception of the significance of the term "scientific." The kind of facts with which we deal evidently has nothing to do with the definition. A cell, as seen under a microscope, is no more an object of scientific investigation than a cough or a chill. Whether we are properly to be called scientific or not depends wholly upon the methods of investigation we employ. What we need to do is to cultivate the scientific method whether our work lies in the laboratory or in the observation of the most commonplace diseases. If this be faithfully done we may be sure that the distinction now so often and so superficially made between the scientific and the practical physician will be laid at rest forever. The first definition of "scientific" as given in the Century Dictionary is: "Concerned with the acquisition of accurate and systematic knowledge of principles by observation and deduction: as *scientific* investigation." Evidently the laboratory can claim no exclusive privilege in the acquisition of knowledge by this means, however much it may have furthered the general principle involved.

In Dr. Wm. H. Welch's recent brief remarks at the annual dinner of the Massachusetts Medical Society, he laid stress upon the fact that the time had come when the same intellectual pleasure might be obtained from study at the bedside as from study in the laboratory, that the solidarity of the whole medical profession towards the one aim of the prevention and cure of disease was much to be desired, and that the present distinction between the scientific and practical physician was wholly false. It is certainly very much to be hoped that the superficial lines of demarcation which the progress of medicine in this country have temporarily rendered inevitable may in the near future be merged in a more reasonable conception which will clearly recognize the fact that the "scientific" physician is he who observes facts in a scientific manner, under whatever form those facts may be presented, and not he alone who observes a special series of facts in a special way. Unquestionably the next advance will be, as Dr. Welch suggested, a united body of men all working toward the same end by the same exact methods, whether the field of investigation be such as appeals to the laboratory worker or to the practitioner. The clinician will come to respect more and more the work of the laboratory, and the laboratory student will likewise come to see that the clinician is using precisely the same methods that he employs, and to similar ends. Petty antagonisms will then, no doubt, give place to an attitude of complete mutual helpfulness.

ADJUSTABLE FURNITURE FOR SCHOOLS.

In our issue of June 21, we commented editorially on the recent agitation regarding improved furniture for Boston's schools. We at that time made the statement that the accomplishment of any far-reaching reform must rest with the school authorities. There has just come

into our hands an order, signed by the Secretary of the Boston School Committee, which reads: "Ordered, that hereafter all school furniture purchased for new permanent schoolhouses shall be adjustable." This evidently does not imply that desks and chairs now in use will be removed to make way for those of improved pattern, but it nevertheless meets the chief requirement that as the school system expands in the future new buildings will be properly equipped. This reform has been long in coming, but now that it has come it is not likely that it will fail of execution, and the medical profession may well take to itself a goodly share of the credit for its ultimate accomplishment.

MEDICAL NOTES.

RECENT DEATHS IN EUROPE. — The following well-known physicians have recently died: George Edward Williamson, F.R.C.S. He had for many years devoted himself to ophthalmology, and was held in high esteem by his colleagues. Thomas Fitz-Patrick, M.D., M.A. (Dublin), M.D. (Cantab.), M.R.C.P. (Lond.). He practised medicine in London, and beyond his talent as a physician was a man of unusual general culture. Julius Althaus, M.D. (Berlin), M.R.C.P. (Lond.). Dr. Althaus was a voluminous writer, chiefly on electrical treatment and disorders of the nervous system. Dr. Heinrich Laudahn, director of the Lindenburg Asylum, Cologne. Dr. Leopold Grossmann, the *doyen* of Hungarian ophthalmologists, at the age of seventy-nine years. Dr. Korsakoff, professor of mental diseases in the University of Moscow.

PLAGUE LABORATORIES IN GERMANY. — The Government of Baden, it is stated by the *British Medical Journal* proposes to establish plague laboratories at Freiburg and Heidelberg for the diagnosis of any suspicious cases, and for the prosecution of researches as to the cause of the disease. The laboratories are to be in connection with the hygienic institutions of both the universities. The cost of each is estimated at 10,000 marks and the equipment at 8,000 marks.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 27, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 79, scarlatina 37, measles 63, typhoid fever 22.

WM. H. WELCH, M.D., LL.D. — The honorary degree of LL.D. was conferred upon Prof. William H. Welch, of the Johns Hopkins University, by Harvard University at its Annual Commencement, on June 27th. The degree was conferred by President Eliot with the following words: "William Henry Welch, professor of pathology in Johns Hopkins University, who holds first place in the medical profession of the United States as teacher, pathologist, and organizer of medical progress."

APPOINTMENT OF DR. FRANKLIN DEXTER. — Franklin Dexter, M.D., has been appointed associate professor of anatomy at Harvard Medical School.

NEW YORK.

OFFICERS OF THE NEW YORK COUNTY MEDICAL ASSOCIATION. — At the annual election of the New York County Medical Association, held June 18th, the following officers were elected: President, Dr. Parker Syms; First Vice-President, Dr. J. Riddle Goffe; Second Vice-President, Dr. Emil Mayer; Recording Secretary, Dr. Ogden C. Ludlow; Corresponding and Statistical Secretary, Dr. J. W. Draper Maury; Treasurer, Dr. Charles E. Denison; Member of the Executive Committee, Dr. F. H. Wiggin.

REINSTATEMENT OF DR. FRANCIS M. BANTA. — Dr. Francis M. Banta has resumed duty as a medical officer of the Fire Department. Dr. Banta, who was appointed by the Republican Fire Board, in place of a physician appointed by the previous Democratic Board, was in turn removed by the present Fire Commissioner, Scamell. He applied to the courts, and the Supreme Court ordered his reinstatement. An appeal was taken, and the Appellate Division of the court affirmed the finding of the lower tribunal.

CHRISTIAN SCIENTISTS AS AN INSURANCE RISK. — At Buffalo recently the Supreme Lodge of the Knights of Honor, one of the largest of the mutual benefit societies, which has branches in many parts of the country, decided after a full discussion that Christian Scientists and other faith curists, because of their rejection of the aid of medical science when ill, are the most dangerous of risks from an insurance standpoint, and that hereafter they shall not be admitted to membership in the order.

A GIFT TO THE PRESBYTERIAN HOSPITAL. — At the last meeting of the Board of Managers of the Presbyterian Hospital it was announced that a gift of \$200,000 had been received from a donor who desired his name withheld, for the erection of a new building for the accommodation of the house staff and nurses. By this arrangement room will be made for one hundred additional beds in the present buildings, thus increasing the capacity of the hospital one-third.

INSANITY AND MURDER. — Mrs. Grace Ramsey, who murdered her husband by cutting his throat while he was asleep in bed a year ago, and who was acquitted on the ground of insanity and sent to the State Hospital for Insane Criminals at Matteawan, has now been declared sane and set at liberty. Her insanity was regarded as being due to pregnancy, and during her confinement in the hospital she gave birth to a child.

ALUMNI ASSOCIATION OF ST. VINCENT'S HOSPITAL. — The Alumni Association of St. Vincent's Hospital was organized on June 18th. The officers chosen were: President, Dr. Charles H. Lewis; Vice-President, Dr. Charles L. Weeks; Secretary, Dr. Joseph A. Dillon.

Obituary.

BENJAMIN DOUGLAS HOWARD, M.D.

DR. BENJAMIN DOUGLAS HOWARD died at the summer residence of Dr. Andrew H. Smith, at Elberon, N. J., on June 21st, at the age of sixty-three. He was born in England, and was graduated from the College of Physicians and Surgeons, New York, in 1858. He served with distinction in the Medical Department of the United States Army during a considerable portion of the Civil War, and was especially identified with the antiseptic treatment of gunshot wounds of the chest by hermetical sealing. He also invented an army ambulance wagon which was awarded the first prize at the Paris International Exposition. After studying for some time abroad he returned to New York to practise, and was appointed professor of operative surgery in the Medical Department of the University of the City of New York. At various times he also held the position of professor of surgery in the Long Island College Hospital, the University of Vermont, and the Medical College at Cincinnati. He was also a Fellow of the Royal College of Surgeons, London. The last years of his life were spent in prison investigation. Drs. Andrew H. Smith and D. B. St. John Roosa are his literary executors.

From typhoid fever New York 12, Boston, Baltimore, Pittsburgh, Providence and Charleston 2 each, Fall River and Lawrence 1 each. From whooping-cough New York 10, Boston 4, Baltimore 3, Washington 2, Pittsburg and Fall River 1 each. From scarlet fever New York 9, Boston and Salem 2 each, Worcester 1. From cerebrospinal meningitis New York 4, Worcester 3, Baltimore, Lynn and Gloucester 1 each. From erysipelas New York 7, Boston 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending June 2d, the death-rate was 17.7. Deaths reported 3,951; acute diseases of the respiratory organs (London) 266, measles 142, whooping-cough 115, diphtheria 77, diarrhea 34, scarlet fever 29, fever 26.

The death-rates ranged from 11.0 in Gateshead to 25.5 in Plymouth: Birmingham 19.3, Bradford 18.4, Cardiff 15.6, Hull 14.6, Leeds 19.1, Liverpool 21.4, London 17.0, Manchester 21.5, Newcastle-on-Tyne 17.6, Nottingham 15.3, Portsmouth 14.2, Salford 21.0, Sheffield 21.7. Sunderland 18.0, West Ham 15.4.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending June 9th, the death-rate was 16.8. Deaths reported 3,748; acute diseases of the respiratory organs (London) 268, measles 128, whooping-cough 111, diphtheria 65, scarlet fever 30, diarrhea 27, fever 24, small-pox (Oldham) 1.

The death-rates ranged from 8.0 in Birkenhead to 24.8 in Liverpool: Bradford 15.9, Cardiff 15.0, Gateshead 15.3, Huddersfield 17.5, Leeds 18.0, London 15.9, Manchester 23.1, Newcastle-on-Tyne 17.8, Nottingham 18.3, Portsmouth 13.4, Sheffield 19.9, Swansea 11.4, West Ham 14.1.

METEOROLOGICAL RECORD

For the week ending June 16th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, JUNE 16, 1900.

APPOINTMENTS.

The following appointments in the Tufts College Medical School have been made by the Trustees: JOHN L. HILDRETH, M.D., LL.D., professor of clinical medicine, emeritus; HORACE D. ARNOLD, A.B., M.D., professor of clinical medicine; GEORGE VAN NESS DEARBORN, A.B., Ph.D., M.D., assistant professor of physiology; HOWARD S. DEARING, A.M., M.D., assistant professor of clinical medicine; HERBERT WARREN WHITE, M.D., assistant professor of theory and practice of medicine; E. CHANNING STOWELL, A.B., M.D., assistant professor of children's diseases; GEORGE W. KAAH, M.D., assistant professor of clinical gynecology.

RECENT DEATH.

WILLIAM FRANCIS HOWARD, M.D., M.M.S.S., died in Lawrence, June 15, 1900, aged thirty-one years.

BOOKS AND PAMPHLETS RECEIVED.

Catalogue of the Medical and Dental Departments of the National University, Washington, D. C., for 1900-1901.

Suggestions to Medical Writers. By George M. Gould, A.M., M.D. Philadelphia: Philadelphia Medical Publishing Co. 1900.

The Duty of State and Municipality in the Care of Pulmonary Tuberculosis Among the Poor. By Edward O. Otis, M.D., Boston, Mass. Reprint. 1900.

Food for the Sick and How to Prepare It, with a chapter on Food for the Baby. By Edwin Charles French, M.D. Louisville: John P. Morton & Co. 1900.

Y., 108; the effects of dust on the upper respiratory tract, Langmaid, S. W., 110; the dust problem and asphalt paving, 247.
- Dyer, I.** Blastomycetic dermatitis and its relation to yaws, 11.
- Dysentery.** Bacteriology of acute tropical dysentery, Flexner, S., 223.
- Ears.** A brief report of a case of cerebral abscess of otitic origin; operation; death, Richards, G. L., 159.
- Editorials.** The pollution of water supplies, 20; the Boston Floating Hospital, 21; the Fourth of July and tetanus, 21; the Harvard Medical Alumni Association, 44; the penalties of the Fourth of July, 45; old age as a cause of death, 46; the medical situation in China, 63; British medical arrangements in South Africa, 69; the accidents of summer, 95; the need of practical laboratory methods of instruction, 95; the sanitation of Boston schools, 96; progress in the treatment of insanity, 120; post-graduate study, 121; medical literature, 144; the Red Cross in China, 145; American routine; German originality, 169; oral sepsis a possible cause of disease, 199; the intradural injection of cocaine, 193; State health inspectors, 194; Dr. Elliston's address before the British Medical Association, 220; hysteria an organic disease, 221; penalties of progress, 214; theory and practice, 277; as to professional visits, 272; the Galveston disaster, 273; another argument for cremation, 301; solitary imprisonment, 301; the hygiene of churches, 328; the Babinski phenomenon, 329; the opening of the medical schools, 325; the New York State Hospital for consumptives, 353; specialism in medicine, 379; plague, 410; annual report of the Boston City Hospital, 411; physicians as speakers, 433; the annual report of the Surgeon General of the Army, 434; sanatoria for pulmonary tuberculosis, 461; recent researches in yellow fever, 462; Henry Jacob Bigelow, 485; a new employment for women, 486; intradural injections of cocaine for surgical anesthesia, 509; prizes as a stimulus to research, 510; newspaper medicine, 537; the United States tax on legacies to educational, charitable and religious organizations, 538; Thanksgiving Day, 565; the etiology of beri-beri, 565; oysters and disease, 584; revision of charter of city of New York, 589; the Third Pan-American Medical Congress, 589; the proposed garbage plant on Long Island, Boston Harbor, 612; the proposed change in the control and management of Bellevue Hospital, 613; the third Pan-American Medical Congress, 613; peripheral neuritis due to arsenic in beer, 614; twentieth century cerebral physiology, 642; the army bill and the Medical Department, 643; newspaper exaggeration, 644.
- Edson, C. E.** The importance of rest in pulmonary tuberculosis, 15.
- Education.** Harvard Medical Alumni Association, 36, 44; the need of practical laboratory methods of instruction, 95; the sanitation of Boston schools, 96; post-graduate study, 121; a method of teaching practical medicine, Harrington, T. F., 256; the opening of the medical schools, 352; the endowment of professional schools, Ross, J. H., 436; classical education for medical students, 464.
- Elevator Disease,** 513.
- Elgin, F. W.** Influence of temperature on vaccine virus, 561.
- Elliston, W. A.** Some incidents in the evolution of the modern physician, 220.
- Enebske, C. J.** Chronic diffuse interstitial nephritis, 513, 528.
- Enteric Fever in childhood,** Blackader, A. D., 458.
- Epidemic.** Report of the committee to define what constitutes an epidemic, Lee, B., 586.
- Ernst, H. C.** The transportation of disease by dust, 107, 116; the progress of medicine, 130.
- Examining Board.** The true function of the State Medical Examining Board, Memminger, A., 88.
- Eye.** Power of the eye, 196; recent progress in ophthalmology, Standish, M., and Hall, W. D., 342, 369; lesion of chiasm; temporal hemiopia, optic atrophy; probable pituitary tumor, with gigantism and defective development, Lord, S. A., 365; eye strain as a cause of gastro-intestinal neuroses, Smithwick, M. P., 444, 453; a case of alexia, mind blindness, etc., with autopsy, Jack, E. E., 577.
- Farenholt, A.** Three cases of gunshot wounds, 503.
- Farlow, J. W.** A case of ozena of probably sphenoidal origin, 66.
- Faure, J. L.** Surgery of cancer, 325.
- Fear.** A case of morbid fear, Courtney, J. W., 5.
- Fibroids.** Remarks on the surgery of uterine fibroids, with especial reference to the importance of early removal in the young, Richardson, M. H., 1, 12; parturition complicated with suppurating fibroids, Stevens, E. H., 56, 60.
- Finlen** treatment of lupus, 171.
- Fisher, E. D.** Address before American Neurological Association, 264.
- Flexner, S.** Bacteriology of acute tropical dysentery, 223.
- Floating Hospital.** The Boston Floating Hospital, 21.
- Food.** Milk; its production, its care, its use, Kotch, T. M., 49; the modification of milk in milk laboratories, Kotch, T. M., 47, 47; breast feeding, Worcester, A., 361, 371, home modification of milk, Townsend, C. W., 369, 372; a new test meal, Austin, A. E., 497.
- Foramen Ovale.** Case of patent foramen ovale in advanced life, Worcester, W. L., 312.
- Foreheimer, F.** Acute dilatation of the heart in influenza of children, 135.
- Forlyce, J. A.** Endothelioma of the skin, developing in the scar tissue of lupus vulgaris, angiosarcoma of the skin, 19.
- Fourth of July and tetanus,** 21; the penalties of the Fourth of July, 45.
- Fowler, G. H.** Spinal analgesia in general surgery, 626.
- Fractures.** Massage and movement in the treatment of fractures, Champoiniere, L., 217; radiography in the study of fractures and of luxations, Mannoury, G., 270, progress in the treatment of fractures since the introduction of the Röntgen rays, Bergmann, E., von, 271; the study of the x ray plates of one hundred and forty cases of fracture of the lower end of the radius, Codman, E. A., 305, 318; subperiosteal fractures, Cotton, F. J., 583, 589.
- Freeman, R. G.** Nephritis in influenza in children, 431.
- Freiberg, A. H.** Cellulitis as material for flat foot supports, 471.
- Friedenthal, W.** In what relation does occupation stand to tuberculosis? 15.
- Fruitnight, J. H.** A fatal post-otitic cerebral abscess with amnesic aphasia, 458.
- Fuller, E.** Anteroposterior subdivision of the bladder, an important anomaly, 347.
- Fuller, G. W.** Report of the committee on pollution of water supply, 562.
- Gage, H.** Results of the operative treatment of cancer of the breast, 203; traumatic joints, 309.
- Galveston Disaster,** 273.
- Garland, G. M.** Report of the Committee on the Harvard Medical School, 37.
- Generative System.** Remarks on the surgery of uterine fibroids, with especial reference to the importance of early removal in the young, Richardson, M. H., 1, 12; cysts in the abdominal wall structurally identical with ovarian cysts, Homans, J., 34; general remarks on the pathology and symptomatology of acute pelvic suppurative processes in the female and their treatment by posterior colpotomy, Cunston, C. G., 51, 59; glandular hypospadias, two urethras, one extending to the bladder, the other two and one-half inches long and terminating in a blind pouch, Stinson, J. C., 55; the mortality of hysterectomy for fibroids, Davenport, F. H., 181, 199; hysterectomy for myoma in America, Cushing, E. W., 183, 190; a case of parovarian cyst with twist of the pedicle occurring during the fourth month of pregnancy, operation, recovery, normal delivery at term, Lund, F. B., 208; two cases of abnormal sexual development, Sears, G. G., 232, 233; a critical review of thirty cases of pyosalpinx, Whiteside, G. S., and Walton, W. J., 310; prostatic deformities due to loss of tissue, Guiteras, R., 343; primary cancer of the prostate, King, E. E., 343; the evolution of my technique in the treatment of fibroid uterine growths, Kelly, H. A., 375; an appreciation of Kelly's method of removing fibroids of the uterus, Smith, A. L., 375; intra-abdominal amputation of the uterus; a modification of hysterectomy, Davenport, F. H., 375; the relationship between dysmenorrhea and appendicitis, McLaren, A., 376; the internal secretion of the ovary, Johnstone, A. J., 377; technique, indications and ultimate results of suturing the round ligaments to the vaginal walls for retroversions and flexions of the uterus, Vineberg, H. N., 377; recent progress in genito-urinary surgery, Watson, F. S., and Thorndike, J., 425; the management of abdominal testicular ectopia associated with inguinal hernia, Powers, C. A., 475; vaginal versus abdominal hysterectomy, Walker, H. O., 607; cancer of the uterus, Sutton, R. S., 608; remarks upon questions arising during the removal of fibroids, with especial reference to the technique of the operation, Richardson, M. H., 619, 636.
- Giddings, W. P.** A case of volvulus complicated by peritonitis; operation; recovery, 160.
- Goitre.** Exophthalmic goitre, Osborne, O. T., 17.
- Goidan, S. O.** Intrapinal cocaineization from the anesthetist's standpoint, 638.
- Goldthwait, J. E.** Knee-joint surgery for non-tubercular conditions, 286.
- Gorgas, W. C.** Vital statistics of Havana, 568.
- Gont.** Pathogeny of gout, Le Gendre, P., 218.
- Grant, J.** Address before the New York State Medical Association, 453.
- Green, C. M.** The value of the hot-water immersion bath in the treatment of threatening puerperal eclampsia, 624, 635.
- Greenleaf, R. W.** The psychic factor in disease, 155, 166.
- Guiteras, R.** Prostatic deformities due to loss of tissue, 348.
- Gunshot Wounds.** Gunshot injuries by the riles of reduced calibre, LaGarde, L. A., 439; three cases of gunshot wounds, Farnholt, A., 503; general remarks on gunshot wounds of 1898 and 1899, 512.
- Gynecology.** Recent progress in gynecology, Reynolds, E., 258; an operation for primary vaginal carcinoma, applicable also to cancer of the rectum in women, Pryor, W. P., 373; the remote results of conservative operations on the ovaries and tubes, Burrage, W. L., 374; the evolution of my technique in the treatment of fibroid uterine growths, Kelly, H. A., 375; an appreciation of Kelly's method of removing fibroids of the uterus, Smith, A. L., 375; intra-abdominal amputation of the uterus; a modification of hysterectomy, Davenport, F. H., 375; the relationship between dysmenorrhea and appendicitis, McLaren, A., 376; the internal secretion of the ovary, Johnstone, A. J., 377; technique, indications and ultimate results of suturing the round ligaments to the vaginal walls for retroversions and flexions of the uterus, Vineberg, H. N., 377; vaginal versus abdominal hysterectomy, Walker, H. O., 607.
- Hair.** Loss of hair, Jackson, G. T., 7; an improvement in instrument and method for removing superfluous hair by the electric method, Pomeroy, H. S., 527.
- Hand.** A case of contracting scar of the palm of the hand remedied by a flap from the abdomen, Briggs, F. M., 422.
- Hanley, J. J.** An impostor, 276.
- Harrington, G. F.** Notes on dermatitis venenata, 227.
- Harrington, T. F.** A method of teaching practical medicine, 266.

- Harris, M. L.** A new electrocystoscope, 347; a cystoscope for the catheterization of both ureters, 347.
- Harris, R. O.** Autopsies and physical examinations, 420.
- Hartzell, M. B.** Malignant diseases of the skin, their etiology and pathology, 9; cutaneous diseases accompanying diabetes, 16.
- Hatch, E. S.** Tendon suture, 256, 264.
- Havana.** Vital statistics of Havana, Gorgas, W. C., 568.
- Heart.** A needle in the heart, 275.
- Hematemesis.** Post-operative hematemesis, Winslow, K., 313.
- Hernia.** The radical cure of hernia, Warren, J. C., 249, 264.
- Heroin.** A contribution to the therapeutic action of heroin, Lazarus, B., 600.
- Herold, H. C. H.** Newark's diphtheria antitoxin plant, 561.
- Herrick, J. B.** Diagnosis of diabetes, 16.
- Hewes, H. F.** Report upon physiological chemistry, 234; achlorhydria; its effects and their treatment, 447, 452; observations upon the symptoms and treatment of hyperacidity of the stomach, 550, 556.
- Higgins, F. A.** Report on progress in obstetrics, 631.
- Hip.** Congenital dislocation of the hip joint, Bradford, E. H., 415.
- Hoffman, F. L.** The practical use of vital statistics, 653.
- Homans, J.** Cysts in the abdominal wall structurally identical with ovarian cysts, 34.
- Hopkins, F. E.** Secondary hemorrhage after the use of suprarenal extract, 65.
- Horlbeck, H. B.** Report of the committee on the etiology of yellow fever, 561.
- Hospitals.** The Boston Floating Hospital, 21; hospital statistics, 247.
- Hydrotherapy** in pneumonia, Baruch, S., 389.
- Hygiene, Health and Boards of Health.** The pollution of water supplies, 20; the sanitation of Boston schools, 96; State health inspectors, 194; the hygiene of churches, 328; public health laboratories, Smith, T., 491; ear sanitation, Woodbridge, S. H., 659; new quarantine methods and changes which are called for in marine sanitation, Doty, A. H., 560; report of the committee on cause and prevention of infectious diseases, Suiter, A. W., 560; etiology of yellow fever, Reed, W., 560; report of the committee on the etiology of yellow fever, Horlbeck, H. B., 561; influence of temperature on vaccine virus, Elgin, F. W., 561; Newark's diphtheria antitoxin plant, Herold, H. C. H., 561; presidential address, Bryce, P. H., 561; report of the committee on the pollution of water supply, Fuller, G. W., 562; teaching of hygiene and granting of degrees of doctor of public health, Johnston, W., 562; vital statistics of Havana, Gorgas, W. C., 568; report of the committee on disinfection, Robinson, F. C., 585; report of the committee to define what constitutes an epidemic, Lee, B., 586; report of the committee on national leper home, Bracken, H. H., 586; report of the committee on animal diseases and animal food, Salmon, D. E., 587; the proposed garbage plant on Long Island, Boston Harbor, 612.
- Hysteria** an organic disease, 221.
- Imposter,** Hanley, J. J., 276.
- Imprisonment.** Solitary imprisonment, 301.
- Infectious Diseases.** Report of the committee on cause and prevention of infectious diseases, Suiter, A. W., 560.
- Insolation** catastrophe at Aldershot, 71.
- Instruments and Appliances.** The use of the angiotribe, Davenport, F. H., 4, 11; the modern urethroscope, Otis, W. K., 321; the best method for obtaining urine direct from the ureters for diagnostic purposes, Brown, F. T., 346; a new electrocystoscope, Harris, M. L., 347; a cystoscope for the catheterization of both ureters, Harris, M. L., 347; a ureter cystoscope (for male or female) built on a new model, Lewis, B., 347; a new spinal jacket, Tracy, E. A., 522; an improvement in instrument and method for removing superfluous hair by the electric method, Pomeroy, H. S., 527; a modification of the old Sims needle forceps, Burrage, W. L., 672.
- Jack, E. E.** A case of alexia, mind blindness, etc., with autopsy, 577.
- Jackson, G. T.** Loss of hair, 7.
- Jeffries, B. J.** Address before the Suffolk District Medical Society, 530.
- Johnston, S.** Address before the American Laryngological Association, 63.
- Johnston, W.** Teaching of hygiene and granting of degrees of doctor of public health, 562.
- Johnstone, A. J.** The internal secretion of the ovary, 377.
- Joints.** Traumatic joints, Gage, H., 309; to what extent does "rheumatic and gouty diathesis" enter into traumatic joints (sprains and bruises), septic and gonorrhoeal joints, acute articular rheumatism, neuropathic joints, arthritic deformans (osteoid, rheumatoid), as an etiological factor? What is the scientific basis for such a term? Porter, W. H., 391; septic and gonorrhoea joints, Porter, O. A., 401; neuropathic joints, Lord, S. A., 406; congenital dislocation of the hip joint, Bradford, E. H., 415.
- Jounesco, T.** Surgical treatment of hydatid cysts of the liver, 325.
- Joslin, E. P.** Recent progress in therapeutics, 477, 504.
- Kelly, H. A.** The evolution of my technique in the treatment of fibroid uterine growths, 375.
- Keyes, E. L.** The therapeutics of urotropin, 347.
- King, E. E.** Primary cancer of the prostate, 348.
- Kirkes'** physiology, a reply, 569.
- Klitledge, T.** A case of Casarean section, 35.
- Klotz, H. G.** Syphilitic lesions of the "wheat" type, 10.
- Knapf, P. C.** Recent progress in neurology, 89, 113.
- Knee.** Knee-joint surgery for non-tubercular conditions, Goldthwait, J. E., 285.
- Koplik, H.** Myocarditis in infancy and childhood, 93; the ambulatory and hospital management of the gastro-intestinal derangements of infancy in the summer months among the poor of large cities, 429.
- Laboratory.** The need of practical laboratory methods of instruction, 95; public health laboratories, Smith, T., 491.
- La Garde, L. A.** Gunshot injuries by the rifles of reduced calibre, 439.
- Langmaid, S. W.** The effects of dust on the upper respiratory tract, 110, 116.
- Lannelongue, M.** Farewell address before the Thirteenth International Medical Congress, 349.
- Larynx.** Address before the American Laryngological Association, Johnston, S., 63; the early diagnosis of laryngeal cancer and the treatment, Mackenzie, J. N., 64; statistics relating to the treatment of cancer by the different methods, Delavan, D. B., 65.
- Lazarus, B.** A contribution to the therapeutic action of heroin, 600.
- Learned, J. B.** "The new method of inducing sleep without drugs." One hundred dollar prize, 47.
- Lee, B.** Report of the committee to define what constitutes an epidemic, 586.
- Legal Medicine.** Arsenic in manufactures, 413; the coroner system in the United States at the close of the nineteenth century, Abbott, S. W., 418; autopsies and physical examinations, Harris, R. O., 420; the co-operation of the medical and legal professions, Sanderson, G. A., 499, 506; criminal neglect; report of a case, Buck, A. W., 502, 508; the duties of the medical examiner in Massachusetts, Mead, J. A., 574.
- Le Gendre, P.** Pathogeny of gout, 218.
- Leinke, A. F.** Tuberculosis of the lungs, 15.
- Leprosy.** The prophylaxis and control of leprosy in this country, Morrow, P. A., 8; lepers in France, 172; report of the committee on national leper home, Bracken, H. H., 586.
- Leszynsky, W. M.** Spasmodic wry neck and its treatment, 592.
- Lewis, B.** The pathogeny of gonorrhoeal nephritis, 321; a ureter cystoscope (for male or female) built on a new model, 347.
- Lips.** Two cases of persistent exfoliation of the lips, Stelwagon, H. W., 8.
- Literature.** Medical literature, 144.
- Liver.** Surgical treatment of hydatid cysts of the liver, Jounesco, T., 325.
- Logan, J. E.** Atrophic rhinitis, 64.
- London.** Letter about Paris and London, 382.
- Lord, S. A.** Lesion of chiasm; temporal hemipia, optic atrophy; probable pituitary tumor, with gigantism and defective development, 365; neuropathic joints, 406.
- Love, I. N.** Address before Mississippi Valley Medical Association, 608.
- Lund, F. B.** A case of parovarian cyst with twist of the pedicle occurring during the fourth month of pregnancy; operation; recovery; normal delivery at term, 208; acute hemorrhagic pancreatitis, its surgical treatment, with report of six cases, 543.
- Mackenzie, J. N.** The early diagnosis of laryngeal cancer and the treatment, 64.
- Macleod, K.** The scope and aim of the section's work, 225.
- Maey, W. A.** Observations on an outbreak of diphtheria, 274.
- Makins, G. H.** The so-called "poisoned bullet," 246.
- Marcy, A., Jr.** Movable kidney from the standpoint of the general practitioner, 17.
- Marx, S.** Obstetrical and gynecological aspect of spinal anesthesia, 637.
- Massage.** Massage and movement in the treatment of fractures, Championnière, L., 217; massage in Japan, Wood, H. C., 568.
- Materia Medica and Therapeutics.** Silver injection treatment of pulmonary consumption, Mays, T. J., 15; purgation with opium, Wainwright, J. W., 160; the intradural injection of cocaine, 193; calcium hydrosulphate paste as a surgical epilytic, Cumston, C. G., 275; Joseph W. England's fat-free tincture of digitalis, Cutler, E. G., 283, 293; anesthesia by subarachnoid injections of cocaine in the lumbar region, Severanu, 325; serum therapy in pneumonia, Smith, W. H., 340; the therapeutics of urotropin, Keyes, E. L., 347; hydrotherapy in pneumonia, Baruch, S., 389; recent progress in therapeutics, Joslin, E. P., 477; intradural injections of cocaine for surgical anesthesia, 509; a contribution to the therapeutic action of heroin, Lazarus, B., 600; the neurophysiological aspect of spinal anesthesia, Corning, J. L., 636; spinal analgesia in general surgery, Fowler, G. R., 636; obstetrical and gynecological aspect of spinal anesthesia, Marx, S., 637; intraspinal cocaineization from the anesthetist's standpoint, Goldan, S. O., 638.
- Mathieu, A.** Treatment of mucomembranous colitis, 240.
- Maunoury, G.** Radiography in the study of fractures and of luxations, 276.
- Maylard, A. E.** Exploratory operations on the stomach, 323.
- Mays, T. J.** Silver injection treatment of pulmonary consumption, 15.
- McCullom, J. H.** A plea for larger doses of antitoxin in the treatment of diphtheria, 627.
- McLaren, A.** The relationship between dysmenorrhoea and appendicitis, 376.
- McLean, M.** Contribution to the management of face presentations, with report of two cases, 376.
- Mead, J. A.** The duties of the medical examiner in Massachusetts, 574.
- Measles.** A case of measles, period of incubation, Smithwick, M. P., 465.
- Medicine.** The progress of medicine, Ernst, H. C., 130; medicine as a science and medicine as an art, Fye-Smith, F. H., 173.
- Meek, E. R.** Method of staining the elastic fibres of the skin, 23.
- Memminger, A.** The true function of the State Medical Examining Board, 88.
- Meyer, A.** The city and its consumptive poor, a plea for a municipal sanatorium outside of the corporate limits, 479.
- Milk.** Milk; its production, its care, its use, Kitch, T. M., 49; the modification of milk in milk laboratories, Rotch, T. M., 357, 372; breast feeding, Worcester, A., 361, 371; home modification of milk, Townsend, C. W., 363, 372.
- Miller, E. F.** A chair devised to meet the anatomical requirements, 212.
- Mills, C. K., and Keen, W. W.** Tumor of the superior parietal convolution accurately localized and removed by operation, 266.
- Mind.** A case of morbid fear, Courtney, J. W., 5; progress in the treatment of insanity, 120; the psychic factor in disease, Greenleaf, E. W., 155, 166; Christian pseudoscience and psychiatry, Baker, S., 265; report on progress in mental diseases, Stedman, H. R., 579, 602.
- Monprofit, A.** Gastro-enterostomy, 324.
- Moorhouse, G. W.** Feeding in typhoid fever, with a report of cases, 494.
- Morrissey, J. J.** A plea for a more rational prognosis in cardiac affections, 11.

- Morrow, P. A.** The prophylaxis and control of leprosy in this country, 8.
- Morse, H. L.** Leucocyte count in serous pleurisy, 695.
- Mouth.** Oral epulis a possible cause of disease, 169; cases of acute oral inflammation, Munro, J. C., 597.
- Moyer, H. N.** Address before Mississippi Valley Medical Association, 607.
- Munro, J. C.** Four cases of actinomycosis, 255, 263; patient after thoracoplasty for sarcoma, probably of the diaphragmatic pleura, 314; patient after pyloroplasty, 314; cases of acute oral inflammation, 597.
- Musser, J. H.** Myocarditis, 92.
- Myocarditis.** Myocarditis, Musser, J. H., 92; myocarditis in infancy and childhood, Koplik, H., 93.
- Nervous System.** Lesions of the cauda equina and conus medullaris, Sippy, B. W., 17; the Fourth of July and tetanus, 21; recent progress in neurology, Knapp, P. C., 89, 113; recurrent luxation of the ulnar nerve, Cotton, F. J., 111; the psychic factor in disease, Greenleaf, R. W., 155, 166; a brief report of a case of cerebral abscess of otitic origin, operation; death, Richards, G. L., 159; hysteria an organic disease, 221; address before the American Neurological Association, Fisher, E. D., 261; Christian pseud-science and psychiatry, Baker, S., 265; imperative ideas in the sane and their management, Angel, E. B., 265; a case of Wernicke's conduction aphasia, with autopsy, Pershing, H. T., 265; a case of bullet wound in the spinal cord, Sailer, J., 267; tumor of the superior parietal convolution accurately localized and removed by operation, Mills, C. K., and Keen, W. W., 266; clinical study of the reflexes, Collins, J., 295; autopsy of a case of adipsia dolorosa, with microscopical examination, Dercum, F. X., 295; the anatomico-cytological relationship of the neuron to disease of the nervous system, Barker, L. F., 296; the pathological changes in the neuron in nervous disease, Spiller, W. G., 297; how does the doctrine affect the conception of nervous disease? Sachs, B., 296; the physiological significance of the size and shape of the neuron, Donaldson, H. H., 296; clinical and anatomical analysis of cases of diffuse degeneration, Putnam, J. J., and Taylor, E. W., 297; section of the posterior spinal roots for relief of pain in a case of neuritis of the brachial plexus; cessation of pain in affected region; later development of Brown-Séquard paralysis in area and pain in other areas as result of laminectomy, Prince, M., 297; revised interpretation of the central fissures of the educated suicide's brain exhibited to the association in 1894, Wilder, B. G., 298; a case of malaria presenting the symptoms of multiple sclerosis, with necropsy, Spiller, W. G., 298; a case of multiple sclerosis, with autopsy, Burr, C. W., 298; two cases of tumor of the spinal cord, Thomas, J. J., 298; lesion of chiasm; temporal hemiopia; optic atrophy; probable pituitary tumor, with gigantism and defective development, Lord, S. A., 365; the treatment of hydrocephalus by craniotomy, Davis, E. P., 431; eye strain as a cause of gastro intestinal neuroses, Smithwick, M. P., 441, 453; a case of alexia, mind-blindness, etc., with autopsy, Jack, E. E., 577; peripheral neuritis due to arsenic in beer, 614; case of myasthenia gravis pseudoparalytica, Paul, W. E., 632; the neurophysiological aspect of spinal anesthesia, Corning, J. L., 636; spinal analgesia in general surgery, Fowler, G. R., 636; obstetrical and gynecological aspect of spinal anesthesia, Marx, S., 637; intraspinal cocaineization from the anesthetist's standpoint, Goldan, S. O., 638; twentieth century cerebral physiology, 642.
- Newspaper.** Newspaper medicine, 537; newspaper exaggeration, 644.

REMARKS ON THE SURGERY OF UTERINE FIBROIDS, WITH ESPECIAL REFERENCE TO THE IMPORTANCE OF EARLY REMOVAL IN THE YOUNG.¹

BY MAURICE H. RICHARDSON, M.D., BOSTON.

THE subject of uterine fibroids has, with broadening experience, acquired for me a renewed importance and interest. It has seemed more important because I have become convinced that the gravity of the tumor is generally underestimated; more interesting because I have become impressed by the splendid results of early operation under our present methods of dissection and of asepsis. The uterine fibroid is commonly regarded as an unimportant lesion, unless it impairs health or threatens life, or unless by its rapid growth it is likely soon to do so.

I have thus far relied upon hemorrhage, pain, pressure or rapid growth to justify the dangers and disadvantages of surgical measures, for until recent years the dangers and disadvantages have been great. Intervention has been a remedy for harm already done—the substitution of a lesser for a greater evil. Has not the time come when, by early operation, we may avoid the one and, at the same time, diminish the other? Can we not, in a word, operate before the tumor has become a great evil—at a time when the operation is comparatively devoid of risk? Ought we not to remove from young women fibroids which cause no trouble, or very little, at a time when unimpaired vitality may permit enucleation without sacrifice of either uterus or ovaries?

Though the fibroid may have given rise to neither disability nor danger, it may, nevertheless, suddenly cause symptoms of such grave importance as to demand operation at a time when the prognosis will be unfavorable. Even if the appearance of grave symptoms is gradual, the patient too often is brought to a realization of their gravity only after the loss of precious time; for she is only too much inclined to rely upon that opinion, expressed perhaps early in the history of her case, that no surgical treatment is necessary or likely to become necessary.

I have seen many cases of this kind. Patients having small fibroids which, though perhaps low in the pelvis, caused no symptoms, have been advised to await later symptoms, and have not only waited for them to appear, but have waited until they have become actually threatening to life. Others, having comparatively large fibroids which, high out of the pelvis, have caused little if any trouble—they, too, have waited far beyond the period of safe extirpation. In not a few cases the symptoms seriously threatening health and life have arisen with comparative suddenness, and have demanded relief at a time when that relief was possible only at a considerable danger to life.

Among the emergencies that I have seen are the sudden first occurrence of severe hemorrhage, symptoms of incarceration, of twisted pedicle, of suppuration, of localized peritonitis, of sloughing.

Until recently the great success of surgical intervention has not been widely known. The dangers of the operation have been greatly overestimated, and its disadvantages greatly exaggerated. Moreover, the

feasibility of saving ovaries in practically all cases and the possibility of saving the uterus in many have been overlooked.

The tendency has been on the one hand toward a fuller realization of the possibilities of danger in the uterine fibroid; on the other, toward extraordinary success in early intervention. The inevitable result of such observations is to make the observer radical rather than conservative in the treatment of fibroids.

Furthermore, with increased experience in the exploration of supposed fibroids, one cannot but become impressed by the frequent errors in diagnosis. The observer is too often confounded by finding on exploration that supposed fibroids have been tumors of the most insidious and lethal nature—malignant adenomata of the uterus, dermoid cysts of the ovary, ovarian adenocarcinomata, ovarian tumors with twisted pedicles, and even extra-uterine pregnancies.

Such errors in diagnosis may be uncommon,—they are uncommon,—but no man, however experienced and skilful, can always avoid them. I have already reported such errors in diagnosis in papers published upon extra-uterine pregnancy, upon ovarian tumors and upon other subjects. Though I have in many cases been mistaken as to the exact diagnosis, the symptoms have not called in vain for relief, and exploration, based upon the arguments herewith advanced, has revealed the truth in time for complete success.

On the other hand, it must be said that errors in diagnosis may lead one into an unnecessary operation—the error, for instance, of calling a simple, unoffending fibroid an extra-uterine pregnancy, and of exploring the abdomen or the uterus; the error of mistaking a simple pregnancy for a fibroid uterus or an extra-uterine pregnancy, and of making an exploration which, if justifiable, is certainly untimely; the error of calling a simple pregnant uterus a diffused fibroid. A few such errors lead one to extreme care in performing operations whenever there is the least question of pregnancy. And yet the surgeon must be just as careful lest he overlook, in fear of pregnancy, a lesion which, for the safety of the patient, must be repaired at the earliest possible moment—such a lesion, for example, as a malignant adenoma of the uterine body, or even an ectopic gestation.

These remarks suggest themselves to me in introducing my subject because they illustrate the extreme difficulties that sometimes arise in connection with it. They are difficulties, moreover, which can be appreciated only by those who have encountered them, and one may encounter them for the first time after so long an experience with fortunate cases that he may have been led to believe the dangers fancied rather than real.

There is a time in the history of all fibroids when mistakes are the least likely to be made, and when all means of differentiation are safe. That time is when no question of pregnancy prevents examination of the uterine cavity, and when the most thorough examinations, under ether, can be made without danger of causing abortion.

Even at such a time the diagnosis may be difficult, or it may be wrong. In one instance the most painstaking examination, under ether, by three men experienced in such things, resulted in the unanimous diagnosis of an unoffending uterine fibroid. A large

¹ Read before the Obstetrical Society of Boston, February 20, 1900.

dermoid cyst of the ovary was later removed by a more accurate diagnostician!

The beauty of operations for the removal of fibroids has long impressed me. Though the operation is, in my opinion, one of the greatest in surgery, inseparable as it ever must be from possibilities of grave disaster, yet it is now one of the most successful. Its success is dependent upon rapid, accurate and intelligent dissection, upon preliminary aseptic details, upon absolute operative aseptis, and upon perfect avoidance of wound contamination from the vagina and from the uterine canal.

The results seem about as perfect as those of any operation can be. With my present methods — which I do not intend here to discuss — the removal of uterine fibromata in patients not reduced by prolonged hemorrhage, and not suffering from other diseases, is attended by a success which ten or even five years ago seemed too much to hope for. Excepting such unavoidable complications as pulmonary embolism, uremia, and the like, it really seems as if the time had come when this great life-saving operation, skilfully performed upon the strong, is practically devoid of risk.

Yet the experience upon which this optimistic view is based does not include only the selected and favorable cases; it includes also the cases in which the patients have been forced to operations in the face of admittedly grave dangers, operations which have been performed in many instances as a last resort — patients who by prolonged suffering have been brought to choose the lesser of two great evils. This experience has included some deplorable cases, but those cases have not been without their lesson. My mortality has been gradually reduced, by the elimination of avoidable sepsis, to a point where, excluding the complications already mentioned, it is practically nothing. With such an experience, it is perhaps but natural for one to become more radical in the treatment of fibroids, seeing as he does that the chief danger lies in the lateness of the operation, rather than in the dangers of the operation itself.

One is led, therefore, to consider other questions than those of technical methods, operative skill, mortality, and the like, — questions of the preservation of sex, of the possibilities of child-bearing, and of the powers of enjoying life. The preservation of these things, it must be admitted, cannot but emphasize the importance of the early treatment of uterine fibroids in the young.

My attention was directed particularly to this question by the following case:

I first saw Miss — March 10, 1898. There had always been great irregularity in the periods, four months often intervening. The flow would at times be excessive, though not enough to produce a lasting anemia. In April, 1898, she had noticed a hardness in the abdomen. There was little if any pain, and that was of an indefinite general character. Though she was somewhat pale, her general appearance was that of a well-nourished and strong girl. There had been no loss of weight. Under ether I discovered a fibroma of the uterus about as large as a coconut. The tumor was smooth, spherical, symmetrical and movable. I advised her to present herself frequently to her physician for observation, with a view to operation if her symptoms should increase enough to demand it. At this time the symptoms were indefinite

the flow was not excessive, there was no discomfort from pressure. It was uncertain whether the tumor was growing rapidly. The patient's circumstances permitted everything necessary. It seemed best, therefore, to watch the tumor carefully, to get an idea of the rapidity of its growth, to try the effect of rest and hygiene.

The patient went south for a time, and then abroad. For six months there was no menstruation, and then a profuse flow began and lasted some six weeks. She became excessively exsanguinated; she was pale, chlorotic and "frightfully out of breath." The tumor rapidly increased in size. There was still no pain.

On November 1, 1899, I found her absolutely without color. The lips were blue and the respirations rapid, though she had not flowed for some weeks. The tumor had risen to the umbilicus. It was, as before, symmetrical and smooth. The ovaries could be felt on its sides. The patient's condition was alarming; it was clear that she could not long survive the great drain from her veins. I sent her home to remain in bed as long as there should be no flowing; to be nourished and stimulated; in a word, to gain all the blood and strength possible in preparation for the operation.

By December 6, 1899, she had gained enough in blood and strength to justify operation. There was no doubt as to the urgency of intervention. So severe had been the exsanguination that it would not have been surprising if she had succumbed to any additional loss of blood, small though it might be. We were ready, however, to operate at the very first appearance of hemorrhage. In the meantime she was kept in bed, absolutely quiet, and was strengthened in every possible way.

On December 6th I opened the abdomen and delivered the tumor. Her condition was then much better than on November 1st, but it was not even then good enough to make the prognosis anything but serious. Though the tumor was evidently a submucous one, enucleation was technically possible. In a strong, full-blooded girl it could, I am sure, have been successfully performed. Such an operation, however, would have been a bloody one, for the venous sinuses were abundant and large, and simple incision down to the tumor could not have been accomplished without a considerable hemorrhage. Enucleation seemed so desirable in this case, and, moreover, it seemed so feasible, that I made a short incision through the uterine wall to see how it would probably work. The hemorrhage which immediately started from the short incision was so severe that I was glad to be able to close it immediately by hemostatic forceps, and to go on to a bloodless hysterectomy. None who were present doubted that enucleation — no matter how rapidly performed — would have been fatal. The uterus was amputated from the cervix without loss of blood, and the patient made a most satisfactory recovery.

The possibility of myomectomy was demonstrated upon the tumor. Separation was comparatively easy, but many and large sinuses were opened in making it.

The point which I wish to emphasize in this case is that an early operation would have enabled me to remove the tumor without sacrificing the uterus.

Without going into details of similar operations performed under the stress of impending death, I would mention the comparative frequency of such cases. I would at the same time lay stress upon the fact that

it is among such cases that the mortality of hysterectomy lies. Since January 1, 1899, I have had 2 deaths in my private operations for uterine fibroid; the recoveries have been 26. The first fatal case was in a woman of forty-four, with a history of one year's tumor, accompanied by excessive flowing. The growth of the tumor was rapid, the flowing excessive, the pain and distress unbearable. The tumor was large and multiple; it was sessile and attached to everything in the pelvis and to the large intestine. The blood supply was extensive and the vessels large. I was tempted to abandon the operation when I realized its extent, dangers and difficulties, but enucleation, once begun, had to be finished, though the difficulties seemed really insurmountable. By removal of the tumor broad areas of oozing capillaries were left uncovered by peritonium. Hemorrhage was controlled only by abundant gauze packing. The patient rallied from the operation, but died of exhaustion at the end of one week.

In this case operation was undertaken at a comparatively early period, but not until the tumor was very large. There was the strongest indication for operation at the time it was performed; but there had been for many months sufficiently strong indications. Who can deny that the chances of recovery in this case were compromised by delay? Had the tumor been removed when first discovered, there is every reason to believe that the operation would have been successful.

So in the case of Mrs. C., age fifty, a patient of Dr. Crocker, of Cambridge. She had had for two years excessive flowing and had been advised to submit to operation for a uterine fibroid the size of an orange. She had become white and waxy with repeated hemorrhages. She had been tamponed and curetted with temporary benefit. She finally was driven to operation by increasing flow and failing strength. The operation was bloodless, convalescence had become well established and all anxiety was over, when she died instantly from a pulmonary embolism starting from the superior vena cava. The pelvic field was perfect.

Death from pulmonary embolism must always be considered in serious lesions, whether medical or surgical. Yet, as I have observed it, it is more likely to occur after extensive operations upon the bloodless, in whose veins hemostatic clots are rapid of formation but easy of detachment. I can recall one other sudden death from this cause after hysterectomy, the patient falling dead while being fitted with an abdominal supporter.

In all my other operations for fibroid in 1899, and so far in 1900 (26 cases), there has been a rapid and satisfactory recovery, though many have presented great technical difficulties. In the whole list there has not been a simple, easy operation. Indeed, I have not included trivial myomectomies performed during operations for other abdominal conditions. The patients, before consulting me, have in most instances waited until they were driven to it by hemorrhage, discomfort, pain, or rapid increase in the size of the tumor. It seems to me safe to say that, when performed early, myomectomy or hysterectomy has a very low mortality.

The chief point of my paper is the advisability of early operations in the young, in order that the uterus may be saved by limiting the operation to removal of

the tumor itself. I have shown — at least to my own satisfaction — that early operations permit the enucleation of small fibromata in a large percentage of cases; indeed, that this operation is often possible in large fibromata. Moreover, I am convinced that the dangers of myomectomy, when it is feasible, are even less than those of hysterectomy, for all my myomectomies have recovered. Many have been for comparatively small tumors, but many have been for very large ones. In all myomectomies one important and unavoidable source of sepsis is eliminated — that of cutting across the uterine canal. The dangers of infection from this source are great, as Homans has always maintained. In at least one case of the past year cultures of the streptococcus pyogenes were obtained from the uterine canal. This danger seems to be overcome by the use of the cautery in cutting across the cervical canal, for I have had no infections since using this method. It seems also clear to me that the smaller the tumor and the easier the operation, the less the risk.

The only objection to early operation in fibroids which possess little pathological significance is that they are not at the time necessary. But can it be said that even the most insignificant fibroid will not at some time assume attributes of grave significance? It certainly cannot. If the tumor can be controlled, so to speak, if it can be kept under frequent and intelligent observation, little can be said in favor of universal extirpation; but every observer knows that the patient once dismissed with the assurance that there is no need of operation is but too likely to keep her tumor to herself until perhaps the period of easy and safe extirpation is long passed. She presents herself again only when she is compelled to do so by the strongest symptoms of suffering or of danger.

Even when under intelligent observation, however, the fibroid may suddenly assume grave attributes. The first hemorrhage may bring the patient to death's door, as in the first case mentioned. Such instances are by no means infrequent. Furthermore, it is by no means unheard of for fibroids to suppurate, to be associated with a pelvic peritonitis, or even with abscess, — a complication of the gravest nature, which demands a heavy toll in disaster.

When the fibroids are extramural, with long pedicles, the pedicles may become twisted. Among the insidious complications must be mentioned the gradual effect of pressure upon the ureters and consequent hydronephrosis. In a word, the fibroid, though often innocuous, possesses possibilities of danger to life and health which I am convinced are underestimated.

On the other hand, the dangers of intervention must not be underestimated. Though my mortality in favorable cases has been so small, yet it is possible that the next series of cases may include some of those disasters which occur so inexplicably. Even in the class under consideration operation should not be performed without the most careful study; and it should be proposed only in those cases in which situation, size, rapidity of growth, or hemorrhage, indicate the possibility of future trouble.

If the truth of these remarks is admitted with reference to fibroids in general, the importance of them seems especially great with reference to young women, for to them early operations mean not only the removal of a fibroid, which if not actually offending may become so, but the possibility of preserving the uterus itself and the power of bearing children.

THE USE OF THE ANGIOTRIBE.¹

BY F. H. DAVENPORT, M.D., BOSTON,
Assistant Professor of Gynecology, Harvard Medical School.

ANY new procedure in surgery has to pass through a period of trial before it is accepted by the profession as an advance. The angiotribe is now passing through such a critical period, and it is with the idea of giving my experience with it that I present this paper.

The angiotribe, as its name implies, is an instrument devised to control hemorrhage by powerfully compressing the blood-vessels, and its chief object is to do away with the use of clamps and ligatures for this purpose. Its use was first advocated, as far as I can learn, by Doyen, of Paris, and was followed by Thumin, of Berlin, who modified Doyen's original instrument. Later Tuffier, of Paris, brought out a new instrument, which is the one I show here to-night. A little more than a year ago it began to be used in New York by Cleveland, and independently by Newman, of Chicago, and it has since then found a wider field in the hands of a good many surgeons. At the meeting of the American Gynecological Society in Philadelphia in May, 1899, Cleveland reported 26 cases, Newman 16, and Stone, of Washington, 11, where this instrument had been used most satisfactorily.

It is essentially a powerful clamp, consisting of two heavy blades, which are approximated by pressure produced by means of a screw which is worked by a wheel. With this instrument it is claimed that a pressure of three thousand pounds to the square inch can be obtained. The broad surfaces of the blades are roughened, and there is a longitudinal groove down the centre of each. A small pin at the end of one blade fits into a corresponding depression in the other, as an additional guard against any possible slipping.

In vaginal hysterectomy, the operation in which the use of this instrument seems peculiarly indicated, my mode of procedure is as follows: Having seized the cervix with the vulsellum I divide the tissues in the posterior cul-de-sac at the junction of the vaginal wall with the cervix, with the Paquelin cautery heated to a red heat. The point of the blade is kept close to the tissues, and the whole breadth of the cul-de-sac is divided. The same is done on the anterior surface of the cervix, and the vagina is divided in the lateral cul-de-sacs as well, but to a moderate depth only. The tissues are then pushed up front and back with the fingers, separating the attachments between the uterus, and the bladder and rectum, until the peritoneum is reached. If there are no adhesions and the uterus is small, the peritoneum is then opened and the anterior and posterior surfaces of the uterus freed.

The blades of the angiotribe are then introduced on the left side under the guidance of the fingers, including as much of the broad ligament as they will grasp and close to the uterus. Care should be taken that the ends of the blades do not include bowel or omentum. The blades are then screwed together tightly, and the clamp allowed to remain for two minutes. The tissues are then divided on the uterine side, leaving a little margin of tissue on the outside of the clamp. When the clamp is carefully removed the edge of the broad ligament will be seen to be a flat ribbon as thin as paper, which is completely dry. The

same is then done on the other side. If the uterus is small the fundus may be turned out anteriorly, and the upper part of one broad ligament, including the tube and round ligament and the ovarian artery clamped from above, compressed for two minutes, then severed, the same done on the other side, and the uterus removed. In case of a large uterus, after the uterine arteries have been compressed, the uterus may be bisected and each half removed separately. A plug of gauze is then inserted between the stumps of the broad ligaments and the operation is complete.

The operation as done with the aid of this instrument is very satisfactory. It is as near bloodless as it can be made. The use of the cautery limits bleeding from the edges of the vaginal opening, and there is practically no loss of blood from the stumps of the broad ligament. The necessary manipulation during the later stages of the operation does not start up any oozing. It also shortens the time of the operation. I had long ago given up ligatures, both from the difficulty of applying them and because if silk is used they become infected and keep up a discharge until they come away, often only after an interval of months.

Leaving a number of clamps from twenty-four to forty-eight hours is very painful for the patient, as is also their removal. Following the use of the angiotribe there is almost no pain, practically no bleeding, and the convalescence is easy and rapid.

In abdominal operations the results are equally satisfactory, though the advantages from using the angiotribe are less obvious. It can with perfect safety be used for clamping off the appendages. In two classes of cases it seems to me indicated: first, in septic cases where there is danger of any ligatures becoming infected, and for cases of secondary operation where there have been disturbances from the stump left after a primary operation. Here it would seem to me to lessen the chance of subsequent irritation if no ligatures were used.

From my experience in 5 cases (a limited number to be sure, but embracing both abdominal and vaginal), I consider the angiotribe an advance in technique. Some objection has been made to the size of the instrument and its apparent clumsiness, but I have not found that a practical objection. It can be adjusted in a narrow vagina, and after having been used is removed, and the field of operation is not obstructed, as is the case when clamps are left on. I understand a somewhat lighter instrument has been devised by Dr. Bissell, of New York, which is giving satisfaction. If sufficient pressure can be secured with a smaller instrument, it might be an advantage in the way of being more easily kept absolutely still while exerting the pressure. Dragging on, or twisting the angiotribe while it is clamped, might possibly interfere with perfect hemostasis.

The compressed tissues are not devitalized. The course of the convalescence in the abdominal cases is uneventful, and in the vaginal cases there is comparatively little discharge. The effect upon the tissues has been studied microscopically by Thumin, of Berlin, who says: "The result was, that, contrary to what might have been expected from such a complete thinning out, the tissues were by no means bruised out of shape. The effect of the instrument is nothing more than a complete compression of the interstitial connective tissue, with all its lymph spaces. All the other

¹ Read before the Obstetrical Society of Boston, February 20, 1900.

elements, muscle cells and elastic fibres are pressed close to each other, and show by their coloration and retained shape that their injury is slight."

Similar investigations by Bissell, of New York, show how complete is the hemostasis. A clot forms on the side of the clamp where the artery enters, and a second one in the central groove of the blades. If a little tissue is left next to the blade when cutting the uterus away, there is a third barrier. Microscopically he has shown that the muscular coats of the arteries are cut and retract and curl inwards, adding to the efficacy of the blood stasis. From this it will be seen that the danger of secondary hemorrhage is slight, and the reports of cases corroborate this view.

My conclusion with regard to the angiotribe, therefore, is that it is a safe and efficient means of controlling hemorrhage, renders the operation easier for the operator and much more comfortable for the patient, and is distinctly an advance, and has come to stay.

Clinical Department.

A CASE OF MORBID FEAR.

BY J. W. COURTNEY, M.D., BOSTON,
From the Nervous Clinic of the Boston City Hospital.

OF all the varied and widely diversified symptoms that arise in connection with that adynamic condition of the nervous system which we designate neurasthenia, none are more interesting than the morbid fears which are prone to fasten upon its victims. It is not in the least surprising that a nervously weak person should be assailed by fears — since fear is the almost inevitable outcome of weakness — but the curious forms which such fears at times invest and the psychopathic effects to which they may give rise are always worthy of serious attention.

An attempt has been made to give certain forms of these fears specific names, but the result of this attempt is undesirable for two reasons: (1) Because it leads us to suppose that all of these forms are intrinsically different from one another; and (2) because the designations selected are, for the most part, of the usual polysyllabic type with which the nomenclature of nervous diseases is already sadly overburdened.

Exactly what to call the variety under which the case to be reported comes is somewhat puzzling. As its basis was a fear of death, it may be considered, primarily, one of "thanatophobia." In its evolution, however, its primary identity became so much encroached upon by other morbid factors that the term selected cannot be said ultimately to entirely cover the condition. At all events, call the case what we may, it was certainly the most difficult, of the kind, to treat that has ever come under my observation, and I doubt seriously my ability to give in words even the faintest idea of the horrible mental torture endured by the patient.

The case was that of an unmarried woman of twenty-two years, American-born, of mixed Yankee and Irish stock. Her father was distinctly neuropathic and finally died suddenly, near sixty, of coronary sclerosis. Her mother is alive and well, but of nervous temperament. Her eldest brother is nervous and high-strung and at one time was prevented from pursuing his business for an entire year through fear of heart disease.

Another brother, younger than the other, is now under my care with very marked neurasthenia, and suffers severely from numerous imperative concepts. There are three other children in the family, all of whom are of nervous temperament and of marked nosophobic tendency.

The previous history of this patient contains nothing worthy of special note. Her present complaint dated back to her father's death some seven years ago. This, as I have said, occurred suddenly, and immediately afterward the patient suffered from severe nervous chills, which persisted for upwards of a month. Recovering from these, she remained in a more or less nervous condition — which had no definite mental expression — up to a year ago last spring, when two other deaths occurred — one in her own family — which completely upset her. The fear of death then took complete possession of her and she began to imagine every one she knew in caskets. She also became very emotional and cried a good deal of the time. She feared death from typhoid, from lightning-stroke, from heart disease and from surgical operation. Her visualizing powers developed to a high degree and she could see herself in the agony, with the family, the nurse and the doctor standing at the bedside. To this general picture the finer details of her demise were finally added with torturing vividness, and she could see herself drawing her last breath and her eyes closing. In addition she could actually *feel* the death chill creep over her. Among other things in reference to her taking off she worried as to whether this should occur on a hot or cold day, a stormy or a fair one.

All this time she was doing her work — that of a stenographer — in a purely mechanical but satisfactory way, and insisted to me that she did not in the least foster the above ideas and fears, but that they surged through her brain at all times and under all circumstances. Her entire family were kept in a continual state of anxiety over her condition and were naturally fearful as to the ultimate results upon her mental stability.

On my first examination, about a year and a half ago, her physical condition, except for some impoverishment of the blood, was found to be good, the only physical signs being a slight hemic murmur over the pulmonic area of the heart and a trifling inequality of the pupils. The eyes had been examined by an oculist and no refractive error made out.

The question of treatment presented exceptional difficulties, as may readily be imagined. The patient was already goaded to desperation by solicitous friends and others who insisted that her sufferings were controllable and urged her to busy herself with various things which would enable her — they thought — to forget them. She insisted that no one could possibly form any idea of how hard and how variously she had struggled to rid herself of her morbidness, but without the slightest avail.

The course of treatment I pursued was somewhat as follows: I began by explaining to the patient in some detail — she was intelligent, had had a high school education — the nature of the general nervous condition upon which the mental symptoms were based, and showed her how necessary I considered it to direct our combined attention to the nervous system in general, without regard primarily to such specific manifestations as the fears. To accomplish this the

only *drug* used was iron. For the rest I insisted upon forced feeding, graduated exercises done in class work, and moderate bicycling, which she had formerly enjoyed.

For a long time it was terribly discouraging for both of us. She returned at intervals, and always with the story that she was worse. In addition, she complained that her stomach had gone back on her and that she had a constant "bad feeling" extending from the left hypochondrium to the umbilicus. To account for this she expressed the fear that there were probably finger-nails in her stomach—she was an inveterate nail-biter—which she had swallowed; she had heard of a girl dying from such a cause.

I insisted that the prescribed treatment should be rigidly adhered to in every particular, and within three months she gained sixteen pounds. I then began to use suggestion without hypnosis, going, however, through the manoeuvres which are ordinarily employed to produce the first stage of the latter. This was done, at first, as often as three times a week. My only success was in substituting a different—though no more desirable—mental condition. Everything began to seem strange to her. As she herself said: "It seems queer to think of living; of having definite work to accomplish; to hear people planning to do things at some future time." The most commonplace acts of life assumed a character hitherto undreamed of by her, and she grew so discouraged at her condition and her impotency to rid herself of her horrid incubus that she threatened on two occasions to drown herself.

I continued my pseudohypnotic séances and set her definite tasks—such as memorizing passages from prose and poetic works, which was not congenial and consequently required considerable mental concentration—to do in the interim between visits. I also used the static breeze to the head, but merely to aid the suggestive measures. I never allowed her to abandon her work for even a day at a time and was finally rewarded—after many relapses—with what may practically be termed a complete cure. She now does not care to have the old fears or the queer thoughts mentioned at all. If they are spoken of, she changes color and turns the conversation into other channels.

COLOSTOMY FOR OBSTRUCTION DUE TO MALIGNANT DISEASE.

BY J. B. BLAKE, M.D., BOSTON.

THE abdominal viscera from a case of extensive malignant disease were recently shown at the Surgical Section. The case seemed of sufficient interest to warrant a description. The patient was an Italian woman, age fifty. She had irregular and profuse menstruation until four months before entrance. Since then flowing had ceased, but the abdomen had increased steadily in size. In bed five weeks before coming to hospital. During this period her bowels moved only six times. She entered March 26, 1900. She was poorly nourished and cachectic. No nodules in breast, but some in left supraclavicular region. Abdomen considerably distended and tympanitic, except in right iliac region. Intestinal peristalsis visible. Uterus fixed in pelvis, and an ulcerated crater replaced the os. Rectal examination showed anteriorly a hard,

nodular, immovable tumor mass. Enemata gave but little results. No radical operation was advisable.

Operation.—A left inguinal colostomy was advised and accepted. After opening the abdomen in the usual position it was impossible to find either the sigmoid flexure or the lower descending colon. After some trouble the splenic flexure was found and brought into the wound, and opened seven hours later. A small amount of feces escaped, and the patient was relieved for a few hours only. She died four days later.

Autopsy.—Nothing of importance in head. Peritoneal cavity: Small intestines and stomach greatly distended; adjacent coils bound together by an almost black, sticky, mucoid-like material. Portion of intestine forming the borders of the surfaces in juxtaposition injected. No free fluid in peritoneum. Surface of intestine pale except the lines of injection along the contiguous surfaces. In splenic flexure is an opening 5 centimetres in size, edges swollen, reddened; surrounding mucosa dark. There is an adjacent pedunculated mass of fat, deep red, moist. Descending colon passes directly backward from splenic flexure for a distance of 12 centimetres. In the remainder of its course it is firmly bound down to the posterior wall of the abdomen. The pelvis is filled with a dense, firm mass; the anterior portion of the superior surface being formed by the wall of the bladder, which is covered with hard, irregular, grayish-white, opaque nodules 1 centimetre and more in size. A coil of small intestine is firmly bound down to this pelvic mass, and the sigmoid flexure is lost in it. Anatomical landmarks are completely obliterated in the pelvis. In the right posterior portion is a small, thin-walled cyst resembling in appearance a simple ovarian cyst, but no other evidence of the tubes or ovaries or of the outlines of the uterus can be discerned. The lumen of the loop of small intestine appears constricted, although its distal as well as its proximal end of the U-shaped figure is dilated. The cecum is bound down to the pelvic mass and the lumen of the ileum near the ileocecal valve appears occluded. The intestine here is bound down posteriorly and is apparently converted into a large cord. Beyond this point the intestine is collapsed. No trace of appendix is found. It is evidently buried in the mass of fibrous tissue about the cecum. Here and there over the serosa of the intestine and mesentery are firm, granular appearing, whitish nodules, .5 centimetre to 1 centimetre in size. Only three or four of these bodies were found. Similar nodular masses bound the sigmoid flexure to the pelvic wall. Gall-bladder distended; united to hepatic flexure by fibrous bands. Diaphragm fifth interspace left side; fourth space right side. In the upper part of the anterior mediastinum the tissue is indurated and a small dense area found, which on section shows a fibrous structure beset with white opaque spots, giving it a rough, granular appearance.

Anatomical diagnosis.—Cancer of bladder and vagina with direct extension into pelvic organs. Metastases in retroperitoneal, bronchial and mediastinal lymph nodes. Stricture of ureters; hydronephrosis of right kidney; obstruction of intestine at ileocecal valve; edema of lungs; chronic fibrous peritonitis; chronic fibrous pleurisy.

The case offers two points of interest: (1) The remarkable extent of the growth and the rapidity of its development; (2) an unusual complication in the

comparatively simple operation of inguinal colostomy. The distended small intestine bulged into the wound and was returned to the abdominal cavity with difficulty. The apparent absence of descending colon was very puzzling for some time and the presence of the omentum at the splenic flexure made it more difficult to bring the intestine properly into the wound. The operation gave no permanent relief, because the small intestine was occluded at the ileocecal valve. In palliative operations, therefore, for the relief of more or less complete intestinal obstruction due to intra-abdominal malignant growths, it is well to bear in mind that the right as well as the left inguinal region may be the seat of the stricture; and it is possible that in these cases a median incision and an exploratory operation, as a preliminary, would be advisable. If the condition of the case demanded, an artificial anus might be made at this opening. There was no indication of the hydronephrosis before death.

Reports of Societies.

AMERICAN DERMATOLOGICAL ASSOCIATION.

TWENTY-FOURTH ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY, 1, 2 AND 3, 1900.

FIRST DAY. — MORNING SESSION.

THE President, DR. HENRY W. STELWAGON, of Philadelphia, read the

ANNUAL ADDRESS.

Our ultimate aim, he said, is the diminution of suffering and the cure of disease. It is well to remember that this end is not attained by the clinician alone, nor by the therapist alone, nor by the pathologist, nor by the bacteriologist, but by these investigators going hand in hand, each having an important and necessary share in the final result. Bacteriology especially must be persistently cultivated. At the same time, the hereditary receptivity, the family vulnerability, the environment, and the state of the general health, are factors of moment in many cases, and their removal or modification by hygienic and constitutional treatment will often render the microbial invasion less calamitous, and be of aid in removing the disease.

The reader referred to the teaching of dermatology in the medical colleges, and the increased importance attached thereto and the great advances therein. He spoke of leprosy as a disease which must as yet be considered from the standpoint of prevention, and the necessity that the matter should be handled by the national authorities.

BULLOUS DERMATITIS (DERMATITIS HERPETIFORMIS) IN CHILDREN.

Dr. J. T. BOWEN, of Boston, detailed 5 cases following vaccination and exhibited photographs. He referred to the ease and frequency with which the laity ascribe any succeeding ill to vaccination. Of these 5 cases, in 3 the eruption appeared within two weeks after vaccination, in 1 within a week, while in another it did not show itself until after the lapse of a month. In 4 of the cases there appeared to be ground for the assumption that the vaccination in

some way influenced the appearance of the eruption. In attempting to classify the cases, certain characteristics that have not been emphasized as usual features of dermatitis herpetiformis force themselves upon our notice. The localization of the lesions was striking, as there was a marked tendency to grouping about the mouth, chin, nose and ears, and upon the backs of the hands and feet. Besides this, the extensor aspects of the extremities were in general more prominently affected. In all the cases the trunk was affected but slightly as compared with the other regions of the body. The itching was not very pronounced. In the present state of our knowledge of the bullous dermatoses it is wise to go slowly and imprudent to draw deductions from any but a large number of carefully reported cases.

Dr. GEORGE T. JACKSON, of New York, read a paper on

LOSS OF HAIR.

This was a study of 300 private cases. Elaborate statistical tables were presented. His conclusions were as follows: Loss of hair is far more frequent among men than among women. Neither the unmarried nor the married state exerts any influence on the hair. Intellectual occupations and worry and strain are predisposing causes. Sixty-six per cent. of the cases begin before thirty years of age. In women general thinning of the hair is the most common form, while the receding forehead is uncommon. In men the whole top of the head is most often affected, and the receding temple is common. The great predisposing cause of loss of hair is heredity. Most of the women who lose their hair show a well-marked history on the maternal side; the men show it on the paternal side. All disorders of the general nutrition of the body are predisposing causes. The greatest exciting cause is dandruff, a term used to include seborrhea sicca, pityriasis, seborrheal eczema or dermatitis. As to treatment, the best drugs are sulphur, resorcin and the mercurials. The only stimulant worth mentioning is massage, and this should not be employed until the dandruff is checked.

The paper was generally discussed by Dr. A. Ravogli, Dr. Isadore Dyer, Dr. J. N. Hyde, Dr. Joseph Zeisler, Dr. T. C. Gilchrist, Dr. Wm. A. Hardaway, Dr. Samuel Sherwell, Dr. Joseph Grindon, Dr. Henry W. Stelwagon, and Dr. George Thomas Jackson.

AN UNUSUAL PHENOMENON OF SYPHILIS: OTHEMATOMA.

Dr. JOSEPH ZEISLER, of Chicago, read this paper. Othematoma consists in a rather suddenly appearing effusion of blood between the cartilage of the auricle and the perichondrium, separating this latter from the former. It is situated on the upper half of the anterior aspect of the organ, and the swelling is considerable. The chief occurrence of othematoma after traumatism is well established. The writer carefully searched the authorities as to the possible connection of othematoma with syphilis, and the only reference he could find to it was by Bouvier, in 1889.¹ Dr. Zeisler's attention was called to this possibility by the following case: Dr. X, about forty years old, had a small wart-like lesion on his right thumb, which was removed by excision and cauterization with nitric acid.

¹ Archive for Dermatology and Syphilis, vol. xx, 1890.

The glands of the axilla became much enlarged. Six weeks after the operation on the thumb, a generalized, copious roseola made its appearance. Mercurial injections, inunctions, etc., were given. About a year later an othematoma appeared on the right auricle. Under a liberal administration of iodide of potassium the othematoma promptly disappeared, never to return again. The most natural explanation of the case is on the basis of perichondritis due to syphilis.

EVENING SESSION.

A CASE OF BROcq'S ERYTHRODERMIE PITYRIASIQUE EN PLAQUES DISSEMINÉES.

Dr. J. C. WHITE, of Boston, reported this case. The patient was a healthy Irishman, with a negative family history, who about twelve years ago noticed red spots of considerable size on his lower leg which disappeared in the spring, and reappeared each autumn, invading more and more the general surface until the entire surface was almost covered. They showed themselves every year at the beginning of cold weather, remained unchanged throughout the winter, and vanished in April. They had never given rise to any subjective symptoms. On inspection his face and neck were largely occupied by bright red areas of irregularly circular outline, varying in size from one-half inch to two inches in diameter. They were mostly smooth, not at all elevated even at the margin, and were not thicker than the normal skin.

Another case was seen about the same time by Dr. Charles J. White, in a young German, age twenty-six. The two cases bore a strong resemblance to each other in the general appearances, but were far from identical, the second one covering much larger individual areas uniformly and being more scaly, as in Brocq's case. It also lacked the peculiar brownish tint of the first case.

Dr. PRINCE A. MORROW, of New York, read a paper entitled

THE PROPHYLAXIS AND CONTROL OF LEPROSY IN THIS COUNTRY.

The reader referred to the growing likelihood of contagion from our recently acquired possessions in the Philippines and Hawaii, and the necessity for national action in order to prevent the spread of the disease. He suggested the employment of skilled experts as quarantine inspectors. He deprecated the medieval conception of the horror and virulence of the disease, which is now known to be no more contagious than tuberculosis. Isolation or segregation undoubtedly are the most effective means known to sanitary science for the control of this and other contagious diseases. Homes or asylums with suitable hygienic surroundings should be provided by the national government for the care and maintenance of lepers. Such asylums should be made comfortable and attractive and arranged with especial adaptation to the requirements and peculiar needs of its inmates. In view of the chronicity of the disease, lepers should not be condemned to close confinement in inactivity, but should be provided with interests, means of employment and recreation. As a large proportion of lepers are able to engage in some kind of industry, such institutions might be made partly or wholly self-sustaining from the proceeds of these industries.

THE PREVALENCE OF PARASITIC DISEASES OF THE SKIN AND MEASURES NECESSARY TO LIMIT THEIR SPREAD.

Dr. WILLIAM THOMAS CORLETT, of Cleveland, read this paper. The frequency of diseases of the skin due to animal and vegetable parasites as reported by this association show that, next to eczema, epizoic dermatoses are the most prevalent of all skin affections in this country, being met with 95 times in 1,000 cases of skin disease, or 9.529%. Favus in this country is almost wholly an imported disease. The frequency as well as the severity of ringworm differs in different countries: in lowlands it thrives and is virulent. The principal sources of infection are asylums and similar institutions where children are often accepted and congregated without due regard to their contagious condition; kindergartens and schools; the poor or slum districts where children are crowded together in uncleanly tenement houses, and domestic animals, especially horses, cows, dogs and possibly poultry. The habit of using the same barber's utensils without previous cleansing for different persons should not be tolerated. The hanging of roller towels in hotels is a dangerous custom. Barber shops should be under the supervision of boards of health. Treatment of parasitic dermatoses should be prolonged until the disease is wholly eradicated, and a certificate to this effect given by the medical attendant before the person is admitted in close communion with others.

Dr. HENRY W. STELWAGON, Philadelphia, reported

TWO CASES OF PERSISTENT EXFOLIATION OF THE LIPS.

The first case was in a young woman, about eighteen. The urine showed considerable deposit of urates. The condition was limited to the vermilion of the lips, neither overstepping the mucous portion of the mouth nor the cutaneous integument. The lips when free from the scale or crust formation appeared normal, at times showing scattered points of superficial abrasion. The first stage in the formation of an exfoliating film consisted of slight but scarcely perceptible thickening. In a short time, from two to five days, the affected parts would break up into plaques, by a breaking through of the film, and the edges of the plaques would gradually become everted, and slowly loosen and detach themselves. If pulled off or forcibly detached the lips would be red, slightly abraded and somewhat tender. The exfoliative process went on unceasingly. The disease is still persistent but no longer under the reader's care. The second case was in a woman aged thirty. The patient was profoundly neurasthenic. Both lips were to a great extent involved, although the central parts were most markedly affected. There was slight seborrhea capitis in both cases. The reader was inclined to consider the disease as allied to eczema seborrheicum.

THE ETIOLOGY AND PATHOLOGY OF CUTANEOUS CANCER.

Dr. A. RAVOGLI, Cincinnati, who read this paper, said that from the greatest antiquity the clinical conception of cancer has been an ulcer, especially of the skin and glands, with exuberant growth of granula-

tions, which when removed has a tendency to relapse, gradually spreading and under marantic conditions causing death. The true etiology was first given by Billroth, who considered as carcinoma only those new growths which result from epithelial production, together with an infiltration in the connective tissues. It is quite natural that the masses of epithelial cells, crowding themselves into the midst of the connective tissues, must produce an irritation which causes a proliferation of the connective-tissue corpuscles. These corpuscles, which have the task of providing for the nutrition of the connective-tissue fibres, are greatly developed in the embryonic stage. In adult life they are very much smaller, but on account of some inflammatory exudation, they return to their embryonic stage; increasing in their volume, their nuclei proliferate, they increase in quantity, producing hypertrophy of the connective tissues, until they reach the form of papillary growths. In carcinoma the presence of sharp epithelial cells crowding down upon the delicate structure of the connective-tissue fibres, causes the connective-tissue corpuscles to take part in the proliferation, hence carcinoma is a malignant production consisting of masses of epithelial cells imbedded in a connective-tissue structure, inflamed and infiltrated.

SECOND DAY. — MORNING SESSION.

The general subject discussed at the meeting was

MALIGNANT DISEASES OF THE SKIN.

(a) THEIR CLASSIFICATION AND CLINICAL FEATURES.

DR. E. B. BRONSON read this paper. The import of the epithet malignant as applied to disease varies according to the circumstances under which it is employed. As most generally used the term implies a rapid, destructive course, tending to a fatal issue. It is thus used to designate certain forms or varieties of a disease of a severe and dangerous type, in contradistinction to other forms of the same disease that pursue a relatively milder or "benigner" course. Thus we have malignant and benign form of syphilis and tuberculosis. Pernicious cell growths may originate either in the epithelial structures or in the connective tissue. In the one case the resulting disease is carcinoma, in the other sarcoma. All known "malignant" growths pertain to one or the other of these two diseases. An epithelioma, though, in the common acceptation of the term, a skin cancer, is not necessarily a malignant growth, only potentially so. A promising field for the study of malignancy in diseases of the skin and of the conditions relating to it is found in those diseases that, beginning as an inflammation or simple perversion of growth, end in malignant cancer. The epitheliomas that develop on old syphilitic lesions, on lupus, or from some indifferent local irritation of the skin, are common instances.

DR. M. B. HARTZELL spoke on

(b) THEIR ETIOLOGY AND PATHOLOGY.

Heredity, age, traumatism and long-continued slight irritations have long been considered as predisposing, in greater or less degree, to the occurrence of cancer. While heredity is no longer believed to play the important rôle formerly attributed to it, yet it is apparently well settled that cancer is apt to occur in suc-

cessive generations of some families, due, as is now believed, not to the inheritance of the disease, but to an inherited susceptibility. The influence of age upon the appearance of carcinoma is so very evident that it is no longer a matter for debate; in the great majority of cases the patient with cancer is past forty years of age, the exceptions to this rule being in most cases examples of rodent ulcer. Ribbert produced numerous tumors in the abdomen, uterus, diaphragm and pleura of an animal (a rabbit) by allowing free epithelial cells to diffuse through the peritoneal cavity. Cancer possesses a considerable number of features, clinical and pathological, which suggest the possibility of its being an infection, although other explanations are not absolutely precluded. We may regard it fairly well demonstrated that this neoplasm results from a profound and more or less permanent alteration of the mechanism of cell division. This alteration may result from long-continued irritation of a mechanical or chemical kind. The immediate causes are therefore multiple. In cases of xeroderma pigmentosum it may be assumed that some inborn defect of the skin exists.

DR. F. J. SHEPHERD, of Montreal, considered

(c) THEIR TREATMENT.

As a surgeon who had to treat all kinds of malignant disease, wherever situated, excision of the growth and the adjacent lymphatic channels and glands seemed the most scientific procedure in the majority of cases. He said that all now believed in the local origin of cancer, and also that whenever found it should be quickly and completely removed. The disease being local, only local treatment was curative. Constitutional treatment was of no avail.

There are two forms of local treatment, removal by knife and removal by caustics. Surgeons favor the former and dermatologists the latter. The weak point in the treatment of malignant disease of the skin by caustics is that it postponed the removal of the neighboring lymphatic tissue and glands. Dr. Shepherd held that there may be malignant disease of the glands and yet they cannot be always told, as in the axilla and submaxillary region. Even the microscope would fail to detect the disease in the glands, the cancer cells in the very early stage being so few and far between. He instanced the magnificent results of the removal of mammary cancer by modern methods of very extensive operations. In Paget's disease of the nipple he advocated removal of the whole breast. In cancer of the lips, scrotum, penis, vulva and whenever the skin was loose, removal by excision was advocated. Certain malignant ulcerations of the skin he admitted might be successfully treated by caustics, especially rodent ulcer and those slow-growing forms of epithelioma situated in regions somewhat removed from glands, as the nose, forehead, temples, cheeks, hands and where the glands are not early affected. He had successfully employed free curetting and the after application of caustics in such cases. The best caustics were arsenic, chloride of zinc and caustic potash. Some hold that arsenic has a selective action: that is, an inflammation may be produced which will destroy cancer cells but not normal tissue. Before employing arsenic the ulceration should be curetted, or the epidermis over it should be destroyed by caustic potash. Several other methods of treatment were alluded to, such as the parenchymatous injections of alcohol, nitrate of silver, chloride of zinc, electrolysis, aniline

dyes and the injection of toxins. Coley's treatment is more suited to sarcoma than carcinoma. In sarcoma of the skin early and complete removal was the best treatment if the growth were local. When general, some cases have been successfully treated by the injection of a solution of arsenic. The injection of toxins had not proved successful in Dr. Shepherd's hands.

DR. POLLITZER, of New York, read a paper on
A CASE OF NEVUS CANCER; METASTASIS; OPERATION; CURE.

The patient was thirty years old when a small, slightly pigmented mole on the back, about an inch to the left of the eighth dorsal vertebra, began to ulcerate. During six years of treatment the ulcer never healed, and finally began to exceed the limits of the original mole. It was then excised, the skin stitched up, and the wound healed well, producing a linear scar. Six months later the skin in the neighborhood of the scar became raised, red, glistening over an irregular area about two inches in diameter, and broke down at two points, producing small ulcers. Soon after the patient consulted the writer. There was then, in addition to the condition described, a small, hard, round tumor clearly below the skin, and an inch and a half from the edge of the red, glistening patch.

The patch, including the scar and a large extent of healthy skin, was excised, the subcutaneous tumor was found within the substance of the trapezius muscle, and the latter was stripped up from its attachments to the spines of the ninth to twelfth dorsal vertebrae and cut out to an extent that included the tumor. Microscopic examination showed the cutis throughout the red, glistening area to be filled with round, oval and irregular tracts of cancer cells, without connection with the surface epithelium. Examination of the tumor in the muscle showed it to be made up of large nests of cancer cells separated by dense masses of connective tissue, which had replaced the muscle fibres.

Six years have elapsed since the operation, and the patient is entirely free from any sign of a recurrence.

Cases of nevus cancer are usually of such striking malignancy that the favorable result in this case, in which a metastatic deposit had already occurred, makes it worthy of record.

SYPHILITIC LESIONS OF THE "WHEEL" TYPE.

DR. H. G. KLOTZ, of New York, described an unusual eruption observed during the early period of secondary syphilis, and quoted similar descriptions from Taylor and Langehert. The lesions resemble wheals, except for the absence of itching and other sensory symptoms, and for their long duration. Nevertheless he believes it justifiable to accept the lesions as wheals, especially as the conditions found in the wheal of urticaria by several authors would fully account for the clinical features. Dr. Klotz called attention to the want of actual knowledge in regard to angioneurosis, and mentioned a recent paper by Brillippsoro, which attempts to establish the origin of the so-called angioneurosis from embolism.

DR. JOSEPH ZEISLER said he had never had his attention called to this distinct syphiloderm as an independent form, but he had seen a case much like that described by Dr. Klotz.

DR. JAMES NEVINS HYDE, of Chicago, saw no reason why the introduction of a poison such as syph-

ilis into the system should not bring about a series of changes in the skin.

DR. JOSEPH GRINDON, of St. Louis, said we should expect, reasoning *a priori*, to see such eruptions in syphilis.

DR. KLOTZ stated that he was inclined to consider it a syphilitic eruption, different from the erythema and similar affections.

ENDOTHELIOMA OF THE SKIN DEVELOPING IN THE SCAR TISSUE OF LUPUS VULGARIS; ANGIOSARCOMA OF THE SKIN.

DR. JOHN A. FORDYCE reported the case of a patient, the subject for a number of years of a lupus vulgaris of the forearm. A nodular growth developed in the scar tissue which followed various operative procedures on the lupous tissue. The tumor was excised and proved microscopically to be an endothelioma, probably starting in the perivascular lymph spaces surrounding the smaller vessels. From the size and appearance of the cells alone, as well as from the general conformation of the cell collections in the connective-tissue spaces, it would be impossible to differentiate the growth in question from a small-celled epithelioma. The grouping of the cells about the dilated blood spaces, together with the absence of other possible points of origin, enabled a diagnosis of endothelioma to be made. Although epitheliomas springing from lupous tissues have not infrequently been reported, the writer believed the case in question to be a unique one in which an endothelioma has been found in such a connection.

Several instances of angiosarcoma were referred to in which single tumors had been found which were identical in structure with the so-called idiopathic pigmented sarcoma of Kaposi. These growths start from the connective-tissue covering of the vessels and are histologically to be differentiated from the true endotheliomas.

TWO CASES OF RHINOSCLEROMA.

DR. C. W. ALLEN, of New York, presented with colored drawings and photographs 2 cases of rhinoscleroma, one of which had been under his observation since 1889, the other for about three months. Both are already known to literature. In the first case the portion of the growth involving the centre of the upper lip, gum and inferior portions of the nose broke down in a gangrenous suppuration, and within the period of a fortnight was completely thrown off, leaving the bones denuded. These subsequently became covered over with a reproduction of the new growth, so that eating, breathing, sleeping, etc., became more natural and life was prolonged after it had been despaired of. In the case of the man, whose affection had existed for nineteen years at least, there was enormous enlargement of the external nose, dilatation of the nostrils, which were also practically occluded. For nine years a tracheotomy tube had alone made breathing possible, and the stenosis extended the whole length of the pharynx, shutting off the posterior nares by bands and masses of fibrous tissue. Despite the severity of the condition present in both cases, there had been recent improvement in the general health.

AN UNUSUAL FORM OF TUMOR OF THE SCALP.

DR. ALLEN presented a colored painting, gross specimen and microscopic preparation. The tumor,

which had been of slow growth upon the scalp of a woman advanced in years, had been widely excited after the diagnosis of probable carcinoma was made. The chief clinical feature of the tumor was its extreme hardness, almost like that of ivory. This was due to a central encapsulated mass which had undergone hyaline or colloid degeneration. Sections made by Dr. Martin Ware, to whom the reporter is indebted for a description of the appearances, showed an alveolar arrangement of polyhedral cells, growing in a very atypical manner. These cells are arranged about a central canal, indicating that the growth emanates from glandular structure, either sebaceous or sweat gland. The cells do not take the hematoxylin and eosin stain well, because of the degeneration they have undergone.

DRS. S. SHERWELL and J. C. JOHNSTON reported A CASE OF XANTHOMA TUBERCULATUM DIABETICORUM, SHOWING RAPID DISAPPEARANCE OF LESIONS UNDER ANTIDIABETIC REGIMEN AND TREATMENT.

As long ago as 1890 Dr. Sherwell sent one of these cases to Dr. A. R. Robinson. The patient in the present case was a woman, age forty, somewhat plethoric, apparently well nourished, who was first seen on January 8, 1900. The urine was full of sugar. The lesions were first noticed between five and six years ago, most marked on the arms, elbows, knees and nates, and are less noticeable during the summer months. Last winter the symptoms became so distressing that she could obtain no relief by night or day. It would seem that from the first she had had classic symptoms of glycosuria. The appearance was such that, roughly speaking, at the distance of the width of a room the eruption might have been taken for a case of variola at the height of the pustular and confluent stage. She was put upon antidiabetic regimen and diet, together with mild laxative alkaline treatment, and rapidly improved. The papular and tubercular masses flattened, the inflammatory halos entirely disappeared. At present there is scarcely even a pigmented spot to mark where the original lesions existed. The glycosuria is quite slight. So far only about 30 such cases have been reported.

DR. JAMES CLARK WHITE inquired whether the blood had been examined.

DR. JAMES NEVINS HYDE said he had seen at least 2 such cases.

DR. SHERWELL, replying to Dr. White, stated that the blood had not been examined. The lesions were not compressible, looking almost like a pus formation or a conical furuncle. The patient felt as if there were crumbs in the bed.

BLASTOMYCETIC DERMATITIS AND ITS RELATION TO YAWS.

DR. ISADORE DYER, of New Orleans, read this paper. In many particulars the case fulfilled the clinical characteristics of yaws. Dr. Dyer examined specimens and confirmed the diagnosis of blastomycetic dermatitis. Under the iodide treatment the improvement was rapid, the lesions flattened, the exudate diminished. Finally mercurial plasters were applied to all of the lesions, successfully reducing the granulations. At the present time the face shows a smooth, glossy area, marked here and there by a fibrous tab, and with a large, branching, somewhat keloidal scar

in the lower part of the area. Over all there is a fine linear network of scars, soft but marked.

THREE CASES OF BLASTOMYCETIC INFECTION OF THE SKIN, ONE OF THEM PRODUCING A "TUMOR" OF THE LOWER LIP.

DR. F. H. MONTGOMERY and DR. H. T. RICKETS reported these cases.

DR. J. N. HYDE, of Chicago, gave

A REVIEW OF THE SUBJECT OF BLASTOMYCETIC INFECTION OF THE SKIN, WITH A REPORT OF TWO NEW CASES.

The subject of blastomycetes was discussed by Dr. James C. White, Boston; Dr. William A. Pusey, Chicago; Dr. John T. Bowen, Boston; Dr. H. G. Klotz, New York; Dr. Samuel Sherwell, Brooklyn; Dr. M. B. Hartzell, Philadelphia; Dr. Joseph Zeisler, Chicago; Dr. John A. Fordyce, New York; Dr. James C. Johnston, New York; Dr. T. C. Gilchrist, Baltimore; Dr. Frank Hugh Montgomery, Chicago; and Dr. James Nevins Hyde, Chicago.

A CASE OF ERYTHEMA ELEVATUM DIUTINUM (?) was reported by Dr. T. C. GILCHRIST, of Baltimore, who said that the case did not recall the diagnosis of lichen planus, and did not at all resemble Galloway's case of ringed eruption.

DR. J. N. HYDE said he had seen a case which was almost identical with Galloway's case.

A vote of thanks was tendered to the retiring president, Dr. Henry W. Stelwagon, of Philadelphia, and Dr. Francis John Shepherd, of Montreal, the newly-elected president of the association, was inducted into his office. This was followed by adjournment.

THE OBSTETRICAL SOCIETY OF BOSTON.

MEETING of February 20, 1900, the President, DR. A. WORCESTER, in the chair.

DR. F. H. DAVENPORT read a paper entitled

THE USE OF THE ANGIOTRIBE.¹

DR. G. W. WASHBURN: I am rather impressed by the apparent clumsiness of the instrument, and would fear that there would be more or less dragging upon the tissues. The danger of secondary hemorrhage is not, it seems, as great as one would fear.

DR. W. L. BURRAGE: I have seen the instrument used in only one case, and was not especially impressed with it then, as it seemed clumsy and heavy. A separate assistant is needed on account of the danger of dragging upon the tissues. I have noticed that some men after using the angiotribe cauterize as well, as if suspicious of the absolute safety of the instrument, which seems to me rather a return to methods discarded years ago. I have been fairly well satisfied with the use of animal ligatures in abdominal work, and would not feel inclined to use it there. Its best field would be in vaginal hysterectomies, where vaginal ligatures are apt to become infected and clamps are greatly in the way. Its clumsiness seems to me rather a disadvantage for use within the abdominal cavity. The feeling of lack of security of which I have spoken makes me feel rather sceptical as regards its use in the future.

¹ See page 4 of the Journal.

DR. J. G. BLAKE: Theoretically vaginal hysterectomy would seem to offer a very good field for the instrument. It is a great disadvantage to obstruct the view with many clamps, which are also very annoying to the patient afterwards, for forty-eight hours very likely. If this instrument can be modified so as to become lighter and yet retain its crushing power I should regard it as a great addition to our armamentarium.

DR. J. C. MUNRO: I should like to ask how many cases of intermediary hemorrhage have been reported where this instrument was used?

DR. DAVENPORT: I could not find a single case out of the 200 or so I examined in which any such hemorrhage was due to the instrument. In one case there was a hemorrhage, but it was thought to be due to an improperly made instrument, the edges of the blades being too sharp. Another case of supposed secondary hemorrhage was in reality bleeding from the cut edges of the vagina and not from the tissues crushed by the angiotribe.

DR. MUNRO: Though this instrument may be of use in the vagina I am sure that in the abdominal cavity I should stick to silk or some such approved method.

DR. DAVENPORT: Dr. Burrage has spoken of some operators using the cautery after the angiotribe. I hardly think it was used so much with the idea of cauterization and so preventing a hemorrhage as to avoid adhesions. Skene showed here some two years ago his electrical clamp, which cooked the parts between its blades. The objection to that is that it requires special apparatus, and can hardly be used at private operations away from a large hospital.

I agree with the speakers that the main use of the instrument will be in vaginal work. In abdominal work I would limit it to septic cases or others where I wished to avoid ligatures. In the case in which I used it in the abdominal cavity I was doing a secondary laparotomy to relieve a tender stump, caused, it was thought, by an infected ligature. Here the use of the angiotribe was very satisfactory. I think if a smaller instrument doing the same work has been perfected it may be an advantage, but this one is not practically nearly as clumsy as it looks.

DR. M. H. RICHARDSON read a paper entitled

REMARKS ON THE SURGERY OF UTERINE FIBROIDS, WITH ESPECIAL REFERENCE TO THE IMPORTANCE OF EARLY REMOVAL IN THE YOUNG.²

DR. F. B. HARRINGTON: The many cases I have seen in which enucleation was quite easy and satisfactory make me feel more and more the importance of saving the uterus when it can be done. I still feel that hysterectomy is almost the most serious operation with which I am called to deal, and I still have a certain hesitation about advising an operation in cases in which the symptoms are not severe, especially cases where I have a chance to watch the patient myself, or where I know she is in good hands. Possibly thinking over this paper will convince me of the need of earlier operation, but at present I am inclined not to be too hasty about urging it.

DR. W. F. WHITNEY: There are many points of interest from a pathologist's stand, bearing upon the views advanced by Dr. Richardson.

Against enucleation, the fact of the frequent multi-

plicity of small growths which cannot be detected in the thickened wall and may subsequently develop into large and dangerous ones must be borne in mind. More precise knowledge is needed on the subsequent history of those that are left behind—whether their growth is accelerated or retarded by enucleation of some of them.

Another question which has yet to be answered is whether enucleation will restore the atrophied or hypertrophied mucosa to its normal condition again, and so prevent recurrence of hemorrhage.

The suppuration is due to infection supervening upon the anemic necrosis to which these growths are very liable. But if this does not happen partial absorption and calcification may be looked for as a favorable result, which, with the associated shrinkage, may account for some of the cases of spontaneous cure.

I have never seen a case of a direct change of a fibroid into a malignant growth; but have frequently seen associated malignant disease, usually cancer, and once or twice sarcoma.

DR. W. L. BURRAGE: I agree with Dr. Richardson in early diagnosis and operation. Many cases are allowed to go on too far, especially the hemorrhagic ones. There is one method of investigation that is too often neglected, that of using the finger within the uterine cavity. Submucous fibroids can be made out in this way and often removed without sacrificing the uterus; if necessary, the uterus can be split in the median line and then closed again after removing the tumor. A large amount of the uterus can be removed and yet enough mucous membrane left to line the cavity. The hemorrhage in this operation can be controlled very easily by an assistant grasping the uterus from above. I would always leave the uterus in young women when possible. As to the danger of the development of other tumors after enucleation we can warn the woman of the possibility, and then operate a second time if necessary, but the chances of such a recurrence are very small. Preserve the organ if you can. Diagnose early and operate early and many women will be saved from later disaster. I agree most cordially with what has been said by Dr. Richardson about the importance of careful preparation. Every drop of blood is of importance. In some cases the patient should be kept in bed for a long time before the operation, and given ergot or hydrastis or stypticin, etc.

I am glad that Dr. Richardson has taken this ground about the importance of the early removal of fibroids. It is time that this teaching should be preached.

DR. BLAKE: In the course of the last thirty years I have had a chance to watch the change in the views held by the profession as to the proper treatment of fibroids and am not yet ready to accept the doctrine of indiscriminate operation. Of course we have all known many cases of women carrying for years large fibroids in comparative comfort, and we also have all had cases in which the hysterectomy we urged was followed by untoward results and cut short lives that might otherwise have continued for years. Colored people are especially apt to have fibroids, as we know, yet many of them get along perfectly well without much suffering. We should in every case consider very carefully whether the gravity of the symptoms justifies so serious an operation.

DR. DAVENPORT: I feel strongly the importance of early operation. The dangers a tumor is liable to

² See page 1 of the Journal.

give rise to are numerous and must not be forgotten. As regards the development of other tumors after one has been enucleated, I hardly feel that we can so lightly say another operation can then be done. Myomectomy is so serious an operation that I think we ought to lay the possibility before the patient and let her decide for herself, whether she wants to run the risk or not of a secondary operation. The question of operation would also be determined for me by my relations with the patient. If the patient were one that I could follow or was under the care of some one in whom I had confidence I might wait. It is surprising how large a tumor can be enucleated yet the uterus be but little mutilated. I am getting more and more inclined to remove small tumors and in my eyes the whole question hinges upon the comparative safety of the operation as now done. A fibroid is a pathological condition and operation in the early stages is almost always successful. The patient has the right to be relieved of possible future danger. As to building up, the method I have found best to avoid loss of blood is whenever the patient is bleeding to pack the vagina tightly, changing the packing whenever needed. This method may be kept up for weeks or months and is much more effective than any drugs.

DR. J. L. HILDRETH: In the past I have many times asked myself what the prognosis was to be in a given case, and now I know no better way of telling than I did then. I wish we could have some tangible principles to work upon, but there are none as far as I know.

DR. G. J. ENGELMANN: I do not think it is as rare to see these tumors disappear as would seem to be the case from what has been said here to-night. The man in general practice is more apt to see such cases than the surgeon, who very likely sees the patient only when she is brought to him to be operated upon. I have five such cases vividly in mind, cases with large, easily bleeding tumors which disappeared in time. Years ago in post-mortem work I saw many cases in which unsuspected fibroids were discovered. I have also seen many cases where treatment has succeeded in keeping the patient along in good health. The question of operation all depends upon the conditions present, whether we can keep the patient under close observation or not. My feeling is to wait till symptoms develop and then operate only when other methods have failed. Rapid growth would indicate operation. I see no way to determine in a given case what the future is to bring forth. I have seen cases where puncture seemed to hasten changes for the worse. Preservation rather than removal is the spirit of modern surgery. I do not believe in the principle of early operation if that means the removal of small tumors before there are any symptoms.

DR. MALCOLM STORER: If symptoms are waited for it will often be found that operation presents many difficulties. The removal of a small fibroid by enucleation before there have been any inflammatory processes to complicate matters is so simple an operation that to me its dangers are far less than those coming from the practice of waiting for symptoms to develop.

DR. RICHARDSON: I would reply to all that has been said by various members about not operating until other treatment is exhausted by quoting from my paper that if the tumor can be controlled we should not operate. I confess to a certain scepticism as to the disappearance of fibroids without operation. All

that I have seen disappear have been through the activity of some surgeon. Of course I have under my care, as has every man, more or less fibroids that I do not operate upon but keep under observation. These cases are quite different from cases seen as I see them at the hospital.

AMERICAN MEDICAL ASSOCIATION.

FIFTY-FIRST ANNUAL MEETING, HELD AT ATLANTIC CITY, N. J., JUNE 5-8, 1900.

SECTION ON THE PRACTICE OF MEDICINE.

(Concluded from Vol. CXLII, No. 25, p. 670.)

DR. SOLOMON SOLIS-COHEN, of Philadelphia, read a paper entitled

THE RELATIVE IMPORTANCE OF VALVULAR AND MUSCULAR LESIONS OF THE HEART.

The exact site and nature of the valvular lesions are of less importance therapeutically and prognostically than the state of the cardiac muscle. Mitral stenosis with great narrowing is an exception to this general rule. Aconite is often used in this condition to reduce the excessive muscular effort. The symptoms and physical signs of cardiac myopathy are inconstant, and in the early history of the case may be slight. In the absence of valvular lesions, intermittence or irregularities of the pulse or apex beat, disturbance of rate or rhythm by slight causes, and recurrent pain referred to the pericardium in non-hysterical and non-neurasthenic subjects, are the principal local symptoms calling attention to the disease of the cardiac muscle. Tinnitus, vertigo, dyspnea, venous ectases, visceral congestion, edema and other evidences of circulatory disturbance may be slight and escape attention until sought for. There is usually impurity or weakness of the first sound of the heart, with approximation of the two sounds in quality or relative accentuation of the second sound; later embryocardia and gallop-rhythm may develop. Gout, syphilis, alcohol and tobacco, lead-poisoning, tea and coffee, sexual excesses, mental strain and physical overwork, either in serious pursuits or sports, are among the chief provocatives of disease of the myocardium, apart from those lesions secondary to the acute infections or consecutive to nephritis or valvular disease. Among the acute infections, influenza is a frequent cause of cardiac muscle disease. The diagnosis between neurasthenia of the heart and disease of the myocardium may be difficult. The chief importance of the subject lies in the avoidance of error in the prognosis and treatment of valvular disease, which may be overtreated or undertreated through failure to estimate properly the condition of the muscle; in the recognition of serious lesion of the muscular structure of the heart in cases that have been supposed to be normal because of the absence of valvular murmurs; in the distinction between organic and muscular lesions and functional disturbance, and in the realization of the fact that the latter may lead to the former. In treatment, judicious regulation of diet, rest and exercise, avoidance of exciting causes, and excesses of any kind, the good functional condition of the skin and eliminative organs are of the first importance. Warm, saline, carbonated baths, and, in some cases, gentle massage and resistance exercises carefully adapted to the individual case are of great

benefit. Nitroglycerin is the most useful single agent of the materia medica. Strychnine, digitalis, adonis, cactus, strophanthus and spartein have their usefulness in individual cases. Arsenic, gold and sodium chloride and iron are useful tonics. Potassium iodide and mercurials sometimes have special indication. Venesection should be made promptly and sufficiently early in the case of sudden and urgent symptoms of cardiac failure.

A CLINICAL STUDY OF MYOCARDITIS.

DR. LOUIS FAUGÈRES BISHOP, of New York City, read this paper. Valvular and arterial disease are modified appreciably by myocarditis. The myocardium is as important as the endocardium or the pericardium in cardiac disease. Myocarditis is eminently a clinical disease. Syphilitic cases are the most acute and often result fatally in young persons. There are two clinical groups of the disease: (1) Myocarditis due to infectious diseases and (2) myocarditis due to disease of the blood-vessels. The significance of pain in the left shoulder and left breast is difficult to determine, but in persons past middle life it should lead one to suspect myocardial disease. The chief symptom of the condition is the lack of power of the heart to respond to extra work. The earliest symptom is irregularity in the force and rhythm of the pulse. The disease is very common in the negro race, probably owing to the tendency of mixed races to degenerative changes. Complete physical rest is important in the treatment of cases of myocarditis. It may be caused by the intemperate use of alcohol, disuse of the muscular system in general, overwork, worry and infectious diseases.

A PLEA FOR A MORE RATIONAL PROGNOSIS IN CARDIAC AFFECTIONS,

by DR. J. J. MORRISSEY, of New York City. Diagnosis should not be based solely upon physical signs, but on a consideration of the cardiac efficiency, the presence of hypertrophy and of the condition of organs far removed from the thoracic cavity, whose relations, while not intimate, yet are closely affiliated with the results arising from an interference with the circulatory system, in consequence of the cardiac disease. Obtain an accurate and comprehensive history of the causation. Closely consider any special features characterizing the case. When a heart murmur is discovered, do not give a gloomy prognosis upon that fact alone; consider the condition of the cardiac walls, the probable length of time the lesion has existed, the presence of dilatation or hypertrophy, or both combined. The occupation and temperament of the patient are very essential factors in the prognosis. Murmurs do not invariably mean endocarditis, and a prognosis based simply on the presence of a murmur would be rank injustice to the patient, and demonstrate incapacity upon the part of the physician. A presystolic murmur does not always indicate a mitral stenosis, nor has a so-called musical apex murmur any particular significance in prognosis, indicating, as it does, the passage of a stream of blood through a small aperture in the segment of a valve. From the standpoint of longevity aortic stenosis is a favorable lesion. It is usually found in that period when a man should be at the highest point of physical capability, between thirty and fifty. It is frequently present as a part of a general decay, and then develops in consequence of

atheromatous changes taking place throughout the system, but it is more frequently present than has hitherto been suspected without such pathological manifestations being present. Do not inform a young man between eighteen and twenty-five that he has heart disease, because you discover some hypertrophy, with no complication, the result in most instances of active exercise. Never hesitate to ask a patient to return for further examination, as the condition then may be entirely different from the original investigation. There are more snap "diagnoses" made in the realm of cardiac affections than in the study of diseases in any other portion of the body.

DR. FRANK BILLINGS, of Chicago, said that acute ulcerative endocarditis might result in sudden death. In atypical cases it may not present the classic symptoms; emboli may or may not be present. It is difficult to diagnose; but among the symptoms of importance are low blood pressure and anemia. Myocarditis frequently is due to chronic toxemias. The disease gives rise to nervous symptoms; gastro-intestinal symptoms may arise; then dyspnea and oppression supervene, the pulse changes in character and there is evidence of malnutrition. Myocarditis requires early attention.

DR. DELANCEY ROCHESTER said that acute ulcerative endocarditis is very difficult to recognize. Leucocytosis is often very marked, and when there is no evidence of a localized collection of pus the occurrence of this phenomenon should lead to a suspicion of the disease. He spoke of a case in which the ulcerative process had perforated the interventricular septum without producing a murmur. The changes in myocarditis are the most serious of any heart lesions and are frequently overlooked. Of the valvular lesions, aortic insufficiency is most dangerous. The presystolic murmur is of less serious prognostic import in cases of mitral obstruction than the diastolic murmur. The condition of the general circulation is very important, since changes in the arteries of the body indicate changes in the coronary arteries. The disappearance of a murmur that has existed for a number of years is serious, because it indicates marked changes in the muscle.

DR. JAMES B. HERRICK, of Chicago, said that the present tendency was to lay more stress on the heart muscle than on the valve. The time has passed when a diagnosis of a cardiac condition can be made merely from the presence of a murmur. Besides making a definite diagnosis of a valvular lesion we must go farther and determine the condition of the muscle, because patients with valvular disease can live a long time if the muscle is intact. In cases of acute articular rheumatism it is difficult to speak of the condition of the myocardium. The significance of a murmur appearing in the course of rheumatism is doubtful; it may indicate myocarditis, endocarditis, or hemic change. In the treatment of myocarditis rest is of the greatest importance. When dilatation has occurred and death is imminent, bleeding is of value.

DR. JUDSON DALAND, of Philadelphia, spoke of a case of acute ulcerative endocarditis in which there was leucocytosis and said he thought that the sign was of no great value. He spoke of a second case in which antistreptococcus serum was used, and in which alarming symptoms developed in consequence.

DR. HOWARD M. FUSSELL, of Philadelphia, spoke of the importance of other signs than murmurs in

making the diagnosis of the condition of a heart. He spoke of loud systolic murmurs at the base of the heart that were transmitted into the vessels of the neck that were not necessarily indicative of aortic stenosis. Heart lesions, on the other hand, may exist without the appearance of a murmur. The treatment should be based on the condition of the pulse, the size of the heart, the character of the first sound, and the absent or feeble apex beat. He does not think that the costal fringe is a sign of great importance in cardiac disease.

DR. BABCOCK, of Denver, said that myocardial changes in rheumatism in children were common. He thinks that the myocardium is the most important factor in the prognosis of a heart lesion.

DR. WITHERSPOON, of Nashville, Tenn., said that in his experience death in cases of aortic stenosis was due to the condition of the blood-vessels, particularly those of the brain. A heart that is compensated needs no treatment.

DR. S. SOLIS-COHEN said that the costal fringe is an evidence that myocardial change is possible if not probable. Organic murmurs do not solely mean valvular disease, but may indicate disease of the papillary muscles, etc. Hemic murmurs should be differentiated; they may be vascular or muscular as well as hemic. He is an advocate of venesection in cases of threatened cardiac collapse.

DR. L. F. BISHOP said that loud murmurs are often due to dilatation of the heart.

DR. MORRISSEY said that he thinks that tachycardia and bradycardia are not distinct entities. It is difficult to diagnose between dilatation, fatty degeneration and myocarditis.

IN WHAT RELATION DOES OCCUPATION STAND TO TUBERCULOSIS?

DR. W. FREUDENTHAL, of New York City, read this paper. In 1,500 cases of tuberculosis tailors were the most frequently affected, those who work in sweat-shops and who live in dark, unventilated rooms particularly. Tuberculosis is a trophoneurosis combined with a vascular insufficiency which produces a favorable seat for the growth of the micro-organism. Such favorable soil is frequently produced in the retropharyngeal space.

DR. J. M. ANDERS, of Philadelphia, read a paper entitled

DIAGNOSIS AND TREATMENT OF THE PREBACILLARY STAGE OF PULMONARY TUBERCULOSIS.

The prebacillary stage is of long duration and signifies the entire time before the bacilli are found in the sputum. During this period the diagnosis is to be made by (1) the use of the x-rays, (2) the application of the tuberculin test, (3) a careful study of history, symptoms and physical signs; among the most important of the symptoms is a two-hour temperature record. This will show an elevation of temperature at a given time daily.

THE IMPORTANCE OF REST IN PULMONARY TUBERCULOSIS,

by DR. CARROLL E. EDSON, of Denver, Col. The indications for rest in pulmonary tuberculosis are the same as those for rest in joint and bone tuberculosis. Local tissue rest is very essential, although the obtaining of absolute rest of the lung is difficult. When the

body is at rest the respiratory and cardiac action is lessened and temperature is lowered. The rest may be taken in the open air and should be continued for a long time.

PULMONARY TUBERCULOSIS; PRESENT CONDITION OF CASES TREATED DURING 1898 AND REPORTED LAST YEAR AT THE COLUMBIAN MEETING,

by DR. C. P. AMLER. Cases of pulmonary tuberculosis should not be reported cured until a long time had elapsed. Of 46 cases called class "A," 35 were apparently cured, nine were greatly improved, and one was stationary. Of 28 cases called class "B," six were apparently cured, 13 were greatly improved, eight were improved, and one died. Of 32 cases called class "C," nine were greatly improved, five were improved, six were stationary, 11 were worse, and one died. The treatment was (1) by hygienic supervision, (2) by climatic influences, (3) by medication, (4) by serum therapy. Cases apparently cured under serum therapy are less liable to relapse.

TUBERCULOSIS OF THE LUNGS.

DR. A. F. LEMKE, of Chicago, said tuberculous lesions probably never heal by resolution—always by cicatrization; hence in attacking them it is rational to further the natural tendency to cicatrization. Healing of a focus of tuberculosis in the lung is probably always altogether the result of tissue changes which diminish or inhibit the absorption of proteins derived from the bodies of tubercle bacilli. Good effects of compression, locally, are brought about by the limitation of areas of disease already existing by favoring fibrosis in and about these areas; by occluding the avenues of dissemination of the virus, and by compressing cavities to enable them to heal mechanically. Other effects of compression are due to rest to the organ as a whole, emptying of secretions, prevention or diminution of absorption of toxic bodies, prevention of secondary infections, and the diminished tendency to hemorrhage. There is no evidence that fresh tubercles can develop in a compressed lung. The average quantity of nitrogen which may be introduced into a pleural cavity without untoward effects is 120 cubic inches. Healthy lung tissue may be compressed for a year or more and retain its capacity for expansion upon the removal of pressure. Uses of intrapleural injections of nitrogen: (1) Curative in pulmonary tuberculosis; (2) palliative—to prolong life for weeks or months, though the disease be too extensive to make recovery probable; to diminish fever and expectoration; (3) to check pulmonary hemorrhage; (4) to compress cavities, tuberculous and others, and establish mechanical conditions that will permit their healing, and (5) to compress the lung just prior to surgical operations.

DR. THOMAS J. MAYS, of Philadelphia, read a paper entitled

SILVER INJECTION TREATMENT OF PULMONARY CONSUMPTION.

In discussion DR. VICTOR C. VAUGHAN, of Ann Arbor, Mich., said that tuberculosis should be diagnosed in the prebacillary stage, if possible, if anything is to be accomplished in the way of treatment. He believes that the temperature of tuberculosis is more characteristic than that of typhoid fever; but many things cause it to vary. Rest is one of the great benefits of sanatorium treatment. When the temperature

is not high a moderate amount of outdoor exercise may be indulged in. Many patients suffering from argyria as a result of the use of silver in the treatment of epilepsy developed tuberculosis.

DR. DELANCEY ROCHESTER, of Buffalo, thinks that the spread of the disease may be in a measure accounted for by the habit that tailors and sewing women have of wetting the thread that they use in the making of clothes.

DR. S. SOLIS-COHEN, of Philadelphia, said that there is a disease before the bacillus gets into the tissues; when the bacillus arrives there is a certain toxemia set up, and then there follows a secondary infection with pus cocci. In tuberculous patients between 12 noon and 2 p. m. is the time of highest temperature in the incipient cases, except in those cases of inverse temperatures. In cases of reported recovery it is essential to state the time that has elapsed since the cessation of symptoms.

DR. KNOPP, of New York City, is glad to know that the idea of a specific climate for tuberculosis had been abandoned. A class of persons almost as frequently affected with tuberculosis as the tailors is that class that are engaged in assorting the soiled clothes in laundries and those that assort rags. The rest cure should be alternated with gentle exercise or with massage. In order to improve and lessen the number of tuberculous cases it is necessary to improve the housing of the poor by doing away with the present class of tenement houses and replacing them by sanitary dwellings. It is necessary to have special hospitals in every city for the consumptive poor, so that to their tuberculosis they may not have nostalgia added by being sent away from home.

DR. NEWTON, of New Jersey, cited a case that seemed to show that certain cases of anemia presented an evening rise of temperature, similar to that seen in tuberculosis.

FOURTH DAY.

CONTINUATION OF THE DISCUSSION ON TUBERCULOSIS.

DR. C. P. AMBLER said that he was not connected with any sanitarium and that the cases that he reported were cases in private practice.

DR. MAYS said that he thought that the doses of silver nitrate that he uses would not produce argyria. He has never seen toxic effects. He believes that no tuberculous patient would throw off the liability to the disease no matter how long he should live, but if a tuberculous patient is relieved of his symptoms for a year he is practically well.

DR. LEMKE said cases of pneumothorax end fatally either because too large an amount of air is forced into the pleural cavity or because there is an infection.

DIAGNOSIS OF DIABETES.

DR. JAMES B. HERRICK, of Chicago, said the crucial test for the existence of diabetes is the finding of sugar in the urine and determination of the permanence or transitory nature of the glycosuria. He spoke of certain symptoms that would lead one to suppose that sugar would be found in the urine. Impotence and psychic disturbance are often early symptoms. Cases are overlooked because there is an error in the technic; the urine may not be examined for sugar, or the sugar may not be present. Casts are frequently found in diabetic urine and usually indicate the development

of coma. Such a condition may lead to the diagnosis of uremia. Urines of low specific gravity may contain sugar, and, consequently, every specimen should be examined for glucose. It is important to recognize the form of the diabetes. A convenient classification is into (1) mild, (2) severe, and (3) malignant.

MORTALITY FROM DIABETES MELLITUS IN THE CITY OF NEW YORK DURING THE DECADE 1889-99.

DR. HEINRICH STERN, of New York: In 1860, of the deaths from diabetes, nearly 50 were in females. The number of deaths from diabetes has been increasing since 1894. The mortality from diabetes is greatest in October and least in November. The greatest mortality is between the forty-fifth and fifty-fourth years. The mortality in females, 64, after the forty-fifth year, is possibly explained by the degenerative changes following the menopause. In childhood and adolescence diabetes is rare. In the colored population during this period there were only 15 deaths.

CUTANEOUS DISEASES ACCOMPANYING DIABETES.

DR. MILTON B. HARTZELL, of Philadelphia, called attention to the fact that in many instances the skin presents pathologic changes accompanying diabetes. The greater number of skin lesions are inflammatory in character. There may be desquamation from deficient secretion of sweat and serum, accompanied by changes in the hair and nails, and by pruritus. Erythema, urticaria, eczema of the genitalia, acne cachecticorum, crops of boils, carbuncle, papillomatosis diabetica, gangrene of the skin, bullous serpiginous gangrene and exanthema diabetorum are common lesions. Psoriasis dermatitis herpetiformis, abnormal deposits of pigment and purpura are rare. Local treatment is the same as that of similar conditions in non-diabetics, but the treatment of the underlying cause is the most important.

DR. S. SOLIS-COHEN, of Philadelphia, dwelt upon the importance of examination of the urine in every case; but every case of glycosuria is not diabetes. A usually unrecognized symptom of diabetes mellitus is bilateral sciatica.

DR. JAMES J. WALSH, of New York City, called attention to the fact that diseases that were formerly considered rare are in reality more frequent. The common occurrence of tuberculosis and nephritis in such cases often leads to an error in diagnosis.

DR. WATKINS, of New York City, spoke of the increase of the biconcavity of the red blood corpuscles in advanced cases of diabetes.

DR. MORRISSEY, of New York City, said that it was necessary to treat the patient and not the disease. In life insurance examinations he finds a large number of alimentary glycosurias. Opium is still the standby in the treatment.

DR. WAHRER, of Iowa, said that it was easier to diagnose the disease than to treat it. He does not believe in a rigid diet without sugar.

DR. A. E. ROUSSELL, of Philadelphia, said glycosuria is sometimes an indication of myxedema, which would be benefited by thyroid treatment. He is of the opinion that the diets as laid down are too rigid.

DR. OSBORNE, of New Haven, Conn., called attention to the relation between pancreatic disease, myxedema, nervous disease, exophthalmic goitre and dia-

betes. He also thinks the diet should not be too rigid.

DR. HERRICK said that the apparent immunity of the colored race might be due to the manner of living of that race. He called attention to the rarity of the disease in hospital patients and its frequency in private practice as confirmatory evidence of this influence of living on the disease. He does not believe in the too rigid enforcement of diet.

DR. STERN said 70 per cent. of deaths from diabetes occurred in the tenement houses, 15 per cent. in hospitals, and 15 per cent. in private practice. It is common in the Irish population. He divides the disease into the preglycosuric stage, the stage called diabetes mellitus, and the postglycosuric stage. Diabetes is a plasmolysis; he recognizes it by an increased output of nitrogen in addition to the glucose. The oxybutyric acid is the result of a diet of fat and meat. The existence of Kussmaul's breathing is necessary to the diagnosis of diabetic coma.

EXOPHTHALMIC GOITRE.

DR. O. T. OSBORNE, of New Haven, Conn., is of the opinion that the name is a misnomer and suggests the name of Graves's thyroid disease. Of the cases 80 per cent. occur in women during the most acute period of their sexual life. He believes that the symptoms are due to hypersecretion of the thyroid body. The course of the disease is divided into (1) prethyroid period; (2) period of incipient symptoms; (3) period of active symptoms; (4) defervescence or stage of complications resulting in death. The treatment should be such as to lessen the secretion of the gland. He recommends absolute rest in bed. There is no question of the advisability of removing parts of the gland when pathologic conditions are present. He doubts the value of suprarenal extract, but thinks that thymus gland extract is better.

DR. JAMES B. HERRICK, of Chicago, said that there were undoubtedly many patients that have the symptoms of the disease before they consult a physician and before the symptoms fully develop. He is of the opinion that he has seen a patient that was benefited by the increase of fibroids of the gland following the opening of a cyst of the thyroid.

DR. S. SOLIS-COHEN, of Philadelphia, believes that there is something more than hyperthyroidism in the etiology of this disease. After rest he believes that the best treatment is by extract of suprarenal body. Digitalis is not to be given in every case. Good results have followed the use of $\frac{1}{800}$ grains of hyoscin hydrobromate over long periods of time and $\frac{3}{16}$ or $\frac{1}{16}$ grain of picrotoxin. Ergot has been found useful.

DR. OSBORNE said that the affection properly belonged under the head of functional disturbance.

TREATMENT OF TYPHOID FEVER WITH BACTERIAL IN CONNECTION WITH OTHER AGENTS.

DR. JAMES M. PECK, of Arlington, Ky., thinks that in private practice the nearer that the physician can reach the conditions of the Brand method the better will be the results. He uses calomel and chlorine, followed by washing the bowel with sterile water. He believes that intestinal antiseptics strengthens the wall of the bowel and prevents sloughing. He reported 77 cases in which the treatment was used, with recovery in every case.

DR. EUGENE WARDIN, of the United States Marine-Hospital Corps, said that it was undoubtedly a fact that the bacillus of Eberth caused the disease. Typhoid fever is no more a local disease of the intestines than small-pox is a local disease of the skin. All the acute infectious diseases are produced by agents that are toxic on the one hand and septic on the other hand. Between these extremes there are all gradations. The typhoid bacillus has little toxicity but is extremely septic, and typhoid fever is a septicemia. He believes that the portal of entry of the typhoid infection is, in the majority of cases, through the respiratory tract.

LESIONS OF THE CAUDA EQUINA AND CONUS MEDULLARIS,

by DR. BERTRAM W. SIPPY, of Chicago. When lesions of the conus medullaris exist sensation will be impaired in the integument of the pelvis, the dorsal surface of the scrotum, the perineum, the anus, the inner aspect of the buttocks, the posterior surface of the thighs. He reported 7 cases, of which 1 came to autopsy. He called attention to slipper anesthesia as an indication of these lesions.

MOVABLE KIDNEY FROM THE STANDPOINT OF THE GENERAL PRACTITIONER.

DR. A. MARCY, JR., of Riverton, N. J., read this paper.

The most important etiologic factor in the production of movable kidney is the absorption of the perirenal fat. He prefers to examine for this condition when the patient is in the upright position. The ideal treatment is surgical and nephrorrhaphy in his experience is the most satisfactory operation.

DR. CLEVELAND, of Cincinnati said that in his experience movable kidney is almost always associated with enteroptosis or gastroptosis and should be classed as a general abdominal condition. He thought that operation would hardly be efficient.

THE ANTISEPTIC TREATMENT OF DIPHTHERIA.

DR. D. BENJAMIN, of Camden, who read this paper, advocates the local application of antiseptics to the false membrane in the throat.

DR. WM. M. WELCH, of Philadelphia, said that it is well known that local applications do not kill the organisms in the false membrane.

THE CLIMATOLOGY OF ARIZONA.

DR. WILLIAM DUFFIELD, of Phoenix, said that Arizona is a territory 400 by 350 miles in extent containing almost every physical feature and variety of climate known. The mean temperature varies from 50.7° to 64° in the different parts of the State. There is very little vegetation except in the irrigated districts. On the plain the mean temperature is 70°; total precipitation is 5.19 inches; mean relative humidity 49 per cent. There were 245 clear days in an average year. The climate has a maximum of sunshine, a minimum of humidity and a possibility of constant outdoor life.

DR. HOWARD S. ANDERS, of Philadelphia, read a paper entitled

CERTAIN CLINICAL FEATURES OF INFLUENZA RECENTLY EPIDEMIC.

The paper was based on a study of 128 cases.

Recent Literature.

The Treatment of Diseases of the Nervous System.
By JOSEPH COLLINS, M.D. 8vo. Pp. xiv, 602,
with 23 illustrations. New York: William Wood
and Co. 1900.

In view of the fact that many of the methods of treatment employed in nervous affections are of a special and somewhat technical character, it is somewhat singular that we have had to wait so long for a comprehensive treatise on the whole subject, giving a full account of these various methods and assigning to each its relative position more justly than the hand-books devoted to any single method are apt to do. The need of such a treatise has been apparent to all save those who still believe that diagnosis and not therapeutics is the goal of all neurological study. The volume before us meets that need in admirable fashion. It treats the subject thoroughly and completely, it recognizes the limits of our therapeutic resources, but it presents those resources in abundant detail and it is in the main a judicious and trustworthy guide to the practitioner. The first part of the work deals with the causes, origin and prevention of diseases of the nervous system; chapters of marked interest which may be read with profit by every physician. Of the various causes, more stress is laid upon syphilis than any other, and the writer, recognizing that syphilitic lesions in the nervous system may do irreparable damage before treatment can modify them, and that treatment is often ineffective when syphilis involves the nervous system, urges energetic and persistent treatment of the disease as soon as it is recognized, even in its "primary" stage—advice which must commend itself to all who are familiar with the course of syphilitic nervous affections. In dealing with other important questions in the causation and prophylaxis of nervous disease, education, temperance, sexual indulgence, the marriage of the neurotic and the like, he takes in the main safe and conservative ground. In the second part the author discusses various methods of treatment—drugs, hydrotherapy, electrotherapy, massage, exercise, rest, occupation, diet and psychotherapy. Certain of these methods have in the past been somewhat unduly extolled as panaceas by unwise advocates. In the present volume they are given their just position, the technique of their use is fully described, and the physician can learn just what benefit is likely to be derived from them. The main portion of the book deals with the treatment of various diseases and morbid states. Of necessity each chapter begins with a brief account of the causes and symptoms of the disease of which it treats, and this is followed by a detailed account of the methods to be employed in the treatment. Of this part we can but repeat our previous commendation, that the author in the main is a safe guide. In many instances, of course, there is room for differences of opinion in regard to treatment, based upon the differences of individual belief and experience; for example, certain distressing cases of the morphine habit forbid us to accept his dictum that there is no danger of forming a habit by using morphine in the crises of tabes; we believe that he undervalues the efficacy of large doses of potassic iodide in the treatment of non-syphilitic tic douloureux; and his hope of benefit from trephining in traumatic epilepsy and cerebral tumor seems un-

duly exaggerated. One important omission is to be noted. The author deals all too briefly with the subject of laminectomy, and in dealing with spinal injuries sums up by stating that "fracture of a vertebra followed by symptoms of compression requires exploratory trepanation (*sic*) in every instance." Although, in the strict sense of the words, this is true, yet to the ordinary reader it would seem to recommend laminectomy in nearly every case of fracture. In the vast majority of cases, however, the fracture is attended with contusion or crushing of the cord instead of simple compression, which is only in the rarest instances the result of fracture. In such cases of crush laminectomy is, of course, unwarranted, and the author ought to have made the distinction clear. Certain over-statements as to the relative frequency of cerebral abscess, multiple sclerosis, etc., impair the value of the book by exciting an unwarranted suspicion of inaccuracy. A certain over-emphasis of statement in regard to various subjects, as, for instance, in his justifiable condemnation of operations for so-called "reflex" disturbances, such as needless gynecological interference in hysteria, tends to weaken the force of his criticism and thus unfairly to depreciate a most excellent work.

Le Lesioni Traumatiche dei Centri Nervosi. By SALVATORE SALINARI. 8vo. Pp. iv, 320. Rome: Press of the Giornale Medico del Regio Esercito. 1900.

This monograph on the traumatic lesions of the nervous centres was awarded the Riberi prize in 1898. The work is divided into two parts, the first treating of traumatic lesions of the brain and its membranes, and the second the lesions of the cord. The direct traumatic lesions of the brain are classed as commotion, compression, contusions and wounds. Commotion is retained as a convenient clinical term for the cases of rapid and complete suspension of all the cerebral functions, from which the patient may rapidly or slowly recover, or which may prove fatal without discoverable lesion of the brain. These latter cases, however, the writer admits might be more properly classed as cases of contusion, since minute hemorrhages are sometimes found. Indeed the writer hardly goes far enough in this regard, for he does not lay sufficient stress upon the fact that fatal cases of cerebral injury without discoverable lesion are for the most part of ancient date and that modern authorities like Phelps refuse to consider them. In cases of compression he inclines toward operative removal of the compressing substance in every case. The distinction between compression and contusion, however, is not easy; he lays most stress upon the presence or absence of general symptoms of pressure, but he recognizes that both conditions may co-exist. In the majority of cases of open wounds and bullet wounds, he advises against operative interference. As complications of the original lesion, he considers foreign bodies, blood clots, meningo-encephalitis, hernia and abscess. Serous meningitis and edema are not considered. Chapters on the localization of symptoms and on the technique of operations conclude this part. The question of the seat and nature of the lesion is first considered in dealing with injuries of the spinal cord. This chapter is far from satisfactory; the importance of the syringomyelic dissociation of sensibility (that is, the loss of sensibility to

pain and temperature, with retained sensibility to touch) is ignored, and the sensory and motor areas of the different spinal segments, so essential in localization, are not well described. He admits the existence of a spinal as well as a cerebral commotion, but his illustrative case of the severer type showed positive signs of hemorrhage at the autopsy. In cases of compression and contusion, which are of course very difficult to differentiate, and for the possible differentiation of which he omits certain important symptoms, such as syringomyelic dissociation, he inclines strongly toward operative interference. The prognosis in open wounds of the spine is of course much more serious, and operative interference seldom affords much chance of relief. The late effects of injury, tabes, multiple sclerosis, progressive muscular atrophy, epilepsy and the traumatic neuroses are very briefly touched upon, and a chapter on surgical technique concludes the work. The work, as a whole, is a careful study of the subject, from the standpoint of the military surgeon, but the benefits of operative interference are viewed somewhat too optimistically, and in pathology and symptomatology the results of more recent work are not sufficiently taken into account.

Diseases of Children. By GEORGE M. TUTTLE, M.D., Attending Physician, St. Luke's Hospital; Martha Parsons Hospital for Children, and Bethesda Foundling Asylum, St. Louis. Lea's Series of Pocket Text-Books. Series edited by BERN B. GALLAUDET, M.D. Illustrated with five plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. 1899.

The author states that in preparing this manual for publication he especially has in view the requirements of the beginner in the study of pediatrics. He has endeavored to cover the subject fully, yet in a concise form, and does not profess that there is any originality in his work, but makes free reference to the standard text-books on pediatrics. In the early part of the work, where he is dealing with the anatomy and physiology of the infant, the statements are in the main correct and to be depended upon, but when he approaches the subject of feeding he shows a lack of proper appreciation of the vital principles of this important subject, namely, in the small amount of space which is given to it. The difficulty in writing a book of this kind is that the writer is so apt to misinterpret what he is practically copying out of the larger text-books, and that in attempting to condense the statements of other authors the real opinion of these authors on different subjects is lost sight of. The part of the book which is devoted to gastro-enteric diseases is insufficient for practical purposes, even if a treatise of this kind is desired, and in some parts a student, or one who was not actually familiar with the disease which is spoken of, might do much harm by following the treatment indicated. Thus, in speaking of the treatment of intussusception, the danger of both inflation and hydrostatic pressure is not sufficiently emphasized. In reviewing a work of this kind, however, we should consider exactly what is intended to be accomplished in such a small space, and certainly in comparison with other books which have dealt in this way with so large a subject as pediatrics this book of Dr. Tuttle's can be spoken of favorably. It would be well, however, if the author had been a little more careful in regard to what he

says about the contagious disease, as, for instance, where he speaks of one attack of measles regularly protecting from a subsequent one. This is well known not to be the case, as undoubted attacks of measles occur in the same individual twice, and even oftener. The prodromal symptoms which are given in measles are not such as are usually seen in that disease, the headache, vomiting and prostration being more significant of scarlet fever than of measles.

Nervous and Mental Diseases. A Manual for Students and Practitioners. By CHARLES S. POTTS, M.D. Small 8vo. Pp. 455, with 88 engravings. Philadelphia: Lea Brothers & Co. 1900.

Brief manuals, written to order as part of a series, are seldom of value and still less frequently of interest. If they present the main facts of a subject clearly and correctly they fulfil their mission. The present volume, in a series of pocket text-books edited by Dr. Gallaudet, is unusually successful in this respect and is far superior to the ordinary work of its class. The author has succeeded in the opening chapters in impressing the broad outlines of the structure and functions of the nervous system so simply and so comprehensively, with the aid of a few well-selected diagrams, as to make it comparatively easy for the student to understand the essential plan of his future study. The succeeding chapters on the various diseases, although exceedingly condensed, are reasonably accurate and up to date, and give in a few words the most important facts. The grouping of the various systemic diseases into one chapter as an introduction to the chapters on the general diseases of the brain and cord is a useful innovation and is well calculated to help the beginner by emphasizing again the importance of the chief tracts in the projection system. The section on mental diseases is put by itself and not incorporated with the other diseases of the brain. It follows the conventional and somewhat antiquated lines of the average treatises in English, paying slight attention to the more modern views of mental disease.

The Nervous System of the Child; its Growth and Health in Education. By FRANCIS WARNER, M.D., F.R.C.P. 12mo. Pp. xvii, 233, with one plate. New York: The Macmillan Co. 1900.

The present volume is addressed rather to the teacher than to the physician. It presents the rudiments of cerebral physiology and the development of the mental faculties in a simple way, with clear directions for observing the normal and abnormal phenomena of speech and action manifested by the child in his early years. For the physician the treatment is too elementary and too incomplete, although he may occasionally find some useful suggestions in it. For the teacher, however, it forms a useful and fairly trustworthy introduction to the study of the mental development of the child and his proper education.

A WHOOPING-COUGH PARTY. — A little girl of Huntington, S. I., recently gave a "whooping-cough party." She was a sufferer from whooping-cough at the time of her birthday, when she was accustomed to entertain her young friends, and her mother solved the difficulty by inviting only such children as were known to have the disease, which was prevalent in the village, or to have recently recovered from it.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 5, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

THE POLLUTION OF WATER SUPPLIES.

WITH our continually increasing knowledge of the sources of disease and the means of their dissemination has come a corresponding ability to prevent their spread. At the same time, if the efforts of health boards are at times fruitless, it must be always borne in mind that the problem of prophylaxis is becoming constantly more complex, as the evils to be contended against grow with the increase of population and the multiplication of industries in localities menacing the public health. We refer particularly to the pollution of water supplies, the danger of which evidently increases in proportion to the proximity of man. The question, therefore, of the prevention of certain forms of disease, notably typhoid fever, is resolving itself into a far-reaching scrutiny of all water used by communities of considerable size.

We are in receipt of an interesting discussion on methods of filtration, and on the pollution of streams and the purification of public water supplies, from the pen of Prof. George M. Kober, of Washington, D. C. Rivers are always purer nearer their source. It is stated, for example, that the Mississippi River at Minneapolis contains only 18.6 total solids per 100,000, whereas at St. Louis it contains 244.3 per 100,000. It is to be borne in mind that water containing a relatively large amount of mineral matter is unfit for drinking purposes because of its irritating effect upon the intestinal tract. Refuse discharged into a river is also to be considered; for example, one paper mill discharges into the Potomac River over 100,000 gallons of liquid each day, heavily laden with sulphuric and tannic acids. Important as such pollutions may be in certain cases, they are of less interest than pollution with organic matter, especially sewage contamination derived largely from surface drainage. This applies with force to the Potomac River, in connection with which Dr. Kober has made special studies, although the conditions described are not to be regarded as peculiar to that river. An investigation for bacteria made by various observers revealed the facts that in-

testinal organisms were found in over 90 per cent. of the samples. The number of bacteria varied from 150 to 20,000 per cubic centimetre, with an average of something over 1,000. More recent examinations show a minimum per cubic centimetre of 48 in July and a maximum of 51,000 for January, 1900, with an average of 3,761 per cubic centimetre. Of the specimens taken on about two hundred different days, 50 per cent., or one-half, revealed the presence of the bacillus coli communis. It has likewise been shown by Theobald Smith and others that the turbidity of Potomac water is accompanied by an increased amount of organic matter and bacteria and that fecal matter and turbidity are coincident. If intestinal bacteria are found, it is evidence that there has been pollution by fecal matter of man or animals, and suggests the possibility of infection with typhoid bacilli. Judging from an epidemic of typhoid fever some years ago which occurred at a distance of one hundred and thirty-four miles from Washington, Dr. Kober concludes that a simultaneous outbreak of the disease in Washington was due to Potomac River pollution, the infection having been carried that distance without loss of virulence.

Dr Kober goes on to say: "What has been said of the Potomac River is equally applicable to the Ohio, Mississippi, Merrimac, Connecticut, Missouri and other American rivers, because they are the sewers and at the same time the source of water supply for nearly all the cities located upon their banks, and these cities, as shown by the statistics collected by the Marine-Hospital Service, show, moreover, a marked prevalence of typhoid fever, thus confirming what has been observed over and over again, that this disease, as also cholera, dysentery and diarrheal diseases, can be carried from one town or city to another by means of a watercourse. About three years ago Surgeon-General Wyman estimated, from statistics received in his office, that every year there are no fewer than 45,000 deaths caused by typhoid fever alone throughout the United States. This number has now reached, very likely, 50,000, and, based upon an estimated mortality of 10 per cent., it is within reason to assume a yearly prevalence of 500,000 cases of this disease."

Dr. Kober scouts the idea that rivers can purify themselves, as was at one time maintained. What is true of typhoid fever applies equally to cholera, dysentery, diarrheal disorders and various parasitic diseases. The cholera epidemic of 1892 in Hamburg is quoted, which resulted in 17,020 cases, with 8,605 deaths. It was caused by a band of gypsies camped on the banks of the River Elbe, and the discharges of one of its members suffering from cholera were emptied into the river, which at that time was served to the inhabitants of Hamburg without filtration. The epidemic spared the adjoining city of Altona, which derives its water from the same river after receiving the sewage of Hamburg, with its 800,000 people, but Altona filtered its water and Hamburg did not.

From these various facts it becomes evident that

the study of river pollution is a matter of great and growing importance, and that it is essential that adequate means of purification be found, since the source of contamination can never be absolutely controlled. A system which has been in use in certain European cities for many years is the utilization of sewage and noxious waste water for irrigation on so-called sewage farms, the purified water being returned to the stream. Within the past ten or twelve years over one hundred communities in the United States have established plants for the disposal of sewage. A possible danger to which attention has of late been called is the pollution even of rivers affected by tide waters. Oysters, for example, may retain typhoid-fever germs in a viable state from fourteen to thirty days.

It is Dr. Kober's opinion that the disposal of sewage by means of irrigation alone should not be relied upon, and that the prevention of the evil effects of river pollution should be supplemented by filtration of the water supply on a large scale. The English method by sand filtration he regards as decidedly the most efficacious, as shown by statistics, both in America and Europe. As we stated at the outset, the whole matter is one of growing importance, and it is to be hoped that the near future will see all precautions taken tending to ensure exemption from this decided menace to public health.

THE BOSTON FLOATING HOSPITAL.

WE are glad to call attention to the fact that an institution now well known in Boston, the Floating Hospital, is about to resume the work which has been so successfully carried on in previous years. There can be no question that this hospital fulfils a very definite need during the summer months, and it is a gratification to note that year by year there is an expansion of the work which renders possible the treatment of a constantly increasing number of permanent patients. However valuable a trip down the harbor may be to young children and to their mothers, it is evident that the real development of this charity on a hospital basis demands a more permanent care than is permitted by one or several days' harbor excursion. This fact the management has clearly recognized, and has, in consequence, developed what may be termed the "permanent department." In this department there are now available three wards, with a capacity of forty-five beds. In addition to these patients, it will also be possible to care for all the day patients that may be sent. The Chairman of the Board of Managers urges upon physicians the necessity of safeguarding the hospital against contagious diseases, by using every precaution in sending patients for treatment. It is clear that a neglect of this advice might result in a serious crippling of the summer's work. Physicians are also warned to caution mothers of day patients against taking any food, since an ample noon meal is provided for the mothers and modified milk for the children. The trips will be made down the harbor

daily, provided the weather is favorable, excepting Sunday, from July 5th to September 1st, inclusive. Admission cards are printed and will be sent to physicians on application to Rufus B. Tobey, chairman, 178 Devonshire Street. We would refer our readers to another column, page 22, for further details regarding the hospital, the terms of admission and the place of sailing of the boat. As we have previously taken occasion to say, we regard this as one of the most beneficent and reasonable of the summer charities, and sincerely wish for it another season of complete success.

THE FOURTH OF JULY AND TETANUS.

THE patriotism which finds expression in noise has no doubt seemed as active this year as in all preceding years. Nevertheless there has been a difference, for Fire Commissioner Russell has, we learn, forbidden the sale of cannon crackers, which has had the double advantage of reducing the amount of noise to a certain limited extent, and, more important, has, we may be sure, prevented some cases of that most dreaded accompaniment of the Fourth of July, tetanus. Experience has, however, shown that there are other means than cannon crackers, which after all are usually beyond the resources of the ordinary small boy, by which tetanus may be acquired. Last week four deaths from tetanus are reported to have occurred in Boston in young men and boys, all traceable to the patriotic enthusiasm inculcated by the 17th of June. One of these deaths resulted from the careless discharge of a cannon cracker, and the others from blank cartridges, which are even a greater source of danger. In each of these cases the wound was made on the hand. It is much to be desired that the toy pistol may go the way of the cannon cracker, for to it, if we are not misinformed, the greater number of deaths from tetanus are due. A certain sacrifice of life must, no doubt, always occur on these occasions of national rejoicing, but it is clearly the duty of those in authority to reduce this death-rate to the lowest possible limit, however unpopular the enforcement of the regulations may be.

MEDICAL NOTES.

PROGRAMME OF ENTERTAINMENTS TO MEMBERS OF THE INTERNATIONAL MEDICAL CONGRESS.— On August 2d, the day of opening of the congress, an evening entertainment will be given by the president of the council in the name of the French Government. August 3d an evening entertainment, by invitation, will be given by the president of the congress. August 5th an evening reception to members of the congress by the President of France at the Palais de l'Élysée. August 8th an evening entertainment in the Palais du Sénat and the Luxembourg Garden, given to members of the congress by the bureau and

the committees of organization of the congress. The Municipal Council of Paris will give an entertainment at the Hôtel de Ville on the evening of August 7th. In addition, special entertainments will be organized by the various sections. Women are invited to all the festivities. A committee of women has been organized for the reception of the families of members under the presidency of Madame Lannelongue and Madame Brouardel.

APPENDIX TO THE INTERNATIONAL DIRECTORY OF LARYNGOLOGISTS AND OTOLOGISTS. — An appendix to the International Directory of Laryngologists and Otolologists, compiled by Mr. Richard Lake, is in course of preparation, under the auspices of the *Journal of Laryngology, Rhinology and Otolology*. It is hoped that all engaged in the practice of laryngology, rhinology and otology will assist as far as possible in making the index complete, by sending their names and addresses to the editor, International Directory of Laryngologists and Otolologists, 129 Shaftesbury Ave., London, W. C.

THE "GOUTTE DE LAIT" SOCIETY. — The new "Goutte de Lait" Society, according to the *Medical Record*, is an organization established recently at Rouen, France, with the object of furthering a rational infant feeding. Every effort is made to induce mothers to nurse their own infants, but when this is impossible, the society furnishes a specially prepared and sterilized milk in suitable quantity for one or two sours a day.

COLLEGE OF PHYSICIANS OF PHILADELPHIA. — At a meeting held June 18th, Dr W. W. Keen announced the completion of the \$50,000 library endowment fund.

HONORARY DEGREES FOR SIR WM. MACCORMAC. — Sir William MacCormac has received the degrees of M.D., M.Ch., honoris causa, in the University of Dublin.

BUBONIC PLAGUE. — It is reported that 74 cases of bubonic plague occurred in Ceylon, with 64 deaths, during one week in the early part of June.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the six days ending at noon, July 3, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 52, scarlatina 22, measles 43, typhoid fever 14.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending at noon June 30 was 156, against 193 the corresponding week last year, showing a decrease of 37 deaths, and making the death-rate for the week 14.66. Of this number 73 were males and 83 were females; 149 were white and 7 colored; 93 were born in the United States, 59 in foreign countries, and 4 unknown; 28 were of American parentage, 111 of foreign parentage and 17 unknown. There were 13 deaths from violent causes. The number of children

who died under one year was 27, the number under five years 41. The number of persons who died over sixty years of age was 28. The deaths in public institutions were 44. There were also 2 deaths on account of the heat.

THE BOSTON FLOATING HOSPITAL. — By the courtesy of the authorities the Floating Hospital is to have the privileges of the City Wharf at Eastern Avenue, foot of Fleet Street (South Ferry). The boat will start at 9 A.M., and returning will land day patients at the same place at 4 P.M. Throughout the rest of the twenty-four hours and on Sunday it will be moored at the wharf of L. Pickert & Co., near the North Ferry, East Boston. Day patients will be received for the trips between 8 and 9 A.M. Permanent patients will be received at any hour, when the boat is at either City Wharf or Pickert's Wharf, East Boston. The age of patients is limited to six years. The demonstrations in sterilization of milk, the preparation of food and the hygiene of children will be continued.

C. S. MINOT, LL.D., PRESIDENT OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE. — At the recent meeting of the American Association for the Advancement of Science, Prof. C. S. Minot, of the Harvard Medical School, was elected president of the association.

A CENTENARIAN. — Mrs. Almira Milligan, of Alford, Mass., died June 23d, at the age of one hundred and two years.

NEW YORK.

APPROPRIATION FOR THE BOARD OF HEALTH. — The Board of Estimate and Apportionment, at a meeting held June 27th, appropriated the sum of \$20,000 for the use of the Board of Health, under the provisions of the emergency law of 1895. The money is to be devoted to improving the sanitary condition of the city and increasing the resources of the Health Department in case of the possible appearance of bubonic plague, Asiatic cholera, or other serious infectious disease during the summer. It is said that a considerable portion of the appropriation will be used in the more thorough equipment of the hospitals for contagious diseases, the North Brother Island, the Willard Parker, and the Kingston Avenue, Brooklyn, Hospitals, and that some of it will also be expended on the study and development of bubonic plague cultures in the bacteriological laboratory of the department.

SUICIDE AND LIFE INSURANCE. — In the suit of the administrator of Frank M. Brady against the Equitable Life Assurance Society to recover \$100,000, the amount of an insurance policy on the life of Brady, taken out by him a month before his death by suicide last autumn, a jury in the Supreme Court, Brooklyn, on June 27th handed in a verdict in favor of the defendant. The latter contended that no payment should be had on the policy, as there was a clause in it to the effect that if Brady should commit suicide, whether sane or insane, within one year after it

was taken out, the beneficiary should not receive the money. The plaintiff contended that the burden of proof was on the defendant to show that Brady really committed suicide, and this was apparently done to the satisfaction of the jury.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—The American Association for the Advancement of Science, which is composed of sixteen affiliated societies, held its forty-ninth annual meeting at Columbia University during the past week. About 500 of the 1,835 members of the association were in attendance, and on the recommendation of the council, a section on physiology and experimental medicine was established.

DAMAGES FOR PERSONAL INJURIES.—The Central Railroad of New Jersey has paid H. B. Park, a student at one of the New York medical colleges, \$10,000 in settlement for injuries sustained by him at the Plainfield station of the company in January last. Young Park, having alighted from a local train, was crossing the tracks to the depot, when he was struck by an express train running at a high rate of speed and seriously injured.

NEW YORK SCHOOL OF CLINICAL MEDICINE TO BE CLOSED.—At a meeting of the corps of teachers of the New York School of Clinical Medicine, held at the Academy of Medicine, June 21, 1900, it was decided to wind up the affairs of the school and close it permanently. This action was taken in consequence of friction between the staff and the lay board of trustees in the management of the affairs of the school.

LEWIS A. STIMSON, LL.D.—At the recent Commencement of Yale University, the degree of LL.D. was conferred on Dr. Lewis A. Stimson, professor of surgery in the Cornell Medical School.

Miscellany.

CHOREA AS A PYOGENIC DISEASE.

A TENDENCY has arisen of late to consider chorea as a infectious disease, although such evidence as exists in favor of this view is circumstantial, rather than direct, and the chain is yet incomplete. A point to which some significance can be attached is the probability that acute rheumatism, with which chorea exhibits certain relations, is also of infectious, though perhaps of multiple, origin. In support of the infectious origin of chorea is the report by Westphal, Wassermann and Malkoff¹ of a case of acute articular rheumatism, followed by chorea, and complicated by endocarditis and nephritis, in which they succeeded in isolating from the blood, the brain and the endocardial vegetation a streptococcus capable of inducing polyarthritis in lower animals. The pyogenic nature of both polyarticular rheumatism and chorea had previously been suggested by other observers, one of whom, Mircoli,² now reviews his earlier investigations

¹ Berliner klinische Wochenschrift, 1899, No. 29.
² Loc. cit., 1900, No. 14, p. 303.

on this subject. Among 17 cases of rheumatic chorea, pyogenic cocci were found in the joints in 14, staphylococci preponderating, while in 3 the diplococcus lanceolatus was present as the etiological agent. From a number of considerations, acute rheumatism is looked upon as a variety of pyemia, but without suppuration; and chorea as a manifestation of the cerebral localization of the pathogenic agency.—*Medical Record.*

Correspondence.

METHOD OF STAINING THE ELASTIC FIBRES OF THE SKIN.

VIENNA, June 15, 1900.

MR. EDITOR:—The majority of the staining methods used for the demonstration of the elastic fibres of the skin are extremely complicated and require a great expenditure of time. It has been my desire in performing this work to find a method which would combine three desirable things, simplicity, rapidity and certainty of results.

In considering former methods, one naturally thinks of Taenzer's; he used the following solution:¹

Orcin	0.5
Aqua dest.	20.0
Spirit.	40.0
Acid nit.	gtt xx

The section remains in this solution for from twelve to twenty-four hours, and then is decolorized with alcohol. A great deal of time is required for this method, which Unna attempted to obviate in the following manner, by using²

Orcin	1.0
Acid hydrochloric	1.0
Alcohol abs.	100.0

The section remains about fifteen minutes in this solution and is heated to about 30°. He claims that by doing this the solution becomes more concentrated. If this is the case, one might suggest that a stronger solution of orcein might be used in the first place.

In the case of very thin sections the heating of the orcein affects them seriously, in thicker sections the connection between the individual tissues becomes loosened, and in any and all cases, with a little too much or too little heat, the desired result is not obtained.

Gutentag's method gives no advantage over former ones.³

Weigert's method gives very good results, but, like the others, it is also complicated and requires a great deal of time.

I have experimented with a large number of coloring materials, thinking to find one to replace orcein, but the results were all unsatisfactory, orcein, in fact, being the only one which acted on the fibres in a directly specific manner.

After having arrived at this conclusion, I attempted to modify the application of the orcein, that the result might be obtained more quickly. I found that if one allows H₂O₂ to work on the section, the elastic fibres become plainly visible, without the remaining tissues being in the slightest degree injured. That caustic potash has a similar effect need not be emphasized here.⁴

Balzer recommends it for the demonstration of elastic fibres of the skin after staining with eosin, but by doing this the rest of the tissue swells up intensely; even by the application of a very diluted solution, an alteration of the

¹ Unna: Notiz betreffend die Taenzerchen Methode. Monatschrift für praktische Dermatologie, Bd. II, 1890, pp. 366-70.
² Unna: Monatschrift für praktische Dermatologie, Bd. xix, 1894, p. 597.
³ Gutentag: Ueber das Verhalten der Elastischen Fasern in den Hautnarben. Archiv für Dermatologie und Syphilis, Bd. xxvii, H. 2, 1894.
⁴ Balzer: Recherches techniques sur le tissu elastique. Archives de Physiologie, 14, ix, 1882.

remaining tissues cannot be avoided. This is by no means the case with H₂O₂. Various concentrations of alcohol, orcein and H₂O₂ were tried and the following solution proved to be the best :

Orcein	3.0
Alcohol abs.	200.0
H ₂ O ₂	40.0

The sections came directly out of strong alcohol into this solution. If a thin section is used three minutes suffices for staining; the whole then appears a brownish red, the elastic fibres being considerably darker than the rest of the tissue, so that they distinctly contrast with the Kollagane even in the case of low power. For differentiation, the same solution is used that the orcein was dissolved in,

Alcohol	100.0
H ₂ O ₂	40.0

For thin sections one minute suffices; the elastic fibres are then shown very clearly, while the rest of the tissue is lightly stained.

If somewhat thicker sections are used, the orcein is allowed to work for about five minutes, differentiating for from two to three minutes; absolute alcohol may be used for differentiation and requires no longer than the above-mentioned solution.

Truly yours,
EDITH R. MEEK, M.D.

Deaths reported 2,391; under five years of age 881; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 592, acute lung diseases 163, consumption 276, diarrheal diseases 137, diphtheria and croup 76, measles 30, typhoid fever 24, whooping-cough 16, cerebrospinal meningitis 13, scarlet fever 11, erysipelas 8.

From whooping-cough New York 8, Washington 3, Boston 2,

Worcester, Waltham and Gloucester 1 each. From cerebrospinal meningitis New York 6, Worcester 3, Boston 2, Baltimore and Everett 1 each. From scarlet fever New York 8, Philadelphia 3. From erysipelas New York 7, Baltimore 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending June 16th, the death-rate was 18.0. Deaths reported 4,004: acute diseases of the respiratory organs (London) 257, measles 138, whooping-cough 108, diphtheria 65, diarrhea 61, scarlet fever 26, fever 29.

The death-rates ranged from 9.4 in Cardiff to 25.2 in Manchester; Birmingham 19.8, Bradford 13.4, Gateshead 17.2, Huddersfield 22.0, Hull 17.5, Leeds 20.4, Liverpool 23.7, London 17.4, Newcastle-on-Tyne 15.8, Nottingham 12.0, Sheffield 22.9, Swansea 14.3, West Ham 13.9.

RECENT DEATH.

PHILEMON EVELETH, M.D., M.M.S.S., died at Marblehead, Mass., May 14th, at the age of fifty-four years.

BOOKS AND PAMPHLETS RECEIVED.

The Missile and the Weapon. By A. L. Hall, M.D., Fulton, N. Y. Reprint. 1900.

Fliegenlarven als gelegentliche Parasiten des Menschen. Von Dr. Erich Peiper. Mit 41 Abbildungen. Berlin. 1900.

Twenty-third Annual Report of the Board of Health of the State of New Jersey, and Report of the Bureau of Vital Statistics. Trenton, N. J. 1899.

A Manual of Operative Surgery. By Lewis A. Stimson, B.A., M.D., and John Rogers, Jr., B.A., M.D. Fourth and revised edition. Philadelphia: Lea Brothers & Co. 1900.

Forty Years in the Medical Profession, 1858-1898. By John Janvier Black, M.D., Member of College of Physicians of Philadelphia, etc. Philadelphia: J. B. Lippincott Co. 1900.

The Normal Position of the Uterus in the Pelvis Considered in Relation to Its Physiologic Mobility. The Results of Modern Aseptic Surgical Technique, as Demonstrated by a Series of One Hundred and Fourteen Consecutive, Unselected Abdominal Sections without a Death; with Clinical and Pathological Reports. By Hunter Robb, M.D., Cleveland, O. Reprints. 1899-1900.

Address.

A REVIEW OF RECENT STUDIES ON THE NATURE AND ORIGIN OF CANCER.¹

BY J. COLLINS WALKER, M.D., LL.D., BOSTON.

IN selecting a subject upon which to address you this evening, I felt I could not choose one of greater interest to practising physicians, who have in your hands the health of a large and important section of the country, than that which dealt with an inquiry into the nature of cancer.

This is a disease the ravages of which are constantly spreading into a wider circle and before which, in the majority of cases, in spite of the wonderful advances of surgery, we still feel ourselves almost powerless.

The knife has undoubtedly accomplished much for which we are to be thankful, and the number of those who have been rescued from what was at one time supposed to be an incurable disease is constantly growing. These successes should not, however, lull us into a sense of security, but should rather stimulate us to further effort; for, although we do not now look upon every case as hopeless, as our fathers did, there seems to be but little doubt that the disease is on the increase, and that it still remains — as it has ever been — one of the scourges of the human race.

It is hardly necessary to remind you that we are living in a wonderful period of progress in medical science, and that this branch of medicine, still perhaps looked upon as theoretical by many of you, has accomplished tasks of the highest practical value not only to the physician and surgeon in his practice, but for the well-being of civilized communities.

I have intimated that this disease is on the increase, and one of the first questions which naturally presents itself to the inquirer relates to the accuracy of this statement. I will, therefore, take the liberty of calling your attention to the study of the geographical distribution of cancer, and to the probabilities of the disease having increased in frequency in some of its favorite localities. Unlike tuberculosis, which seems to be spread pretty evenly throughout the globe, sparing no races, cancer appears to be confined to certain tolerably well-defined regions of the earth's surface.

It appears to be almost unknown in the far north, including the northern coast line of Europe and Asia, and in the tropics it is also exceedingly rare.

The disease appears to abound and to be pretty evenly distributed throughout the larger part of middle and southern Europe. The northern border of this region extends as far north as Norway, where we find that in 1893 6.39 deaths occurred to 10,000 living persons; and Sweden, where in 1894 the rate was 8.5 deaths to 10,000 living persons. Coming farther south to Denmark, we find the rate computed for five years (1890-95) as 11.9 to 10,000. In Holland it is said to be as high as in any country of Europe. The above figures give what was probably the average of deaths from cancer in middle Europe from this disease during the last decade.

On the other hand, in Greenland, Iceland, the Faroes, Hebrides and Shetland, it is an extremely rare disease. Lange saw no cancer in Greenland, and Panum had but one case to report in the Faroe Islands.

Again, in parts of southern Europe, such as Greece, and particularly Turkey, we hear little of cancer. The commonest forms of cancer, such as those of the uterus and breast, are very rare in the latter country. A female physician having an extensive practice in Constantinople during nine years saw but 20 cases of uterine cancer, and 31 of cancer of the breast. In the other portions of southern Europe, such as Spain and Italy, it maintains a high average.

In northern Asia, in Siberia, according to Behla, cancer is almost unknown and only observed sporadically in southern Asia. Thus we find it rare in Persia, Arabia and India, except in the western and southern portions of the latter country. In northern China and Japan the disease is more on a par with that in Europe. In southern China, and in fact in the greater part of that country, the inhabitants do not appear to be susceptible to the disease, although those who come to this country are said to lose this immunity.

Turning to Africa, we find Egypt and Abyssinia almost exempt. In Algiers and in Madeira the disease is more frequent. In western and central Africa, according to Livingstone, the disease was in his time almost unknown.

I need hardly tell you that cancer is common in Great Britain, though the mortality appears to be lower in Ireland than in other parts of the United Kingdom. Coming west to North America, we find the disease is found all over the United States and Canada, but in the more northern portions of the continent, such as Alaska and the most northerly parts of British North America, the disease is rare.

In New York State in 1895 there were 5.3 deaths to 10,000 inhabitants, and in Massachusetts the rate was 6.4 to 10,000 inhabitants; and in San Francisco it is quoted as high as 7.9 to 10,000 inhabitants. In the tropics of America it is absent, and it is little known in the lowlands of Mexico; but in the high tablelands of that country it is common. In South America it is said to be most common in Peru, but in Brazil and the more southern portions it is said to be extraordinarily rare.

In Australia the disease is said to be quite common, in Queensland in 1891 the rate was 2.60 to 10,000 living persons, and in 1895 this rate had risen to 3.67. In New South Wales in 1896 it took third place in the mortality list. In New Zealand the rate in 1895 was 5.53 to 10,000 (Behla).

Bearing these data in mind, a glance at the map of the Eastern Hemisphere will show a dark belt extending across Europe and Asia from the Atlantic to the Pacific. This belt is widest at its western end, taking in as it does the whole of the Atlantic coast line of Europe. It gradually narrows towards its eastern extremity, which includes Japan. The breadth of the cancer belt in the Western Hemisphere is somewhat greater than the average of that of Europe; but, like the latter, it is situated in the temperate zone. This does not hold true of the Southern Hemisphere, however, for we find it there encroaching more extensively upon the tropics. Much, however, remains to be worked out as to the geography of the disease in this region of the world.

In connection with mention of the tropics it is worth noting that malaria and cancer are said to be in an inverse ratio to one another; where malaria is common, as in Jamaica and the east coast of Africa,

¹ Read at the Annual Meeting of the Maine Medical Association, June 14, 1900.

cancer is rare. On the other hand, in Holland malaria and cancer are both common, and—as we shall see presently—cancer is often found in low-lying marshy districts where one would expect to find malaria.

This brings us to the study of localities in different countries, and we find that certain portions of many countries are much more favored by the disease than others. Haviland's work has been much quoted, but is worth repeating in this connection. A glance at his map shows that the southwest portion of England and Wales is a region where there is a low mortality from cancer. This section belongs geologically to the oldest formations, silurian and carboniferous, and includes the highest and best drained mountainous districts of the country. He found a low mortality from this disease in the chalk hills and the red sandstone districts; in other words, in the elevated districts of England which form the sources of the rivers which drain the country. The high mortality, on the other hand, is to be found near those portions of the rivers where they have reached their full formation in the low-lying level districts and regions liable to serious floods; and these regions are composed of more recent geological formations in which clays of different ages predominate. In a certain region where the river frequently overflows its banks, the mortality for women rose as high as 8.1 to every 10,000 living. In Liverpool the cancer death-rate at the same time was only 4.1 to every 10,000 females living. In Norway, on the other hand, the disease is more frequent on the highlands and less on the coast.

Coming now to the condition of certain localities, we find a state of things which might almost justify one in the assumption that cancer was endemic. D'Arcy Power describes a district in England, the condition of soil being identical with those described by Haviland, a flat country covering 60 square miles and consisting of gravel overlaying boulder clay. It has many streams and fens. The population is about 12,000. From 1872 to 1898 there were 173 cases of cancer under observation of the local physicians. In a village of 1,036 inhabitants in this district there were 42 cases of cancer during the same period. Many used water from the same well, but in many cases there was no common source of contagion of this kind. Seventy-one cases were cancers of the alimentary canal or organs suggesting water as an infecting agent. Behla, a practising physician for twenty-two and one-half years in Luckau, a town in Germany of 5,000 inhabitants, describes a remarkable increase of cancer in one of the suburbs of this town containing about 1,000 inhabitants, while in the adjacent district of the same size there was hardly a case of the disease. From October 1, 1875, to April 1, 1898, there were 663 deaths, of which 73 were cancer (mostly of the stomach and liver); that is, 1 in 9 deaths were from cancer; whereas in Prussia in general the rate is only 1 in 40 deaths. The majority of the houses in this district had had cancer cases in them, and on a certain side of a certain street every house had been infected, and in certain houses 3 or 4 cases of cancer had occurred. In a little over one year's time 10 men died of cancer in this district. Such a region seems fairly to have earned the name of "Cancer Village." In many of the neighboring villages there had been no deaths from cancer for

twenty-five years. Similar experiences are cited by Behrens, Pfeiffer and others in different parts of Germany; Espine reporting that in the canton of Geneva in Switzerland there are villages where cancer is extraordinarily prevalent, particularly cancer of the stomach.

I have already mentioned an example of a cancer street. Amaudet describes such a street in Corncilles in Normandy, in which out of fifty-four houses seventeen had contained cases of the disease. These houses are near the middle of the street, and occupied both sides; many of them having 2 cases.

Examples of "cancer houses" could be given in great number, but one or two will suffice. The following case reported by Power, is perhaps as striking as any:

Mrs. A., forty-five years of age, lived in a certain house for thirteen years, and then died of cancer of the stomach. Mrs. B., forty-seven years of age, succeeded to her place, and occupied her bedroom. She lived in the house for twenty years and died of cancer of the liver. Mrs. C., sixty-seven years old, who had lived in the house for eight years, succeeded to the position previously held by the other two women, and to their bedroom, and died of cancer of the breast eight years after the death of Mrs. B.

Webb reports in the *Birmingham Medical Review*,² several cases of cancer houses in the village near his residence. In two houses built as one building there were 6 cases following one another at regular intervals during a period of twenty-six years. None of the individuals were blood relations. Two were cases of cancer of the rectum; 2, cancer of the stomach; 1, cancer of the uterus, and 1, cancer of the breast. The drain and water supply were common to both. In another group of cottages there were 9 cases in fifteen years. All the inhabitants used water from a certain pump by the roadside and close to a very filthy hovel.

Mollier reports 4 cases of cancer occurring in ten years' time in a house in Lyons on the banks of the Saône. Three of these were cases of cancer of the stomach.

Fissinger lays stress upon solitude. A house near a wood with bushes and swamps near the banks of a river are conditions which appear to be favorable for the development of the disease. Noel calls attention to the fact that excise officers in England, whose duty it is to traverse the woods, often suffer from cancer, as do also the country laborers who work in the woods.

Coming now to the question of the increase of cancer, we find a pretty general expression of opinion that there has been a marked increase in the amount of the disease during the past fifty years, a period of time during which sufficiently careful statistics have been kept to enable an accurate estimate to be made.

It is true that some have objected, like Payne and Neusholme, two able English observers, that these observations were fallacious. Payne attributes the increase of cancer to the diminished mortality from phthisis and other infectious diseases; a larger number of persons therefore surviving to become the victims of cancer later. Neusholme regards the increased figure as due to more accurate diagnosis and careful autopsy records. Andrews, of Chicago, shares these

² No. 32, 1892, p. 342.

views. Nevertheless, the mass of evidence seems strongly to favor a serious increase of cancer during the period mentioned. For instance, Neusholme himself shows that in the period 1866 to 1868, there were in England and Wales 25,567 deaths from cancer, and in the period 1894 to 1896 there were 67,888 deaths from the disease. In other words, during twenty years the deaths from cancer had more than doubled. Cancer is no new disease or one which has been set aside from a more comprehensive one, as appendicitis from peritonitis, so that increased accuracy of diagnosis would probably eliminate as much as it added. Many cases of tuberculosis and syphilis formerly supposed to be cancer are now recognized not to be such, and would offset the additional cases of cancer now handed in in the reports of more accurate diagnosticians and pathologists.

The more recent studies of Haviland in Great Britain show an enormous increase of cancer in that country. In the period of 1857 to 1860 the death rate of England and Wales for males was 1.94 to 10,000 living, and for females 4.33 to 10,000. In 1881 to 1890, the death-rate for males was 4.30, and for females 7.38. In other words, during an interval of a little over twenty years, the rate has more than doubled for males, and not quite doubled for females.

Taking now two specimen low mortality areas, such as York and Gloucester, we find that the low mortality groups are still found in the same districts, although the standard death-rate has been raised from 4.3 to 7.4. The same may be said of the high mortality groups. In the Thames Valley district the death-rate for females above thirty-five years of age from 1851 to 1860 was 13, and from 1881 to 1890 was 23 to 10,000 living persons.

In other words, cancer is still comparatively low and still comparatively high under the conditions which existed in 1851 to 1860, but the rate in all these districts has been increased after the interval of twenty years.

In Ireland in 1864 there were 1,498 deaths from cancer with a population of 5,678,307. In Ireland in 1884 there were 1,947 deaths with a population of 4,962,693. In Scotland in 1864 there were 1,300 deaths from cancer with a population of 3,118,701. In Scotland in 1884 there were 2,110 cases of cancer with a slight increase in population.

Finkelburg, in 1894, shows from a careful study of the distribution and frequency of cancer in Prussia that there has been a considerable increase in the mortality of carcinoma, although the general mortality rate was lowered during that period. The mortality was much greater in the cities than in the country, in large and well-cared-for cities especially. In Berlin the death-rate for cancer was 62.3 per 100,000 living persons. This increased mortality in the cities is attributed to the increased mortality among women.

Although Andrews doubts the accuracy of our population figures, Massey claims that our statistics are sufficiently accurate to show that the ratio of deaths from cancer to 100,000 living persons in the United States is on the increase. Massey's interesting tables arranged for seven of our principal cities show also the ratio of deaths from cancer to each 1,000 of all deaths in each city. He points out that, while it is evident that a lessened number of deaths from

preventable diseases of early life will give rise to an artificial increase in the proportion of disease of later life which has not been prevented or cured, the charts do not show the result which should be expected from this line of reasoning. If this argument were correct, the ratio of cancer deaths to the total deaths ought to be greater than that compared with the living population, whereas the charts show this ratio is less in all cases. The conviction is warranted, he says, that there is a widespread increase in the causes of this disease throughout the country.

The greatest increase has occurred in San Francisco. Here the ratio has crept from 1866 to 1898 from 16.5 to 103.6 cases to 100,000. Here we have the enormous increase of more than sixfold in thirty-two years. In Boston the ratio has almost trebled between 1863 and 1887. After the latter date there was a temporary decrease followed by a tendency to increase up to the present time. In seven American cities in 1870 there were 999 deaths from cancer, or 35.4 per 100,000 living persons. In 1898 the death-rate was 66.4 per 100,000. The ratio has therefore almost doubled in twenty-eight years. At this rate in 1900 there would be an average of 80 deaths in each city to every 100,000 living persons. Massey calculates that there must have been about 49,800 deaths from cancer in the United States in 1898, and that there must be at the present time 100,000 victims of the disease within our borders. These figures give color to the startling statement made by Roswell Park a year or two ago that in 1909 there will probably be more deaths in the United States from cancer than from consumption, small-pox and typhoid fever combined. This author shows that in New York State cancer is the only disease tabulated which shows a progressive and steady increment. In 1887 there were 2,363 deaths from cancer, and 11,609 deaths from consumption. In 1898 there were 4,456 deaths from cancer and 12,552 deaths from consumption. In Roswell Park's own city and neighborhood the deaths from this disease exceed in ratio that of almost any other section of the country. It is, as he justly says, a veritable "Tropic of Cancer." It is difficult, under these circumstances, to avoid asking one's self the question whether cancer is or is not an infectious disease.

The endemic character of cancer and the steady increase of the disease, and the fact that in certain localities there is a sudden invasion of this disease, all suggest strongly a local cause. To search for this requires special knowledge of the most diverse character. As Park suggests, a combination of the zoölogist and the botanist and the veterinarian is needed for such an investigation.

The work of Behla again merits notice in this connection. After a careful study of the meteorological condition of his native town, of its water and other possible sources of infection, he turned his attention to the food supply — practically those forms which were eaten uncooked. The gardens containing lettuce, radishes, berries, apples, etc., were watered with water from the trench which surrounded the district. The water remaining in this trench was very foul and contained quantities of vegetable and animal organisms. The fresh lettuce was rinsed out in these dirty pools, and the water was also used to wash the kitchen utensils and the towels. This stream did not touch any other portion of the town. In many other

villages of Germany where cancer prevails Behla was able to obtain the same history of the use of foul water for domestic purposes.

Foul and stagnant water, sluggish streams with wooded banks which are often overflowed appear thus to be favorable conditions. It is well known that trees are subject to xylomata, or wood tumors, which are destructive. These affections of trees appear to be contagious, as neighboring trees are usually affected. A form of ameba (plasmiodiophora Wassica) grows on certain cabbages and other vegetables, forming large tumors. It is possible that the seeds of disease shed from trees or plants may float upon the water used for washing and drinking purposes, and thus be conveyed to the human organism. Pfeiffer has suggested that the micro organisms may be conveyed by an intermediate host, and has carefully studied the sporozoa and other protozoa forms found in insects with the hope of discovering the cause of the disease. We have but recently been made familiar with the mosquito as an active agent in the spread of malaria, and in a like manner wasps have been suggested as the carriers of disease from tree to tree and plant to plant, as on these insects both protozoa and fungi abound, and perhaps also to human food. It can readily be seen that if such articles of food and drink were infectious, they would, if handled by man, convey the poison to the nose, lips or tongue, and if swallowed could transport the disease to the stomach, intestines or internal organs. We can easily imagine that a micro-organism could, under the circumstances, attach itself to a break in the epidermal or epithelial coverings of the body, or when these cells were by age or a blow or chronic irritation rendered less resistant to morbid influences. In this way a single cell may become the point of entrance of the disease into the body. Behla suggests that summer is the season of the year when infection is more likely to occur, but unfortunately there is no known period to guide us. It is interesting to note in this connection that the dog, an animal which comes in contact with earth and water so freely, does not have cancer in the regions so often found diseased in man, but more upon the surface of the body, as on the ears, the tail, the scrotum, prepuce, vulva and anus. Observations on the food of man have not as yet brought out any suggestive data. Beneke has noted that cancer is rare in prisons where animal food is not freely furnished and work is hard. Certain monk orders are said to be exempt from cancer, but there are no facts to show that vegetarians as a class are less liable than meat eaters, although Paget thinks that meat eaters are more liable.

In Normandy the cider made from very foul water has been blamed for the increase of cancer. Those addicted to alcohol have been said to be more liable. These are probably only predisposing causes which favor irritation of the stomach or intestines.

A study of the health of a locality before and after the introduction of a pure water supply might throw light upon this question.

So far as animals are concerned, the disease is found in herbivorous as well as carnivorous. It is more common among mammals and is rare in birds. In cold-blooded animals it is not seen. The disease is rare in the digestive tract, but, as we have already seen, is more common on the outer skin and urogenital tracts. Cancer is not observed in dogs under two

years of age, and it is well to remember that if animals should be used for experimental purposes they should be taken at an age when they are more liable to cancer.

Of 49 cases of carcinoma collected by Fadyean, 25 were in the horse, 16 in the dog, 5 in the ox, 2 in the cat and 1 in the sheep. It appears to be extremely rare in pigs. Several cases of cancer of the stomach in horses are reported by this writer, although this is a very rare seat of the disease in animals. There are no statistics to show whether animals have cancer in the specially infected districts. One observer has stated that cattle in low-lying pastures are more liable to cancer than those in higher and drier grazing country.

The data which have thus far been brought forward are in some cases strongly suggestive of the communicability of cancer from one individual to another. Is there any clinical evidence bearing upon this point?

Cancer of the base of the tongue is reported by Scott in American trout transported to New Zealand.

Roswell Park cites a number of interesting cases collected from literature. Thus Kuhn reports the case of a woman contracting an encephaloid cancer of the finger while caring for a cancerous cow. Jürgens reports the inoculation of an epithelioma from a fowl to the thumb. Budd reports the case of a pet dog contracting cancer of the tongue from licking the cancerous lip of his master. A London surgeon was affected with cancer of the tongue after having taken into his mouth some of the discharge from a cancerous breast. A physician inoculated an acne pustule on his face while scraping a cancerous uterus. Budd mentions five French hospital surgeons who have died of cancer, one eight months after receiving a wound while operating on a cancerous patient.

The situation of cancer in the human body certainly is suggestive of inoculation. Thus Andrews has studied the locality of 7,881 cases of cancer and endeavors to show that primary cancer is more common on exposed surfaces, such as the lip, the face and the hands, and in such situations in the digestive tract where a microbe would lodge easily and not be swept away. Estimating according to area and placing the intestine, which has a large area but small percentage of cancer, as one, we find the lip stands at the head of the list; the other portions of the digestive tract follow in the order we might expect, as the tongue, the stomach, rectum, mouth, esophagus, etc.

Now that attention is being brought to the possibility of contagion, practitioners will doubtless begin to report examples which they have observed in their practice. We all remember how improbable the theory of the contagiousness of tubercle seemed when it was first brought forward. In my own experience, particularly with cancer of the breast, I have noticed of late years the frequency with which the husband is affected with keratosis semilis or the early stages of rodent ulcer. The milder forms of this affection often pass unnoticed, but may be none the less a possible source of contagion. Coming as they do on exposed parts of the body, they could easily be communicated from husband to wife and find a lodgment in an organ which is susceptible to the disease.

Cases of inoculation are so striking when they do occur as not to pass unnoticed. I have seen cancer of the prepuce clearly communicated from the glans penis by contact and not by extension. In the same way

cancer has been known to jump from the tongue to the cheek. Cancer has followed the track of the trocar, the punch, or of the exploratory operating wound. It is my habit in operations for cancer of the breast to avoid touching the disease with the knife-blade and to keep all portions of the wound carefully protected with gauze held in place by catch forceps until the last trace of cancer has been removed.

Coming now to experimental inoculation, we find that well authenticated cases are exceedingly rare even in animals. Cornil reports a case of sarcoma of the breast in which the surgeons inserted a small fragment of the growth beneath the skin of the breast of the opposite side. The small wound healed by first intention, but two months later a nodule of sarcoma formed at the site of the inoculation. Hahn reports a similar case. Bosc cites 3 cases of inoculation of cancer from man to man. Alibert, who derided the theory of contagion, is said to have inoculated himself with cancer juice and subsequently to have died of carcinoma.

Inoculations have been made into dogs, cats and rats from carcinoma of man; various organs have been inoculated, and also the peritoneum and the circulating blood. In very few cases has there been any result, and these have been regarded rather as transplantations and independent growths of the inoculated or grafted tissues rather than as growths of the local tissue as the result of an infection.

This does not prove by any means that the cancer germ, if there be such, is not inoculable. Doubtless nature fails continually to infect the human organism. It is possible that there may be a certain stage in the life history of the micro-organism in which it is capable of being inoculated and other periods in which it is inert.

One of the earliest of the modern attempts at experimental inoculation was by Langenbeck, who made an emulsion of an encephaloid cancer and mixed it with the defibrinated blood of a dog and injected it into the femoral vein of a dog. Two months later nodules were found in the lung. In 1888 Hanan transplanted into the tunica vaginalis of the testicle of two rats materials derived from non-ulcerated metastatic glands following a cancer of the vulva. One of the rats died seven weeks later with nodular cancer involving the peritoneum. As the inguinal canal in the rat is not obliterated, this appears to be a direct extension of the disease from the point of inoculation. The inoculation was also successful in the second rat and material taken from this rat and inoculated into a third rat also proved to be successful.

Inoculation from animals into animals of the same species seems to be more successful than into animals of a different species.

Wehr has implanted malignant tumors of the prepuce and vagina of dogs and has succeeded in producing a fatal carcinomatosis. Klencke has also succeeded in transmitting melanosarcomata of horses. In this connection the most interesting experiment of Lock cannot be passed by. This investigator believes that cancer is due to the entrance of normal epithelium into the lymph vessels with continuation of growth. Hence he opened the peritoneum of a rabbit and scraped the epithelium of the ovaries. The animal was killed after fourteen months. The animal showed cancerous nodules in the mesentery; white areas in the liver; a small mass on the wall of the uterus and

an infiltration of the diaphragm. Cancer is an extremely rare disease in rabbits; hence Lock concluded that his operation produced the disease.

Moran was able to transmit cancer in white mice in 8 out of 10 cases. He also performed an experiment which is interesting as suggesting the possibility of the theory of an intermediate host as the carrier of the virus. Placing healthy mice in cages over a vapor of turpentine and camphor to protect them from insects, they remained in perfect health. In other cages he placed mice with bed bugs taken from the cages of cancerous mice, and observed after a few months that all the animals infested by these insects were suffering from cancer.

Irritation seems to play an important rôle in the production of cancer; cancer of the breast, lip and scrotum often have a history which suggests irritation or a traumatic origin, but attempts to produce cancer by trauma in animals have not succeeded.

The question of heredity, as a factor in the causation of the disease, is one about which statisticians differ greatly; it has been placed below 10% by some and as high as 30% by others. How often do we hear a patient exclaim, when informed of the diagnosis, that they have never heard of an instance of the disease in the family for generations. Yet, in some instances, we hear of very striking examples of family susceptibility to the disease. Space does not permit me to cite more than one, which I have selected as showing at the same time a remarkable susceptibility of a certain organ. Power³ reports a case of cancer of the breast with the following family history: The father died at forty-six with cancer of the breast; a brother died at sixty-five with cancer of the throat; a second brother died at twenty-five with cancer under left arm. First sister died at sixty-three with cancer of the breast; second sister died at forty-six with cancer of both breasts; third sister died at forty with cancer of both breasts; fourth sister died at fifty-four with cancer of breast; fifth and sixth sisters now living with cancer of the breast.

A consideration of the so-called parasites of cancer brings us to a new and the latest phase of the question of the nature and origin of carcinoma.

When the anatomical nature of the disease was better understood and the scientific world realized the active part played in the development of the growth of epithelial cells, attempts were made to recognize a specific cell, by Lebert and others, which could be regarded as the typical cancer cell. The attention of investigators being concentrated on the behavior of the epithelium brought out theories like those of Tiersch and Conheim. Tiersch assumed that an antagonism was brought about between the epithelium and the surrounding connective tissue and, the resisting power of the latter having been weakened, an ingrowth of epithelium had to follow.

Conheim's ingenious theory of the isolation of fragments of embryonic tissue, which for a time remained latent and subsequently developed into tumors, aroused great interest by the skillful manner in which it was presented. It accounted, undoubtedly, for certain forms of growth, but did not succeed in maintaining its ground as a potent factor in the development of cancer. Rippert believes that the first change takes place in the connective tissue as the result of some chronic inflammatory process, and

³ British Medical Journal, 1898, vol. i, p. 154.

a portion of the epithelial tissue is thus isolated from its surroundings. When thus put under abnormal conditions the epithelial cell acquires great productive power, which is characteristic of cancer.

Hausemann's theory places the primary change in the epithelium itself. As a result of this new influence the epithelium undergoes a change known as anaplasia, or an increase in reproductive and regenerative power and a loss of differentiation for the function for which it was originally intended. It is a change backward toward the embryonic state.

Many of these theories receive an apparent justification in the experiment of Lock in the epithelium of the ovary above described.

Virchow was the first to call attention to the change in the interior of the cell and the presence of bodies having a well-defined outline; he called them physalides. It was in 1889 that Thoma first ascribed a parasitic origin to the nucleated bodies found in cancer. Darier also about this time observed organisms in a disease described simultaneously by Podwysoski as psorosperme folliculaire vegetante, and by White as keratosis follicularis, and assumed that they belonged to the family of coccidia. This organism consists of a granular mass of protoplasm, with a nucleus not easily seen and without an enveloping membrane during its period of growth, while it inhabits an epithelial cell. It finally breaks away from its host and segmentation and sporulation take place. These organisms are very common in the livers of rabbits—an animal, by the way, in which cancer is extremely rare. A more careful study of these cell inclusions with fuchsin gave to Russell the suggestion that they might be vegetable organisms belonging to the family of yeasts, but the general opinion prevailing at that time was that they were some form of protozoa. Opinion has now veered round to the view that they are vegetable rather than animal organisms and belong to a class of fungi, known as blastomyces, or a variety of yeast. It was not then known that this plant produced lesions very similar to the so-called protozoa; that is, that it produced inflammatory reaction in the tissues into which cultures of this organism were injected. When examined under suitable staining all these so-called protozoa forms can be simulated by the blastomyces. When inoculated into guinea-pigs this organism has its proper membrane, which is filled with protoplasm and contains a body resembling a nucleus. The cell averages 8 to 10 μ in diameter. It grows by budding and in the process the parent cell may give rise to several buds. Under certain circumstances spore formation may also take place. It grows in strongly acid media and can thus be separated from many of the forms of bacteria.

The parasitic bodies seen in the tissues and cells of a growing carcinoma are thus described by Plimmer: They are from .004 to .04 millimetre in diameter. There is a central portion which represents a nucleus, around which is a protoplasm surrounded by a capsule. The nucleus differs in its reaction from the ordinary cell nucleus. The protoplasm is generally homogeneous and the capsule is very strongly marked in outline. It multiplies by division into two by budding, or the nucleus divides first and the protoplasm afterwards undergoes segmentation. These organisms stain usually with protoplasm and not with nuclear stains and thus distinguish themselves from

ordinary cell formations seen in neoplasms. I quote Plimmer's description, as he has studied them with Ruffer and has reported having examined 1,278 cases of cancer and found these bodies in 1,130. He found them at the growing edge and not in the degenerated parts. In ordinary cancers they are found only in small numbers, but in very malignant growths they are exceedingly numerous. Ruffer and Plimmer believe that the parasite can be seen alive if teased in salt solution, and changes in the shape of the nucleus have been observed. They are now generally recognized as a frequent occurrence in the cells of a growing carcinoma. Dean, however, shows that they sometimes take a nuclear stain, which he thinks throws some doubt upon the parasitic theory. When kept under cover-glass their reproduction by budding has been observed. These structures have none of the reaction of any known degeneration. The organism, as it appears in culture, differs materially from that observed in the tissues. Many of these appearances are simply degenerated forms of the organism and it is undoubtedly the case that other cell degenerations have been mistaken for it, thus giving rise to much confusion.

I have endeavored to describe these organisms under the varying conditions under which they are examined by the pathologist, as they seem to have the property shared by many bacteria, to which they stand next in the scale of plant life, of changing their character in accordance with the nutrient material in which they happen to grow, and this may account for the varying appearance in cell inclusions which we find in carcinoma. They have a chemistry of their own and they are capable, though harmless at first, of being raised in virulence by cultivation from one animal to another until they become extremely pathogenic to the same species of animal. Their classification is quite unsettled, some, apparently, being only stages in the life history of higher fungi.

Busse was one of the first observers to recognize the blastomyces as a pathogenic organism and succeeded in obtaining a culture of it from the sarcoma of the tibia in a woman. Romer, in 1891, first studied experimentally its pathogenic qualities. Attempts were now made by Sanfelice, Plimmer and others to obtain cultures from human cancers, but great difficulty has been found in accomplishing this.

Kahane obtained the organism from a cancer of the uterus. Curtis obtained it from a tumor of the back. Corselli and Frioco isolated blastomyces and found the organisms thus obtained pathogenic in animals. Bonomé cultivated the organisms 7 times from malignant growths, in 1 case of sarcoma and 6 cases of cancer, out of 26 cases.

Sanfelice succeeded in isolating an organism, but could make it live but a short time, and got no satisfactory pathogenic action in animals. He then took an organism obtained from the skin of a lemon, cultivated it on vegetable culture media, and succeeded in obtaining a distinctly pathogenic action in guinea-pigs and other animals. He was able to produce inflammatory reaction in the shape of tumor-like growths and infection of the lymphatic glands. Busse and other investigators have also succeeded in producing these inflammatory growths and even septicemia. Investigations now began to follow two general lines. Systematic attempts were made to isolate and culti-

vate from cancer in man an organism which when injected into animals would produce typical cancer. Inoculation of blastomyces were also made into suitable animals in order to produce a tumor in structure and development similar to cancer.

The *saccharomyces neoformans*, as Sanfelice calls it, occurs in two forms: in one it possesses a capsule and can be cultivated in artificial media; in the other it has no capsule and resembles the fuchsin bodies of Russell, and cannot be cultivated in artificial media. This second form is only observed when the parasite has been in the organism for a long time. Sanfelice found that in order to make these organisms grow in the media, they must be obtained in the form usually found in infections running a rapid course, and that in those running a more prolonged course it could but seldom be obtained. He was able to pass the actively growing organisms through several animals by introducing it into the peritoneal cavity, and recovering it from the lymph glands. By repeated inoculations in this way into guinea-pigs the faculty of further growth in artificial culture media was lost, but at the same time the organism appeared to have changed its character, and was now capable, not of continuing to cause inflammatory foci, but of producing a malignant growth.

This diminishing power of being cultivated which exists in the organism after going in inoculated animals is suggestive of the difficulty of obtaining cultures from human cancer, and may be due to some change in its physical structure as I have just indicated.

Sanfelice's inoculations were made on guinea-pigs, mice, rats, rabbits and hens. The organisms were obtained either from original cultures of blastomyces or from carcinomata. Local reaction of an inflammatory nature followed in all cases, but in from six to twelve months a "tumor" formation occurred at this point. Although this growth was accompanied by alteration of the adjacent lymph glands, and some of the tumors bore a resemblance to sarcoma, they appeared to consist histologically of inflammatory tissue, and, as a rule, eventually disappeared. These granulation tumors, as they might fairly be called, contained the blastomyces, although there was a decided change in its appearance from that observed in the cultures, and this seemed to be constant, the organisms in these artificially produced growths resembling those seen in the cells of cancer.

Up to 1898 Sanfelice had inoculated 59 dogs, but in only 3 cases was there a result which resembled a malignant growth. In the first of these the appearance was that of "sarcoma," to which I have already referred. The second was that of a bitch whose breast gland had been inoculated with one of the cultures passed through several animals. There followed a local reaction for a few days, which disappeared. After a month's interval signs of a growth were observed. There was a gradual increase in the size of the gland, with cachexia and death in ten months, and at the autopsy a tumor was observed, about one-half the size of an egg, in the left posterior milk gland; the nipple was retracted and the skin adherent; the glands in the groin were enlarged. Sections of the tumor and of the adjacent glands showed them to be adenocarcinoma. Cultures were negative. The organisms were found in the sections studied. The third positive result was in a dog inoculated with the *saccharomyces neoformans* passed through several animals. The testi-

cle was the part inoculated, and five months later several nodules were found in the organ, and in six months the animal died, apparently from some accidental cause. An adenocarcinoma was found in the testicle, but not in the adjacent glands. Blastomyces bodies were numerous. Inoculation of dogs and cats in the veins produced only connective-tissue proliferation.

Plimmer's experiments were made into a culture medium obtained from a cancer of the breast. Small fragments of the growth were placed in this and were subjected to anaërobic conditions. Organisms were obtained by him in this way, and were used for inoculations of animals. In some cases the result was negative, but in others a new growth was obtained. A rabbit cornea thus treated showed masses of epithelial cells between the layers of the cornea. In guinea-pigs, which die in from thirteen to thirty days, Plimmer found small, transparent nodules, which he describes as endothelial growths surrounded by round-cell infiltration. In one case the growth resembled the growing edges of a human cancer. The inoculations were made intraperitoneally and subcutaneously.

Among the numerous experiments in this direction we may mention Podwysoski, who inoculated animals with fragments of a parasitic tumor-like growth on cabbage and similar plants. The resulting growths resembled sarcoma. Spores of the parasite were found in the cells of the new formation. These growths were, however, evanescent.

Nils Sjöbring obtained cultures from a cancer in an ascitic fluid and pepton gelatine. In a hanging drop he found ameboid, rhizopodal and involution forms of the organism. He produced in animals several tumors having epithelial structures in them, and one which had the appearance of a cylinder-cell carcinoma. There was, however, no metastasis.

A review of this subject would not be complete without reference to the rôle played by these organisms in certain forms of skin disease. Protozoa have been seen in herpes zoster, varicella, psorospermosis follicularis and molluscum contagiosum.

Cases of blastomyces dermatitis have been reported recently by Rixford, Hessler, Wells, Gilchrist and Hektoen. Some of these cases resembled scrofuloderma of a severe type, and were characterized by extensive inflammatory infiltrations of the skin, with ulceration. One case died of what might be called an "acute protozoan infection." Another case resembled clinically chronic pyæmia.

It is interesting to observe that some of these forms of dermatitis, particularly one described by Hektoen, was characterized by a marked epithelial hyperplasia; but the dominating feature was inflammatory and sometimes even suppurative. Cultures were obtained from these lesions, and carefully studied by Hektoen, and found to be pathogenic to animals; but a comparison of the different cases of this blastomycetic dermatitis shows that it may be produced by organisms which differ so much in certain cultural and pathogenic characteristics that they must be regarded as separate though closely allied varieties.

I have thus endeavored to place before you a review of the literature of this question as it stands today. From a statistical and clinical point of view there is much that is suggestive. The attention of the profession has been aroused to a new study of cancer. There are many data accumulated that would

seem to throw a new light upon this problem. There seems to be but little doubt that cancer is increasing. Although many good authorities attribute the apparent change to better sanitation for the young, and improved diagnosis, it seems highly improbable that the statistics of Massey, Haviland and others are wholly fallacious. The histories of villages, streets and even houses are—to say the least—strongly suggestive; and purely clinical evidence, when it shall have been accumulated in a more convincing mass, will, I think, tend only to strengthen the feeling that carcinoma is an infectious disease.

We must remember, however, that Koch has laid down as a crucial test that certain conditions must be fulfilled before it can positively be asserted that a given organism is the specific cause of a disease. These are: It must be found in all cases of that disease; it must be found in no other disease; and it must appear in such quantity and be so distributed that symptoms can be accounted for by its presence; also, that the organism must be capable of being isolated from diseased tissues and be grown upon some artificial culture media, and when injected into an animal must be capable of reproducing the disease. As a corollary to this we may add that it should be possible to recover the organism in culture from the artificially produced disease. A glance only at the work of the leading investigators in this disease is sufficient to show that these conditions are still far from being complied with.

Of all the experimental work which I have quoted there are but two instances in which a genuine carcinoma has been produced by inoculating an animal with a culture of the so-called parasite of cancer, and in each of these the final requirement of the Koch law has not been met, namely, that cultures taken from these tumors should reproduce their kind.

Foulerton, of the Middlesex Hospital, London, says: "From evidence available, one can only say that it is not improbable that some, at any rate, of the cases which are now on clinical and histological grounds classified amongst sarcoma may prove to be really cases of yeast infection. But as to the exact causation of carcinoma we are still absolutely ignorant."

It is true that the organisms are found more frequently, as our histological technique has informed us, but it is not possible to bring under one heading and classification the numerous bodies which have been described, for it can hardly be impossible that all observers are describing the same organism. A glance only at a few of the sections which have been prepared by the best laboratory workers would convince one that either the organism is capable of assuming the most diverse appearance under varying conditions, or that we have here many different organisms with which to deal.

Interesting as the outlook is at present, and encouraging as is the situation, the facts at present brought forward by the highest authorities do not justify us in any better verdict than "not proven."

It is partly as an object lesson that I have brought this subject to your attention this evening, for no one who is conversant with the work that is now going on to solve this question can ignore the prominent part taken by Americans in the line of research. The organization of a laboratory at Buffalo by Roswell Park for the study of cancer, and its endowment by

the government of the State of New York, is not only a new departure from the American point of view, but is actually the first instance of an organization for this purpose in any country. Although as yet no official announcement has emanated from this source, I am in the position to state that investigations of the most scientific and accurate character have been carried on there during the past two years, and that much strongly confirmatory evidence has been produced to strengthen Sanfelice's statement. Through the benevolence and public spirit of a Boston lady, the Caroline Brewer Croft Fund has been bequeathed to the Surgical Department of Harvard University, and under the provisions of the bequest work has begun in the surgical laboratory of the Medical School. Under the supervision of Dr. E. H. Nichols, who has lately returned from a tour of inspection abroad, investigations are being carried on in a manner that ensures a critical analysis of all that has thus far been done along the various lines of investigation.

In planning the work for the future, we are endeavoring to approach this subject from every possible point of view. If a parasite exists, does it belong to the animal or vegetable kingdom? Will a study of the disease in animals—fishes, for example,—give us valuable information? Is it possible that the subject must be approached again from a bacteriological point of view? I have not even mentioned bacteria, as there is no evidence at the present time to show that bacteria play any part in the origin of the disease. It is possible, however, that the microbe of cancer exists, but that it is too small to be visible with our most powerful lenses. We know there are many diseases regarded as infective in which no bacteria have as yet been demonstrated, and yet we have proof of the material character of the organisms which produce them, for filters exist which are fine enough to prevent their passage.

It is only by long and patient research that we may hope to unlock the secret of this as well as many another enemy of our race, and it is a matter of congratulation that American teachers are now recognizing the value of scientific work as one of the proper functions of a medical school, and are prepared to take their place with those of other nations in the development of the future of medicine.

ADDRESSES OF CONFEDERATE SURGEONS WANTED.

—We are requested to publish the following notice: All surgeons, assistant surgeons, acting assistant surgeons or contract surgeons, and hospital stewards, who served in the army or navy of the late Confederate States, will please send their post-office address to Deering J. Roberts, M.D., Secretary Surgeons' Association, C. S. A., Nashville, Tenn.

Original Article.

A CASE OF MURAL ENDOCARDITIS.

BY HAROLD WILLIAMS, M.D., BOSTON,
Professor of Theory and Practice of Medicine, Tufts College Medical School;

WITH PATHOLOGICAL REPORT

BY T. LEARY, M.D., BOSTON,
Professor of Pathology, Tufts College Medical School.

THE following case is reported because of the rarity of the pathological lesion and because of the absence of murmurs in spite of the extensive disease of the mitral valve. The patient, a lady somewhat inclined to obesity, fifty-four years of age, the wife of a physician, was cared for by her husband; by Dr. R. H. Fitz, who saw her once or twice a week throughout her entire illness, and by me. The autopsy was made by Dr. Leary.

The first symptoms began on the 22d of December, when, after a short walk, she was seized with an attack of angina pectoris with dyspnea and with pain. She with difficulty reached her house and was put to bed, where she remained until her death, March 15th. I first saw her on the evening of February 9th. On this occasion she was in a condition of collapse, occurring after one of the attacks of dyspnea, from which she had suffered at intervals since December. This collapse was almost complete; the face was ashen, the temperature subnormal, the body bathed in sweat. No pulse could be felt at the wrist. The heart sounds were faintly audible. She was breathing in short gasps. She was taking ether by inhalation. A subcutaneous injection of morphia was given and reaction set in. On the following day a careful physical examination of the chest was made as follows: Patient was lying on her left side; no orthopnea; breathing was shallow and labored; there was retraction of intercostal spaces and also of interclavicular space. Percussion, flatness of both sides of chest, below sixth rib behind. Dulness over lower lobe of left lung. Auscultation, numerous sonorous and sibilant râles over entire back, subcrepitan râles over area of dulness at the left lower base.

Heart: Action feeble, apex pulsation not visible, no abnormal pulsation, no thrills. Percussion, cardiac area of dulness enlarged slightly to left. Auscultation, heart sounds feeble, rhythm disturbed, no murmurs, no accentuation of pulmonic second sound.

The subsequent history of the case was a history of frequently occurring attacks of dyspnea. These attacks were always without pain, and nearly always were predicted by patient. They began usually with a quickening of the pulse, which soon became trigeminal and weaker until it was lost at the wrist. The dyspnea was intense. It consisted of a rapid series of gasps accompanied by a rhythmical movement of the right arm. Consciousness was retained throughout the attack. The suffering in these attacks was intense; they were precipitated by the least movement; by examination of the chest; by conversation; by the most trifling emotional causes. They were but slightly amenable to the usual remedies, each drug relieving for a limited time, as if the reserve force aroused by its especial agency was quickly exhausted. Finally, the attacks became almost continuous; the decubitus changed from the left to the right side and the patient

succumbed March 15th. At no time were murmurs detected by any of the physicians in attendance. The apprehension of the patient and the supervention of paroxysms of dyspnea upon the least change of position precluded extended examination, but the diagnosis was made as follows: Fatty heart, with sclerosis of coronary arteries; hypostatic pneumonia, lower lobe of left lung; hydrothorax.

Autopsy.—The description of lesions in organs other than the heart, arteries and lungs is purposely omitted. The changes in other tissues were all dependent upon the cardiac lesion, and were in no way remarkable. Left pleural cavity contains a large amount of clear serous fluid. Lung everywhere compressed, particularly lower lobe, whose tissue is dense and contains no air. In upper anterior portion of lower lobe is a dark-red, wedge-shaped area of consolidation with its base 2 centimetres in diameter on the pleura. At its apex was found a firm, red clot filling a branch of pulmonary artery. Right pleural cavity contains a smaller amount of fluid, and lung shows no gross signs of compression. In upper lobe of lung is a consolidated area, which occupies the greater part of upper portion of lobe. This area is discolored dark blue and projects above surrounding lung substance. On section, lung shows a diffuse, very firm consolidation. Cut surface is bluish black and much blood may be scraped from it. At apex of consolidated area is found a long, firm, red clot, plugging one of the primary divisions of the branch of pulmonary artery supplying the lobe. Sections of left lung show edema and compression of alveoli. Some evidences of chronic passive congestion are shown by alveolar epithelial cells containing pigment granules, although the vessels of the alveolar walls do not in most cases contain blood. Sections of right lung at base show a condition of marked chronic, passive congestion with bronchopneumonia. No adhesions in either pleural cavity. Pericardium contains no fluid, surface smooth.

Heart, 405 grammes (normal 250) found in diastole. All cavities dilated contain recent clots and fluid blood. Heart muscle dark; cut surface dull. Left ventricle: The mitral orifice measured 10.5 centimetres (normal 10.4 centimetres). Valve flaps show slight diffuse thickening. The chordæ tendineæ were generally thickened and shortened in such a manner as to absolutely preclude closure of the mitral valves. The papillary muscles are thickened and opaque at their apices, and several of the chordæ tendineæ are interadherent. Attempts to fold back the walls of the ventricle in order to inspect the interior met with considerable resistance, on account of the tension of mitral segments. The endocardial surface of ventricular wall over triangular area, having for its base the posterior flap of the mitral and bounded by lines converging to the apex, is thickened, white and very opaque. On section into muscle, a superficial layer, varying in thickness from .1 to .3 centimetre, white, firm and fibrous, could be readily moved about on the underlying muscle substance, to which it was united by loose attachments. This layer, in places, includes one-half the thickness of heart wall. In the lower portion of this area are two small, firm, dry, dull-white clots, which are attached to the endocardium, filling folds between the columnæ. Elsewhere the endocardium is translucent and its outline cannot be distinguished on section of muscle. Ventricular

¹ Read before the American Climatological Society, Washington, D. C., May 3d.

wall: Left ventricle .8 to 1.3 cubic centimetres in thickness (normal 1.1 to 1.4). Under area of endocarditis varies from .4 to .6 centimetres. Right ventricle dilated. Tricuspid orifice 12.5 centimetres (normal 12 centimetres). Walls .2 to .4 centimetre thick (normal .5 to .7?). Endocardium smooth, translucent. Valves show nothing abnormal. Both auricles dilated and walls thickened. In right auricle are two old red clots in the folds of the pectinate muscle. The left coronary shows nodular projections throughout its course. Some of the areas are opaque, but none show calcification. The lumen of the right coronary at about 2.5 centimetres from its origin shows a sudden diminution in size, and is transformed into a fibrous chord, through which the canal could not be followed. This constriction extends for 1.2 centimetres and suddenly stops—the lumen of the vessel immediately beyond being larger than the proximal portion. Except for this area of constriction the vessel shows a less degree of sclerotic change than does the left coronary.

Microscopical examination of branches of the coronary arteries shows arteriosclerotic areas, many of which are in the proliferative stage, while most show degenerative changes in the new tissue. Microscopical examination of the affected area in wall of left ventricle shows a proliferative endomyocarditis. Most of the inner layer of heart muscle has been replaced by dense fibrous tissue, and the opaque endocardial layer described is made up of this tissue, with few islands of muscle substance. The muscle fibres show hyaline degeneration and many exhibit a separation of the primary fibrillæ. In the longitudinal sections segmentation of fibres, oftentimes with considerable displacement, is everywhere present. This change is more marked in the comparatively normal muscle fibres than in those imbedded in the inflammatory tissue. Sections of ventricular wall, from other areas, show a slight diffuse chronic myocarditis with muscular segmentation. Aorta shows nodular arteriosclerosis affecting principally the arch. Nodules are discrete and become fewer in number below the arch. One focus at commencement of thoracic aorta is covered with a calcareous plate. Vessel has lost little of its elasticity, judged by gross tests. Microscopical examination shows an arteriosclerosis, which in most nodules is in the late stage of proliferation, with hyaline degeneration of new tissue. Few patches show complete fatty metamorphosis beneath the endothelium. Splenic artery is tortuous and generally thickened, with no prominent nodules. Endothelial coat granular. Renal arteries show nodular thickenings; endothelium smooth.

CONCLUSIONS.

We have to do with a generalized arteriosclerosis, affecting vessels of medium and small size particularly.

The localization of the extreme process in a portion of the wall of left ventricle is undoubtedly dependent upon the obliteration of the right coronary artery, the area affected representing the distribution of the terminal branches of that vessel.

The muscular segmentation, which was found generally throughout heart muscle has rarely been described except in connection with acute diseases. It has always been a question whether the process was not a post-mortem change. In this case the autopsy

was performed only twenty hours post mortem and the tissues immediately placed in fixing fluids.

The absence of cardiac murmurs is remarkable, as, judging from the post-mortem picture, it would have been impossible for the flaps of the mitral valve to meet unless systole were accompanied by extreme distortion of the left ventricle. The absence of pain is also a remarkable feature.

Clinical Department.

CYSTS IN THE ABDOMINAL WALL STRUCTURALLY IDENTICAL WITH OVARIAN CYSTS.

BY JOHN HOMANS, M.D., BOSTON,
Lecturer in Harvard College on Ovarian Tumors.

I WAS much surprised while operating in June, 1899, on a very old-standing enormous adherent ovarian cyst, weighing 102 pounds, to find a large cyst in the abdominal walls in the epigastric regions, entirely distinct from the ovarian tumor but of the same character. The universal dense adhesions complicated the relations of the ovarian tumor so much that this independent cyst merely attracted my attention and surprise. I did not investigate the relations of the extraneous cyst, as the operation was a laborious and difficult one demanding my whole attention.

When, however, I saw the patient again in August, 1899, I was astonished to see various cysts, entirely independent of one another and of the abdominal contents, scattered about in the abdominal walls. This appearance was something entirely unique in my experience. There were at least four cysts in the abdominal parietics, varying in size from that of a horse chestnut to that of an orange. One of these cysts I cut out and sent to the pathological department of Harvard College and received the following report from Dr. R. B. Greenough, who was taking the place of Dr. W. F. Whitney: "Of abdominal walls, microscope shows a dense fibrous tissue and fat and muscle, with a small area of more cellular fibrous tissue in which there appear epithelial structures of the type of ovarian cystadenomata; a single layer of cylindrical cells forming irregular gland acini. Malignant cystadenomata of ovary." Olshausen¹ mentions a similar case in which the anatomical structure closely resembled a glandular ovarian cyst, and in his case, as in mine, the abdomen also contained an ovarian cyst.

The clinical features of the case, which are interesting from the enormous size of the tumor and its slow growth, are as follows: Mrs. G., thirty-nine years old, when she first consulted me on January 15, 1889, had a large ovarian tumor. By March 9, 1892, the tumor was still larger and her umbilical girth was 51 inches. I estimated the weight of the tumor at about 65 pounds. I saw her again November 20, 1895. Her umbilical girth was 53½ inches. She moved about easily, although somewhat embarrassed by the weight of the tumor. She had not emaciated notably in the clavicular, facial or lumeral regions. Her weight was 209 pounds, and she was much taller than the average woman. In June, 1899, she came to my office again, and her size was so great that the front of her abdomen almost touched the front of the

¹ Zeit. f. Geb. u. Gyn., Bd. lxi, 42, and American Journal of Obstetrics, January, 1900, p. 124.

coupé in which she sat. I removed the ovarian tumor on June 14, 1899, and will simply say that the tumor and its contents weighed 102 pounds, that it was very adherent and that there was an independent cyst in the epigastric region distinct from the ovarian tumor and imbedded in the abdominal parietes. She recovered rapidly, and went home well July 12, 1899.

Dr. Whitney reported the tumor to be a cystadenoma of the ovary.

On August 28th I saw her again. She was enormously distended and in great distress, crying out with pain and discomfort. About 30 pounds of ascitic fluid were removed by an incision through the old scar. The intestines were chronically inflamed, red and thickened. Several cysts were found in the abdominal walls; one to the right of the umbilicus was emptied of its thick, ovarian-like fluid and its smoothly-lined cavity was packed with gauze in hopes of obliterating it. There was another one near the umbilicus the size of a butternut, and at least one or two others larger. One cyst removed for examination was sent to the Medical College. The report of its character has been given above. The patient was relieved of her pain and distress and bid fair to recover, but died on September 1st rather suddenly, apparently from a thrombus. No autopsy was allowed. From this case and that of Olshausen it seems that persons with ovarian tumors within the abdomen may have others like them developed in the abdominal walls.

A CASE OF CÆSAREAN SECTION.¹

BY THOMAS KITTREDGE, M.D., SALEM, MASS.

Mrs. M. M., twenty-eight years old, was sent to the Salem Hospital at seven o'clock in the morning of January 31, 1900, by Drs. Mignault and Daniel R. Brown. She had been in labor twenty-four hours; the pelvis was very narrow, the head would not engage, and could not be reached by forceps. The woman was in excellent condition, having a normal temperature, and pulse of less than 100. She was immediately prepared for abdominal section. She was given a hasty surgical bath; the abdomen was scrubbed; permanganate of potash and oxalic acid were applied, also ether and absolute alcohol. The abdomen was then covered with towels wrung out in 1-2,000 bichloride solution. She was given one-thirtieth grain of strychnia, hypodermically, and catheterized. The vagina was rendered antiseptic by soap and water, and a 1-2,000 bichloride solution.

Instruments, dressings and all the accessories of an abdominal operation were sterilized in the usual way by steaming and boiling, and the hands and arms of the operator and assistants rendered antiseptic by scrubbing and rinsing, and then treating with chloride of lime and carbonate of soda.

With Dr. Elliot, house officer at the Salem Hospital, to assist me in the operation, Dr. Edward L. Pierson to hold the broad ligaments, and Dr. Ara N. Sargent to take the child, the patient was anesthetized, and the operation began at a little after eight o'clock. A median incision was made, from three inches above the symphysis pubis to half-way between the umbilicus and ensiform cartilage (about ten inches),

and even this long incision made an opening barely large enough to deliver the uterus. The uterus was lifted out of the abdominal cavity and surrounded by warm moist towels; sterile gauze strips were then packed into the abdominal wound to prevent the entrance of blood and meconium, while Dr. Pierson grasped the broad ligaments from behind. An incision in the uterine wall was made, extending from just below the fundus to near the junction of the cervix and the body of the uterus. As the muscular tissue was cut by the scalpel it retracted immediately, leaving bevelled edges to the wound in the uterine wall, and this bevelling of the edges caused some difficulty in closing the incision later on. At a point just above the junction of the cervix a vessel of considerable size was cut (probably one of the uterine sinuses), from which there was, for a moment, a considerable hemorrhage. An attempt to control it with the artery forceps failed, probably from retraction within the muscular tissue; but while the attempt was being made, it ceased and did not recur. The left shoulder of the child presented in the wound (the head being in the right upper part of the uterus, with face to the back), and with some little difficulty the child was lifted out through the incision, which was barely long enough, although as long as it could be made with safety. It was immediately handed to Dr. Sargent; the finger was easily passed beneath the placenta, which was attached to the left posterior wall of the uterus; the placenta was carefully peeled off, and the child, with placenta attached, taken by Dr. Sargent, who succeeded, with little difficulty, in establishing respiration and making the child cry. The child, a male, weighed eight and one-half pounds, was well nourished, and in normal condition.

By the time the child and placenta had been taken away, the uterus had contracted to the size of a coconut, and was hard and firm. The uterus was flushed with normal salt solution, both within the body and through the os into the vagina. There was practically no bleeding from the cavity of the uterus or from the wound. As no kangaroo tendon of sufficient size was at hand, four interrupted silkworm-gut sutures (boiled until they were as soft as ordinary silk) were passed through the muscular wall of the uterus, and the edges of the wound brought into apposition. Owing to the bevelled edges previously spoken of, there was some separation of the superficial part of the incision, which necessitated numerous sutures in the peritoneal coat. These last sutures were of fine intestinal silk, and were interrupted.

The whole uterus was flushed with normal salt solution and dropped back into the abdomen. When the deep sutures were in place, but before they were tied, thirty minims of ergotol were given hypodermically. The abdominal wound was closed with interrupted silkworm-gut sutures, the abdomen bathed with sterile water, and the usual sterile abdominal dressing applied. The pulse was strong and full throughout the operation, and rose but little above 80. There was absolutely no shock. The patient was placed in bed, with a pillow beneath the knees, and the foot of the bed raised. At the end of a few hours the foot of the bed was lowered to its natural level, in order not to interfere with the drainage from the vagina.

There was rapid recovery from the ether, and there was no vomiting. The patient was given hot water,

¹ Read before the Essex South District Medical Society, April 10, 1900.

in small quantities, at short intervals during the first twenty hours, and then gradually given the usual liquid diet. The bowels were moved by a saline enema (to avoid distention with gas) on the next morning after the operation, and she had to be catheterized but a few times.

On the third day, during the temporary absence of the nurse from the room, the child began to cry, the patient got out of her bed, walked across the room, took the baby from its crib, and carried it back to her own bed. The patient made an uninterrupted recovery. The sutures in the abdominal wound were removed on the fourteenth day, and she was ready to go home at the end of three weeks.

The baby did well; was put to the breast at the usual time, and the mother continued to nurse it. There was rather less lochia than after a normal delivery. No gauze was placed through the os before closing the uterine wound, as I felt that drainage from the cavity of the uterus would be better without it.

I regretted very much not having absorbable suture material to close the muscular wall of the uterus, and considered silkworm gut safer than the large silk which I should have been obliged to use. On another occasion, having to deal with bevelled edges to the uterine wound, as in this case, I think I should not attempt to bury the deep sutures, but should pass them through the muscular wall and peritoneum, with the exit of the sutures some little distance from the line of incision. This, it seems to me, would bring the surface of the wound into closer apposition, and put less strain upon the sutures in the peritoneal coat, and perhaps obviate the necessity for them.

I have neglected to state that careful pelvimetry revealed a pelvis shortened in all its diameters, the anteroposterior being less than three inches, with a very oblique superior strait. After the operation the patient was recognized as a woman who had been delivered, one year previously, of a dead and maimed child, with great difficulty and after a long struggle, by three members of the hospital staff.

Reports of Societies.

TENTH ANNUAL MEETING OF THE HARVARD MEDICAL ALUMNI ASSOCIATION.

THE tenth annual meeting was held at the Harvard Medical School building at noon on Tuesday, June 26, 1900. Dr. David W. Cheever, the president, presided. About forty members were present. The secretary's report was read and approved. It showed a membership of 1,232.

The treasurer's report was read and accepted. It showed a balance on hand of \$2,504.01. The dues for 1900 do not appear in this report. The least sum received in any previous year has been \$600, which added to the amount on hand makes \$3,104.01.

The following officers were then elected, for three years: President, Clarence John Blake, M.D., 1865, Boston, Mass.; Vice-Presidents, James Forster Al-leyne Adams, M.D., 1866, Pittsfield, Mass.; Wooster Parker Giddings, M.D., 1871, Gardiner, Maine; John Winters Brannan, M.D., 1878, New York, N.Y.; William Wotkyns Seymour, M.D., 1878, Troy, N.Y.; Oscar Joseph Pfeiffer, M.D., 1884, Den-

ver, Col.; Leonard Wood, M.D., 1884, Havana, Cuba; James Woods Babcock, M.D., 1886, Columbia, S. C.; George William Perkins, M.D., 1886, Ogden, Utah; William Barnes, M.D., 1887, Decatur, Ill.; William Sydney Thayer, M.D., 1889, Baltimore, Md.; Secretary, George Shattuck Whiteside, M.D., 1897, Boston, Mass.; Treasurer, William Herbert Prescott, M.D., 1888, Boston, Mass.; Councillors for the term ending 1904, Walter Prentice Bowers, M.D., 1879, Clinton, Mass.; John Baldwin Walker, M.D., 1888, New York, N.Y.; William Henry Robey, Jr., M.D., 1895, Roxbury, Mass. Dr. D. D. Gilbert, of Dorchester, a graduate of Harvard College but not of the Harvard Medical School, was elected to honorary membership.

On motion of DR. BLODGETT, the following resolution was unanimously passed, tendering the thanks of the association to Dr. Walter Ela at the close of his ten years of service as treasurer:

Resolved, That this association desires to place on record its sense of appreciation of the able manner, the untiring zeal, faithful devotion and uniform courtesy with which Dr. Ela has so long administered the financial affairs of the association, with the expression of its sincere regret that he feels himself obliged to decline re-election.

On motion of Dr. Folsom, it was voted that Dr. Stone receive the thanks of the association for the duties he has discharged in the last three years.

ANNUAL DINNER.

The tenth annual dinner was at the Vendome at one o'clock. Drs. William T. Councilman and James R. Chadwick were present by invitation and spoke. The graduating class were also invited. One hundred and fifty-six were present.

THE PRESIDENT said in his address: Since the last meeting we have received 119 new members. There are now 1,232 members. Of those who have just come in, 3 are life members and we have altogether now 59 life members. The fact of life membership does not mean only that we have received temporarily a larger sum of money, but it means that that money is set apart as a permanent fund and not used in the annual expenses, and we hope to have it accumulate until we can get by and by sufficient money to make some important endowment; this is the advantage of life membership, and why we always desire those who can afford to do so to become life members.

We have lost 17 members by death: Enoch Adams, 1851, of Litchfield, Maine; Arthur Appleton Beebe, 1898, of Boston; George M. French, 1884, of Malden; John Henry Gilbert, 1853, of Quincy; W. H. H. Hastings, 1868, of Boston; Thomas L. Jenks, 1854, of Boston; Lawrence G. Kemble, 1883, of Salem; Alfred H. Lindström, 1894, of Boston; J. W. Merriam, 1892, of Iquique, Chile; G. C. Pierce, 1866, of Ashland; E. A. Perkins, 1854, of Boston; J. K. Phillips, 1885, of Bangor, Maine; Samuel Q. Robinson, 1876, of Boston; F. D. Stackpole, 1878, of Roxbury; Russell Sturgis, Jr., 1881, of Boston; I. T. Talbot, 1854, of Boston; James J. Tucker, 1867, of Chicago, Ill.

Our school has been prosperous. The classes have been large and we think the scholarship has been creditable. We are crowded for room, owing to the increasing need of laboratories. The future will require a new site, and many of us think that one which

has been looked at for us is all that could be desired. But I am aware it is not from the president you wish to hear, but from others. First I will call for the regular report on the Medical School, which will be read by Dr. GEORGE M. GARLAND, of Boston.

REPORT OF THE COMMITTEE ON THE HARVARD MEDICAL SCHOOL.

The committee would first notice and speak of the fact that the school is one centre of the most profound enthusiasm. Every man is not only radiant about what has been done, but is beaming with the hope and promise of what the school intends to do—a most hopeful condition. And as it is true that all radiant force is more effective as it is focussed on one centre, it seemed to me that the radiant energy of our school was brilliantly focussed in our worthy dean. In hearing the account of all that the faculty have been doing and of all that is laid out for the future, I was reminded of the story of a young Texan who recently came to Boston to have his appendix removed. On the second day after the operation the doctor found him sitting up and reproved him for his recklessness. He replied, "Why, Mr. Doctor, you don't seem to understand the situation. I came on here from Texas to get rid of my appendix, do up your blooming little town, have my life insured and get married, and I have only a month to do it in."

My predecessors have told you about the changes in the methods of teaching in the last year or two,—the concentration of study, the regulation of the sequence of topics and one or two other measures which have come into vogue in the school. More than that, a series of articles have recently appeared in the *Boston Medical and Surgical Journal* from different members of the faculty, one of which by Professor Councilman has portrayed most vividly and instructively the great change in the methods of study and the greater necessities and obligations brought upon the professors of the different departments, especially his own department of pathology. Another article by Professor Bowditch—his address before the Fifth Medical Congress in Washington—outlines the immediate future and the prospect of medical education in this country. His conclusions I take the liberty to read: "If the views here presented are well founded we may expect that a medical school of the first rank will in the immediate future be organized and administered somewhat as follows: (1) It will be connected with a university, but will be so far independent of university control that the faculty will practically decide all questions relating to methods of instruction and the personnel of the teaching body; (2) it will offer advanced instruction in every department of medicine and will therefore necessarily adopt an elective system of some sort, since the amount of instruction provided will be far more than any one student can follow; (3) the laboratory method of instruction will be greatly extended and students will be trained to get their knowledge, as far as possible, by the direct study of nature, but the didactic lecture, though reduced in importance, will not be displaced from its position as an educational agency; (4) the work of the students will probably be so arranged that their attention will be concentrated upon one principal subject at a time and these subjects will follow each other in a natural order; (5) examinations will be so conducted as to afford a test of both

the faithfulness with which a student performs his daily work and of his permanent acquisition of medical knowledge fitting him to practise his profession." Other articles of interest are one by Mr. Cannon on "The Case Method of Study," and one by Dr. Burrell on his experience with this method in surgical teaching—a method used elsewhere with gratifying results. Mr. Cannon has by very able discussion of this question brought it into notice as a practical, profitable means of training students along one line of study. The only objection I have heard to this method was that it did not sufficiently train to individual observation. Now, it is not a fair criticism of any method to say it does not do something else. If it does well the work intended it is a profitable measure to employ. I am glad it is receiving so much attention not only in our own school, but in other schools and being received with so much approval. It is not intended as a method to teach independent and individual observation; it is merely intended as an auxiliary to such individual and independent observation.

We stand to-day at the beginning of a new epoch. Before speaking of that in detail I want to look back for a few minutes to another epoch which occurred in our school in 1871. The essentials of the change at that time were the establishment of a three years' course, with a graded sequence in subjects. At that time also the didactic lecture was losing prominence and the so-called introductory lecture passed for good and all. My class were gathered together to listen to an introductory lecture by our honored chairman of to-day, Dr. Cheever. If I do not mistake, Mr. Chairman, it was the last introductory lecture of the Harvard Medical School. The president of our university the other day apologized for the way he and his associates had imposed upon the students. He speaks of the six mortal hours of talk every day of the week thirty-five years ago. Twenty-nine years ago began the changes. We had Bowditch back fresh from Europe from Ludwig's laboratory, with his own laboratory well equipped for original investigation and for teaching the students to look into nature rather than into books. We had Wood just starting the chemical laboratory; Ellis, with his clinical method of investigation where the student was put in direct contact with the patient. We had the beginning of the district work in obstetrical practice under Dr. Richardson's guidance. The good work of instructing the students directly from nature itself was nobly begun at that time. The chief epoch which faces us to-day is the merging of the faculties of the Medical, Dental and Veterinary Schools into one faculty. There will be one faculty with one dean, and each school will be represented by administrative boards which will carry on the individual work of its department.

It is interesting to contrast the condition of affairs in 1871 at the beginning of the old epoch and the state of the school at the present epoch. In 1871 there were 34 members on the faculty, 5 other instructors, and 196 students. In 1899 there were 40 members of the faculty, 101 other instructors and 558 students. Such an increase of teachers and students and the immense ramification of laboratory work in place of didactic talk in the lecture-room has proven the inadequacy of our present medical building. Steps have been taken for the securing of larger

accommodations. A syndicate of gentlemen have purchased twenty-six acres of land situated between Huntington Avenue, Francis Street and Longwood Avenue, known as the old Francis Estate. Gradually as funds are accumulated the various buildings of the different departments of the Medical, Dental and Veterinary Schools will be erected on that site.

This is also the last year in which students will be admitted by entrance examination. Hereafter a university degree will be required. Hereafter the degree of *cum laude* will be given only to those who obtain an average of 80% during the whole course. Hereafter this distinction has been conferred upon the obtaining of 75%.

The income of a fund received from the late Benjamin E. Cotting will next year become available and be given to such students as the medical faculty may select, having regard to the pecuniary needs, intellectual capacity and faithfulness of the student rather than the highest scholarship. Next year, also, two fellowships in surgical pathology of \$500 each will be awarded from the income of the Austin Fund and a second Hilton Scholarship will be available.

Next year we lose Dr. Schaper, assistant professor of histology, who returns to Europe. Prof. Wm. T. Porter will go on his sabbatical year. Dr. Franklin Dexter has been appointed associate professor of anatomy. Dr. Franz Pfaff has been appointed assistant professor of pharmacology and therapeutics.

This year 153 men applied for a degree; 18 failed to get it; 84 received the degree, and 51 the degree *cum laude*.

I noticed in my conversation with members of the faculty the greatest readiness in giving me information, and also an evident respect for your opinion, your good word and your good service. In this matter of the progress of our school we as the general profession have a work to perform. The school always needs money. It is our duty and privilege to hunt out such people as can give money and tell them where they can put their money to good uses.

Dr. Keen in a recent address reported these figures: "In 1898 84 theological schools reported endowments of \$18,000,000, and 71 schools do not report this item; 19 out of 151 medical schools report endowments of \$1,906,072. Five theological schools have endowments of from \$850,000 to \$1,369,000 each. Yet in 1899 there were only 8,000 students of theology for whom this enormous endowment was provided, as against 24,000 students of medicine. Each theological student had the income of an endowment of \$2,250 provided for his aid, each medical student the income from \$83. As against 171 endowed chairs of theology there are only 5 in medicine." He continued: "I do not grudge a dollar to the theologian, but I plead for his medical brother, that, with a vastly more expensive education, he shall have a reasonable provision made for his training.

"The tide of charity in the United States has reached a remarkable height. The *Chicago Tribune* publishes an annual list showing that in 1894 the charitable gifts and bequests in the United States amounted in round numbers to \$20,000,000, in 1895, to \$29,000,000; in 1896, to \$34,000,000; in 1897, to \$34,000,000; in 1898, to \$24,000,000; and in 1899 to the enormous sum of nearly \$80,000,000. I hope that we may be able as ministering angels throughout the

community to convert some of the people and some of this money to medical uses."

In conclusion, I have one other piece of cheering information, the message of the presiding genius of the Christian Science Convention, warning her followers not to be too hard on our profession, not to believe all that is said against us, and that on the whole we are doing as well as we know how. In an atmosphere of such kindness it was cheering to know that we are doing our best and are not wholly as bad as we seem.

THE PRESIDENT then introduced one who may be called the apostle of the new method of education, Professor Councilman.

DR. COUNCILMAN: In the first place, I wish to thank you for the honor you have done me in making me, several years ago, an honorary member of your association, and again for asking me to address you to-day. I have now been connected with the Medical School of Harvard University for eight years; and it may be permitted me to give some retrospect of those years, to briefly review what has been done, and as briefly to speak of the future.

I can speak of the progress which has been made in pathology with perfect propriety, for it has been due to a number of circumstances with which I had but little to do. The important position which pathology now holds in medicine is due primarily to the recognition of the importance of the knowledge of the causes of disease. It is felt that the knowledge which is gained from the study of pathological processes, their causes, the character of the lesion, is of immediate importance in the treatment of disease. The early recognition of the character of an infection influences the treatment, and may make a difference between life and death for the patient. It is the recognition of this, which may be called the practical side of pathology, which has led to the creation of laboratories in connection with our hospitals. In these laboratories all the appliances and facilities for work are found; and they are immediately directed by men for whose services the hospital pays, and regards the money as well spent. Boston was almost the first city in the country to recognize the important part which the laboratory plays in furthering the work of the hospital, and the laboratories in connection with her great hospitals are models for the other cities to imitate.

These laboratories are so well known that inquiries concerning their organization come from all parts of this and from other countries, and the number of medical visitors leads us sometimes to wish that their importance was not so generally recognized. Not only do the laboratories serve the important practical end of directly assisting in the treatment of the sick, but they serve an equally important end in contributing to the advance of knowledge by original research, and to the extension of knowledge by teaching. It is necessary for the efficient conduct of the laboratory that research work and teaching should be prominent; for no man can preserve his intellectual vigor and spend all his time in making the routine examinations required by the clinic. It is well that he should have done such work and that he continues to do a certain amount of it, but even the routine work will not be so satisfactory if his faculties of observation and deduction are not continually sharpened by research. The laboratory must also serve to stimulate research in the hospital, for investigation and teaching are just as necessary in the wards of the hospital as in the

laboratory. There should be perfect unity between the wards and the laboratory. Each should further and assist the work of the other.

Under the present conditions the laboratories in the hospitals are connected through the men in them with the laboratory at the Medical School, and an important part of the teaching of pathology is carried on in the hospital laboratories. It is best for the laboratories and the school that this should be the case. Through their connection with the Medical School the men in the laboratories are brought in contact with men in other departments and following other lines of investigation, and the introduction of students into the hospital laboratories widens their influence.

It has been the aim of the department of pathology to have perfect accord between the hospital laboratories and the pathological laboratory at the school. A most important function of the school laboratory must be the teaching of undergraduates, for the large spaces required for class teaching are found there. The school laboratory also serves an important place in connecting pathology with physiology, anatomy, and bacteriology, standing in much the same relation to these branches as the hospital laboratories to clinical medicine. Research is, of course, carried on in the laboratory of the school.

A great change has been effected in teaching pathology to undergraduates. This consists primarily in concentrating the instruction in pathology and the allied subject of bacteriology. The entire time of the student in the first half of the second year is given to these subjects. The instruction at the same time has been made much more practical, much less time being devoted to lectures and more to laboratory work and demonstrations to small classes. A printed syllabus giving a concise account of the various processes studied has, to a great extent, taken the place of lectures. The belief has gradually become very strong with me that students learn but little from being told. They must above all learn to see clearly and to interpret clearly what they see. It is the power of being able to do this which we wish to give our students. In accordance with this idea, even instruction has been cut down. It was formerly considered that an ideal state of instruction would be reached when one instructor would have not more than 10 students, who could always turn to him for any question and have him always at their side for help. In the laboratories I frequently left 75 men for an hour or two without any instruction save the syllabus and the specimens they were studying, and have seen no lack of either industry or interest. For certain sorts of instruction very small classes are the best; and for this purpose the entire class is divided into groups of 10, which groups go separately to autopsies at the hospitals and to demonstrations which are given in separate rooms. The result of one year's experience in this mode of teaching has been most gratifying, and has fully justified the experiment. Men have been thrown on their own resources. They have felt that what they acquired was by their own efforts. The work has been made more interesting, and there has been much closer sympathy between student and teacher. The results of the examination have also shown the efficiency of the plan. The percentage of rejections in pathology since I have been at the school has previously been from 20-33%. This year, with a much more difficult examination and one more varied in its character,

but 5 out of a class of 154 were rejected. I am also sure that the men have gotten more out of the subject than any class in pathology ever did before. With the view of enabling the student to continue his interest in pathology and to overcome a serious defect necessarily connected with the short course, weekly demonstrations in gross pathology will be given at the hospitals during the time of the year when the course is not given at the Medical School, and which can be attended by students from all classes.

I should not omit to speak of a most important aspect of the teaching. In order that the student may understand the vital connection between pathology and the clinic, courses are given in surgical pathology and in neuropathology. These courses are optional, but they have been so well given that they are attended by practically the entire class. In these courses the student studies his pathology in direct connection with the vital phenomena of disease. A part of the course in the theory and practice of medicine as given by Dr. Fitz is very similar to these courses.

When we look toward the future, it seems to me that there are several well-defined ways in which we must advance. The increase of our knowledge, and with that the opening of new paths of research, has become so vast that no man can master all that pertains to any of the great subjects in medicine. It would be impossible for any one to even control the literature in pathology, to know what is being done in all subjects pertaining to this. At the same time the close union which exists between pathology and clinical medicine and surgery has opened paths of research which perhaps are better approached from the clinical side. This has been recognized in Harvard by the creation of the surgical laboratory, in which questions more immediately connected with surgery will be studied. The same thing is eminently true of certain branches of internal medicine, especially neurology. So great has been the recent advance of our knowledge of the anatomy, physiology and pathology of the nervous system that it is impossible that the questions in connection with it can be adequately treated from the side of anatomy, physiology and pathology alone. Moreover, in no department in medicine are these so intimately connected with one another and with the clinic. Our knowledge of the nerve tracts in the brain and cord has been gained by a study of embryonic development and by the pathological degenerations which take place. The physiology also of the nervous system has received its most important aid from a study of the effect of degeneration or injury of certain parts. We hope to see a department of neurology with a laboratory in which all questions connected with the nervous system can be studied from an anatomical, physiological, pathological and clinical point of view. A neurological clinic with a small but well-selected number of cases must form an important part of such a department. Only a small part of the energies of the department should be expended in teaching. Its real work should be directed to an increase of knowledge by research.

While, undoubtedly, progress in teaching has been made, it must be confessed that progress in other directions is a little disappointing. The work which we accomplish is not commensurate with our opportunities. The Medical School should be one of the crowning glories of the university. We should add to its lustre, but we are living in its light. We have not

done, we are not doing, our share in advancing knowledge, and that, too, with the fullest opportunities before us. One of the reasons that the Medical School has not advanced with the university is that we are still, in a great measure, under the influence of the grammar-school idea of education — very much in the condition that the American college was in the old days when a fixed college course was supposed to cover the entire field of what could be known. We have endeavored in the same way to teach to the student the medical art; if not to give him all that was known, certainly to give him the most that could be useful to him. We have scarcely realized how broad medicine has become. The Medical School must not only be a real part of the university and imbued with the university spirit, but in the number of its departments and in the development of which each is capable is almost a university in itself.

Teaching must certainly be regarded as one of the chief functions of a university, and there has been a gradual evolution, a change for the better in methods of instruction in all departments; but the progress in this direction has been much slower in medical than in other departments. Harvard probably owes her pre-eminence among other educational institutions more to the introduction and the wide extension of the elective system than to any other factor, and this has been gradually extended to the Medical School. In the elective system we recognize that certain studies are essential. In these essential studies again there is a choice. On certain of them a great deal of stress should be laid, and a corresponding amount of time should be devoted to them. Outside of these a certain amount of choice is given the student. He can take certain special courses, the importance of which is estimated by the amount of time given to them; and on this the time devoted to examination is reckoned, which time counts in the total number of hours devoted to examination.

Opportunity should be given the student to choose the kind of instruction which will most appeal to him and under which he will make the greatest progress. He should have the same subject presented to him in a great many different ways. We should remember that we are not teaching boys of the grammar-school age, but intelligent men from twenty-two to twenty-seven years, who know, as a rule, under what kind of instruction they will make the most progress much better than we do. In order to give this greater amount of freedom to the student, the first thing would be a better organization of the various departments in the Medical School. The number of departments could be greatly restricted and the various specialties included under the head of either medicine or surgery.

Under the present system which prevails in almost every American medical school the scheme of instruction in every department is fixed. There are so many hours devoted to lectures, so many to laboratory work, so many to the clinic; and these hours are so arranged that the various sorts of instruction will not occupy the same hours, and will interfere least with the office hours of the instructor. The head of the department determines everything — the amount and character of the instruction and the manner in which it is given. He also chooses the men who are to give the instruction, and it cannot be otherwise but that he chooses men who are in sympathy with him and believe in

his methods. In the first place, this does not give sufficient freedom to the student, enabling him to develop in the way which is best suited to him; but it equally restricts the instructor and interferes with his development. Both the instructor and student are in a narrow way, and must walk between the high walls on either side. The instructor knows that the head of the department obtained his present position by following in the footsteps of his predecessor; and the instructor's best prospect for success is by continuing in the same direction, and assisting the chief in carrying out his policy. The power of the head of the department, the one man, is almost absolute. He is only controlled by the faculty as a whole, and in most cases they are interested in continuing the system. One might compare such a system with the organization of a great department store or army, where it is the only system that will work; but the conditions in educational work are different. In the department store or army it is easy to determine what constitutes success, and the chief pays the penalty of failure. But how can that be determined in educational work? If we judged the work of an honest man by our own views of the importance and truth of his work, it would often interfere with the accomplishment of every reform. In the university the reasons for the dismissal of a man from his position should be very few.

The organization of the department could be very simple. It should have an official head chosen by the department, who should represent it; but all measures affecting the department should come from the department as a whole. The department should include all those connected with it. Within the department every individual should be absolutely free to teach what he chooses, how he chooses, and when he chooses. The value of the instruction which is offered will be judged by the men who are most interested and the only men who are capable of passing the proper judgment upon it, the students.

Every facility for instruction, and for the particular sort of instruction which a man wishes to give, should be granted. The more varied the instruction the better; for certain ways of presenting the subject will appeal to some men, other ways to other men. Some men would feel that they could best lecture upon a subject. Give them a room, and let them lecture. Others might prefer to give their instruction to small classes by questions and explanatory answers, some by laboratory work, some by clinics. A man might consider himself especially gifted in the use of drugs, and capable of demonstrating their efficiency in disease. He could teach from this point of view. Each man should receive the reward of his work, and in this way come into competition with his fellow-instructors. He should receive all the money which the students pay for instruction less a certain amount which goes to the university. His pay will be according to the value of the instruction he gives, and this will be determined by the body of men most capable of judging. This leaves it perfectly free for every man to develop how he will, to the greatest extent he will, and as early as he will. The latter is most important, for it secures the services of men at the age when they are at their best. There will be sufficient reward to stimulate every man to do his best; for there is not only the pecuniary reward which comes from successful teaching, but the reward which

comes from wide reputation. His reward does not depend upon any fortuitous circumstances, but upon what he does; and he will seek to add to his reputation by original work. Admission into such a department should be absolutely free, the only condition being that a man should show proof of the earnestness of his purpose and his ability. The only way he can show this is by the work he has done; and this would further increase original investigation, and further the realization of the university ideal. A man's ability to teach cannot be determined beforehand; only competition with others will determine that. The department would probably include men who were not good instructors in the narrow sense, but who are good investigators themselves, and capable of directing investigation. Every investigator is really a teacher of high quality, for the influence exerted by the honest work of a man is often of more value than any direct instruction he could give. The character of the instruction which each man gives would to a large extent be determined by the facilities for instruction which he possesses. A man with a hospital position would probably give clinical instruction, but there is a great deal of instruction in both medicine and surgery which is not immediately dependent upon the use of clinical material. There could be courses, for instance, in the special pathology of the organs, working back to the clinical features from the point of view of the lesions, instead of the other way. Such a system would also enable a medical school to draw into its teaching force men from adjacent cities who have good opportunities to teach. Students from such cities would probably find it to their advantage to take certain branches of instruction there. The student should be allowed to take up a subject when he chooses and spend as much time upon it as he chooses. It would be better to strongly advise students to complete certain branches before entering the clinical studies, and the student would soon find that it was to his advantage to do so; but in ordinary life there is no restriction to a man's beginning his dinner with a cigar and following with coffee and pie, yet few choose this method.

In such a system the examinations are of the greatest importance. The character of the examination should be determined not by one man, but by a committee of the department. It should be made as thorough as possible and as practical as possible. A man should be required to show not what he has memorized, but what he can do. The examination should do away absolutely with the time and brain consuming practice of cramming, and should be a real test of a man's ability. Examinations on a subject could be held much oftener than they are, probably four times in the course of the year instead of once; and a man could present himself for examination in a subject when he is ready. When the requirements had all been fulfilled, he should obtain his degree. Why is it necessary to have a fixed time for medical study? It would be perfectly possible for one man to accomplish in three years what another man requires five years for. The adoption of the system would undoubtedly enormously increase the amount of post-graduate teaching, and men would gladly avail themselves of the exceptional opportunities for instruction which they could find in the summer. There is nothing new in this, it is not an untried system: it is but the *Lehr und Lern Freiheit*—the freedom of

study, the freedom of teaching, which is the fundamental basis of the German university. It is the system under which the University of Edinburgh has undergone such an enormous development; and there is no doubt that its adoption would place the Medical School in the position, as compared with other medical schools, which Harvard University holds among other institutions of learning. It would enable us to develop not only students, but teachers, who would go out from us, and widely extend our influence. Under our present system it has not seemed to me that there is an extraordinary demand for our men from other schools.

The system would enable us to utilize the local conditions to the fullest extent, but more is required. We must have a university hospital, the appointments to which are controlled by the university. Without this we must always be limited to the *locus*. Under the present system the surest way for a man to obtain a position in the university is to connect himself with a hospital and gain possession of clinical material. A man enters a hospital in the lowest position, and gradually ascends by a system of promotion. There is no reason to believe that the best men always secure the positions in the first place. There is no possibility of telling how a man will develop in the course of ten years; and once in the hospital his promotion is sure, provided he is careful not to violate traditions and to do what the hospital requires of him. His promotion does not depend at all upon his development, upon the reputation he has made. In seeking a reputation, he is again confined to the *locus*. He does not appeal to the world; for it is the local, and not the general, reputation which will help him. The two sorts of reputation are not always synonymous. There are plenty of instances of men with a high local reputation who are scarcely known outside of the *locus*, and I have known at least one instance of a man whose work was known throughout the world, and who had made most important contributions to knowledge, being refused the lowest position in a hospital.

Under the system of promotion, advance, though sure, is slow; and a man usually has passed beyond his best years and has become too thoroughly moulded into the prevalent local form to advance when the chance comes to him. With a university hospital it would be possible to call men to the highest clinical positions from any place in the world, and give them the best opportunities. The services in the hospital could be made continuous, for the short services interfere in the most serious way with the best development of the hospital and of the school. The hospital need not be large. Thirty-five medical and thirty-five surgical beds and a large out-patient department from which to select the most suitable cases would be sufficient, certainly in the beginning. The expense for the maintenance and construction of such a hospital need not be very great. I have every confidence that we shall have such a hospital. When anything is greatly needed, means will generally be found to provide it, and I know of no more pressing need for this community than the creation of a university hospital. Nothing has interfered more with the advance of medicine in this country than the relation which exists in most places between the schools and the hospitals. We know certainly of one conspicuous example where there is the closest union between the school and the hospital, where the hospital is recognized as a

department of the university, in the same way as the chemical or physical department, and where, in consequence of this, the school has in a few years attained a world-wide reputation.

The university ideal—which seeks, above all, the advancement of knowledge, and in its teaching the development of the best in the individual—must prevail in all the departments of the university, in the clinical as well as in the scientific departments of the Medical School. The reputation of the school can only be formed from the work it does, from the character of the men it sends out. The reputation must be general; it must attract the best men from all parts of the country. Our medical students come from a more limited area than do the students from any other department of the university. With the introduction of the new requirements for admission the territory from which we have drawn our students will not furnish us with sufficient men. We must attract the best men, because only in this way can we turn out the best. We must train men in the things which are necessary for the successful practice of their profession; but we must also do what we can to develop the man, to bring out the best that is in him. If he thinks that there is something higher than a position of social respectability, with a practice sufficient to enable him to keep up such a position, we must do what we can to enable him to carry out his aspirations.

THE PRESIDENT then called attention to the fact that the Medical School and the hospital are not everything in regard to medical education in Boston, and that a few minutes were to be devoted to considering the great scheme of founding a superb medical library, and introduced as the father of that library Dr. James R. Chadwick.

DR. CHADWICK said in brief: I was going to prelude my description of the building which we are erecting for the medical library with a contrast between the collections of medical books at the beginning of this century and those that existed when our present medical library was founded twenty-five years ago, but the time is too short. Twenty-five years ago the books doctors had to consult were scattered all over the city. The Treadwell Library at the Massachusetts Hospital had 4,000 or 5,000 volumes, the Medical Observation Society had 1,000 volumes, the Medical Improvement Society 500 volumes and the Public Library 10,000 volumes, and there were various other small collections. A man had to go about the city for hours and days to get at the books he wanted, and then found the files of periodicals very imperfect. We decided to unite as many of these collections as possible, and succeeded so well that in a year or two we had collected 4,000 or 5,000 volumes in Hamilton Place. In 1878 we bought the house in Boylston Place, and have there developed the library until at the present day we have 32,000 volumes, about 28,000 pamphlets and a large number of portraits. We bought last spring a lot of land on the Fenway, 75 feet wide by 100 feet deep, besides the grass plot in front, at an expense of \$42,000 and have contracted for a building, which, furnished, will cost about \$110,000, in all expending between \$150,000 and \$160,000. The building is of gray stone and brick, 75 feet front and an L running back to the alley in the rear 100 feet.

On the ground floor we have the usual cellars, furnaces, janitor's room, vault for articles, a room to un-

pack and pile up the boxes, arrange the books and put them on a dumb waiter that will go up to the stacks. On the next story one enters on the front into an octagonal hall with an entrance from the vestibule into the directory for nurses; next to that a sitting-room for nurses; in the rear a chamber for the registrar for nurses and bath-rooms in the rear of that. Across the hallway we have a large cloak-room; beyond that a lecture-room opening into the hall for meetings, which is 32 by 28 feet and will accommodate from 75 to 95 people, a hall large enough for the ordinary section meetings of the medical societies, with a cloak-room and every accommodation. We have had a donation of \$5,000 from Congressman Sprague and his mother to dedicate this hall to the memory of Dr. Richard Sprague, who died about five years ago. He has recently given in addition to that three handsome carved oak chairs to be put on the platform. There is an elevator. You go upstairs—not quite a high story—and enter into what we call Hólmes Hall; a portrait of Dr. Holmes at one end and a replica of the bronze bust in the Public Library at the other end. There will be alcoves of books and in each will be a little square table, a place for a man to sit and do his work. On the shelves will be the books most in demand. The room is 72 feet long by 32 deep, beautifully lighted with big windows overlooking the Fenway. To the rear is the librarian's room. The stack-room has five stories of stacks taking about 10,000 volumes. In the rear is the cataloguer's room and a room in which the current periodicals will be exposed. Half a story up are toilet-rooms, cloak-rooms, a room for medical students and another for committee meetings. On the next story we have a hall that will seat 300 to 350 men. Therefore we shall have accommodations for all large meetings, and in the rear is another hall the same size as Sprague Hall for section meetings. I am assured that the collection of medals of Dr. Storer is to be given to us. We have a great many portraits by some of the best portrait painters of the day that have had to be stored in the Art Museum for fear of fire.

There is one thing more. We are going to pay \$150,000 to \$160,000 for this. The question is of paying for it. We want you to do it. We have raised within a year in cash \$70,000. We have as a result of former investments, selling our present building and a lot on which we expected to build—that is, not sold yet, but assessed for \$25,000 and undoubtedly will sell for that within a few months—we have got about \$110,000 toward this \$150,000 or \$160,000 we need. The young men who really encouraged us to start on this great movement could not subscribe large sums to the general fund, but came forward in the beginning and offered to pay the interest on a mortgage of \$25,000 for five years. We need \$15,000 more to pay off all indebtedness and enter upon that place without debt. I hope all who have not had an opportunity to put their names down on the little books will apply for the privilege, and they will get it.

DR. GEORGE S. DERBY, the president of the graduating class, spoke briefly of the justifiable pride felt by the class in having successfully finished the four years of study, mingled with regret at the thought of opportunities not accepted. Plans for the future are, of course, uppermost in the minds of his classmates, many hoping to lead busy, useful lives in the service of

the communities in which they live, some looking forward to helping in the advance of the scientific side of medicine, a few of the more conceited even looking forward to making a living out of practice.

The deepest feeling, however, is gratitude, for which there are many causes. The thorough grounding in the theory and practice of medicine, the benefits of modern laboratory and clinical methods, the use of the case system, make all glad that they are entering on their active careers at the beginning of the twentieth rather than at the beginning of the nineteenth century, that they have acquired easily the accumulated knowledge of the century just closing, though looking forward confidently to even greater triumphs in the century just dawning. The class are grateful to their teachers for their conscientious work and inspiring example, grateful to the profession for the high standard of skill, industry and self-sacrifice always maintained, yet humble to think of calling themselves doctors. Finally, there is the feeling of gratitude for having studied medicine in spite of all obstacles and a greater gratitude for having studied medicine at Harvard.

In conclusion, DR. CLARENCE J. BLAKE, the newly elected president, was introduced. He said in brief: Mr. President: It is an honor to be your successor, as it has been always a pleasure and an honor to have been your pupil. A member of the Massachusetts Medical Society recently found it necessary to qualify in an adjoining State. He was asked, "How long have you studied medicine?" His answer was: "Forty-two years." Those of us who are graduates in medicine, all of us, appreciate the truth underlying that remark, and therefore understand better the meaning and the possibility of such associations as this, because of that study of medicine after graduation which is the sterner curriculum, since its examinations are held every day and its tests are made in our contact with the individual patient. In the graduate study of medicine we find it worth while to circumscribe our work, carrying it in one direction between two lines; those lines are honor and service, between them flow all the possibilities of the medical profession. In thanking you for this reception, in thanking you for giving me the opportunity to join you as presiding officer, in thanking you for the honor, I cannot but think also of the service which this implies. I will honestly try to render that service, to keep the two lines parallel, and so in response to your greeting, let me use a word which those of us who have studied in Vienna remember as the greeting of the medical students of the Josephinum, a greeting always extended and always responded to whenever and wherever met: Gentlemen, "*Servus.*"

On Wednesday, Commencement Day, the association had a spread at 21 Thayer Hall, where between two and three hundred were entertained.

Recent Literature.

System of Diseases of the Eye. By American, British, French, Dutch, German and Spanish authors. Edited by WILLIAM E. NORRIS, A.M., M.D., and CHARLES A. OLIVER, A.M., M.D. Vol. IV, Pp. 949. Philadelphia: J. B. Lippincott Co. 1900.

With the appearance of the final volume of this System of Diseases of the Eye the labors of Dr. Nor-

ris and Dr. Oliver have, as editors of the various monographs therein presented, reached a satisfactory conclusion. The high standard already created by what have preceded is maintained and possibly the subject matter is even more interesting, being, taken rather broadly, a discussion having bearing upon Anomalies of the Motor Apparatus, Diseases of the Cornea and Lens, Ametropia and Medical Ophthalmology in the guise of sixteen papers prepared in most cases by individuals who by predilection or environment seem to be very well fitted to carry on investigation in some particular direction. Mr. Swanzy's paper, Eye Diseases and Eye Symptoms in their Relation to Organic Diseases of the Brain and Spinal Cord; that of Dr. Lawford, Ocular Lesions Dependent upon Disorders of the Secretory and Excretory Organs; Mr. Story's paper entitled, Ocular Lesions in Variola, Rubioli, Morbilli, Scarlatina, Erysipelas and Diphtheritis; and that by the younger Hutchinson, Eye Affections due to Graves's Disease and Herpes Zoster, come to us at first hand from British writers and leave but little to be desired either as regards thoroughness in preparation or method of treatment. The chapters prepared by American writers are as follows: Diseases of the Lens, by Dr. Norris; Ametropia, by Dr. Oliver; Motor Changes Associated with Functional Neuroses, by Dr. Standish, and Toxic Amblyopias, by Dr. de Schweinitz. Those papers which have passed through the vicissitudes of translation certainly have lost none of the excellent features of the original, a flattering commentary upon the linguistic attainments of the various gentlemen to whom this very important duty had been delegated. The papers by foreign writers are: Anomalies of the Motor Apparatus, by Dr. Landolt; Diseases of the Cornea, by Dr. Nuel; The Ocular Lesions of Influenza, Dysentery, Cholera, Malarial Fever, Dengue and Yellow Fever, by Dr. Santos-Fernandez; Hysteria, by Dr. Parinaud; The Entozoa of the Human Eye, by Dr. Salzmann; Simulated Blindness, by Dr. Baudry, and The Ocular Signs of Death, by Dr. Gayet. It is unfortunate that the limited space at command renders it impossible to review in detail the different papers which go to make up this valuable book and prevents more than the mere mention of the fact that it contains 949 pages, including a complete index, 51 full-page plates and 211 text illustrations; that it is a fine example of press work and binding, and must sooner or later, with the other three volumes that have preceded it, be considered by ophthalmologists generally as a highly prized standard of reference.

Introduction to the Outlines of the Principles of Differential Diagnosis, with Clinical Memoranda. By FRED J. SMITH, M.A., M.D., (Oxon.), F.R.C.P. (Lond.); Physician (with care of out-patients) and Senior Pathologist to the London Hospital. Pp. ix, 353. New York: The Macmillan Co. 1899.

In this volume of 341 text pages is gathered a large amount of information, succinctly expressed. The author does not claim originality for his work, but he does believe that he has arranged the "old phenomena of disease in such a way as to show more clearly their fundamental meanings and relationships." To accomplish this end the parallel column has been frequently used, in general with good effect, and brief

statement everywhere takes the place of extended exposition. We cannot but feel that this method has been overdone in places; for example, a tabular view of the anatomy of the nervous system compressed into a few pages may hardly be expected to give any sort of an accurate or helpful idea of that intricate subject. A complete omission is more desirable than such a necessarily imperfect statement. As a book of ready reference we should heartily commend the volume to the attention of our readers. As a textbook for students we think such a compendium is of doubtful value, as laying stress by its very form on details, to the exclusion of the fundamental principles underlying those details. No doubt this depends somewhat upon the constitution of the individual mind, but we suspect that the author's hope that he has shown the "fundamental meanings and relationships" of disease by this condensed and over-tabulated form of exposition will not be shared, at least, by all his readers. The book is satisfactorily printed and bound, has an index and is of convenient size.

Manuel Complet de Gynécologie Médicale et Chirurgicale. Par A. LUTAUD, Professeur libre de Gynécologie, Médecin adjoint de Saint-Lazare. Nouvelle édition, entièrement refondue, contenant la technique opératoire complète et 607 figures dans le texte. Paris: A. Maloine, Editeur. 1900.

The fourth edition of this work has been greatly enlarged and extended as compared to the earlier editions, and the publisher's work is, as a whole, good. It is profusely illustrated with very good cuts. Its chief interest lies in the admirable opportunity which it presents of comparing French practice with that with which we are familiar; in this respect an especially striking feature is the profusion of instruments and machinery which are figured and described, and the exceedingly free use of compression forceps, in which the author follows Péan, whose pupil he was in earlier life. In the comparison between the vaginal and abdominal route for operating it is very fair, and the vaginal route is less strongly emphasized than would be the case with most French authors.

Paralytic Deformities of the Lower Extremities. By E. NOBLE SMITH, M.D. London: Smith, Elder & Co. 1900.

Mr. Smith's monograph on the subject of infantile paralysis presents an evidence of improvement and advance in the method of treatment of paralytic deformity. Comparison of this with the work of Hoffa, however, indicates that the German surgeon has presented a more thorough monograph on the subject. Mr. Smith has improved in his illustration from his previous works and has given the medical profession an interesting account of what is being done in this branch of orthopedic surgery.

Congenital Dislocation of the Hip. By DR. MAX SCHEDE. Hamburg: Graefe Sillem. 1900.

Dr. Schede, whose work on congenital dislocation has been of great value, reports with excellent skiagraph reproduction the results of his experience in treating this deformity. Dr. Schede is an advocate of the bloodless method of treatment and shows the results of the reduction by this method. The monograph is a valuable contribution to the subject.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 12, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE HARVARD MEDICAL ALUMNI ASSOCIATION.

THE tenth annual meeting of the Harvard Medical Alumni Association, of which we publish a full report in another part of this issue, has recently been held. Young as the association still is, it has already risen to a place of usefulness and power in the medical community, and so indirectly in the community at large. We are not disappointed each year as we read the speeches given at the annual dinner to find expressed sentiments which look forward with confidence to the constantly increasing improvement of medical education in the broadest sense. This year was certainly no exception to this rule. In various ways the past year has seen developments which bid fair in the immediate future to elevate medicine to the position of complete dignity which it has, for diverse causes, been slow in attaining. It is always to be borne in mind, as the incoming president of the association, Dr. C. J. Blake, said in his introductory remarks, that much of the serious study of medicine comes after graduation rather than before. One of the most important schools at which such study may be presented is a suitable library building with an adequate supply of books. This need, which has been growing year by year, has finally been realized by the building, which is now nearing completion, of the Boston Medical Library, which for a long time to come it is hoped will prove a sufficiently commodious repository for the books and other possessions of the Library Association, and at the same time serve as an adequate meeting place for the various medical societies. Dr. Chadwick, the librarian, said, in speaking of the library and its growth, that twenty-five years ago the books of reference in Boston were scattered so widely that the difficulties of the reader were enormously increased. The concentration which has gone on since that time has finally resulted in a library which, in its new quarters, will be convenient for use and really of service to the student even in the highly specialized

fields of medical research. At the same time it must be remembered that new books are appearing at an unprecedented rate, and that scientific periodicals of value are multiplying in equal proportion. This means a constant and no doubt increasing outlay in the future, a demand which must be met if the library is to fulfil completely its object. There can, however, be small reason to doubt that this demand will meet with a ready response, when the necessities of the case are clearly set forth. The influence of this library should extend far beyond the confines of Boston, and be a source of education to physicians throughout the State.

A dinner of the Alumni Association rarely passes without allusion to the progress of medical education, a topic much discussed of late, and one about which it might seem the last word, for several years at least, had been said. That such is decidedly not the case, a reading of Dr. W. T. Councilman's speech, which we publish in full, will prove. Whether we are radical or conservative in our views of these questions, no one, we venture to think, can fail to derive a stimulus and renewed enthusiasm from his views and opinions. There are several points which strike us with special force, to which we beg leave to draw particular attention. Dr. Councilman, in the first place, believes in the individual and not in the various extraneous circumstances of that individual's life and education, which have tended to mould him into a certain stereotyped form. Give men an opportunity, let them do, in great measure, what they wish to do, and see if they can do it well. Let every man be encouraged in his independence of thought, and not forced into a groove which others have followed for generations. By this means teachers are developed and research is stimulated. As Dr. Councilman says, "This leaves it perfectly free for every man to develop how he will, to the greatest extent he will, and as early as he will." To his early development particular importance is to be attached, that he may be of use before age has sapped his enthusiasm. This sort of advice we need, and particularly should it be impressed upon the young men whose future is yet unformed, for the time is rapidly coming when the beaten track traversed so long by men of note will be found to lead to no profitable end. Again, Dr. Councilman is eager to recognize the close relationship between clinical and laboratory teaching. With the necessary growth of specialism, he sees a new possibility of more adequate teaching through a combined knowledge on the part of the instructor of the pathological anatomy as well as the symptomatology of disease, and urges that the student's mind should be directed to the whole subject and not to one of its aspects merely. There is absolutely no evidence throughout his remarks that he looks with favor upon the separation of the laboratory from the clinic, a charge at times made against laboratory students and departments primarily concerned with the theory of medicine. As we have observed the trend of events in the teaching of medicine, we have become

more and more convinced that the growing tendency of the future will be a closer union between medicine as taught in the laboratory and medicine as taught by the bedside. Conscientious clinicians will be welcomed in laboratories just as laboratory workers are welcomed in the wards of a hospital. Science, we are convinced, will not suffer thereby, as some seem inclined to think. Finally, Dr. Councilman believes in the dignity of medicine as a branch of knowledge, and he thinks it lies with physicians to dignify it. "The work," he says, "which we accomplish is not commensurate with our opportunities. The Medical School should be one of the crowning glories of the university. We should add to its lustre, but we are living in its light."

We do no justice to this address by these brief comments. We would urge our readers to atone for this deficiency by a reading of the full report. However opinions may differ as to detail, the broad-minded and liberal point of view and absolute freedom from pettiness must impress the most thorough-going conservative.

THE PENALTIES OF THE FOURTH OF JULY.

It was reported several days ago that one result of Philadelphia's Fourth of July was "Ten dead and three hundred in the hospitals." This reads like the war news with which the last year or two has again made us familiar, rather than as the record of a day of national rejoicing. We have no doubt that other cities have suffered in proportionate measure, and the query naturally arises whether we are to continue complacently to look on at this destruction of life and limb without an organized protest which will really prove efficacious. It may be our imagination or the fact that we have sought a place of retirement during the celebration of the holiday, but it seems as if the conventional noise were decreasing year by year. This, however, evidently does not mean that the element of danger is thereby removed. There is apparently a growing tendency, on the contrary, to use the more powerful explosives, as, for example, dynamite, in the construction of Fourth of July toys. The accident in Philadelphia which led to the death of a number of children and the injuring of twenty or thirty more, was said to have been due to the explosion of dynamite, this dynamite being publicly exposed for sale on a crowded street. We learn also that the authorities at once arrested the vender of these wares, and were inclined to mete out summary punishment. But why not be forehanded in such matters and prevent the sale of such articles entirely, except by properly licensed persons? Clearly something radical needs to be done in spite of the fact that the glorious day comes but once a year. Thus far we have not heard much of tetanus; it is to be hoped that the precautions taken may have done a good work in averting this added menace to life.

OLD AGE AS A CAUSE OF DEATH.

IN a recent number of the *Bulletin of the New York State Board of Health*, some pertinent statistics and remarks are made on the subject of "Old Age as a Cause of Death." The question is brought up as to whether senility in itself is ever to be regarded as a sufficient cause of death. Inasmuch as the very onset of old age in a physical sense is due to certain organic changes in more or less vital organs, this should be regarded as doubtful. The well-worn saying that a man is as old as his arteries is applicable here, but a man of sixty dying of conditions incidental to pathological changes in his arteries would not be classed as a death from old age. A man of eighty, on the contrary, with wholly similar alterations would, in most statistical returns, be placed in that category. It is clear that there is absolutely no accuracy in such classification. We are too apt to put down vague symptoms, the explanation of which is obscure, coming on in late life as a part of inevitable physical decay, and group them under the misleading but convenient heading of senility. Whether death occurs at thirty or ninety, there must evidently always be a perfectly definite cause, but our tendency, engendered no doubt by the practical demands of the situation, is to study the diseases of youth and middle life in a much more conscientious way than we are inclined to do those of age. We have long felt that a valuable research would be an investigation into the causes of senility in more detailed fashion than has yet been attempted. The following statistics from the publication we have mentioned are of considerable interest as showing the lack of accuracy in the tabulation of returns:

Of the 435 deaths noted in May of this year 170 were certified as from *old age* without other causes being given. The ages of these were sixty-three to one hundred; 4 were in the decade of the sixties; 45 in the seventies; 113 in the eighties, and 22 were over ninety. The phrases used were old age, senility, senile debility or decay or marasmus or atrophy or exhaustion. There were 80 deaths placed in this class of which *grippe* was returned as the cause, all of them occurring at advanced age, and with old age as a contributing cause. Sixty-eight were over seventy-five years of age, 6 being past ninety. *Grippe* has no separate place in the *Bulletin*, and is either registered under the class of local diseases or in the unclassified group, save those in which the element of senility was placed as the chief or contributory cause of death. There were probably 1,300 deaths in all from *grippe* during the month in the part of the State represented by these 80 occurring in old age. Sixty-five of the deaths classed as from old age were reported as *heart failure*, heart atrophy and the like, with or without old age as contributory. The average age was seventy-nine. Heart failure, a justifiable term, though an unfrequent cause of death, and generally misused on death certificates, when reported at advanced age without definition as to the condition of the heart except its enfeeblement of action, can no doubt be interpreted as due to suspension of vital forces incident to old age. One-eighth of the deaths as from old age were reported as heart failure past the age of seventy-five. There were 26 certificates on which the cause of death was

given as general debility, 14 as exhaustion, 10 as asthenia and inanition, 3 as paralysis of the vital nerve centres, and 11 as other indefinite conditions, such as nervous prostration; all occurring at advanced age. These are undoubtedly phrases used by the reporter which could have been replaced by senility, where they should be classed instead of swelling the unclassified group.

The writer of the above report is of the opinion that unclassified groups should not be enlarged, and that a general term, senility, is far preferable to a multiplication of inaccurate subheadings. True as this may be in the present state of our knowledge, it simply adds weight to our proposition that we decidedly need more scientific study of this class of senile changes to the end of an ultimate adequate classification.

MEDICAL NOTES.

APPOINTMENTS AT JOHNS HOPKINS UNIVERSITY.—Dr. F. S. Cullen and Dr. W. W. Russell have been appointed professors of gynecology at the Johns Hopkins Medical School.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the eight days ending at noon, July 11, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 72, scarlatina 17, measles 65, typhoid fever 23.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending at noon, July 7th, was 204, against 195 the corresponding week last year, showing an increase of 9 deaths, and making the death-rate for the week 19.17. Of this number 122 were males and 82 were females; 200 were white and 4 colored; 133 were born in the United States, 68 in foreign countries, and 3 unknown; 54 were of American parentage, 134 of foreign parentage, and 10 unknown. The deaths from consumption were 23, pneumonia 13, whooping-cough 2, heart disease 19, bronchitis 6, and marasmus 3. There were 15 deaths from violent causes. The number of children who died under one year was 38, the number under five years 65. The number of persons who died over sixty years of age was 47. The deaths in public institutions were 65.

CUBAN TEACHERS AND THE FLOATING HOSPITAL.—A contingent of the Cuban teachers, now studying in Cambridge, was given this week an opportunity to study practical philanthropy by a trip down the harbor with the Floating Hospital.

NEW YORK.

NATIONAL VOLUNTEER EMERGENCY SERVICE MEDICAL CORPS.—The first annual meeting of the National Volunteer Emergency Service Medical Corps was held at the New York Academy of Medicine on July 3d. Among the founders of the association, besides physicians, lawyers and business men, are a considerable

number of prominent clergymen of various churches and denominations. The first board of directors was superseded by a provisional board of administration, pending the appointment of a permanent board. In his address the director-general, Dr. Gottlieb, described the general object and scope of the organization as follows: "While we all appreciate the noble work accomplished by the various Red Cross societies, the time has come when these must give way to later and more improved methods. This can best be done by a thoroughly trained and disciplined corps, with all the advantages of regular drills, routine emergency work, and the resulting comradeship of its members, with a staff corps enrolled from among the foremost men of the nation. From such a body the government could draw material in case of need. Within the past few years we have all become painfully cognizant of the numerous local and national disasters in which the hands of both civic and military authorities have been tied for various reasons, such as time required for the course necessary for official sanction, unavailable funds, inability to procure immediate equipment, and lack of expert service. I would have an organization capable of dealing with such catastrophes as are occasioned by floods, hurricanes, epidemics, riots, railroad accidents and war."

CLEANING OF TENEMENT HOUSES.—The Health Department expended a portion of the \$20,000 emergency fund recently allotted it in the thorough cleansing and disinfection of the courtyards and cellars of about a thousand downtown tenement houses on July 6th, under the direction of Sanitary Inspector Blauvelt. Other sections of the city will be disinfected in turn, the object being to keep down the mortality incidental to hot weather.

BIOLOGICAL LABORATORY OF BROOKLYN INSTITUTE OF ARTS AND SCIENCES.—The biological laboratory of the Brooklyn Institute of Arts and Sciences began the regular class work of its eleventh season on July 5th. The number of instructors has been increased since last year by the addition of W. L. Tower, of Harvard University, Dr. Henry A. Kelly, of New York, and Dr. H. C. Cowles, of the University of Chicago.

NEW YORK SCHOOL OF CLINICAL MEDICINE.—We learn from Dr. Thomas H. Manley, professor of surgery at the New York School of Clinical Medicine, that the school, erroneously announced last week as about to be closed, is to continue its sessions. Only six of the teaching staff have resigned.

Obituary.

ALEXANDER J. C. SKENE, M.D.

DR. ALEXANDER J. C. SKENE, of Brooklyn, New York, died at his summer home in the Catskills on July 4th. He came of a noted Scotch family, and was born in 1838 in the Parish of Fyrth, Aberdeenshire. He came to this

country when nineteen years old, and studied first at the University of Michigan and afterwards at the Long Island College Hospital, Brooklyn, being graduated from the latter in 1863. After serving with distinction as a surgeon in the Civil War he was appointed adjunct professor at the Long Island College Hospital, and soon achieved a high reputation as an operating and consulting gynecologist. His work on "Diseases of Women," published in 1883, gave him an international name. For many years he was professor of gynecology at the Long Island College Hospital, as well as dean of the faculty. About a year ago he resigned both these positions in order to take charge of the organization and establishment of a charitable hospital for women. It was to be known as the Skene Hospital for Self-Supporting Women, and he hoped to open it during the coming autumn. It is probable that the project will now be carried forward to completion as a memorial to Dr. Skene. Among the societies of which he was president at different times were the American Gynecological Society, the New York Obstetrical Society and the King's County Medical Society. Aside from his eminence in the medical profession, Dr. Skene was one of the most highly esteemed citizens of Brooklyn. He was also a great lover of art, and was himself a sculptor of ability.

Correspondence.

"THE NEW METHOD OF INDUCING SLEEP WITHOUT DRUGS." ONE HUNDRED DOLLAR PRIZE.

NORTHAMPTON, MASS., July 5, 1900.

MR. EDITOR:—The new method of inducing sleep without drugs consists in bringing under will power the functions of organic life immediately on retiring. The organs of respiration and circulation respond to our bidding. Certain other groups of muscle, by contraction and relaxation are made accessory in directing the arterial and vital currents away from the gray matter of the brain. As a result, automatic thinking, which is the immediate cause of sleep's delay in the case of the average brain-working business man, is absolutely shut out, and normal sleep is inevitable.

Believing that the medical profession has power to turn the attention of suffering humanity from the mysterious chimerical and damaging drug agents they now depend upon, and that it is our duty to shed light rather than darkness, I offer a prize of one hundred dollars for an essay which shall describe any method of extemporizing sleep immediately on retiring for the brain-working classes that will equal or surpass the new method above referred to.

The principle employed is that of withholding power. The belts turned off, automatic thinking ceases. An equilibrium of circulation is established, and the normal conditions that precede and invite sleep prevail. Dr. H. O. Marcy, of Boston, says: "Every night I waft myself to gentle slumbers by the use of your 'method.' Long may you live to help suffering humanity."

To give the technique in full would require more space than can be allotted here. Suffice it that mental and physical conditions, positions and changes, extemporized and controlled by will power in the horizontal position, with suitable temperature and ventilation of body surface as well as lungs, are the sheet anchor of the new method.

Time allotted for preparing essays, from June to December of the present year. Length of essay must not exceed five thousand words; to be in print or typewritten, without the name of writer. Judges of the merits of essays shall be representative men of scientific medicine. Time for awarding prize, January 1, 1901. Results will be announced in this JOURNAL.

J. B. LEARNED, M.D.

METEOROLOGICAL RECORD

For the week ending June 30th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,451; under five years of age 1,135; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 757, diarrheal diseases 375, consumption 219, acute lung diseases 204, diphtheria and croup 62, measles 31, whooping-cough 22, typhoid fever 21, cerebrospinal meningitis 13, scarlet fever 8, erysipelas 6.

From whooping-cough New York 7, Pittsburg 5, Washington 4, Salem 3, Baltimore and Worcester 1 each. From typhoid fever New York 7, Pittsburg 5, Washington 3, Providence 2,

Cambridge and North Adams 1 each. From cerebrospinal meningitis New York 6, Washington 2, Boston, Baltimore, Providence, Worcester and Lynn 1 each. From scarlet fever New York 4, Boston 2, Washington and Worcester 1 each. From erysipelas New York 5, Baltimore 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending June 23d, the death-rate was 14.9. Deaths reported 3,325: acute diseases of the respiratory organs (London) 181, measles 117, whooping-cough 82, diarrhea 64, diphtheria 56, scarlet fever 28, fever 18.

The death-rates ranged from 9.9 in Nottingham to 22.4 in Salford; Birmingham 15.4, Bradford 13.6, Croydon 13.5, Gateshead 12.4, Hull 13.3, Leeds 17.5, Leicester 10.9, Liverpool 21.2, London 13.3, Manchester 20.8, Newcastle-on-Tyne 16.0, Norwich 10.0, Portsmouth 10.2, Sheffield 16.1, Sunderland 21.2, West Ham 11.9.

RECENT DEATHS.

LOUIS ARCULARIUS, M.D., a prominent German physician in New York, died of apoplexy on July 1st, at the age of sixty-two. He was born in Hessen, Darmstadt, and studied medicine at the Universities of Giessen and Heidelberg. For over thirty years he practised in New York, where he was a member of a number of German societies, medical, scientific and musical.

THOMAS P. EDWARDS, M.D., of Newark, N. J., died suddenly of cardiac disease on July 4th. He was born in Marcy, N. Y., and was thirty-nine years of age.

BOOKS AND PAMPHLETS RECEIVED.

Address.

MILK; ITS PRODUCTION, ITS CARE, ITS USE.¹

BY T. M. BOTCH, M.D., BOSTON.

MR. CHAIRMAN AND GENTLEMEN OF THE CONFERENCE:—The remarks of the gentlemen who have just spoken regarding milk and its production are very pertinent to the subject, and indeed pertinent in the sense of the extreme importance of the subject. Physicians have long recognized what a dangerous food milk may be under certain conditions. It is probably the most dangerous food that we can supply to the people at large, and yet it is the food that is evidently demanded by people all over the world, and has been for centuries; that is, the milk question has existed for many centuries. It dates back to the time of the Egyptians, and in their hieroglyphics we see what a change took place in regard to the production of milk as time went on through the different dynasties; that is, in the earliest times before the value of milk as a food was recognized. From these records found on the pyramids, and traced from century to century, it is evident that the cow at first was neither developed for nor used as a food producer. In the beginning the udders were small, and knowing how extremely realistic the Egyptians were in their representations, we are led to believe that what is seen on the pyramids and in the hieroglyphics is a true record. This is interesting to us as physicians, and also must be interesting to you health officers throughout the State and throughout the country; in fact, throughout the world.

The cow was not originally a food producer for the people, but simply gave sufficient milk for a limited time, and was not intended to produce milk throughout the year. As time went on the value of milk as a food was recognized. Later it came into use as a medicine by physicians, and soon became an important article of food for the table of the rich and of the poor. In order to obtain a sufficient amount of this food the cow had to be developed in some way, and gradually, as the hieroglyphics show, the udders were depicted as being larger and larger until finally the udder was fully developed and the cow became an animal directly connected with the food supply.

Although at different periods statements have been made that milk is not a good food, yet it has continued to be used, and its dangers being recognized, the people are now demanding a safe milk and are supporting the health officers in the measures which they take to get it. The physician is continually meeting with cases of sickness which arise from milk, and it is the duty of the health officers to aid the physician by such regulation of the milk supply as to prevent this transmission of disease by milk. Milk, is such a good culture ground for all forms of pathogenic organisms that it becomes a source of the greatest danger to, and one of the causes of the great mortality among, infants and young children. It is true that the health officers have been somewhat hampered in their efforts by the ignorance of certain physicians who are dealing with the diseases, but have no idea of the source of such diseases. The health officer who is dealing directly with the milk well knows it is dangerous, and therefore it is extremely impor-

tant that when you health officers are discussing this subject you should impress upon the physicians that they should by their influence with the public support what the health officers do. The health officer lays down certain laws and in doing so the milk dealers find that in order to conform to these laws they must raise the price of their milk, and the people are very apt to refuse to pay the high price which is giving them the best milk. The physician should therefore come forward and insist that the health officer is right, and in this way the physician and health officer working together will be able in the future to make milk a safe food, and in doing so will give to the public a good food. There is no doubt that milk is the ideal food if it is good and if it is safe.

You would perhaps like to hear a little about the way in which the milk is produced and cared for by some of the farms in the East. I have always been thankful to the health officers for what I have learned from them and to the expert farmers for what they have taught me. The physician is too apt to turn aside from them and not obtain valuable knowledge which is ready to be given to him if he is ready to take it. I have been very much impressed with this, and have felt that I was often so powerless in curing infants and children after the disease transmitted by the milk had once begun, that it became very evident to me that we should turn our attention especially to the prophylaxis of these diseases.

In attempting to get good milk, that is, safe milk, for children, my attention was first called to the farmers, and I at once made up my mind that the cry of cheap food for the people was one which should be strenuously put down by the health officer, by the physician, and through them by the intelligent public. The cry of cheap food and cheap milk is a dangerous one, and one which of course is heard all over the world, but, as is true of everything which has to be produced in the world, you cannot get what is good cheaply, and you cannot produce and deliver milk for four or five cents a quart in the best way. It must cost more and the people must learn that it must. I do not believe that it is the poor people who will suffer, nor is it the people in moderate circumstances that will suffer when paying a higher price for their milk. I have had quite a large experience in inducing people to buy what I believed to be safe milk and safe preparations of milk, rather than cheap preparations, and I have found in the East, and I think the same experience will be met with all over the country, that it is not the poor people nor the people of moderate means who object to the price; it is the rich people, the millionaires, who find the most fault if you ask them to pay ten or twelve cents a quart for their milk. This is simply one phase of human nature. The millionaire has often been a smart business man who has been trying to get the most for his money all his life, and he is not half the time intelligent enough to look into such a complicated problem as milk. He therefore finds fault with the cost of it. The poor man, however, has it practically brought before him every day. He sees his children sick and often dying with diseases evidently caused by cheap milk which he has been in the habit of giving them. As soon as he appreciates this he does not grumble about the price, but he saves in other ways and gives his children safe milk and one of higher price. In medicine, antitoxin, which preserves so many lives when

¹ An address delivered before the Health Officers of the State of Michigan, at Grand Rapids, October, 1899.

people are attacked with diphtheria, is expensive, but the poor get it. The best apparatus in surgical cases is used and a high price is paid for it, in like manner it is of great importance that good milk should be obtained and paid for, and that millionaires and the fortunes of the millionaires, and that the riches of the country should be turned in this direction to aid the health officers in bringing about a change and making it understood that good things cost. Then after a time, when the milk has been made good, as happens in all commodities, cheaper methods of making it good will be discovered and the milk itself will become cheaper. I have been much impressed with this principle, which I believe is at the root of obtaining all good things, and therefore also good milk.

Those who are engaged in the production of milk should not consider in the beginning to too great an extent the expense. They should be willing to pay a sufficient amount of money in getting good milk for the people, and they will then find that after a time they will receive a fair return for it and that it will be in the end a good business transaction. This has been proven in a number of places in our large cities in the East, and I think it will be proven here in the West in the same way. It has resulted in this way in New York, in Boston and in Philadelphia, where milk is by certain companies produced and delivered in what we consider the best way. For instance, in supplying New York and Philadelphia, a farm has been started in New Jersey midway between Philadelphia and New York, so that the milk can be brought in a couple of hours to either city.

In arranging for a milk supply, there is no part of it which is too insignificant to be attended to. It means that the water that the cows drink should be fresh water, that the milk should be as free from dirt as possible, that those who milk the cows should not have the care of the cows, and should not be in the position of farm hands. On these farms which I have just referred to, the milkers are a set of intelligent young men trained for this purpose, and being trained as a milker means to be trained to take antiseptic precautions as a surgeon is trained; and just as in surgery the operations in the last decade have been more successful on account of antiseptic precautions, which practically means absolute cleanliness, so should it be in the milking of the cows; the clothes of the milker should be clean, and such as can be boiled or steamed before being used again. The superintendent of a farm of this kind should be a man who is educated in such a way as to understand the laws of hygiene. The milkers should be under the supervision of a physician, for a milker when suffering from disease can infect the milk which he is drawing from the cow. All these factors of the problem have to be taken into consideration. The physician should examine the milkers from time to time and see that they are healthy. I have had an instance brought to my notice where a milker who came from Pennsylvania and went to a farm in Baltimore had some disease on his finger which he transmitted to a cow, and the milk of that cow which was used to supply milk for a boarding-school caused a violent form of diarrhea in 70 of the scholars, the disease being directly traced back to the man who milked the cows.

These pathogenic organisms which cause disease can get into the milk in a variety of ways and we should in every possible way shut out all means of

entrance. The milkers should never be allowed to go into the milk house, one man being especially detailed to take charge of the milk house. The milk house should be kept completely antiseptic and absolutely clean, and the milk should be quickly bottled in sterilized glass jars with a sealed top, and then be delivered immediately to the people. It is extremely important that as clean a stable as possible should be used for the cows, and that special men should be employed to take away the manure as fast as it accumulates. Dust as far as possible should be prevented from entering the stalls of the cows, and for this reason the hay and other food of the cow should not be kept in the same stable as the cows are. When all these precautions are taken, those who are engaged in the production of milk in this way will soon get the reputation with the public that they are providing a milk that is not a dangerous milk, and when the public has been made to understand by physicians that milk is a very dangerous food unless it is produced and looked after in this way, these are the men who will have a monopoly of the trade and will eventually deservedly obtain a good profit. There is no question that these men will succeed, but they must have the ability and business insight to take up the question in this way and to carry it out.

The general care of the cow, of course, is very important. You gentlemen know a great deal more about it than I do as a physician. They should have running water in the stalls and the troughs should be arranged so that live steam can be turned into them from time to time, so that they can be kept as antiseptic as possible. On these farms to which I am referring, the water which the cows drink comes from a well that is a hundred yards away from any building and which is protected so that nothing can filter into it. It is cemented up to the water line with a double wall around it, so that no one but the superintendent of the farm can get at it. In fact, what is most needed in the production of a safe milk is that the cow should have pure water to drink and should be surrounded with absolute cleanliness. In regard to the actual care of the cow, it is found that care should be taken not to brush or wash the udder too much, as the udder of the cow is very sensitive and this will often produce sufficient irritation to interfere with the different components of the milk.

The milk, besides being tested as to its quality, should be examined by a bacteriologist, who should be paid to give a careful report of its condition from day to day. The milk from one of the farms to which I have referred has been examined for each day of the year and in certain months the number of bacteria in the cubic centimetre was found to be under 2,000, which is an extremely good record when we consider that 10,000 has been given as the limit for good milk.

One of the gentlemen has referred to the use of the separator in the production of milk. There is no question but that by its centrifugal action it removes a large amount of filth from the milk, and it has also been found that large numbers of bacteria have been separated by the action of the centrifugal machine and removed in this way, so that there are much fewer bacteria in milk that has been passed through the separator.

There are, of course, many other points which could be spoken of in treating this subject. Certain principles however must be insisted on in the

production of good milk: (1) That it must be obtained from healthy cows in the most cleanly and antiseptic ways known; (2) that it should be taken care of under the most strict precautions, and (3) that it should be delivered to the consumer as quickly as possible. This cannot be done at present cheaply, and you as health officers must insist that the people should have good milk and safe milk, no matter what it costs.

GENERAL REMARKS ON THE PATHOLOGY AND SYMPTOMATOLOGY OF ACUTE PELVIC SUPPURATIVE PROCESSES IN THE FEMALE AND THEIR TREATMENT BY POSTERIOR COLPOTOMY.¹

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

BEFORE considering the pathology of acute pelvic suppuration as it occurs in the female, we would first give our views on the etiology. It is our firm conviction that all forms of suppurating salpingitis and oöphoritis are the result of the direct extension of an inflammatory process in the endometrium, the infection being propagated by the mucosa of the uterus to that of the tubes, and in some instances by means of the lymphatics. Gonorrhæal infection and puerperal infection are the only processes that can give rise to pus in the pelvis with the exception of appendicitis. As to abscess of the broad ligament, it may be said that, with very few exceptions, this lesion is always due to puerperal infection, and that the process extends from the uterus to the broad ligament by either the lymphatic or venous circulation. We do not believe that auto-infection in the virgin or malformations of the uterus can ever give rise to acute suppurating salpingitis. Catarrhal salpingitis in the nulliparous female may give rise to a suppurating salpingitis if later during labor a slight infection occurs, as has been observed in one or two instances in our practice.

There are three distinct varieties of peri-uterine suppuration, namely, salpingo-oöphoritis, pelviperitonitis and abscess of the broad ligament, and a few words regarding the pathology of these conditions will, perhaps, aid us in demonstrating why, in a large number of cases, the vaginal incision is superior to the abdominal route.

Inflammatory lesions of the tubes cannot be described separately from those occurring in the ovary, because the two lesions are so intermingled that usually it is impossible to separate them one from the other. All the classifications given in the text-books up to the present time are more or less imperfect, and Bouilly has very aptly said that the primary affection is always identical, and according to the virulence of the infectious agent, the nature of the soil and the method of treatment employed, it ultimately results in various lesions which only represent certain degrees or complications of the primary lesion in the uterus.

Acute catarrhal salpingitis is the first stage of inflammation of the tubes; the tube is red, swollen and has a cylindrical form which may reach the size of the little finger or even more. The fringes of the pavil-

ion are agglutinated, but microscopically only a slight hypertrophy of its cell elements can be found. At a more advanced stage the tube presents the lesion of an acute purulent salpingitis. The pavilion has become occluded, but an important fact to be remembered is that the uterine orifice still remains patent and the pus escapes into the uterine cavity instead of becoming collected in the tube. Later on the uterine ostium becomes occluded in its turn.

A word now as to normal position of the tubes and ovaries. In a normal condition the tube forms a curve in such a manner that the ampulla is in direct relation to the posterior layer of the broad ligament and is suspended above the retro-ovarian fossa, or Douglas's cul-de-sac. Now, when the organ is the seat of an inflammatory process and becomes heavy by the occurrence of a more or less large amount of serous exudate in its meshes, it naturally tends to fall into the retro-ovarian fossa behind the uterus and it is in this region that it will usually be found on examination. But this position is not always the same in every case, for the simple reason that the tube, being a movable organ, may contract adhesions very rapidly after inflammation has occurred and may consequently be glued down at most any point. Another condition may also occur, namely, the tube itself is healthy, but another organ in the neighborhood, the seat of an inflammatory process, may contract adhesions with the tube which will give it an entirely different position in the pelvis.

This varying position of the tubes has certainly a very great importance, both in the diagnosis of pelvic lesions and their treatment.

Pelviperitonitis, which is, as we understand it, an inflammation of the peritoneal pelvic tissues, has been, we think, absolutely demonstrated, and is admitted a rather frequent lesion by the larger number of authorities who have written on this subject. If we leave aside the accidents produced by appendicitis it may be said that inflammation of the pelvic peritoneum is always due to acute suppurating lesions of the internal genital organs. There are few cases of salpingitis or ovarian abscess which do not bring about more or less extensive changes in the peritoneum, sometimes of very serious character. Pelviperitonitis is rarely met with as a unique lesion, excepting when it occurs in puerperal infection.

There are two types of pelviperitonitis, the first being those instances where the infection extends to the healthy peritoneum, in which case the collection will, in the large majority of cases, be found filling Douglas's cul-de-sac. It is just in these cases that the lesion is suited for posterior colpotomy. The second type is represented by those cases where the collection is seated in variable regions, and when Douglas's cul-de-sac is divided up into pockets.

An intraperitoneal collection forms very rapidly, sometimes as quickly as three or four hours, but when seen in this early stage it cannot be distinguished by palpation because it has not become encysted, and the sensation that one gets by the finger in no way differs from that obtained before its formation, this being due to the mobility of the coils of intestine. It is only a few days after that false membranes are thrown out and wall off the collection. This collection usually forms behind the uterus in Douglas's cul-de-sac and there becomes encysted; it then undergoes a purulent transformation, excepting

¹ Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, February 28, 1900.

in those cases where it remains serous. Adhesions are thrown off between the tubes and coils of the intestine, the omentum, the top of the uterus, broad ligaments, rectum and pelvic wall.

Sometimes the pus extends upwards into the anterior cul-de-sac and adhesions are thrown out between the pubis and the sacrum, in which case the uterus floats, so to speak, in a well of pus.

Now the reason why the pus nearly always collects in the cul-de-sac of Douglas is explained very well by Delbet as follows: "The part of the peritoneum which is first diseased is always that which is situated behind the uterus; it becomes infected nearly always by means of the tube whose pavilion is behind the broad ligaments, nearly above the cul-de-sac of Douglas. When the tubes are healthy the uterus itself always contracts adhesions with the rectum on account of the disposition of the lymphatics."

When once the collection has formed, adhesions wall it off and the pressure within increases and causes Douglas's pouch to bulge into the vagina. This pocket hardly ever extends above the top of the uterus, but there are cases on record where it has extended upwards to the umbilicus, burrowing underneath the omentum, which forms a vault over it.

In the beginning the collection is serous, of a yellowish color, which is more or less tinted red by the admixture of blood, but it is always transparent. It may remain in this condition, but most always it undergoes a purulent transformation. When once pus is formed it may become absorbed when it is not present in any large amount, but in practice we should never count upon such an outcome.

The pus has always a tendency to make its exit through different organs in the neighborhood, which at first ulcerate, and the intestine and more particularly the rectum are its favorite points of exit, but all abscesses have not the same tendency to open outwards, and there are certain cases where they become encapsulated by neoformed membranes which line the pocket and whose walls become extremely dense; a most important condition for the treatment which we recommend, because they are rigid and almost sclerotic. The inflammation and induration of the subperitoneal cellular tissue contributes also to this condition, and when these cases are examined bimanually, they feel like hard cartilaginous masses. In this case an incision in the posterior cul-de-sac is quite insufficient, because the pocket, if it is single, will be emptied, but its rigid and resisting walls will not collapse and come together, and sometimes an enormous cavity is thus formed which will prevent healing from taking place. But these cases are infrequent, and what causes the great danger in pelviperitonitis are the adhesions which are thrown off, and these are not only the source of persistent pain, but from the malposition that they produce in the genital organs will nearly always render the patient sterile.

When the inflammatory process has extended to the subperitoneal tissue, the damage done is so important that a vaginal incision is more than insufficient, as well as in the case of multiple collections which are composed of secondary pockets independent of the first in which the infectious organism has had its starting point.

We would now like to say a few words on the pathology of suppurative processes in the cellular tissue of the pelvis, and we would here point out that

there are two distinct regions in which this lesion occurs, and which naturally give rise to two forms of abscess, namely, the cellular tissue of the broad ligaments and that present in the sheath of the hypogastric artery.

It is the inflammation of the connective tissue which is found along the vessels irrigating the pelvic organs that gives rise to abscess of the broad ligament. These vessels are the utero-ovarian artery and the lymphatics of the fundus uteri, tube and ovary. The topography of these abscesses is most interesting on account of their treatment. On their inner aspect abscesses of the broad ligament are in relation with the side of the uterus, which organ they push more or less to the opposite side, and they may even raise up the peritoneum on the anterior and posterior surfaces of the uterus, but only in the neighborhood of its borders. They have a tendency to extend towards the iliac fossa, where they form rounded tumors of varying size and which are perfectly independent of the abdominal wall. When once they have reached the iliac fossa they may extend in two different directions: (1) In some cases they extend upwards under the peritoneum towards the lumbar region, sometimes as far as the diaphragm; (2) in other cases the abscess descends towards the abdominal wall raising up the peritoneum in the vicinity of the ligament of Fallopius and is then in direct relation with the abdominal wall.

A typical abscess of the broad ligament does not come very near the vaginal cul-de-sac, from which it is separated by about two centimetres of tissue, in which is contained numerous vessels of fair size and sometimes the ureter. It is on account of the immediate neighborhood of these vessels that curettement of these abscesses is extremely imprudent, if not to say dangerous.

In the commencement of an inflammatory process there is only an edema, or serous infiltration, but little by little the meshes of the cellular tissue become distended by a serous liquid, which is thick and of a lemon color, and the pathologic process continuing its progress transforms this liquid into small foci of pus. The character of this pus has a very great bearing from the point of view of treatment, and one can readily understand that an incision is more proper in a case where the pus is whitish in color and of a bland odor than when the collection is greenish in color and presents a fetid odor.

A hypogastric abscess simply means an inflammation of the cellular tissue surrounding the internal iliac artery and the lymphatics of the cervix uteri and the upper part of the vagina. There is little to be said regarding these abscesses excepting that they are rather frequent in occurrence. The pathological process is the same as in the case of abscess of the broad ligament, and only differs from the latter by its seat. An important fact to be mentioned, and which applies to all purulent collections whether in the tube or the broad ligament, is that their upper wall is formed by the visceral peritoneum, which has become thickened and has lost its normal resistance, so that an irrigation made with any force whatsoever may break through it and enter the general peritoneal cavity.

The following five figures represent diagrammatically what could be felt by palpation in some of our cases, all of which were operated on by posterior colpotomy and made eventful recoveries. I have selected these five drawings from many others that I

have made of cases of pus in the pelvis because they very well demonstrate the different positions that the purulent collections may have in the pelvis.

Fig. IV

Fig. V.

In considering the symptomatology we first wish to point out the extreme frequency of purulent or serous peri-uterine collections, and at the same time the fact that in many instances they are very latent, if I may be allowed to use the expression. I have known of cases where from 25 to 100 grammes of pus have remained pent up in a pocket situated somewhere in the neighborhood of the uterus, and the patients did not have a rise in temperature for years, until suddenly some intervening cause exaggerated the local condition and then all the symptoms of the presence of pus occurred.

In the case of salpingitis and oöphoritis the patients usually come to the surgeon complaining of more or less distress in the lower abdomen which has been present for a certain time, and it is very difficult in these cases to estimate the exact time at which the adnexa were invaded by the inflammatory process, because the constitutional make-up of the patients varies very greatly from this point of view. There is, however, a fairly good classification which simply divides those cases which present very acute onset and those where the affection develops insidiously. In the first case a patient will seek relief for more or less severe abdominal pains which have come on after being exposed to cold or after overwork. The commencement of the symptoms is in most cases very sudden, and generally coincides with menstruation. In other cases the patient suddenly presents serious symptoms of an acute peritonitis, but these instances are usually met with after a normal labor, a miscarriage or during an acute gonorrhœa. The inflammatory process appears to invade all the tissues of the pelvis and only becomes localized later on, and when the acute attack has blown over bimanual examination will reveal the formation of pus tubes.

In the second class of cases the lesions are exactly the same as in the first, but they undergo their evolution silently. The various symptoms which later on will form the picture of salpingitis appear one after the other; they may be only slightly marked or they may give rise to considerable trouble, but they always appear *separately*. We thus get in the first place pain, which is sometimes complained of on one side, in other cases it is bilateral; then disturbances in the menstruation arise and so the disease continues its progress. Of course the division into acute cases and insidious cases is entirely artificial, and between the two extremes there are very numerous intermediary conditions.

The first symptom is pain in the region of the adnexa, usually on both sides, but perhaps more especially on the left. It sometimes reaches a very extreme acuteness and never is present in any constant type, excepting that it is increased when the patient gets tired and usually becomes better when the patient remains quiet in the horizontal position. The pain increases sometimes a few days before menstruation occurs and diminishes after the blood makes its appearance, but in other instances I have found that it began during the flow and in infrequent cases it did not appear until after menstruation was finished.

Menstruation itself is nearly always disturbed, the most marked derangement being frequent and repeated periods of flowing, with the loss of considerable blood. On the other hand, amenorrhea is infrequent in these cases. The blood appears every fifteen or twenty days and the flow may last a week or more, which is the cause of the anemia almost always noted in these cases. The concomitant metritis gives rise to a more or less purulent discharge during the interval between the metrorrhagias, and this leucorrhoea is sometimes accompanied by pains of a colicky nature. It has been thought that these colics have their starting point and their maximum of violence in the adnexa, and that they coincide with the evacuation of pus, but as the internal orifice in the tube has in these advanced cases become obliterated by the inflammatory process, it is very probable that the pus cannot make its exit, and that the uterus, which is always very greatly diseased, is the source of the purulent discharge. For that matter we all have had cases where a severe mucopurulent discharge was present due to an infectious metritis, but where the tubes were perfectly healthy.

Disturbances in the digestion nearly always complicate these purulent lesions, and have a very notable influence for the worse on the patient's general condition.

If the patient recovers from her first acute attack she is apt to think that she is well, because the pains have disappeared and have only left behind them a feeling of weight in the pelvis, but suddenly the acute symptoms will return, usually at about the time of menstruation, after the patient has taken cold or has become fatigued. In one or two instances in which a pain was complained of in the region of McBurney's point I was able to demonstrate at the operation that it was due to an adhesive inflammation which had arisen between the appendix and the diseased adnexa.

Inspection of the abdomen usually does not show anything in particular. Vaginal examination gives a very incomplete idea of the condition present, but by bimanual palpation a very good idea of the exact con-

dition of affairs may be obtained. In cases of catarrhal salpingitis the tubes feel like little hard, irregular cords, pointed at their uterine end, swollen at the other. The anatomical relationship of the tubes has become changed and on account of the thickening they have undergone they become heavy and fall down behind the uterus into Douglas's cul-de-sac. Cystic salpingitis feels like an oval, hard and irregular mass which gives rise to the sensation of fluctuation in certain points. In all these tumors we can find a distinct separation from the uterus and they are united to the cornua by a kind of pedicle. The uterus is pushed to the opposite side if the lesion is on one side only, but when the latter is bilateral the uterus is more frequently pushed forwards towards the pubis.

Acute secondary pelviperitonitis is practically only a complication of acute purulent salpingitis, and is consequently preceded by the latter affection. It disappears in a few days if the patient is kept quietly in bed, but it usually leaves the adnexa more or less bound down in a mass of exudate. In the beginning there is a sharp pain in the hypogastric region, chills and temperature reaching 39° C. to 40° C., nausea and vomiting, in fact, all the signs of an ordinary acute peritonitis, but what should be remembered is that the secretion coming from the genital organs is always increased in amount. At this time fluctuation is difficult to make out, but in some cases the serum infiltrates the vaginal walls, which become thick and to which the French authorities have given the very apt term of "cardboard vagina."

The serous fluid next transforms into pus and this pus becomes encysted and then all the local symptoms become more marked, but the general symptoms undergo a decided improvement. The pelvic abscess is thus composed, as I have already pointed out in speaking of the pathology, and then its next move is to make its exit. When the abscess discharges through the rectum we have all the symptoms of an acute proctitis, namely, a recurrence of the fever, tenesmus and a very acute dysuria. When the abscess bursts through the vagina, the fact is simply known by the presence of pus coming from the genital canal. If the abscess pocket should burst into the general peritoneal cavity, a condition that my personal experience would lead me to believe as being extremely infrequent, it would naturally give rise to all the symptoms of an acute septic generalized peritonitis.

Evacuation of pus may recur several times when the abscess has been left alone because it cannot thoroughly empty itself, and finally most rebellious fistulae form, which may cause the patient's death by general hectic.

As regards the diagnosis of the abscess of the broad ligament, it has been pointed out that the condition presents alternatives of increase and decrease in the size of the tumor, and it is a well-known fact that the cellular tissue of the broad ligament may be the seat of an inflammatory process which is very long in its course and difficult to cure, but which has little tendency to undergo suppuration.

All pelvic inflammatory processes have generally a chronic evolution, and the acute or subacute cases are in most instances simply a lighting up of a latent focus. A pyosalpinx, after having produced very acute symptoms, may continue its evolution insidiously, only giving rise to pain and disturbances of

menstruation up to the time when a perimetritis develops and then a pelvic collection is formed. If it undergoes an intraperitoneal rupture the prognosis is always bad, but the pocket may open into no matter what organ situated in the neighborhood, and one or more fistulae are formed. An abscess of the broad ligament may undergo resolution, but usually the suppurative process continues and the pocket may open into the vagina, the rectum, rarely through the abdominal wall and still more infrequently into the uterus or bladder. After the pus has been voided the symptoms improve, but the collection will surely reform sooner or later and, as in the case of pyosalpinx, fistula formation will result.

After its sudden commencement and high elevation of the temperature a pelviperitonitis will either pass on to the chronic state, or the liquid collection will become absorbed or be evacuated into another organ. In the puerperal form of pelvic suppuration the prognosis is extremely serious.

An experience of more than six years in vaginal work has demonstrated to me the fact that posterior colpotomy is a very innocent operation and in the highest degree conservative. It may be performed not only in cases of acute purulent lesions in the pelvis where it would be imprudent, not to say dangerous, to perform laparotomy or vaginal hysterectomy, and also in cases of chronic purulent pelvic lesions. Posterior colpotomy should, in my opinion, be preferred to laparotomy or vaginal hysterectomy in every case where the patient is a young woman, when it is the duty of the surgeon to preserve the adnexa at any cost, and I know of patients who have had their pelves full of pus which was removed by vaginal incision and who afterwards became mothers. This conservative operation in no way compromises the result if any more radical operation should be deemed necessary later on, and I have never seen a fistula follow in any of my patients, whose number is already fairly considerable. To sum up, I may say before describing the technique and indications and contraindications of the operation, that every suppurating pelvic collection that is accessible by Douglas's cul-de-sac is suited for posterior colpotomy and drainage, the technique of which I will now describe.

In practice the operation may be considered in most cases one of emergency, and consequently no very elaborate preparations can be made, but if one has a day or two at his disposal the ordinary preparation as used in any abdominal operation should be employed, and particular care should be given to completely empty the intestines.

The instruments necessary are few and simple. Two ordinary hysterectomy valves, a few artery forceps, two stout tenaculum forceps, a long and stout pair of curved scissors, two large glass or rubber drainage tubes and an irrigator are all that are necessary. To operate easily in the vagina depends entirely upon the valves used and none have given me such perfect satisfaction both in simplicity and effectiveness as those devised by Segond, of Paris. We believe that the operators who speak of the vaginal route as a blind method do so because their vaginal retractors are improperly constructed and are insufficient, and it is for this reason that I have insisted on this point.

Another thing that is essential in vaginal work, in order to do it properly, is the right kind of an operat-

ing table, one in which an exaggerated Trendelenburg position can be obtained when the patient is in the lithotomy position, and a table that fulfil this to perfection and which is remarkable by its great strength and perfect simplicity is the one invented by Pryor, of New York. This table has given me entire satisfaction, and it is particularly useful in home-to-home operating, as it can be folded up into very fairly small dimensions.

After having seized the cervix with the two strong tenaculum forceps, one retractor is placed on the posterior vaginal wall, and the cervix is drawn upwards towards the pubis until it cannot be drawn any farther by a gentle traction. With the stout curved scissors a transverse incision varying from four to six centimetres in length is made in the vaginal mucous membrane at the point where it joins the cervix. The mucosa should be boldly cut through with one cut of the scissors, and then introducing the finger through the incision the adhesions are rapidly broken down, the peritoneum is felt, and then guiding the scissors along the finger introduced into the wound the surgeon incises the peritoneum, keeping close to the posterior aspect of the uterus. In very pronounced cases the purulent collection may project so distinctly into the cul-de-sac that the abscess pocket is opened at the same time that the incision into the mucous membrane is made. I would here say that occasionally considerable hemorrhage may arise from the vaginal incision, and if it is very considerable I think it is better to immediately ligate the vessel or vessels giving rise to the blood before proceeding, because in one case recently operated on quite a serious post-operative hemorrhage ensued, which was only arrested after considerable difficulty. I will say, however, that this case was simply the removal of the adnexa through the vagina, and not a pus case, and that the clamps placed upon the ovarian artery held well and the pedicle was carefully inspected and no oozing came from it, and after considerable trouble the bleeding point was located in the right-hand angle of the vaginal incision. This is, however, the only case where the vaginal arteries have ever given me any trouble. After the sac has been incised the pus flows out freely, and then the cavity should be explored with the finger in order to ascertain if other pockets exist, and if so they should be broken down and emptied. On several occasions I have found large pus tubes on both sides present, and in these cases, having made sure by digital examination that the general peritoneal cavity was protected by the formation of adhesions, I have opened these pockets with the scissors and inserted a large drainage tube in each tube with very happy results.

After the pocket or pockets have been thoroughly evacuated the cavity is carefully irrigated with a 1-2,000 solution of cyanide of mercury or a 1-3,000 solution of citrate of silver.

If the pocket is very small, a wick of iodoform gauze may be sufficient, but it is better practice to obtain a free drainage and for this purpose two glass drainage tubes or two red rubber drains should be introduced well up into the cavity. The vagina is next carefully packed with gauze, and an ordinary aseptic dressing is placed over the vulva and held in place by a T bandage. The next day the pocket is carefully cleaned out with peroxide injected into one drainage tube, and after a couple of days the vaginal packing

is removed and renewed. As the pocket retracts it forces the tubes downward and after a few days usually they may be changed for ones of smaller calibre.

Posterior colpotomy has been more particularly advised in cases of pelvic suppuration and the so-called retro-uterine hematocele. This latter condition does not come into the province of this paper, but I would like to say one or two things regarding its treatment by the vaginal incision. As we all know, hematocele is due to the rupture of an ectopic gestation in a large majority of cases, and when it results in a large collection of blood and all evidences of hemorrhage have ceased, posterior colpotomy is, in our opinion, by far the better method to adopt under these circumstances. Laparotomy is always a very serious operation when dealing with a hematocele, and is always attended by many difficulties, and posterior colpotomy should be preferred to the abdominal route because it is a more simple operation, far less dangerous, and just as efficacious if not more so than the abdominal incision. In cases of hematocele the adnexa can be explored with as much ease through the vaginal incision as through the abdomen and they can be removed with just as much ease through the vagina if it is deemed necessary to do so. We believe that there is less liability of infecting the cavity after the blood has been removed when posterior colpotomy is done, because we get a natural and easy drainage and it can be treated more directly than through the abdomen.

Posterior colpotomy may also be used as a preparatory step towards vaginal or abdominal hysterectomy, and after the purulent pockets have been emptied and drained they diminish in size, the patient's general septic condition can be improved, and then if total hysterectomy is deemed necessary, it can be done under far more advantageous conditions.

In principle, all cases of pelvic suppuration should be treated by incision and drainage, and this having been said we should examine more closely what should be our conduct in the presence of primary or secondary pelvic suppuration, be it either acute or chronic. In those cases where the purulent collection is localized within the pelvis and when it is not composed of a large number of pockets, posterior colpotomy is proper. On the other hand, when dealing with those cases where the purulent collection is so divided into minute cavities that the mass forms a sponge full of pus, so to speak, colpotomy is insufficient and vaginal hysterectomy is, in our way of thinking, the proper operation to select.

In doubtful cases vaginal incision can be performed, the parts can be explored and will be no detriment to the performance of vaginal hysterectomy if necessary. When we are dealing with a peri-uterine collection which projects into the posterior cul-de-sac, vaginal incision is indicated. Even in those cases where a very prolonged inflammatory process has been present and has changed the walls of the pocket so that they have become sclerous and adherent, vaginal colpotomy may be indicated, provided that the pocket is a small one. Every time that the collection is situated high up in the pelvis, but is accessible to the finger in the vagina, the vaginal incision is indicated. When there are several pockets they may all be opened one into the other through the vaginal incision.

In those cases where the collection is situated high up in the pelvis and cannot be reached by the finger

in the vagina, posterior colpotomy is contraindicated and abdominal section should be resorted to. When the purulent collection is very large and surrounds the uterus, so that it floats, so to speak, in pus, vaginal incision is proper, but on account of the multiplicity of the pockets vaginal hysterectomy will have to be resorted to, because in most instances drainage would not be sufficient.

In this latter class of case it is practically useless to endeavor to preserve the tubes and ovaries, because the pus and false membranes which completely surround these organs will progressively give rise to their destruction.

When we are dealing with an acute suppurating salpingitis or a puerperal pelviperitonitis, the serious general condition of the patient demands the evacuation of the pus by posterior colpotomy, because laparotomy and hysterectomy are particularly grave under these conditions.

In cases of acute gonorrhoeal salpingitis or pelviperitonitis the general condition of the patient will be the guide which will dictate to the surgeon how he should act, but generally speaking, a large number of these cases will recover perfectly after the pus has been evacuated through the vagina unless the pocket has become secondarily invaded by the streptococcus or the staphylococcus. Abscess of the broad ligament is subject to the same treatment.

In closing this paper I would say that posterior colpotomy is, in my opinion, a justifiable procedure in a large majority of cases, and, like everything else in surgery, if we can cure a patient by a simple operation, that is the one to be selected. I have endeavored to point out that the operation in question will not cure every case any more than will any other one operation, but it certainly has a vast field of usefulness and in many cases a patient will be left with all her organs of generation in a very fair state of health, and we should always endeavor not to sacrifice these organs whenever the condition justifies.

PARTURITION COMPLICATED WITH SUPPURATING FIBROIDS.¹

BY E. H. STEVENS, M.D., CAMBRIDGE, MASS.

WHEN I accepted your secretary's kind invitation to present a case of suppurating uterine fibroid complicating pregnancy, with an operation, I expected to be able to refer to other cases of a similar nature which had been reported. With the limited time at my disposal for looking over files of medical journals and books of reference, I have been unable to find a single case. I presume there are many such cases which have escaped my attention. I hope some one will be able to refer me to such reports. Such cases must be relatively rare and therefore all the more interesting.

The case which I shall report to-night occurred in my practice in 1897. It has seemed to me of sufficient interest to warrant my bringing it to the notice of this society. In looking over the records of my obstetric cases (something over 2,200), I find mention of 18 cases where uterine fibroids complicated labor. In all of these cases the mother recovered. In only

¹ Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, February 28, 1900.

2 cases was the child lost. This does not include the case before us.

March 1, 1897, I was consulted by Mrs. P., age thirty-nine. She gave the following history: Ten years married; miscarried at three months nine years ago; not pregnant since. Health always good up to nine months ago, when she began to have a bearing down in the pelvis, with pain in the back. She consulted a Boston physician, who said she had an enlarged uterus. Was treated by electricity for several months. Thinks treatment relieved symptoms. Menstruation has been regular and normal in amount up to January 12, 1897, since which time it has not appeared; she has had difficulty in passing water for two or three weeks past. Experienced a feeling of discomfort at the stomach—not amounting to nausea—for about the same length of time. General health good. Vaginal examination reveals a mass which nearly fills the pelvis. This mass is connected with the body of the uterus. The cervix, which is soft and patulous, is well up behind the pubes. The whole mass is movable, but cannot be pushed up above the brim of the pelvis. Diagnosis: Uterine fibroid, probably complicated by pregnancy.

Patient consulted Dr. W. H. Baker, who confirmed the diagnosis and advised waiting developments. On two occasions it was found necessary to use a catheter to empty the bladder. On April 15th a sudden attack of pain lasting half an hour. An examination made two hours later showed the pelvis free from the mass which had filled it; the cervix in its normal position. In the abdomen a rounded tumor could now be felt, which was quite freely movable.

From this time until October 25th, when she was confined, her health was good. On the above date she was delivered of a healthy female child weighing eight pounds. The first stage of labor lasted three hours, second stage two hours. The delivery was in every way normal. The uterus contracted quickly, a very small amount of blood being lost. On my next visit eight hours later, temperature 100°, pulse 80; feeling perfectly comfortable. At five o'clock the next morning, twenty hours after delivery, woke with a severe chill. Temperature at this time 105°, pulse 130. When seen two hours later was complaining of headache. Temperature 102°, pulse 110; no pain or tenderness in the abdomen; lochia free and in appearance normal. A careful examination of the vagina showed nothing wrong. The uterus was thoroughly cleaned out and drained with iodoform gauze. (This was done as a matter of precaution.) At my next visit, five hours later, temperature was 100°, pulse 80; comfortable in every way. By evening, temperature had risen to 102°, pulse 100; lochia free and normal in appearance. Drain removed and uterus carefully cleaned; passes urine freely.

Morning of second day. Nurse reports patient as having a restless night with slight chill at 2 o'clock A. M., temperature reaching 103.2°. Uterus and vagina again carefully cleaned; lochia perfectly free from odor. Seen at 10 A. M. by Dr. W. H. Baker, temperature 99½°, pulse 80. Appears perfectly comfortable. A thorough examination by Dr. Baker failed to discover any tenderness. A few hours later came a severe chill with high temperature and pulse, which continued through the night.

Morning of third day, 8.30. Again seen by Dr. Baker. Breasts filling; lochia free from odor;

uterus with tumor freely movable, no tenderness. Dr. Baker advises free use of alcohol; a continuance of the intrauterine douche, with generous feeding. At this time the question of doing something surgically was discussed and decided in the negative. As the pulse and temperature continued high with other evidences of general septic infection, I decided to use antistreptococcus serum. Twenty cubic centimetres were injected at 4 P. M., temperature being 104°. Four hours later temperature had fallen to 100°, with free perspiration; general condition good.

Morning of fourth day. Passed a fairly comfortable night, temperature 103°, pulse 120. Little milk in breasts; lochia becoming less, entirely free from odor. Second injection of 20 cubic centimetres of serum given. Four hours later temperature 101°, pulse 100; taking two ounces of brandy every two hours. Stomach retains food well. Evening temperature 103°, pulse 120.

Morning of fifth day. Passed a restless night, pulse 112, temperature 102°. Dr. W. L. Richardson in consultation. He agrees in diagnosis of general septic infection. Advises continuation of intrauterine injections and full doses of alcohol. The question of hysterectomy was again discussed and decided negatively. Dr. Darling reports no growth from blood taken the day before. A culture taken from the cervical canal shows a variety of bacteria but no streptococci. The urine, which is fair in quantity, shows albumin for the first time.

Morning of sixth day. A severe chill during the night, followed by high fever and great prostration. Color beginning to be bad. At times has profuse perspiration; mind clear. Takes from 12 to 16 ounces of brandy every twenty-four hours. Bowels have moved freely each day. From the sixth to thirteenth day, no chills. Has only a slight discharge from vagina, which is tinged with blood and entirely free from odor. All injections were discontinued. Pulse and temperature continue high, with free perspiration. No tenderness or pain on pressure. Mind clear when awake; sleeps a good deal.

Morning of fourteenth day. Had two chills since yesterday, temperature reaching 106½° after one of them. Vomited for the first time this morning. Mind wanders in sleep.

Sixteenth day. Seen by Drs. J. Homans and W. L. Richardson, who agree that the tumor is probably suppurating. They advise abdominal hysterectomy as a last resort.

Seventeenth day. Temperature 103°, pulse 120. Slight chill during night; mind dull, but rouses and talks about operation. A complete hysterectomy was done by Dr. W. H. Baker. There were no adhesions, the peritoneal cavity being perfectly normal in appearance. The operation was quickly done and was well borne. Very slight vomiting from ether. Six hours after the pulse was 110, temperature 102°. Very little pain.

Eighteenth day. Slept five hours; had one-eighth grain morphia subcutaneously. Abdomen very little distended. Mind more clear than for two days. Has not vomited since last evening. Pulse 110, temperature 102½°. Takes brandy and champagne freely. Evening temperature 103°, pulse 120.

Nineteenth day. Slept but little during night; was kept awake by the incessant itching of a rash which covers the entire body, in appearance like that seen

after the injection of diphtheritic antitoxin. Has vomited several times; extremities cold; several loose dejections. Abdomen not tender; very little distention. Pulse 130, temperature 98°.

Twentieth day. Has slept only three hours of the last twenty-four. Suffers very much from constant irritation of skin. The rash, dark red in color, has become confluent over the entire body. Face, hands and legs, swollen and tender to pressure; abdomen moderately distended; no vomiting. Temperature 97°, pulse 140. Evening temperature 104°, pulse 140. Other conditions same as in morning.

Twenty-first day. Rash less red, and less swelling about face. Almost constant delirium. Pulse 150, temperature 106°. During the day she became comatose and died about midnight, five and a half days after the operation. No autopsy. The wound was examined and found to be perfectly healed.

This most unfortunate case presents several points of interest.

The first question which I have asked myself over and over again is: Could anything more have been done to prevent this tumor from becoming septic?

The second question which presents itself to my mind is: Would the result have been different had an operation been done within the first three days after the first chill?

The third important question is: Did the use of antistreptococcus serum do harm?

In answer to the first question I can only say: The surroundings were the very best. A carefully trained nurse was in attendance. No pains were spared to have everything used about the patient as aseptic as possible, both before and after labor. At the first warning of trouble the vagina and uterus were carefully and thoroughly cleaned.

To the second question my answer is: Should another similar case present itself to me I should not hesitate to advise an early operation.

To the third question: Did the serum injected do harm? It certainly did no good. The appearance of the rash two days after the operation caused great discomfort as well as great depression. My own opinion is that it did do harm.

There was no evidence that the organism which caused the trouble in this case was a streptococcus. In fact, the clinical aspects of the case would be against such a theory. I have used serum several times since in non-puerperal cases, but have always had positive evidence of the presence of streptococcus, either from its presence in the blood or from the point of infection. If antistreptococcus serum is expected to be of service we should have a streptococcus infection. Where such infection is known to exist we are justified in resorting to almost any measures which experience has shown may be of benefit.

BRITISH LOSSES IN SOUTH AFRICA.—The total losses, exclusive of sick and wounded, have been 29,706, of which the killed in action were 254 officers and 2,403 non-commissioned officers and men; died of wounds, 70 officers and 610 non-commissioned officers and men; missing and prisoners, 65 officers and 2,624 non-commissioned officers and men; died of disease, 133 officers and 4,204 non-commissioned officers and men, and invalided home, 844 officers and 18,433 non-commissioned officers and men.—*Medical News.*

GLANDULOPENILE HYOSPADIAS; TWO URETHRAS, ONE EXTENDING TO THE BLADDER, THE OTHER TWO AND ONE-HALF INCHES LONG, AND TERMINATING IN A BLIND POUCH.

BY J. COPLIN STINSON, M.D., C.M., SAN FRANCISCO.

M. B., age seventeen years. No history of malformations in other members of the family. The case is reported more as an anomaly than for any other reason. An aunt died of phthisis. As a boy he had a tubercular knee-joint, which with local and constitutional treatment got well. Since then his general health has been fairly good. A couple of years ago he was operated upon for a convergent strabismus, with fair but not complete success. He is inclined to be anemic, has smoked and inhaled cigarettes for a number of years, using on an average one hundred and twenty a week. About June, 1898, he became infected with gonorrhoea. No history of any operation of the urethra, penis, etc. Examination showed a free, purulent discharge. His penis is above the average size. The glans is well developed; on its under surface is a deep vertical groove which represents the glandular urethra. There is a depression at the proximal (nearer his pelvis) end of glandular groove which admits a small probe about one-eighth of an inch. The proximal portion of glans for about three-fourths of an inch is covered on its superior surface and lateral aspects with prepuce, but the inferior surface is free from covering. There are two linear scars on the skin of the prepuce, one on each side, extending in a semicircle around the prepuce. The scars do not meet on the superior surface of prepuce, but for about one-third of an inch in the median line of the superior surface the skin is entirely free from the scar tissue. Where each cicatrix terminates the skin is heaped up into a mass of fine scar tissue, each mass being about one-fifth of an inch in diameter. The glans penis is drawn downward and is fixed at about a right angle to the shaft of the penis. This is probably due to adhesions, contraction of scar tissues, and the loss of prepuce and subcutaneous tissues on the under surface of glans and penis. There are two urethras, one extending to the bladder, the other two and one-fourth inches long passing parallel with the main tube, but ending in a blind pouch. The external orifice of urinary urethra is situated in the penile urethra about one-half inch posterior to proximal portion of glans; the opening is small, admitting about a 16 French sound, and its edges are somewhat cicatricial. It is situated slightly to the right side of median line, and on inspection a small patch of mucous membrane of urethra can be seen. The canal of urinary urethra is apparently of normal calibre. The incomplete urethra is situated close to the left of the urinary urethra, about in the median line. Its external orifice is small, but readily admits the bulbous end of a pocket-case probe, which passes downward along the median line for two and one-half inches, where it terminates in a blind pouch which does not communicate in any manner with the urinary urethra. This I have tested in several ways, for example, by probes, small sounds and injections. He has no disturbance with micturition or urination, except that

the stream is about half the normal size, and passes downward at right angles to the shaft of the penis. Copulation is not interfered with. There was considerable discharge of pus from both urethras. This shows that the one ending in a blind pouch is also lined with mucous membrane. I had considerable trouble treating the short tube. I used daily mild antiseptic solutions but with no quick results. I then employed applications and injections of carbolic acid in tincture of iodine, one in ten, with a fine probe and a hypodermic syringe with a fine but blunt needle. With the iodine-carbolic solution the discharge ceased. Altogether four injections of carbolic-iodine solutions were made at two-day intervals with the blunt-pointed hypodermic syringe. The last injection was made July 28, 1898. Since then no discharge at all has been noted. No operation was done for the deformities.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

C. H. HARE, M.D., SECRETARY.

REGULAR meeting Wednesday, February 28, 1900,
Dr. R. A. KINGMAN in the chair.

Dr. C. G. CUMSTON read a paper entitled

GENERAL REMARKS ON THE PATHOLOGY AND SYMPTOMATOLOGY OF ACUTE PELVIC SUPPURATIVE PROCESSES IN THE FEMALE AND THEIR TREATMENT BY POSTERIOR COLPOTOMY.¹

Dr. BAKER: I think the society is certainly indebted to Dr. Cumston for his very clear description of the pathological process present in these cases, which is too often overlooked by writers in general. I think the treatment by vaginal or abdominal route in these cases must depend upon (1) the individual case, as he has suggested; (2) upon the experience of the operator. For my own part I should feel generally in such cases I can save more tubes and ovaries by the abdominal route than I can by the vaginal. After separating the adhesions, oftentimes opening the tube, resection of the tube, washing it out, etc., I think that I can save more tubes and ovaries by careful work in the abdomen than I can by the vagina. However, I think that the operator must be largely guided by his own personal experience. I have been very much interested indeed in Dr. Cumston's paper.

Dr. STEVENS: I think that Dr. Cumston's conclusions have been demonstrated in former times before operations were done as much as they are at present. It was not an uncommon thing to see a woman who had a pelvic abscess, pelvic cellulitis, as it used to be called, with free discharge of pus into the vagina, or into the rectum more commonly, make a perfect recovery and bear children. I can remember more than one case where that has happened, and if that would happen under those conditions where the thing was left long enough to discharge, it certainly must be very much more favorable when operation can be done earlier and very much less destruction of tissue go on. I have been very much interested in the doctor's

paper, and I should feel a good deal as Dr. Baker does that the experience of the operator would have a good deal to do with success in this operation. It seems to me desirable always to get the pus out through the vagina when it can be done, and the technique that Dr. Cumston has pointed out I think would be a help to all of us in those cases.

Dr. BRECK: I have very little to add except that I believe in the operation thoroughly and have done it quite a number of times. It has been a source of satisfaction in several cases with very large abscesses where I was obliged to explore cavity after cavity bimanually, opening one into another to see the thorough recovery which followed. I should like to say a word about one condition that is sometimes mistaken for the ordinary pelvic suppuration, and that is, for instance, a case like this: A gonorrhoea which is evidently extending into the uterus and apparently into the tubes, producing a mass to one side of the uterus, and you operate and relieve what you suppose to be a tube filled with pus. A sinus remains open (as in a case which I operated upon this morning) for some unexplained reason, and after dilating that opening and curetting a few hairs come away, showing the nature of the case at once. I have had one or two of those cases in which there was every reason to think there was the ordinary pelvic suppuration, and in which a small cyst has been found to be present, showing one way in which the operator may be deceived.

Dr. BOLAND: The possibilities of the usefulness of this operation in ectopic gestation are very suggestive, but in the few cases I have seen (there was one or two where there was great uncertainty, and one in which the diagnosis lay between extra-uterine pregnancy and twisted pedicle) the abdominal route was safer and better. In the ectopic gestations I have had it was not so much a question of getting rid of the blood as of preventing further hemorrhage. Where you have no sepsis to deal with, the abdominal route is safe unless the woman is terribly collapsed, and even then I have seen them considerably collapsed and recover.

Dr. DENNETT: I have seen Dr. Cumston remove ovaries and tubes through the vagina. I believe one objection urged against it is that you are working in the dark. By his method you are not working in the dark. I have seen him take down the ovaries and tubes so that they are plainly visible with the instruments that he uses. I believe that infection sometimes takes place when the ovaries and tubes are normal, and not through the lymphatic system by the micro-organisms going through the uterus itself. I think cases have been reported as such. I think Dr. Cumston seems exceptionally successful through that route, and I was surprised the first time I saw him operate at the ease with which he did that work, both removal of the ovaries and tubes and uterus.

Dr. KINGMAN: I am glad Dr. Cumston has brought up this matter, for many will agree with him in the advisability of operating on this class of cases through the vagina who might have some difference of opinion when it came to some other forms of vaginal operating. Personally I have been in favor of the vaginal route for these cases and operate by preference by that method. I have a case for to-morrow at the Carney Hospital, with a large accumulation of pus in the pelvis extending upward, which I suppose will be operated by that method. It seems to me it offers

¹ See page 51 of the Journal.

a favorable opportunity of saving organs which otherwise might have to be sacrificed, and this is certainly a consideration of value.

DR. CUMSTON: I would like to give an instance where vaginal colpotomy was the only thing that saved the patient's life. A young lady was confined in August. Normal labor. Nothing went wrong for the first two weeks, and about the only thing in her previous history was that as a young girl she had been in a private hospital for what was called an abscess of the ovary, and a very excellent surgeon in this city had charge of it at that time, but when I questioned him on the subject he had only a faint recollection of the condition. This patient went well until two weeks after confinement, when the temperature began to go up. I found the uterus all right. The temperature stayed up several days about 38.5° C. As it would not go down by douching, I went over the endometrium carefully with the curette, with the result that it dropped immediately after the operation, but only to remain a day or two, and went up and continued to go up every day, until after watching that patient a fortnight I came to the conclusion she was going downhill and would probably die from septicemia. In the meantime she complained of pain on the left side at the site of her former trouble. Palpation revealed a mass. It was tender to pressure, and it was hard to say what size it might have been, but perhaps the size of a mandarin orange. On consultation with the gentleman who had formerly taken care of her, we agreed that the proper thing was to drain that pocket which was done through the vagina, but unfortunately for myself I considered the pocket so small that I put in gauze drainage and not a tube, as is my habit. The patient simply went downhill until five days later she was almost moribund, thoroughly septic. Consultation again with the same surgeon. He thought she could not live and that another operation was useless. I was not satisfied, and with him I agreed to have another gentleman in consultation. That gentleman decided in my favor that a second operation was the proper thing. I went in again, opened up another small pocket, put in two large drainage tubes and drained that cavity for somewhat over four weeks. That patient is practically well to-day. She went out about the last of November for the first time, and is now about and going out every day and in comparatively good condition. The only trouble she has is at the time of menstruation; she has some little pelvic pain on that side, which I think is due to adhesions. I was perfectly able to demonstrate the exact nature of the lesion on palpation through the incision. I could demonstrate to my entire satisfaction that all the trouble was on the left side. She was saved by the operation. It was no case for hysterectomy. I have seen other cases where perhaps the condition was not quite so bad as in this patient, but very serious, and if allowed to go on as in this would have presented the same symptoms.

There is one thing in reply to Dr. Boland I would say. I mentioned in my paper in regard to pelvic hematocoele that I should not advise posterior colpotomy except in those cases where the collection of blood had become encysted and I was positive the bleeding had stopped.

DR. E. H. STEVENS, of Cambridge, read a paper

PARTURITION COMPLICATED WITH SUPPURATING FIBROIDS.²

DR. BAKER: This case is certainly a most unusual and very instructive one. It seems to me that Dr. Stevens has hardly laid stress enough on the thorough work that he did with this uterus during the puerperium. From the time of the first rise of temperature, which to his mind meant some infection, knowing the location of this to be probably inside the uterus he began at once his work with the endometrium, cleansing the cavity with the curette and ensuring perfect drainage from the uterus. In going over the case from time to time with Dr. Stevens it so happened that the times that I saw her after the operation occurred just after he had done some such thorough work as I have just described, the temperature had dropped and things looked very much more favorable and as if things then were going on all right, but we were led into error. I think the lessons drawn from this case, unusual although it is, and the only case, so far as my knowledge goes, where a like condition has been present, is, that in such a case, not yielding to the first curetting, and the first thorough cleansing of the interior of the uterus, knowing the presence of a fibroid in the substance of the uterus, we should proceed at once to hysterectomy and not lose any more time. My experience of nearly thirty years in the diagnosis, course of development and appropriate treatment of fibroids of the uterus has been full of the greatest interest and importance. Without enlarging the scope of the subject of the paper of Dr. Stevens to too great an extent, I would briefly say that as the result of that experience, in a large majority of cases I have found the existence of fibroids of the uterus in married women to be the cause of sterility. In a small minority I have found pregnancy occur, and during the course of such pregnancy to greatly increase in size, and with the subsequent involution of the uterus after labor to find a corresponding diminution in the size of the fibroid, even in some cases its absolute disappearance. That the existence of a fibroid during pregnancy does complicate matters to a somewhat serious extent, I think no one could question, but I feel unwilling to accept my fixed rule of procedure to be applied to such cases in general, and know of no subject the individuality of which case must be more carefully considered than the appropriate treatment of one belonging to the class described by Dr. Stevens. Among the cases of this class which come prominently to my mind is the following:

Mrs. E. W. P., referred to me by Dr. J. M. Smith, of Barnstable, Mass., January 29, 1882, was thirty-two years of age. Had been married four years. First noticed at the time of her marriage an enlargement of the abdomen on the right side, which seemed to her about the size of her fist, and which slowly but steadily increased in size. This gave her no special pain until about a year before she consulted me. Then it was noted that about the menstrual period it increased much in size and became painful. Being the wife of a sea-captain she sailed with her husband from Zanzibar for home, September 24, 1881, and when she consulted me she had had no menstruation for five months. There was no special inconvenience noticed except frequency of urination and constant nausea. She was examined by a prominent authority

² See page 56 of the Journal.

in London in November, with the opinion that she was not pregnant and that the absence of her menstruation was due to the change of climate. About a month before she consulted me she felt a decided quickening, and this motion had grown stronger in the last month. Physical examination showed the uterus to be enlarged unequally. The left half of it seemed soft to the feel, and through the abdominal walls I could detect the motion of the fetus. The left half, however, felt hard and had risen to a point about five inches above the umbilicus. Diagnosis of pregnancy at the beginning of the sixth month complicated with fibroid, interstitial in character. I referred the case to Dr. O. W. Doe for delivery. April 29th Dr. Doe brought on labor at the eighth month, considering it unwise to wait any longer for natural delivery, on account of the great size of the patient. He delivered her safely and her convalescence was uneventful. I saw the patient six months afterwards, the mother and child both being well, and although I could still detect the presence of the fibroid, it had diminished two-thirds in size from that which it was when I first saw her.

Other cases I have in mind, but am not able at this moment to refer to the notes of them, where the fibroid has entirely disappeared during the puerperium. Some eight or ten years ago, the late Dr. Francis Minot reported to the Obstetrical Society of Boston one or more similar cases, and my remembrance of the discussion at the time was that his paper brought out a number of illustrative cases where fibroids had entirely disappeared after labor.

DR. BRECK: I would like to show a specimen which somewhat bears on the present discussion—pregnancy with fibroid tumor in which hysterectomy was done. Single woman, thirty-six, about five months pregnant. She had a large tumor to the left and above the uterus which reached high into the left hypochondrium and which was movable. The size of the tumor was that of an average musk melon, and that of the abdomen what might be expected at seven and one-half months' pregnancy. Thinking it was probably ovarian I advised operation, and yesterday morning operated with the assistance of Dr. Twombly. We made an incision just below the umbilicus, and introducing the hand found this tumor proceeding from the left cornu of the uterus with a very large pedicle. It showed the muscular fibres of the uterus so distinctly that I thought at first it might be a uterus bicornis, but further examination showed it was probably a fibroid. The question was whether to let the tumor alone or attempt removal. In manipulating the uterus to see if he could get the pedicle, the question was decided by a very profuse hemorrhage which took place at the junction of the tumor with the uterus. This could not be permanently controlled on account of the friability of the uterine tissue. It was temporarily controlled by gauze pressure and the complete operation done, the uterus being amputated above the cervix. The patient has made³ a complete recovery, the convalescence having been a very smooth one.

DR. CUMSTON: The question of complications due to fibroids during pregnancy and the post partum is extremely important both to the general practitioner and the surgeon, and is a vast subject. I think the society is indebted to Dr. Stevens for his valuable contribution to the subject.

³ March 16, 1900.

We all know the frequency of metritis in cases of fibroid, and the serious complications which may ensue from the lesions of the endometrium; we also know of the renal complications due to these growths, such as pyelonephritis. Various forms of cystitis are also met with. Hemorrhage complicating fibroid growths of the uterus is probably the most frequent and one of the most serious complications which may occur, and is more frequently met with during the post partum, although cases are recorded where loss of blood occurred during gestation, in which case the neoplasm was usually seated in the cervix.

Of these complications I will say nothing, and shall confine my remarks to the inflammatory and infectious processes occurring in fibroids and which frequently complicate the post partum. Naturally their frequency has considerably diminished since the introduction of antiseptics. The septic complications are of two origins: They are either produced indirectly by the fibroid, following obstetrical manipulations and operations of all descriptions necessitated by the presence of the growth, and where proper surgical antisepsis and asepsis have been improperly carried out; or the complications may be produced directly from a necrosis of the growth which has been produced by laceration or compression that they have undergone during labor, or following a softening of the fibrous mass during pregnancy.

It is, however, necessary, in order that infection shall take place, that an entrance has been given to the pyogenic germs existing without, because it is well known that a subperitoneal fibroid, for example, which has lost all its connection with the uterus and which is free in the abdominal cavity will never give rise to any septic process. But even after a perfectly normal labor, numerous lesions can be produced in the lymphatic and venous channels which allow an easy access to pathogenic bacteria if strict surgical cleanliness is not observed.

My experience with pregnancy complicated by fibroids giving rise to septic conditions is limited to two, and I will briefly report these cases and quote a few others that have been reported in the general medical literature.

CASE I. We saw in consultation a young woman, twenty-five years old, who had been delivered of her first child four weeks previously. The labor, other than being rather tedious and long, had been perfectly normal. Twenty-five days after the confinement the patient had a chill and the temperature went up to 39° C. At our visit we found the abdomen distended, the pulse 120, presenting the peritoneal type. The urine contained a considerable amount of albumin, and indican was present. Upon examination the uterus was found to reach nearly to the umbilicus; the cervix was soft and the uterine cavity, which was greatly dilated, was found filled with a dirty, fetid pus. In the right iliac fossa a large purulent pocket was found communicating with the cavity of the uterus. This was opened by posterior colpotomy and explored, which resulted in removal of the debris of a fibroid tumor about the size of an orange, which had become compressed during labor and had undergone gangrene. The bits of neoplastic tissue were removed, the cavity was irrigated and thoroughly drained, and the patient made an uneventful recovery.

CASE II. The patient was a woman thirty-two years of age, who had been married five years, during

which time she had had four miscarriages, all occurring about the second month. When seen for the first time a pregnancy of about four months, complicated with a fibroid tumor, was diagnosed. About two weeks after seeing the patient, she developed all the symptoms of a pelviperitonitis, and in a few days gave issue to a fetus about five months old. About ten days after the miscarriage the patient had a chill, the temperature reached 40° C. and the pulse was rapid and intermittent. This condition did not change, and as the symptoms of septicemia were rapidly increasing, we decided to open the abdomen. Laparotomy was performed and we found a large subperitoneal fibroid, which had contracted firm adhesions with the parietal peritoneum, the omentum and intestine. Palpation of this large tumor showed that in certain spots it was fluctuating, and an incision was made over the most prominent point of fluctuation, which gave issue to about a litre of yellowish, creamy pus. On account of the great adhesions binding the growth, which would necessitate a very long and tedious operation for its removal, and could not be withstood by the patient on account of her very poor general condition, we drained the pocket and closed the abdomen. The patient, however, died in twelve hours after the operation, but unfortunately no autopsy could be obtained.

Here are a few other cases which I have found reported. The first is that recorded by Hegar of a patient three months pregnant, and who presented a large uterine fibroid, which had become softened and inflamed. Peritonitis developed and laparotomy was done, but the patient died three days afterwards.

Trenb reports the case of a woman twenty-seven years old, who for several years had presented an abdominal tumor which extended up to the umbilicus, but had never given rise to any pain. Menstruation had always been regular, and when seen she had been married for a year and was about three months pregnant. She then developed a peritonitis, and a miscarriage occurred five days later. There was a severe hemorrhage following this, which was controlled by ergot. There then developed a fetid vaginal discharge, with fever and a poor general condition. The tumor was found to extend above the umbilicus, and curettement under narcosis was decided upon, and at the same time to make a complete examination. The tumor was found to be solid, and no fluctuation could be made out. The uterus could not be mapped out from the tumor, so that in all probability it was a fibroid very intimately connected with the body of the organ. Curettement brought away the débris of yellowish tissue, and consequently the diagnosis of a gangrenous fibroid was made. On the next day the abdomen was opened, but the adhesions attaching the growth to the abdominal wall and intestine were so thick and firm that it was considered dangerous to break them down. A median incision was made, extending along the entire anterior wall of the uterus in order to enucleate the neoplasm, which was found free in the uterine cavity. The tumor was removed, the uterus and abdomen were sutured and the cavity of the uterus tightly packed with gauze. The patient recovered in spite of two utero-intestinal fistulae. This was a case of a fibroid tumor which had attained an advanced degree of necrobiosis.

Frommel's case was a woman in the fifth month of gestation. The fibroid, which was about the size of a

fetal head, was inflamed and softened; peritonitis developed and myomectomy was done. She recovered, and was delivered at term.

Croffard reports the case of a woman in the sixth month of a pregnancy complicated with a uterine fibroid. The neoplasm surrounded the cervix like a cuff. Symptoms of infection arose and as the fetal foot protruded it was seized and the child delivered. Infection, however, continued and seventeen days later the abdomen was opened. The neoplasm, which was gangrenous, was so adherent that removal was impossible. As much of it was removed as was possible by the thermocautery and the tubes were removed. The patient recovered.

Bonipiani has recorded a case of a thirty-five-year-old primipara who had a fibrous tumor in the posterior wall of the uterus. Artificial abortion was performed during the sixth month, after which the patient developed a pelviperitonitis, but recovered.

There are a few rare instances of so-called spontaneous purulent disintegration taking place in fibroids during pregnancy, which are in all probability due to septic infection. I have only been able to find two, one reported by Krukenberg, the other by Cappil. In the first case the patient was suddenly taken with chills and presented symptoms of severe peritonitis. Miscarriage took place and six hours after this the patient died. Necropsy revealed pus in the broad ligament, in the peritoneal cavity and uterine cavity. In the second case there was an ovarian cyst and on the right upper angle of the uterus was a fibroid with torsion of the pedicle, which had resulted in gangrene of the neoplasm. From this condition there had resulted a local inflammatory change in the neighboring intestinal coils, with the result that the intestinal bacteria had invaded the growth and suppuration had resulted.

In some cases we get an edematous softening of the fibroid which is followed by a necrobiotic disintegration. The edematous condition is usually due to hemorrhage into the neoplastic tissues resulting in cystic formation. There results an engorgement of lymph and if any chance for infection is offered after delivery the neoplasm becomes rapidly purulent.

Other complications due to fibroids may occur during the post partum, such as phlebitis, inversion or prolapsus of the uterus, all of which appear to be infrequent, and this also may be said of eclampsia and rupture of the bladder, both of which are due to prolonged pressure by the growth. One case I find recorded long ago by Depaul, in which intestinal compression occurred, the patient dying with all the symptoms of strangulation of the intestine.

DR. BRECK: Dr. Cumston has referred to myomectomy during pregnancy. If the conditions were anything like what they were in my case I can hardly consider it possible. The uterine tissue was friable and the uterine vessels so dilated I do not see how hemorrhage could be controlled.

DR. BAKER: I think as we get more and more experience in operating upon fibroids that the cases are very few in which myomectomy cannot be done to-day. I have notes of cases of fibroids of the uterus where I have persisted with the operation and removed as many as thirteen without removing the uterus or interfering with the ovaries or tubes in any way, and left the woman in a condition that I hope she may yet be a happy mother.

DR. KINGMAN: I am a strong believer in myomec-

omy. I have a patient in St. Elizabeth's Hospital from whom I removed a tumor of about two pounds' weight, an interstitial fibroid protruding somewhat into the cavity of the uterus, giving rise to profuse hemorrhage in a young married woman anxious to have a family. The tumor was very easily taken out with almost no hemorrhage. It seems to me it is a great accomplishment to be able to save the uterus and appendages, and not feel that in the large majority of cases we must sacrifice them.

DR. STEVENS: My experience with uterine fibroids subsequent to pregnancy would be in accord with Dr. Baker's. Without any question, in a number of instances the size of the tumor has very markedly diminished during the involution of the uterus and in two instances has practically entirely disappeared. In regard to this particular case I have reported, it may seem a little strange that the question of suppuration of the tumor had not been decided on earlier. It was not tender in any particular, and it seemed to all of us who saw it that with a suppurating fibroid under those conditions, which had acutely become septic, we must get some localized tenderness. In regard to doing a myomectomy in case of a suppurating fibroid subsequent to delivery, it seems to me that we should always bear in mind the chance of having a septic uterus and that if we leave the uterus and take away the tumor we may not remove all of our foci of sepsis and still have trouble. If a similar case should present itself to-day I should not hesitate to do a complete hysterectomy.

DR. BOLAND: In regard to fibroids complicating pregnancy, one case gave me a good deal of trouble in delivery, which was a breech. I found an intramural fibroid as big as the fetal head. It was in the time of the Apostoli treatment. I got the outfit and used it faithfully. The tumor had disappeared very largely by the end of about three months, and until Dr. Baker spoke I supposed the reduction in size was due to the electrical treatment. As she did not pay her bill she has not reported since, so I cannot give the final result.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

TWENTY-SECOND ANNUAL CONGRESS, HELD AT THE HOTEL ARLINGTON, IN WASHINGTON, D. C., MAY 1, 2 AND 3, 1900.

FIRST DAY.

THE President, DR. SAMUEL JOHNSTON, Baltimore, Md., in delivering the opening address, referred to the increased attention which had been given in recent years to affections of the larynx and their bearing on other complaints. A large amount of credit for this was due to the association, whose meetings had been annually increasing in interest. At the last meeting in Chicago many important papers were read, and he trusted that the present meeting would be even more memorable. To attempt to make a survey of the progress that was being made even in this one branch of medical and surgical science would involve a herculean task, which he shrank from undertaking. He would therefore confine himself to a few practical suggestions as to the policy which should be followed by the association in the future. Among the points on which he laid

most stress were extreme care as to the qualifications of the new members they admitted and the adoption of such measures as were deemed most efficacious for the purpose of inducing old and experienced members not only to retain their membership but also to keep up an active interest in the association. He next touched on the necessity of scientific research and clinical laryngology going hand in hand, and in regard to the arrangement of programmes for their meetings, he suggested that it would be better to have a few good papers with ample time for their proper discussion than that they should have a great array of papers, many of which could not be read, much less discussed, for want of time. He concluded by suggesting the introduction of some sort of a censorship to prevent theories which had not stood the test of clinical experience being supposed to carry with them the endorsement of the association when published in the *Transactions* of the association or elsewhere.

LARYNGEAL IRRITATION A CAUSE OF ASTHMATIC PAROXYSMS.

This was the subject of the first paper on the programme. The author, DR. WILLIAM C. GLASGOW, St. Louis, Mo., being absent, the paper was read by title.

DR. THOMAS AMORY DEBLOIS, Boston, read a paper on

FRACTURES OF THE NOSE.

He stated (1) that a broken nose was generally not broken; (2) that the subject could be divided according to the degree of injury; (3) and also relatively to the parts involved. By his first assertion he implied that in most cases there was no fracture of the bone itself. It might be more properly classed as a dislocation. The nasal bones became separated at their internal borders from the nasal processes of the superior maxillaries; this, although accompanied by more or less violence, was not in itself a true fracture, and this solution of bony continuity was by far the most common variety of broken nose. Secondly, the injury might not alone involve the small nasal bones (for it was impossible to move one without the other), but it might be more severe, and result in fracture of the nasal process of the superior maxillary or the zygomatic arch of the malar, as from the kick of a horse. The author exhibited drawings showing examples of the different kinds of simple fractures and dislocations which were commonly met with, and then proceeding to deal with the subject of treatment, said that in many cases where the patient could be seen sufficiently often it was found that apparatus could be dispensed with. In cases where for one reason or another apparatus of some sort was considered advisable, he was in the habit of using soft-rubber tubes, applied internally, for the purpose of getting the nose back into its proper position and shape. This was in cases where the same object could not be effected by manipulation of the fingers. In some cases he also used external splints, and these he made of plaster of Paris. He understood that Dr. Leland, of Boston, thought that splints ought to be dispensed with altogether, but his own experience was that they were necessary in some cases, though by no means in all.

DR. EMIL MAYER, New York, in opening the dis-

cussion on the paper, said he was opposed to the use of the soft-rubber tubes, because of their irritating tendency. This was why vulcanite tubes were often used.

DR. DEBLOIS explained that he used the rubber tubes not so much as splints as for the purpose of restoring the nasal organ to its natural shape. They were never allowed to remain in the nostrils for any length of time.

DR. WILLIAM E. CASSELBERRY, Chicago, said he was afraid the rubber tubes would cause unnecessary pain. He advocated the giving of ether to patients who had to be operated on for nasal fractures or dislocations.

DR. JONATHAN WRIGHT, Brooklyn, remarked that the Greeks had frequent occasion to deal with broken noses in connection with their popular sports, and they used practically all the methods that were used now, together with some that might well be used. He advised those not familiar with it to study the Hippocratic method of treatment. One thing particularly to be avoided was the introduction of absorbent material into the nostrils.

DR. JOHN O. ROE, Rochester, said he had found aluminum a good material to use for external splints, one recommendation it had being its lightness.

DR. H. L. SWAIN, New Haven, Conn., remarked that useful hints as to the treatment of broken noses were to be found in the work of an author less ancient than Hippocrates—he alluded to the work of Dr. Jonathan Wright, of Brooklyn, where he thought some things would be found that were not known to the Greeks.

Some remarks followed from Drs. F. C. COBB and J. PAYSON CLARK, of Boston, both of whom urged the avoidance of splints as much as possible.

DR. SIMPSON, New York, having exhibited a splint which he recommended, DR. DEBLOIS closed the discussion by replying to some of the criticisms.

DR. J. E. LOGAN, Kansas City, read a paper on

ATROPHIC RHINITIS.

He protested against the multiplicity of terms that were used to describe this disease, and said they were as much in the dark as they were ten years ago as to its etiology. While something was to be said in favor of the germ theory, the experiments in the way of inoculation so far failed to support it. He was disposed to think that the disease had its origin in the accessory sinus.

The view of the author of the paper received some support from DR. CLARK, Boston, but was dissented from by DR. WRIGHT, Brooklyn. The latter suggested that a more probable source of the disease was to be found in the occlusion of the connecting veins. Dr. Wright also called attention to the fact that the complaint was more common among broad-nosed people, and referring to statistics quoted by the author to show its greater frequency among women than among men, he suggested that the sexual life might also have something to do with it. He thought, however, that the origin of the disease was not to be traced to a single cause, but to a combination of causes.

The discussion was continued by Drs. SWAIN and CASSELBERRY.

DR. EMIL MAYER, New York, contributed a paper on

RECURRING MEMBRANOUS FAUCITIS DUE TO THE BACILLUS OF FRIEDLÄNDER,

at the same time reporting a case which showed all the same symptoms as those reported in Europe. His patient was a young woman who had recurring membranous growths at intervals never exceeding a fortnight, and yet never showed any constitutional effects.

The paper was discussed by Drs. J. E. BOYLAN, Cincinnati; A. W. DE ROALDES, New Orleans; SWAIN and WRIGHT.

The secretary read a paper by DR. T. R. FRENCH, Brooklyn, on the

EMPLOYMENT OF THE UPRIGHT POSITION IN ETHER OPERATIONS UPON THE NOSE, THROAT AND OTHER PORTIONS OF THE HEAD,

with exhibition of a chair to facilitate such operations.

Several members said that they would have liked to discuss the paper, but the chair ruled that it would be irregular to do so in the absence of the author. The secretary was instructed to request Dr. French to bring the subject up at another meeting at which he could be present.

The presentation of a number of instruments and specimens closed the proceedings for the day.

SECOND DAY.

The second day's proceedings commenced with a business meeting, at which reports were presented from the secretary, the treasurer and other officials, showing the affairs of the association to be in a satisfactory condition. The nomination of officers for the ensuing year resulted as follows: President, Dr. Henry L. Swain, New Haven, Conn.; First Vice-President, Dr. Henry L. Wagner, San Francisco, Cal.; Second Vice-President, Dr. Arthur Ames Bliss, Philadelphia, Pa.; Secretary and Treasurer, Dr. James E. Newcomb, New York, N. Y.; Librarian, Dr. J. H. Bryan, Washington, D. C.; Member of Council, Dr. Samuel Johnston, Baltimore, Md.

A discussion on the subject of

THE EARLY DIAGNOSIS OF LARYNGEAL CANCER AND THE TREATMENT

was introduced by DR. JOHN N. MACKENZIE, of Johns Hopkins University, Baltimore, who dealt with the methods of diagnosis and general principles of treatment. The subject he considered of such importance that, as he mentioned, he had left a sick bed in order to be present and take part in the debate. The present unsettled condition of the question led him to confine himself to the statement of certain views that were entertained on the subject, and the submission of certain propositions, which some might consider either revolutionary or reactionary, but which nevertheless he hoped would meet with some support. Leaving out of account the possible existence of a cancer bacillus, there remained three methods of diagnosis, namely, (1) the naked eye, or diagnosis by ocular examination; (2) thyrotomy; and (3) the microscope. The second, of course, was often included in and ancillary to the first. In his opinion, it was impossible to exaggerate the importance of examination by the naked eye. It was the most practical of the three methods, and it was unfortunate that it was so often relegated to a subordinate position.

Every resource of clinical work should be made use of before the recourse was had to the microscope. It indeed should be the very last court of appeal. The literature of the day showed that far too little reliance was placed on clinical work, and far too much on the microscope. There was no solitary sign by which they could detect cancer. They must group all the phenomena and form their diagnosis accordingly. But supposing they had weighed all the facts, and a reasonable doubt still existed, would they not then be justified in removing a portion of the growth for the purpose of subjecting it to microscopical examination? In spite of all the authorities to the contrary, he emphatically said, "No." The reasons he had for objecting so strongly to the removal of any part of the affected tissue were that it exposed the patient to auto-infection, stimulated the growth of the cancer, if such it proved to be, and often led to misleading conclusions. It was not to be forgotten that cancer was an infectious process. He believed that sooner or later its bacillus would be discovered, and that then the disease would cease to be treated surgically—the place of the knife being taken by an antitoxin. Meanwhile the cardinal fact that they had to face was that the surgical treatment of cancer had resulted in failure because the methods had not been sufficiently radical. They had not completely removed the disease. So long as they left the lymphatics to carry infection to other parts, they were bound to fail, and after painful experiences he had come to the conclusion that the only hope of success lay in the total extirpation of the organ and also the lymphatics. Surgeons had ceased to trifle with cancer in other parts of the body, and there was no reason why they should continue to trifle with cancer in the larynx.

DR. D. B. DELAVAN, New York, who was down on the programme to report on the

STATISTICS RELATING TO THE TREATMENT OF CANCER BY THE DIFFERENT METHODS,

said he was very much in the position of the author who headed one of his chapters, Snakes in Ireland, and then proceeded to say, "There are none." In regard to cancer, it was not literally true that there were none, but such as existed were of very little value, principally because of the tendency on the part of surgeons to report only their successes, and withhold all mention of their failures. For this reason, in collating such statistics as he had, he had found it necessary to eliminate all the American operators. Only a few European operators had reported both failures and successes, and the statistics he had gathered from their reports left the entire matter in a very unsatisfactory condition. He suggested that surgeons should be urged to practise greater frankness. The speaker proceeded to give the meeting the benefit of his researches for what they were worth.

DR. J. SOLIS-COHEN, Philadelphia, spoke on the surgical procedures connected with cancer. He remarked that Dr. Mackenzie had struck the keynote of the matter, so far as surgery was concerned, when he said that a more radical operation was necessary in order to make sure that the whole of the infected area was removed. As regarded the procedure, the first danger to be guarded against was from the accumulation of septic material and its passage into the lungs. To avoid the latter, he operated with the head lower than the shoulders, which was easily accomplished by

allowing it to hang over the table. In some cases it might be found desirable to perform a preliminary tracheotomy, but if the patient was in such a condition that he could not wait for the radical operation it should be performed at once. In order to prevent septic pneumonia, it was necessary to shut off all communication from the mouth to the air passages. Another important point was to avoid all dressing, and it was also essential to be careful in the after treatment, the patient being put in a bed with the foot-board raised, so as to keep the head low. The operation required the co-operation of the laryngeal mind and the mind of the general surgeon.

DR. SWAIN said that in view of the discouraging statistics it was desirable, if possible, to look on the brighter side, and with that end he related some of his experiences at New Haven.

DR. C. C. RICE, New York, said it was important that the laryngologist should not turn over his patients to the general surgeon until he was sure of his diagnosis. He thought, too, that some laryngologists were inclined to operate too early. Especially after hearing the discouraging statistics, he thought they would do wisely if they did not come too soon to the conclusion that an operation was required.

DR. EMIL MAYER, New York, said the assistance of a general surgeon was always desirable, because additional operations were sometimes found necessary outside of the region of the larynx.

DR. A. B. THRASHER, Cincinnati, thought the removal of a small part of the growth with a view to microscopical examination was sometimes justifiable.

DR. W. K. SIMPSON, NEW YORK, agreed with the last speaker, and said he considered it would be very unwise to extirpate the larynx without a previous microscopical examination.

DR. F. C. COBB, Boston, gave the results of some of his experiences with thyrotomy.

The authors of the papers then replied on the debate, Dr. MACKENZIE stating in answer to questions that his experiences with the entire extirpation of the larynx without the removal of the lymphatics consisted of three dismal failures. The plan he recommended of including the lymphatics in the removal had not yet been tried, so far as he knew.

DR. COHEN said that in the next case in which he was called on to operate he would insist on taking out the entire larynx and the lymphatics.

Other papers on the programme had to be postponed for lack of time.

THIRD DAY.

A paper was presented by DR. ARTHUR AMES BLISS, Philadelphia, on

SEVERE HEMORRHAGE AFTER OPERATIONS ON THE THROAT AND NOSE, WITH A REPORT OF FIVE CASES.

In the absence of the author it was read by title.

DR. F. E. HOPKINS, Springfield, introduced the subject of

SECONDARY HEMORRHAGE AFTER THE USE OF SUPRARENAL EXTRACT.

He said that the universal use of suprarenal extract had caused its value to be so fully recognized, and he himself had been so strongly impressed with the fact

that it enabled them to perform bloodless operations on the nose, and also to cut into the septum internally, that he was unwilling to believe anything against it. Yet he had been forced by experience to acknowledge that there was a danger of secondary hemorrhages occurring, and he thought it his duty to call attention to this danger in order that it might be guarded against, and not at all from any wish to decry the merits of suprarenal extract, or to advise against its use. These secondary hemorrhages came on several hours after the operations, and were often so profuse as to alarm the patient. At first he had supposed that the hemorrhages might be due to the too early removal of the packing, or to some exertion on the part of the patient—to anything, in short, except the trusted suprarenal extract; but he had come reluctantly to the conclusion that there was a likelihood of having more profuse secondary hemorrhages after the use of cocaine and suprarenal extract than after the use of cocaine alone. This opinion was confirmed by the responses he had received to a circular letter he had sent out to other specialists asking their experience. Indeed, so thoroughly was the danger of these secondary hemorrhages recognized by some operators that they always packed the part carefully before dismissing their patient.

Dr. SWAIN said that while he had not noticed any serious increase in hemorrhages after such operations since suprarenal extract had come into use, he thought it natural that the greater contraction caused by a combination of cocaine and suprarenal extract should be followed by a correspondingly greater relaxation. There must always be some after-hemorrhage whether cocaine alone or a combination of cocaine and suprarenal extract was used.

Dr. J. W. FARLOW, Boston, said that he had heard some of his assistants complain of these secondary hemorrhages, but personally he had never had any of the trouble described. The fact that so many others encountered them made him think there must be something in the way of the preparation of the extract or in the treatment to account for the different results.

Dr. A. W. WATSON, Philadelphia, said he had found cocaine just about as useful as suprarenal extract. The reason for the hemorrhages coming on later after the use of the latter was evidently that its action tended to defer the relaxation. He made it a point after administering cocaine always to keep his patients with him until the natural relaxation came on.

Dr. HOPKINS, in his reply, repeated that he did not wish to discourage the use of suprarenal extract, but only to show the necessity of greater care in its use.

A CASE OF OZENA OF PROBABLY SPHENOIDAL ORIGIN

was reported by Dr. J. W. FARLOW, Boston. The patient, a young lady, suffered from nasal discharge and the formation of offensive crusts. She had been treated without success by several physicians before coming to the author of the paper. Dr. Farlow and his assistant took great pains over the case, which proved to be one of a very obstinate character. Ultimately by washing out the sphenoidal sinus such a marked change was effected as to indicate that that was the source of the trouble.

Dr. LOGAN said the case just reported coincided

with two he had had, in which relief was given by opening and draining the cells.

Dr. SAMUEL W. LANGMAID, Boston, expressed the belief that in the near future they would hear of many more cases of sinus inflammation. No doubt influenza was the cause of much of this sinus trouble, and they would probably get cases of chronic sinus inflammation as the result of recent epidemics of the complaint referred to. They ought in all such cases to ascertain the condition of the sinuses, and not be content with the superficial work of spraying the nose.

DrS. WATSON and FARLOW added some remarks on the same lines.

Dr. J. B. CLARK, Boston, contributed two papers:

(1) BULLOUS MIDDLE TURBINATES; (2) TWO CASES OF BENIGN GROWTH OF THE LARYNX.

In regard to the first class of cases, he said that removal of the growth was the one rational treatment.

Dr. A. B. THRASHER, Cincinnati, described a case in which he had successfully removed a fibroma of the larynx.

Dr. C. C. RICE, New York, reported two cases of

PARTIAL PARALYSIS OF THE VOCAL CHORDS,

which, he suggested, were due to over or improper use of the telephone.

Dr. A. W. DE ROALDES, New Orleans, reported a case of the

REMOVAL OF A PIN FROM THE LARYNX

after it had been there two years, causing the child who had swallowed it infinite suffering, and leading it near to death's door before the parents brought it to the reader of the paper for radical treatment. Immediately after the operation the child began to improve, and soon was quite well.

A conversation of some length followed on the removal of pins by other operators, and also as to the best way of removing them.

The report of Dr. D. B. KYLE, Philadelphia, on

A PECULIAR CASE OF MIGRATORY FOREIGN BODY,

with x-ray illustration, was discussed in the same connection.

Dr. T. M. MURRAY, Washington, read a paper on

TRACHEAL INJECTIONS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

In answer to criticisms, he said he did not mean to convey the impression that tuberculosis could be cured by the process indicated. He did maintain, however, that it was a valuable aid to recognized methods of cure, and particularly the climatic one, while it gave the patient much immediate relief.

The other papers, several of which had to be read by title, were: "Correction of the Deviation of the Nasal Septum," by Dr. John O. Roe, Rochester; "Angioma Cysticum of the Nose," by Dr. H. L. Wagner, San Francisco; "The Surgery of the Turbinal Bodies, with a New Method of Operating," by Dr. Boylan, Cincinnati; "Dermoid Cysts of the Nose," by Dr. H. S. Birkett, Montreal; "Recurrent Tonsillar Tumors," by Dr. R. P. Lincoln, New York; and "Hemorrhage from a Peritonsillar Abscess," by Dr. W. F. Chappell, New York.

Recent Literature.

On Diabetes Mellitus and Glycosuria. By EMIL KLEEN, Ph.D., M.D. Pp. 313. Philadelphia: P. Blakiston's Son & Co. 1900.

In 1898 Naunyn published the most comprehensive work on diabetes which has ever been written. In the same year appeared the second edition of Von Noorden's work, based on an observation of 353 patients and Williamson's treatise. In 1899 the friends of Kütz gave to the world the investigations of the late scientist on 1,100 patients and published 692 protocols of his cases. These four volumes are standard works and one naturally looks at a new book on diabetes with a critical eye. Does the author present the sum total of the literature in a clearer manner, is the wealth of his material greater, or has he been more prolific in original work? Only when one or all of these specifications are fulfilled is a new book justified.

Dr. Kleen published the present volume in Swedish in 1898, and a few months ago its translation into English was completed. It opens with the following sentence: "Under the name diabetes mellitus are included different pathologic conditions which, however imperfectly understood, undoubtedly in most cases affect the central nervous system, and which are characterized by a faulty metabolism, as a result of which, under ordinary diet, there takes place the excretion in the urine of an abnormally large amount of sugar." It is only justice to the author and translator to say that the latter part of the book reads more smoothly. The historical review of the subject contains no reference to Dobson's use of opium in the last century or to Rollo's genius in pointing out a hundred years ago that vegetable food should be excluded from the diabetic's diet, which should consist of a restricted amount of animal food and fat. As this is essentially our treatment to-day, Dobson and Rollo deserve credit for their discoveries.

There is a good chapter on the geographical distribution of the affection. "Among all people beyond the pale of culture, diabetes is very rare." "With . . . a more intense culture . . . we are bound to find more diabetes mellitus." As to the influence of diet in the etiology, he thinks "it is too rich a diet, both as regards the mixed nutriment and more especially as regards alcohol, . . . and that the importance of large quantities of starch and sugar has been exaggerated . . . laborers on sugar plantations show no special disposition to glycosuria."

The chapter on glycosuria is simply a compilation of the existing literature, to which the writer contributes but rarely from his own experience. The differences which he points out between simple glycosuria and mild diabetes are well drawn. On page 74 occurs the following sentence in reference to the amount of sugar in the urine: "Higgins and Ogden speak of 20% (?)." If the author had read the article of Higgins and Ogden with even a moderate degree of care, he would not have misquoted them and so found it necessary to doubt their statement. They say nothing about 20% of sugar in the urine.

Symptoms and complications occupy more than a fourth of the book, but the chapter is remarkable by the absence of statistics from the author's own cases. He mentions 3 cases of recovery from diabetes. When the patients came under observation they showed

no sugar, but its presence at an earlier date was certified by reliable authorities. The first was following influenza. Eight and eight-tenths sugar was found in the urine, but six months later the ingestion of 300 grammes of carbohydrates provoked no glycosuria. The second developed after a violent blow on the forehead, and the urine contained sugar a year and a half after the injury, but six months and two years later respectively was sugar free. The third was a teacher in whose urine 7.5% sugar had been found, but five months later was able to take 200 grammes of carbohydrates a day without glycosuria. It would be of great interest to know the condition of these patients after the lapse of a few years. The section closes with an account of 24 cases. We are disappointed again here to find instead of scientific studies simply pleasing narratives of patients. No data are offered regarding the amount of proteids and fats in the patient's diets and only scant records of the carbohydrates. Ammonia and acetone are never quantitated and B-oxybutyric acid is estimated but once quantitatively in the whole book and then only imperfectly. The amount of urea is but rarely stated, and in 3 of the cases there is no record of the twenty-four hour amount of urine.

A chapter of seven pages is devoted to Diabetes Infantilis. That a fourth of even this short account is taken up with the records of 2 cases in girls, fourteen and nineteen years of age, respectively, shows the rarity of the disease in early life. An excellent summary on diabetes following extirpation of the pancreas follows. How conscientiously the author has studied the literature is evident from his discussion of metabolism and nutritive needs. The origin of acetone and diacetic acid in B-oxybutyric acid is clearly brought out. "Whenever I see a frank Gerhardt's reaction with the urine of a patient receiving an abundant supply of calories with his food—which generally presupposes a certain amount of carbohydrates—I know at once that an exclusive diet on meat and fat will not remove the glucose from his urine." That this is not a universal experience the following case, which was furnished us by Dr. Pfaff, will show: A boy came under his care on August 21st. He was on a liberal diet, weighed 90 pounds, and passed 6 to 7 litres of urine daily. The amount of sugar was between 5 and 6% and Gerhardt's reaction was present. On the 26th of October following the weight of the boy was 98 pounds; sugar and the Gerhardt reaction were both absent.

The rules laid down for the investigation of a case of diabetes are good. We feel that much is learned by knowing the amount of urea, as this to a great extent is the measure of the nitrogenous portion of the patient's food. As a rule an excessive amount of urea means neglect on the physician's part to provide his patient with an adequate supply of fat.

The chapter on treatment is disappointing and as far as it relates to diet will we fear do more harm than good. Without adducing a single experiment in support of his position he says: "I have no doubt that this dietetic principle (restriction of proteids) is at present on its last legs." Unfortunately for the writer's conclusion, Naunyn and Lenné give facts to support their position.

One finishes the chapter with the impression that the treatment of diabetes is a *laissez faire* procedure, while on the contrary if there is a disease which taxes the ingenuity, the judgment, the enthusiasm and

skill of the doctor, it is this. The writer lays so much emphasis on the harm of an absolute diet that the good results from such treatment in the prevention and cure of complications, the general well-being of the patient, and the gain in the power of assimilating carbohydrates are not adequately presented. He says: "The disadvantages of the absolute diet, even in mild cases, are unfortunately very great . . . they almost invariably lose flesh." In our opinion, if a mild case of diabetes loses flesh on a diet just strict enough to keep the urine sugar-free, the fault is with the doctor. He does not know how to feed his patient. The author so fears underfeeding his patients and their death from coma that in severe cases, though without B-oxybutyric acid, he allows 80 to 100 grammes carbohydrates in twenty-four hours and in the severest cases of all is forced to the conclusion (not shared by Naunyn, von Noorden, Külz, Lenné, Ebstein) that he promotes "best the interests of such patients by allowing them a generous if not an unlimited amount of bread and potatoes." A pint of cream contains about four times as many calories with only one-third as much sugar forming material as bread, but, strange to say, cream is not mentioned in the whole article on treatment. We agree with Dr. Kleen in recommending ordinary bread instead of diabetic breads and are glad to coincide in general with his views on drugs.

Atlas and Epitome of Special Pathologic Histology.

By DOCENT DR. HERMANN DÜRCK, Assistant in the Pathological Institute; Prosecutor to the Municipal Hospital L. I. in Munich. Authorized translation from the German. Edited by LUDVIG HEKTOEN, M.D., Professor of Pathology in Rush Medical College, Chicago. Circulatory Organs, Respiratory Organs, Gastro-Intestinal Tract. With 62 colored plates. Philadelphia: W. B. Saunders & Co. 1900.

This is a small book composed of 148 pages of text and 62 colored lithographic plates made from microscopical drawings. The volume deals with the special pathological histology of the circulatory and respiratory organs and of the gastro-intestinal tract. Most of the plates have two figures. The lithographic work has been excellently done. The drawing of most of the plates is good. The text consists of short descriptions, in most instances facing the plates, and a condensed discussion of the subjects with which the book deals. The most important defect which we have met with in looking over the book is the treatment of the intestinal lesions in typhoid fever. The plates illustrating these are among the most inferior of the book. We think that the book will be of considerable use to medical students as an aid in their study of pathological histology.

The International Medical Annual Synoptical Index to Remedies and Diseases. For the twelve years 1887 to 1899. New York: E. B. Treat & Co. 1900.

This small volume of 391 text pages aims, as stated in the preface, to "fulfil all the requirements of an ordinary index, and at the same time contain in a very condensed form those facts which are likely to be wanted for reference in everyday practice." This idea has been consistently carried, with the result that in small compass is contained a large number of useful therapeutic facts systematically arranged, which will no doubt be of service to the practitioner.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 19, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE MEDICAL SITUATION IN CHINA.

It is evident that whatever the immediate outcome of events in China may be, the world at large is likely in the future to have a constantly increasing interest in the customs and manners of the Chinese. This is particularly true in matters pertaining to medicine, for the state of medical science in any country is undoubtedly an excellent index of its progress toward civilization. Medicine often runs counter to religious observances, as shown by the prejudice even in our own day in certain quarters against dissection and similar means of studying the human body. If such prejudices have not been wholly overcome, even in communities which boast the highest civilization, it is by no means surprising that in China, where superstition still dominates thought, medical practice is at a peculiarly low ebb. In conversation with a medical missionary some years ago, he said that the difficulties of performing even the simplest mutilating surgical operations were almost insuperable owing to the fanaticism of the Chinese, who were far more willing to die than to enter a future existence cursed with a body devoid of any of its physical attributes. It is clear that for a nation about entering upon what is likely to be a protracted war which will undoubtedly lead to a great loss of life, the prospect is something appalling from the medical point of view. We are unfortunately familiar enough with the fact that deaths from disease in any long-continued campaign are always in excess of the deaths from casualties in action. The boon to modern armies of an efficient and properly equipped medical service has done far more to mitigate the horrors of war than all other means combined. So far as we can learn, this is entirely lacking among the Chinese. The wounded and the sick must die without medical or surgical aid, in any modern sense of the term. To draw a still darker picture, it is altogether depressing to think of the possible fate of prisoners of war whom the Chinese armies may from time to time take. If present indications are to be

trusted, this war will do much to restore conditions under which armies suffered in the Middle Ages.

A recent editorial in the *Lancet* discusses in considerable detail the present situation in China with regard to the condition of medical knowledge. It appears that in all China there are but two schools at which there is an attempt to teach systematic modern medicine and surgery, one at Tientsin and the other at Hong-Kong. Li Hung Chang has been the patron of the school at Tientsin, his idea being to provide physicians trained in western methods for his army and navy. He is said to have stated that "he hoped anatomy and chemistry would form a prominent part in the training of the students, for he held these sciences to be the basis of all true medical knowledge." These are notable sentiments, no doubt shared by a certain number of the better educated among the Chinese, but how small an impression they have made in the country at large is sufficiently shown by the fact that but two schools have been established at which such doctrine could, in any sense, be taught. All the evidence goes to show that practically throughout China the same old superstition and fanaticism regarding medical practice prevails as has prevailed for hundreds of years.

However earnestly and conscientiously the missionary enterprises to the Chinese may have been carried out, we are being forced to the conviction that they have failed, that no material part of the population has been Christianized, and that the very missionaries themselves are being exterminated. We have long been convinced, and have previously expressed our conviction in these columns, that the introduction of modern medical methods into China, quite independently of any creed of which they might be the expression, would accomplish far more than the insistence upon the acceptance of this or that dogmatic belief as a preliminary to scientific progress. In other words, it is desirable that the teaching of the facts of science, and particularly of medical science, should precede the inculcation of doctrine. Recent events appear to have proved the correctness of this position, but the *Lancet* analyzes the situation still further in a way which had not hitherto occurred to us. We quote its conclusions:

The medical missionaries from Great Britain and the United States of America have done a great deal of excellent hospital work in China; but it is perhaps unfortunate that the medical work has been accompanied in almost every instance by religious proselytising. There seems little reason to doubt the fact that the progress of medicine and, what is still more important, the progress of general education and science and even of civilization, have been thwarted by the fact that the converts are in most instances tinged with conversion to a new religion. The young Chinese trained in medicine are almost all Christians, and the fact is deterrent to the advance of medical science amongst the Chinese. We believe that were science to be taught to the Chinese in a purely secular way Christianity might follow, but it seems impossible to civilize the Chinese by means of Christianity. The

Japanese have become civilized irrespectively of Christianity. Encourage secular western education and especially medical science in China, send Chinamen thus trained into every centre and town of China, and a leaven will be introduced and a diffusion of knowledge spread through the length and breadth of China which will in the near future bring many good things in its train — among others, we truly believe, a considerable conversion of Chinamen to Christianity.

It is altogether easy to conceive that with the deeply rooted prejudice against Christianity, the Chinese physician, however skilled he might be, would by the very fact of his identification with the hated foreign religious teachers at once lose his influence over his countrymen. Such advice may be late, but we quite agree with the *Lancet* that the proper method to pursue is to demonstrate the results of Christian civilization first, in the hope that the doctrine underlying such civilization may ultimately be adopted by a sufficient number of the natives to bring about radical reforms. Experience at least has shown that the other order of procedure has led to most unfortunate results.

BRITISH MEDICAL ARRANGEMENTS IN SOUTH AFRICA.

It is a common experience that when an investigation of whatsoever sort is instituted its promoters are very apt to find a justification for their efforts. It is scarcely human to be above criticism, and it appears, on the other hand, always a difficult matter for the investigators to preserve a fair judicial attitude toward the object of their investigation. The criticism of the British Army Medical Service in South Africa is a case in point. It requires no reiteration here to recognize clearly the fact that medical arrangements in time of war, and particularly if that war is being conducted in a foreign country under highly disadvantageous hygienic conditions, are likely to be imperfect, even to the extent of positive danger. The difficulties of the situation must be admitted, and criticism made in a spirit of fairness and with as complete a view as possible of all the facts. The last few weeks have made us familiar with the scathing criticism which Mr. Burdett-Coutts has seen fit to visit upon the British Medical Corps in their treatment of the sick during the South African campaign. We have hitherto hesitated to comment upon the matter, because we felt we were not in possession of information which would permit a fair expression of opinion. It appears to be freely admitted that in certain camps there has been a large amount of typhoid fever and a crowding of the hospitals and improvised shelters far beyond what any one concerned would wish. This means added suffering, no doubt, and very possibly what a critic might regard as neglect. At the same time it must be remembered that the difficulties of providing in all cases proper sanitary arrangements are almost insuperable under such circumstances. We are by no means disposed to palliate faults which might have been corrected, but

we are convinced that a charitable point of view will bring us nearer a just estimate of the entire situation.

The *British Medical Journal* comments on the charges which have been made and publishes a letter from Mr. Treves, which certainly should be given due weight before we hastily attempt in our minds to fix the blame :

There is no doubt, the writer says, that there has been a great deal of typhoid fever in the army, especially among the forces engaged north of the Orange River. Mr. Fripp, the chief surgeon of the Imperial Yeomanry Hospital, in a letter dated June 4th, informs us that he had shortly before visited Bloemfontein and Kroonstad. In Bloemfontein there were at that time over 5,000 sick, most of whom were suffering from enteric fever; while in Kroonstad the three hotels, the town hall, and the church had been converted into hospitals, even the billiard tables being requisitioned to accommodate cases of enteric fever. He adds that as the railway had been opened, the surgeon-general was engaged in rapidly pushing up adequate hospital accommodation. The train in which Mr. Fripp returned brought down 241 sick to Bloemfontein, where they were admitted into one of the general hospitals, bringing the number of sick it contained "to the huge total of 1,800." Mr. Fripp describes the water supply all over the country as extremely bad. "Water," he says, "in the small streams at the bottom of the river beds is often very muddy." Dead horses are generally to be seen in the streams, and they are never above the strong suspicion of being typhoid infected. It is impossible for all water that is required for drinking purposes to be boiled; there is not fuel enough.

Mr. Treves writes a very judicial letter, not however without feeling, at what he regards as the baseless charges made by Mr. Burdett-Coutts. The exact present situation cannot be known to Mr. Treves since he is now in England, but it seems inconceivable to him that a department which withstood so well the trials of the Natal campaign should have suddenly collapsed as its critic implies. We quote some of Mr. Treves's remarks :

My experience had induced me to think that the organization of the army medical service was sound and good, that the general scheme of work and of administration was efficient, and that the lavish arrangements planned by the director-general were carried out by his subordinates in a liberal, thorough and business-like manner. I cannot think that our sick have been treated with "neglect" and "inhumanity," as Mr. Burdett-Coutts asserts. Instead of neglecting their patients the surgeons I met worked with heart and soul, sparing themselves in no particular, and of the untiring and unselfish devotion of the nurses I have already spoken. This war has been a war of surprises. The casualties have been higher than the gloomiest ever dreamt of, and there was no reason to anticipate that the outbreak of enteric fever would assume the enormous proportions it has assumed. I left South Africa with the impression that nothing more could have been done to mitigate the sufferings of the sick and wounded than had been done when a temperate regard for the circumstances of war was kept in mind. The army medical service can lay no claim to the gift of prophecy, nor to the power of anticipating the future, but so far as any reasonable foresight can go the department seems to have done all that in

fairness could have been expected of it. Mr. Burdett-Coutts will, no doubt, substantiate the points detailed in his report, but his preliminary account is conveyed in language which so savors of the theatrical that it fails to carry with it an overwhelming conviction. Mobile field hospitals, if they have to do the work they are intended to do, cannot take beds with them. It is better for a typhoid patient to lie upon a blanket and waterproof sheet on the ground — as Mr. Burdett-Coutts describes — than to be hurried helter-skelter to the base. No human being can tell how the progress of an epidemic may proceed, nor how the numbers of the sick will be distributed. Preparations may be made for 1,000, and the admissions may not reach 10. It is impossible to avoid overcrowding at times, and equally impossible to provide in every detail for emergencies which no reasonable foresight could anticipate. The seat of war is at least three weeks distant from the seat of supplies, and in those three weeks a region free from disease may become the seat of a desperate epidemic. The movements of the troops cannot be exactly foretold. It would be better for the country to be flooded with doctors and nurses rather than that the soldiers should suffer, but it is quite impossible that the medical arrangements can at a time of war overthrow all those circumstances of transport and supply upon which the conduct of the campaign depends. Unfortunately in war the war comes first, but I should imagine that in no campaign has there ever been such solicitous and successful care for the sick.

This whole unfortunate matter must now, no doubt, be sifted down to bottom facts, and we hope it may result in future benefit. As we look at the question from a necessarily superficial and distant point of view, we cannot restrain the conviction that the degree of inhumanity and neglect will be found to be far less than Mr. Burdett-Coutts imagines, however conscientiously he may think he has tabulated the facts of his investigation.

MEDICAL NOTES.

SMALL-POX AND TYPHOID FEVER AT NOME. — It is reported that both of these diseases have appeared at Cape Nome. Quarantine and sanitary arrangements are very imperfect, and unless stringent action be taken considerable epidemics are feared.

INTERNATIONAL CONGRESS OF THE MEDICAL PRESS. — An International Congress of the Medical Press will be held in Paris, beginning July 26th, in connection with the Exposition.

BOSTON.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 18, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 57, scarlatina 18, measles 40, typhoid fever 8.

NEW YORK.

MORTALITY STATISTICS. — The Health Department reports for the month of June show a still further reduction in the mortality of the city. The deaths recorded during the four weeks ending June

30th represent an annual death rate of 17.49, as against 18.83 for the four weeks preceding. The mortality is also less than in the corresponding four weeks of last year, when the death-rate was 18.60. As before, the deaths from pneumonia show the greatest decrease, the weekly average from this disease being 139.5, against 215 in May. The weekly average of deaths from pulmonary tuberculosis declined from 174.5 to 142.5; from bronchitis, from 35.25 to 24.25; from whooping cough, from 14.5 to 8.75; from scarlet fever, from 11.5 to 7; and from influenza, aside from pneumonia, from 7.5 to 4. The mortality from diphtheria, measles and typhoid fever remains about the same. On the other hand, with the advance of warm weather, there has been a considerable increase in the number of deaths from diarrheal diseases, the weekly average for the four weeks in June being 73, against 17.5 in May. In the week ending June 9th there were only 16 deaths from this cause, but in that ending June 30th the number amounted to 171, 160 of which were in children under five years of age.

VACATION SCHOOLS. — The attendance at the opening of the vacation schools of Manhattan on July 8th showed an increased interest in the movement, the number of applicants at most of the schoolhouses being about twice as large as there were accommodations for. There are ten of these vacation schools, each accommodating six hundred, and they are all situated in the crowded tenement-house districts on the lower East Side. The small children are given kindergarten instruction, and for the larger ones are courses in drawing, cooking, dressmaking and manual training of various kinds. The hours are from 9 to 12, and there are frequent trips to Central Park and the large suburban parks. In addition, the playgrounds of the schools are open every afternoon, and instruction is given then in gymnastics and games.

NEW HOSPITAL OF NASSAU HOSPITAL ASSOCIATION. — The new hospital established by the Nassau Hospital Association in Mincola, Long Island, was opened with appropriate ceremonies on June 30th, and among those who made addresses were Dr. Walter B. James, of New York, and Superintendent C. Irving Fisher, of the Presbyterian Hospital, New York. The hospital, which is a large frame building, with wings on either side and an operating pavilion in the rear, standing on a plat of five acres, is designed to supply the needs of the new Nassau County, which consists of that portion of Leeds County which was not included in the limits of Greater New York.

DECISION IN THE FAYERWEATHER WILL CASE. — The final decision in the noted Fayerweather will case was handed down by Judge Lacombe in the United States Circuit Court on July 12th. By the terms of the will, which has now been declared valid, \$210,000 is bequeathed to the Woman's Hospital, \$50,000 each to St. Luke's and the Presbyterian Hospitals, and \$25,000 each to the Mount Sinai Hospital, the Methodist Hospital, Brooklyn, the New York Cancer Hos-

pital, the Manhattan Eye and Ear Hospital, the New York Eye and Ear Infirmary, and the Montefiore Home for Chronic Invalids.

A HEAVY HEART. — In making the autopsy at the morgue, on July 8th, of the body of an unknown man who had died suddenly on the street, Dr. Hamilton Williams, coroner's physician, found that the heart weighed 36 ounces, which is believed to be the largest on record in America. The man's general weight was about 190 pounds.

DEATHS FROM TETANUS. — On July 14th it was reported that four deaths had occurred in New York from tetanus, the result of Fourth of July accidents, which, with one exception, were injuries to the hand from pistols. On the previous day one death in New York and one in Hoboken were reported from the same cause.

Miscellany.

THE INSOLATION CATASTROPHE AT ALDERSHOT.

THE *Medical Press* comments as follows on the recent unfortunate experience of the British troops at Aldershot: 'The unprecedented disaster which befell the troops in training at Aldershot a few days since belongs, like so many of the disasters which have befallen our troops in the field, to the eminently preventable variety. Hot days are not altogether unknown in June, and the provision of suitable headgear is precisely one of the things that a reasonable administration would have taken care to secure. The arrangements as a whole seem to have been a hopeless bungle, for not only were the men marched out regardless of the overwhelming heat and the absence in great part of proper covering for the head, but the commissariat department appears to have miserably failed to fulfil its functions. What can a sprinkling of medical officers do when suddenly confronted with several hundred cases of insolation or heatstroke? Obviously very little, for in such cases moments are precious and instant refrigeration is as imperative as it is unobtainable. Such an occurrence is disheartening, and we trust that the responsibilities will be brought home to the persons to whose want of foresight and organizing capacity the disaster is directly attributable.'

Obituary.

JOHN ASHURST, JR., M.D.

IN the death of Dr. John Ashurst, which occurred July 7th, Philadelphia loses one of her best known practitioners, and this country a man whose work has been generally and favorably recognized. He was born in 1839 in Philadelphia, and in 1860 was graduated at the University of Pennsylvania. He served during the Civil War as an assistant surgeon. He had also been connected with the medical department of the University of Pennsylvania as professor since 1877. In that year he was made professor of clinical surgery, and in 1888 he was elected to the John Rhea Barton Chair of Surgery, which he held up to last

year. Dr. Ashurst was a prolific writer on surgical topics, and as a citizen apart from his profession was highly esteemed in the community in which he lived.

Correspondence.

ETHNOLOGY AND ARCHEOLOGY AT THE PAN-AMERICAN EXPOSITION.

BUFFALO, N. Y., July 3, 1900.

MR. EDITOR:—The Pan-American Exposition has seen fit to entrust the care of the department of ethnology and archeology to a practising physician. I should be very glad if you would allow me to reach your readers with the following request for assistance.

Many members of the medical profession are interested in the study of American ethnology and archeology, and not a few have valuable collections of Indian relics and skeletons from Indian graves. Those not directly interested in this study are so circumstanced as to be aware of the hobbies of their neighbors and could doubtless furnish the address of collectors. I should be greatly obliged for information and for the loan of collections for the use of this department of the exposition. Exhibits which represent study in some special line of American ethnology and archeology will be particularly suitable.

Very truly yours,

A. L. BENEDICT, M.D.,

Superintendent of Ethnology and Archeology.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 7, 1900.

APPOINTMENTS.

The following gentlemen, in addition to those already announced, have been appointed upon the Consulting Board of the New York State Hospital for the care of Crippled and Deformed Children: DRs. SAMUEL B. WARD and A. VANDER VEER, of Albany, JARVIS S. WIGHT and JOHN A. MCCORKLE, of Brooklyn, and RICHARD B. COUTANT, of Tarrytown.

SOCIETY NOTICE.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION. — The twenty-sixth annual meeting of the association will be held Tuesday, Wednesday and Thursday, October 9th, 10th and 11th next, at Asheville, N. C., under the presidency of Dr. Harold N. Moyer, of Chicago.

BOOKS AND PAMPHLETS RECEIVED.

Rochester Academy of Medicine, Constitution and By-Laws. 1900.

The Legal Prevention of Tuberculosis. By Clark Bell, Esq., LL.D., New York.

Transactions of the Massachusetts Medico-Legal Society. Vol. III. No. 2. 1900.

Short Papers on Nursing Subjects. By L. L. Dock, New York. M. Louise Longeway, Publisher. 1900.

Third Annual Report of the Trustees of the Boston Insane Hospital, for the Year ending January 31, 1900.

Conditions of the Throat and Larynx Simulating and Predisposing to Tuberculosis. By Lennox Browne, F.R.C.S.E. Reprint. 1900.

Metropolitan Water Board Investigation. Argument of J. H. Benton, Jr., before Joint Special Committee of Massachusetts Legislature, May 4, 1900.

Nineteenth Annual Announcement and Catalogue of the Woman's Medical College of Baltimore, Session 1900-1901. With the Report of the Hospital of the Woman's Medical College (Hospital of the Good Samaritan), for the year ending January 1, 1900.

A Dictionary of Medicine and the Allied Sciences. Comprising the Pronunciation, Derivation, and Full Explanation of Medical, Pharmaceutical, Dental, and Veterinary Terms; together with much Collateral Descriptive Matter; Numerous Tables, etc. By Alexander Duane, M.D. Third edition. Enlarged and thoroughly revised. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1900.

Lecture.

MORBID CONDITIONS CAUSED BY BACILLUS
AÉROGENES CAPSULATUS.¹

THE SHATTUCK LECTURE.

BY WILLIAM H. WELCH, M.D., LL.D.,

Professor of Pathology, Johns Hopkins University, Baltimore.

MR. PRESIDENT AND FELLOWS OF THE MASSACHUSETTS MEDICAL SOCIETY:—Although the subject which I have chosen for this lecture relates for the most part to infrequent affections, the scientific and practical interest attaching to them is considerable and varied. Many instances of the presence of free gas in parts of the body where it does not normally occur and in association with various diseases were recorded by writers of past centuries and were even then the subject of much speculation. The discussion turned generally around the question whether the gas was atmospheric air or the result of putrefaction—a question which in most cases could be solved only by bacteriological examinations. The most numerous and important of such examinations have been made during the last decade, and, although these have left problems still unsolved, they have corrected many current errors and have shed a flood of light upon conditions which were formerly among the most mysterious in pathology.

While it has been demonstrated that various bacteria may be concerned in producing gaseous affections, it is now evident that the bacillus which I discovered in 1891, and to which I gave the name *Bacillus aërogenes capsulatus*, is the one whose causative agency is best established and most frequently in action. What I shall say will relate mainly to this micro-organism and its pathogenic effects.

Historical.—As a certain amount of confusion concerning the dates of the first publications² on this bacillus exists in foreign literature on this subject, it may be well to state that I reported my observations in November, 1891, to the Johns Hopkins Hospital Medical Society and that the full report of these observations and of the characters of the bacillus was published in July-August, 1892, by Dr. Nuttall and myself.³ E. Fraenkel's first publication⁴ was a short preliminary one which appeared in January, 1893, and was followed in the same year by his valuable monograph on gaseous phlegmons.⁵ In August, 1893, one year after the publication of the paper by Nuttall and myself, appeared simultaneously the interesting articles of P. Ernst⁶ and of Graham, Steward and Baldwin.⁷ Early in 1894, Mann published from my laboratory an observation of emphysematous gangrene caused by *Bacillus aërogenes capsulatus*⁸ and in January, 1896, Dr. Flexner and I published an extensive paper reporting 23 human cases, including not only 6 personal observations of emphysematous gangrene but also examples of submucous gas cysts, pneumoserositis, and various other pathogenic mani-

festations of this bacillus.⁹ In July, 1895, appeared Goebel's preliminary communication¹⁰ and in the following year his full paper on foamy organs.¹¹ Of the subsequent records the most numerous and valuable have appeared in this country, although they appear to be little known to most European writers.¹² I shall have occasion to refer later to many of these publications.

Nomenclature.—Dr. Fraenkel has kindly favored me with cultures of the bacillus which he cultivated from gaseous phlegmons and to which he gave the name "*Bacillus phlegmones emphysematosæ*." There can be no question whatever as to the identity of his bacillus with our *Bacillus aërogenes capsulatus*, a point upon which we are both agreed, and which is also made certain by Goebel's studies under Fraenkel's supervision. According to the generally accepted principles of the nomenclature of zoological and botanical species, the latter name, as being the first one applied, should be preferred to the former. It is, moreover, as pointed out by Muscatello, not open to the objection of implying exclusive relationship to a single disease, as is the case with Fraenkel's designation of the bacillus. As a matter of fact, the capacity to produce gaseous phlegmons is only one of many pathogenic manifestations of *Bacillus aërogenes capsulatus*. Unfortunately I think that we both erred against the canons of botanical nomenclature in using a trinomial rather than a binomial name for a species.¹³

Characters of bacillus.—Since our first publication only one material addition has been made to the extended description given by Nuttall and myself of the morphological and cultural characters of *Bacillus aërogenes capsulatus*, or the gas bacillus, as I shall briefly call it.¹⁴ Fraenkel noted the presence of spores in a few of the bacilli growing in one lot of agar containing sodium formate and in 1897, Dunham¹⁵ observed spores in blood-serum cultures, but not in other media.

Our further studies of the gas bacillus obtained from different sources have shown a moderate range of variation in some of its properties. This is true especially of spore formation, rapidity of liquefaction of gelatine, presence of capsules, retention of Gram's stain, and virulence. While some specimens of the

² Centralbl. f. allg. Path. u. path. Anat., vi, p. 465.

³ Jahrb. d. Hamburg. Staatskrankenanstalten, iv.

⁴ Thus v. Hübner in 1890 (Centralbl. f. Bakt. xxv, p. 513, et seq.) in an elaborate study of pathogenic anaerobes is entirely ignorant of our work and that of other American investigators on *Bacillus aërogenes capsulatus*. The information of Hirschmann and Lindental (Sitzungsber. d. k. Akad. d. Wiss., Math.-Naturw. Cl., Wien, 1899) on the American work is second-hand and both incomplete and inaccurate, in these respects being in unfavorable contrast to that of Muscatello and Gangitano (Riforma Med., 1900, ii, p. 508, et seq.) writing also on the subject of emphysematous gangrene. Knowledge of *Bacillus aërogenes capsulatus*, under the name "*Bacillus perfringens*," has begun to appear in France in the last two years, but without any evidence of acquaintance with the American publications. Even allowing for the great difficulties in keeping pace with the literature of any subject in medicine, a decade would certainly seem sufficient for the light to penetrate even into dark places.

⁵ Migula, who, with considerable success, has attempted to reform bacteriological nomenclature, has given the binomial names "*Bacterium Welchii*" to *Bacillus aërogenes capsulatus* and "*Bacterium emphysematosum*" to *Bacillus phlegmones emphysematosæ* (System der Bakterien, ii, pp. 392 and 385, Jena, 1900). He is, however, in error in describing this organism under two different names, as his *Bacterium Welchii* and *Bacterium emphysematosum* are identical.

⁶ As regards these characters, it will suffice here to say that the micro-organism is a rather coarse, non-motile anaerobic bacillus staining by Gram, growing on all of the ordinary culture media under anaerobic conditions, best at body temperature, but also at room temperature, forming spores incessantly, according to the race and the culture medium, and capable of forming gas not only by fermentation of sugars but also from proteids. The full description of the characters may be found in Welch and Nuttall's paper. The gas, according to Dunham's analyses, is composed approximately of 64% hydrogen, 28% carbon dioxide and 8% of a residual gas believed to be mainly nitrogen. It has no foul odor.

⁷ Bulletin of the Johns Hopkins Hospital, 1897, viii, p. 68.

¹ Delivered before the Massachusetts Medical Society, June 12, 1900.

² Levy's description in 1891 (Deutsche Zeit. f. Chirurg., xxxii.) of "*kleine, feine*" bacilli, cultivated from a gaseous abscess and growing in long threads and chains only at body temperature and cultivable only in the first generation, without animal experiments, cannot be accepted as an identification of *Bacillus aërogenes capsulatus*, or indeed be readily reconciled with its characters.

bacillus seem never to form spores on any culture medium, others, and these appear to be the more common, do so occasionally, especially upon blood-serum, in mannite bouillon, and on plain agar. In animals inoculated with pure cultures we have not observed spore-bearing bacilli.

As a rule the bacillus liquefies gelatine slowly, but some specimens do so scarcely at all, and others with fair rapidity.¹⁶

As stated in our original articles, capsules are not constantly present, but I have generally found no difficulty in demonstrating them in the situations and by the method described by us, and, with the exception of Hirschmann and Lindenthal, most other investigators have been able to demonstrate capsules when these are searched for by suitable methods.

While the bacillus is to be ranked among those which stain by Gram, it is sometimes rather noticeable in cover-slips from cultures that among well stained bacilli others are partly or wholly decolorized, and this may be observed in members of a single chain. In the tissues the bacilli stain well by Gram. Differences in the viability of cultures were pointed out in our first paper.

It sometimes happens that original cultures from human beings show only a feeble growth, with relatively weak power of gas production, while subsequent cultures, especially those obtained after passage through the animal body, present the usual vigorous growth and other typical characters. Pratt and Fulton¹⁷ from a typical case of foamy organs with gas throughout the body were unable to cultivate the bacillus at all, although twelve anaërobic culture tubes containing various media were inoculated from different parts of the body. This negative result they attribute to the fact that the body had lain in a cold-storage vault for sixteen hours after death, an explanation which has some support in an observation previously reported by Welch and Flexner, but still seems hardly satisfactory, as under similar conditions the bacillus has been often cultivated.

Lactose, glucose and saccharose are all fermented by the gas bacillus, the first with the largest production of gas and the last with the smallest. There is apparently no fermentation of mannite, at least the gas is not appreciably more than in sugar-free media. The amount of hydrogen greatly preponderates over that of carbon dioxide.

E. Fraenkel, in 1893, was the first to demonstrate the etiological relation of the gas bacillus to gaseous phlegmons, our previous investigations being concerned mainly with the so-called foamy organs (Schaumorgane) and the presence of gas in the blood, our results being confirmed a year later by P. Ernst. Soon after Fraenkel's publication we were able to confirm his discovery of the causation of gaseous phlegmons by *Bacillus aërogenes capsulatus*, and to repeat with like results his animal experiments.

Material or cultures fresh from the infected body are usually highly virulent for guinea pigs, pigeons and sparrows (E. Fraenkel), which succumb to a rapidly spreading local necrosis of the tissues with abundant development of gas, the bacilli invading the blood during life only in small number or not at

all. There is more or less bloody edema, but otherwise little inflammatory reaction, leucocytes being present usually only in small numbers in the exudate. Rabbits and mice, while not wholly immune, are far less susceptible than guinea pigs and pigeons. Dr. Lanier, in my laboratory in 1896, succeeded in producing typical gaseous phlegmons around the fractured bones of rabbits inoculated intravenously with pure cultures, and Muscatello has obtained the same results. Welch and Nuttall reported an instance of death of a pregnant rabbit after intravenous inoculation, the infection with the gas bacillus originating in a dead fetus. There are considerable differences in the degree of virulence of the bacillus, even in fresh cultures, and old ones may be of slight virulence.

One of the most interesting and valuable tests of the gas bacillus is its power of producing gas abundantly in the blood, organs and tissues of rabbits killed a few minutes after intravenous injection, a power not possessed by colon bacilli. The differential value of this test is as great as that of cultures in fermentation tubes. The blood and tissues of the dead rabbit make the culture medium, the body of the animal takes the place of the test tube, the inoculation is an aseptic one, the bacteria are spread by the blood-current and the conditions are anaërobic. This procedure, which was introduced by Nuttall and myself and has been fully described by us, we have found useful in isolating the bacillus, in separating it from other bacteria which may resemble it, and in the demonstration of one of its most fundamental characteristics, namely, the power to produce gas from proteid material.

Among the points distinguishing the bacillus of malignant edema from *Bacillus aërogenes capsulatus* may be mentioned the following: The malignant edema bacillus is somewhat thinner, has greater tendency to grow into filaments, is less readily stained by Gram, produces spores regularly in culture media, is motile, liquefies gelatine more rapidly, produces a foul odor, produces less gas in lactose bouillon, peptonizes clot casein, generates little or no gas in rabbits inoculated intravenously and then killed, and by subcutaneous inoculation in susceptible animals causes spreading bloody edema with little or no development of gas bubbles, and appears after death in filaments on serous surfaces.

The bacillus to which Lindenthal¹⁸ has quite unnecessarily given the name *Bacillus emphysematis vagina* is doubtless identical with *Bacillus aërogenes capsulatus*. The same is true of Veillon and Zuber's¹⁹ *Bacillus perfringens* found by them in appendicitis, by Guillemot^{19a} in gaseous gangrene, and by Soupault and Guillemot^{19b} in gaseous abscesses, and of Buday's²⁰ *Bacillus cadaveris butyricus*, found in foamy organs. I am strongly inclined to the opinion that the anaërobic bacillus isolated by Achalme and others from several cases of acute articular rheumatism and found by Savtchenko and Mielkich in the soil is likewise identical with our gas bacillus.²¹

Distribution.—The surmise expressed by Welch and Nuttall that the gas bacillus is widely distributed in nature has since been confirmed. The natural habi-

¹⁶ In our original communication we noted peptonization and softening of the gelatine, but this was so slow and slight with the particular specimen studied that we then preferred to class the bacillus among the non-liquefiers. Further experience has shown that the bacillus is a liquefier, but generally a slow one.

¹⁷ Boston Medical and Surgical Journal, June 7, 1900, p. 599.

tat of the organism is the intestinal canal and the soil, the home of so many other anaërobic bacteria. Welch and Flexner in 1896 brought evidence of the presence of the bacillus in both of the situations mentioned. Clopton, of the Johns Hopkins Hospital, has found the bacillus twice in the appendix vermiformis. Howard²² has recently reported the presence of morphologically identical bacilli in the intestines of 25 consecutive human cases examined post mortem, and in 10 of these he demonstrated the bacillus by cultures and inoculation of animals. The same conclusion has been reached by Hirschmann and Lindenthal. The gas bacillus has been repeatedly cultivated from the intestine in my laboratory, but we have made no systematic study of the frequency of its presence. I have found the bacillus also in the intestines of rabbits, dogs and swine, and here it is interesting to note the frequency with which submucous gaseous blebs are found in the pig's intestine at autopsy.

In 1896 Dr. Walker at the Johns Hopkins Hospital succeeded in finding the gas bacillus in dust collected by sweeping floors, proving its presence both by cultures and animal experiments. My assistant, Dr. Harris, has cultivated the bacillus from the contents of an old cesspool. I had previously reported in 1896 the isolation of the bacillus from a bullet removed from the head of the tibia in a case of gaseous phlegmon, and E. Fraenkel²³ has cultivated the gas bacillus from a splinter of wood extracted from a wound in a case of tetanus. These observations confirm the natural inference to be drawn from the study of cases of traumatic emphysematous gangrene, in most of which the source of infection is manifestly foreign material, especially dirt, in wounds. In the light of these demonstrations of the wide distribution of the gas bacillus in the outer world and in feces, the conclusion is warranted that it must occasionally be present upon the human skin.

We are not informed whether there are differences in the regional distribution of the gas bacillus. The fact that during the last decade a larger number of cases of emphysematous gangrene have been reported from Baltimore than from any other single locality is due probably to our interest in the subject and consequent search for cases. The bacillus has been found not only in America and Europe, but Dr. Flexner has brought back reports of three infections with the gas bacillus in Manila observed during a stay of three months.

GAS BUBBLES IN THE BLOOD AND ORGANS.

We turn now to the consideration of the various conditions in which the gas bacillus has been found in human beings. We need not pause to consider the presence of this bacillus in ordinary cadaveric decomposition, a circumstance sufficiently explicable by the occurrence of this organism in the healthy intestinal canal.

Of an entirely different nature are the cases in which gas bubbles are found in the blood and organs within a few hours after death and without any trace of ordinary putrefaction. Such a condition has been recognized at autopsies as soon as one, two, three, five, eight hours after death. It may occur not only after death from gaseous phlegmon, when, however,

it is by no means constant, but also after death from the most varied causes. It has been observed repeatedly in autopsies on pregnant and puerperal women, especially after death from abortion, operation for placenta previa and acute sepsis. There is every gradation from cases with a few bubbles of gas in the blood or tissues to those with extensive emphysema of the organs and tissues. The term "foamy organs" (Schaumorgane of the Germans) may be applied to the latter condition. The liver is the organ most frequently the seat of early and abundant development of gas, but there is no definite rule as to the distribution and amount of gas in different cases. As will be explained later, the invasion in the majority of cases is from the intestine. That the gas bubbles may be dislocated from their original position in liquid and soft material in the body is self evident, but I have not found them unassociated with gas bacilli.

Formerly this early presence of free gas in the heart and vessels, without evident post-mortem decomposition, was very generally explained by the assumption of entrance of air into the circulation, even when no portal of entry could be found.²⁴ The most extensive application of this explanation was made in the pregnant and puerperal cases. It is remarkable that the first case of this nature to be examined bacteriologically was that reported by me in 1891. In this and in all subsequent similar cases with satisfactory bacteriological examination *Bacillus aërogenes capsulatus* was found.

The main questions which arise concerning the interpretation of these cases are whether the invasion of the bacilli and whether the development of the gas are ante-mortem or post-mortem phenomena.

Rabbits survive the introduction of large numbers of gas bacilli directly into the circulation, unless there exists somewhere in the body necrotic or damaged tissue offering little or no vital resistance. If the animal be killed within a few minutes after the intravenous injection of the bacilli and kept in a warm place there are abundant multiplication of the bacilli and large development of gas throughout the dead body within the space of six or eight hours; whereas if the bacilli be introduced at one point, as for example the right heart, of a rabbit just killed, it takes a much longer time, often twenty-four to forty-eight hours, for gas and bacilli to make their appearance at points far distant from the seat of inoculation. It seems justifiable to draw from these three groups of experiments, which have been fully reported by Welch and Nuttall, the conclusion that when bacilli and gas are found within a few hours after death widely distributed in the body, the gas bacilli have entered the circulation during life, but probably in most cases only shortly before death.

There is one factor, however, to be considered which is absent in the experimental cases and may be present in human beings, to wit, the quick disappearance of the bactericidal power of the blood. This factor is an important determinant of the rapidity of onset of post-mortem decomposition. After death from certain diseases, and particularly from snake venom, bacteria may make their appearance in the blood and organs very soon after death. An explanation of these cases is furnished by the experiments of Ewing and myself,²⁵ which demonstrated that the blood of rabbits

²² Contributions to the Science of Medicine, dedicated by his Pupils to William Henry Welch on the Twenty-fifth Anniversary of his Doctorate, p. 461, Baltimore, 1900.

²³ Münch. med. Woch., 1899, Nos. 42 and 43.

²⁴ Cless: Luft im Blute, Stuttgart, 1854, and Couty: Thèse de Paris, 1875.

²⁵ Lancet, 1894, i, p. 1236.

killed by rattlesnake venom is practically devoid of bactericidal power, so that immediately after or even shortly before death bacteria can start growing in the body as they would in a tube of beef broth. But after all due allowance has been made for the possible reduction or loss of bactericidal power of the blood, I still consider that it is not possible to explain some of the cases in which bacilli and gas have been found in the heart, blood-vessels and organs very soon after death, especially when the corpse has been kept in a cold place, otherwise than upon the assumption of the distribution of the bacilli by the circulating blood.

It is another question whether gas as well as bacilli may be present in the circulating blood and internal organs during life in the class of cases now under consideration, and I regret to be unable to furnish a positive answer to this question. I do not see how an affirmative answer can be obtained otherwise than by the actual demonstration of gas in these situations either during life or immediately after death. Gas bubbles and bacilli have been found in the heart and vessels within an hour after death, but that is time enough for bacilli which have already been introduced to multiply and begin to form gas. I at first thought that absence of nuclear staining around the gas bubbles and masses of bacilli might serve as an indication of their presence during life, and this view is advocated by P. Ernst, but I have since learned from experiments on rabbits that this is not a decisive criterion, although often both in rabbits and human beings there is no defect in nuclear staining around bacilli and gas bubbles.

I know of no other pathogenic micro-organism which offers such difficulties in determining whether its effects in the interior of the body have been produced before or after death. The difficulty arises from the circumstance that these effects in most cases and most situations consist almost entirely in local necrosis and formation of gas, whether the invasion and growth of the bacilli be before or after death, and that unlike most pathogenic bacteria the gas bacillus grows better in the dead than the living body. Possibly some importance in the solution of the problem may attach to the demonstration of emboli of liver cells and of bone-marrow cells, which were in enormous numbers in the pulmonary vessels in a case of gaseous phlegmon of the submammary tissues following infusion of salt solution. At the autopsy made by Dr. Carroll the liver and other organs were emphysematous. Further observations with reference to these emboli in this class of cases are needed.

I do not consider that there is any inherent improbability in the supposition that gas bubbles may be in the circulating blood during life without causing speedy death from gaseous embolism. It is only when a large volume of air is introduced quickly into the blood-current that sudden death results from air embolism. Very exaggerated ideas have prevailed among physicians as to the dangers from the entrance into the circulation of small quantities of air. Laborde and Muron²⁶ injected into the external jugular vein of a dog 1,120 cubic centimetres of air in the space of one hour and a half without causing death, and Jürgensen²⁷ into the left femoral artery of a narcotized dog weighing 43½ kilogrammes, 3,650 cubic centimetres in the space of two hours and twenty-five minutes with only

slight disturbance of the respiration and of the action of the heart. Hare,²⁸ likewise, on the basis of experiments, controverts current beliefs in the dangers from entrance of air into veins.

I have come across in the older literature from the days when venesection was a common practice reports of cases in which blood containing bubbles of gas escaped during venesection from veins of the arm.²⁹ In none of these was there evidence that air had gained entrance to the circulation. Maisonneuve³⁰ in incising two gaseous phlegmons of the thigh following compound fracture observed the escape of blood containing gas bubbles from the cut veins, and was able to trace the gas within the veins for a long distance.

It seems to me very improbable that an anaerobic bacillus such as the gas bacillus can multiply in the circulating blood, still this bacillus is less sensitive to the presence of oxygen than many anaerobes, and we do not know whether the loose combination in which oxygen is present in the blood would necessarily prevent its growth under all circumstances.

I see no reason why this bacillus might not multiply in the liver, spleen and most other internal organs, as we know it can do in parts open to inspection during life. We have positive evidence in the cases reported by Graham, Steward and Baldwin and by Dunham that gas bacilli may be conveyed by the circulation from an infected portal of entry — in the one case the puerperal uterus and in the other a urethral wound — to distant parts of the body and there produce subcutaneous emphysema and necrosis. There is no part of the body which offers such favorable conditions for the post-mortem growth of the bacillus as the liver, probably on account of its content of carbohydrate, and if the liver, like the integuments, were open to inspection during life, I believe that we should find evidence that in certain cases the emphysema of this organ, which is such a conspicuous post-mortem phenomenon in instances of invasion by the gas bacillus, had begun during the life of the patient. Emphysema, due to gas bacilli, of mucous membranes open to inspection we know can exist during life. This subject will be considered subsequently.

In the great majority of instances, however, in which gas bubbles are found in the blood and internal organs at autopsy the evidence is in support of the view that the development of the gas is a purely post-mortem phenomenon. Certainly the greatest caution should be exercised in the interpretation of any such cases as vital processes, even in early autopsies without ordinary putrefaction.

One thing which our investigations have established is that the finding of gas bubbles in the blood-vessels and heart within as short a time as one hour after death furnishes in itself no proof of the entrance of air into the circulation. I shall refer later to the question of gaseous embolism in cases of emphysematous gangrene and of physometra.

EMPHYSEMATOUS GANGRENE.

In a few instances we have found in wounds, usually compound fractures or gunshot injuries, in which dirt had gotten in, *Bacillus aerogenes capsulatus*

without the presence of gas or other evidence that the bacillus was producing any characteristic effects.⁸¹ Such cases have always been watched by the surgeons with anxiety and it is probable that at least in some the early recognition of the bacillus, followed by free incisions and thorough cleansing and disinfection, has warded off a subsequent grave infection. In view of the wide distribution of the gas bacillus in the outer world and in the intestinal contents it is probable that it must not so very infrequently gain access to wounds without securing a foothold. While this innocent behavior, with which we are also familiar in the case of the tetanus bacillus, may sometimes be due to attenuated virulence of the bacillus, it is probably oftener attributable to accessory circumstances, such as the resistance of the patient, the condition of the wound and surrounding tissues, and association with other micro-organisms and with foreign substances.

It is as a cause of that most dreaded of wound complications, emphysematous gangrene, that *Bacillus aerogenes capsulatus* especially claims the interest of surgeons. The classical clinical descriptions of this disease we owe to Maisonneuve,⁸² and to Pirogoff,⁸³ the former giving to it the name "gangrène foudroyante," and the latter designating it "primary mephitic gangrene" or "acute gangrenous edema." Among other more or less common designations are "emphysematous or gaseous gangrene," "gaseous phlegmon," "septic emphysema," "érysiplèe bronzé" (Velpeau), "progressive gangrenous edema," "gangrenous septicemia," and "emphysematous cellulitis."

This wound complication was more common in pre-antiseptic times, especially in military surgery, than it is to-day, but at least 70 cases have been reported during the last quarter of a century. In pre-bacterial days the affection was attributed by some writers to the penetration of air into the tissues, but by most to the decomposition of the tissues, particularly of adipose tissue and bone-marrow, brought by an injury into contact with the atmosphere.

Botini⁸⁴ in 1871 was the first to demonstrate the infective nature and transmissibility of emphysematous gangrene. Later Gussenbauer also recognized the disease as a definite infection and attributed it to the bacteria of putrefaction. After Pasteur's discovery in 1877 of his "vibron septique," more commonly, since Koch and Gaffky's investigations, designated *Bacillus œdematis maligni*, and especially after Chauveau and Arloing's⁸⁵ paper in 1884, cases of emphysematous gangrene have been usually reported, especially in France, as instances of Pasteur's gangrenous septicemia or Koch's malignant edema. W. Koch's⁸⁶ attempt to identify the disease with symptomatic anthrax (Rauschbrand) was based on faulty bacteriological studies and has met with no confirmation. In 1884 F. J. Rosenbach⁸⁷ reported finding in cover-slip specimens from two cases of traumatic emphysematous gangrene coarse bacilli, some of which had terminal spores. These emphysema bacilli, as he calls them, he was unable to cultivate, only aerobic

methods being employed. It is probable that Rosenbach saw *Bacillus aerogenes capsulatus* in these cases, but without distinguishing it from associated spore-bearing bacilli.

A critical examination of the records of alleged malignant edema in human beings shows that in very few was the organism concerned satisfactorily identified as the genuine malignant edema bacillus. Very often it has been simply assumed without more than a microscopical examination that bacilli found in spreading edematous conditions with or without gas have been those of malignant edema, and even where cultures and animal experiments have been employed the descriptions are frequently so meagre as to leave the identity of the organism wholly in doubt. In France it is usually assumed without any discussion and even without any bacteriological examination that gangrène foudroyante is malignant edema (Pasteur's septicemia),⁸⁸ and the same ignorance of the present status of this subject is still sometimes encountered in England, Germany and elsewhere. Nevertheless, the investigations of the last seven years, beginning with those of E. Fraenkel, and soon followed by observations of myself and collaborators, have demonstrated that by far the most common and important specific cause of gaseous phlegmons or emphysematous gangrene is *Bacillus aerogenes capsulatus*.

Whether the bacillus of malignant edema can produce an identical or similar anatomical and clinical affection in human beings I regard as an unsettled question. It is certainly remarkable in view of current doctrines in text-books that neither E. Fraenkel nor I, with our relatively large experience, nor indeed, so far as I am aware, any one who has made himself thoroughly acquainted with *Bacillus aerogenes capsulatus*, has encountered an instance of emphysematous gangrene in man caused by the bacillus of malignant edema. The whole subject of human malignant edema is one which needs thorough revision and investigation by more exact bacteriological methods than have yet been applied to it.⁸⁹ I have already mentioned the chief points of difference between the bacillus of malignant edema and *Bacillus aerogenes capsulatus*.

There is a relatively small group of cases of gaseous phlegmon attributed by those reporting them⁴⁰ either to the colon bacillus or the proteus bacillus. In most of these cases anaërobic culture methods were not employed. No one has succeeded in producing experimentally gaseous phlegmon with either of these bacilli, and I think there is good reason to be sceptical concerning their capacity to produce this disease, unless, perhaps, *Bacillus coli* may do so in diabetics.

It is possible that some of those reporting the colon bacillus as the cause of emphysematous gangrene may have confounded with it a facultative anaërobic bacillus which we have isolated from two cases of this disease and which has been studied in my laboratory by Dr. Lanier. It resembles in anaërobic cultures very

⁸⁸ An exception is Guillemot (Bull et mem. Soc. med. d. hôp. de Paris, 1900, 3. s., xvii, p. 216) who has found *Bacillus aerogenes capsulatus* in a case of gaseous gangrene, and who controverts the prevalent belief of authors who attribute this disease exclusively to Pasteur's vibrio.

⁸⁹ In the case reported recently by Bräbe (Wien. klin. Rundschau, 1900, xiv, pp. 145 and 167) the identification of the malignant edema bacillus seems satisfactory. Here there was extensive bloody edema without gas, so that the case was not one of emphysematous gangrene. On the other hand the latest writers on the subject, Häming and Silberschmidt (Correspondenzbl. f. schw. Aerzte, 1900, xxx, p. 361) bring no proof of any consequence that they were dealing, as they supposed, with the malignant edema bacillus in two cases of gangrène foudroyante.

⁴⁰ Chlari, v. Dungen, Bunge, Klemm, Hlava, Evans, Grasberger, Hauser, Margarucci, Muscatello, Hirschmann and Lindenthal.

⁸¹ Such cases have been reported by Bloodgood, of the Johns Hopkins Hospital, in *Progressive Medicine*, December, 1899, iv, p. 158.

⁸⁷ *Die Mikro-Organismen bei den Wund-Infektionskrankheiten des Menschen*, p. 91, Wiesbaden, 1884.

closely *Bacillus aërogenes capsulatus*, but it is capable of aërobic growth also, and then the rods are thinner and more like colon bacilli. It has the power of producing gas abundantly in the blood and tissues of rabbits killed a few minutes after intravenous injection, a power not possessed by genuine colon bacilli. I have already spoken of the importance of this test, which has been employed by none of the writers who have claimed to find colon bacilli as the cause of gaseous phlegmons. This bacillus, when virulent, is capable of causing the same spreading and fatal emphysematous necrosis in guinea pigs and pigeons as is *Bacillus aërogenes capsulatus*.

I have been accustomed to speak of this bacillus, to which I have called attention in previous publications, as the aërobic variety of our gas bacillus. I believe, however, that it is identical with Sanfelice's *Bacillus pseudo-œdematis maligni*,⁴¹ with which he is inclined to identify Klein's "new bacillus of malignant edema."⁴² Chavigny⁴³ has isolated apparently the same bacillus, which he likewise identifies with Sanfelice's *Bacillus pseudo-œdematis maligni* (not to be confounded with the pseudo-edema bacillus of Liborius), from a case of gaseous gangrene, and he also calls attention to the probability that others may have mistaken it for the colon bacillus. While, therefore, unwilling upon existing evidence to accept the colon bacillus as a demonstrated cause of gaseous gangrene (except perhaps in diabetics), I am of the opinion that an aërobic bacillus, probably identical with Sanfelice's *Bacillus pseudo-œdematis maligni*, is capable of producing this affection, but it is much less frequently concerned than *Bacillus aërogenes capsulatus*.

I have collected 46 cases of emphysematous gangrene, in all of which *Bacillus aërogenes capsulatus* was demonstrated, and, therefore, all reported or observed during the last seven years.⁴⁴ This is a far larger number of cases than has ever been brought together before.

Thirty-two are reported by American observers and only 14 by foreign investigators. Of the former group of cases 16 were observed in Baltimore, most of the cultures having been studied in my laboratory; of the foreign group of cases all are reported from Germany, Austria, Italy and France,⁴⁵ 4 by E. Fraenkel, 1 (not absolutely certain) by Passow, 5 by Hiitsch-

mann and Lindenthal, 3 by Muscatello assisted by Gangitano, and 1 by Guillemot.

Cases of gaseous phlegmon in which *Bacillus aërogenes capsulatus* was not demonstrated are not included, although many of these presented the same clinical characters and doubtless in some at least the gas bacillus was the active agent. This is true especially of the cases of gangrène foudroyante, usually without satisfactory bacteriological examination, attributed by French writers to Pasteur's vibron septique. Gertler's⁴⁶ 8 cases of gaseous phlegmon cannot be utilized for our purposes at all, as they are without any satisfactory bacteriological reports.

A complete analysis of these 46 cases would afford material more than sufficient to occupy this entire address, so that I shall be able to present here only some of the more important points.

Thirty-five of the patients were males, 10 females, and of 1 the sex is not stated. The preponderance of males is explained by the fact that most of the cases were due to severe injuries. Robust workmen in the prime of life furnished the largest contingent of cases.

In 80% of the cases one of the extremities was the seat of the emphysematous gangrene, the lower being affected a little over twice as often as the upper extremities. In several instances the emphysema extended from the thigh to the abdominal wall or from the arm to the subcutaneous tissues of the shoulder and chest. There were three examples of primary emphysematous phlegmon of the abdominal wall; of these 1 following removal of the appendix (Bloodgood), 1 from an unrecognized strangulated Littré hernia (Martin) and 1 affecting the deep tissues of a nephrectomy wound (Muscatello). In all of these the infection is believed to have started from the intestine. In one of Dunham's cases there was emphysematous gangrene (originating in a prostatic abscess opening in the buttock) of the scrotum, penis and anterior abdominal and thoracic subcutaneous tissues. In three instances (Carroll, 2; Dobbin, 1, reported by Bloodgood) the breast and submammary tissues were the primary seat of the disease, all of these resulting from the infusion of salt solution. In one case (Dunham) the gaseous phlegmon appeared at the angle of the lower jaw after incision of a foul submaxillary abscess. In one instance (Welch and Flexner) it started within the pelvis from traumatic rupture of rectum and extended through the sciatic notch down the thigh.

Of especial interest are three examples of multiple or metastatic emphysematous gangrene, one of the forearm and opposite shoulder, another of the thigh and both shoulders, and still another of one shoulder and the buttocks. In the older literature are similar cases; thus Nélaton observed emphysemia not only in the injured leg but also in the opposite uninjured extremity. In 1897, Leech⁴⁷ reported without adequate bacteriological examination, a case of emphysematous gangrene of the right leg following about three weeks after injury of the right thumb, which became inflamed, there being no evident local cause of the affection of the leg. These cases are to be explained by transportation of the bacilli through the lymphatic or blood current from the primary focus of entrance.

In all but 5 of the 46 cases the emphysematous gangrene followed traumatic or a surgical operation.

⁴¹ Ann. d. Ist. d'Igiene sper. d'R Univ. di Roma, 1891, n. s., i, p. 365, and Zeit. f. Hyg., 1893, xiv, p. 352.

⁴² Centrabl. f. Bakl., 1891, x, p. 186.

⁴³ Ann. de l'Inst. Pasteur, 1897, xi, p. 860.

⁴⁴ This list includes 16 cases observed in Baltimore, mostly at the Johns Hopkins Hospital, of which 2 are unpublished, and the remaining 14 have been published by Mann (1), *Annals of Surgery*, 1894, xix, p. 187; Welch and Flexner (6), *Journal of Experimental Medicine*, 18'6, i, p. 5; Martin (1), *University Bulletin*, 1896, i, No. 3; and Bloodgood (6), *Progressive Medicine*, December, 1899, iv, p. 158. The notes of an additional unpublished case observed in Manila have been given me by Dr Flexner. There are also 3 unpublished cases for the records of which I am indebted to Dr. Carroll, of Washington. The references to the remaining 26 cases are as follows: E. Fraenkel (4), *Ueber Gasphlegmonen*, Hamburg u. Leipzig, 1893; Passow (1), *Charité-Annalen*, 1895, xx, p. 275; Dunham (5), *Bulletin of Johns Hopkins Hospital*, 1897, viii, p. 68; Ferguson (1), *Transactions of Indiana Medical Society*, 1897, p. 339; Erdmann (1), *Medical Record*, February 5, 1898, p. 205; Le Boutillier (1), *Medical Record*, March 5, 1898, p. 353; Love and Cary (1), *Medical Record*, April 8, 1899; Norris (1), *American Journal Medical Sciences*, 1899, cxvii, p. 195; Hirschmann and Lindenthal (5), *Sitzungsber. d. k. Akad. d. Wiss., Math Naturw. Cl. Wien*, 1899, cviii, Heft. 3, Abth. iii, p. 67; Thorndike (2), *Boston Medical and Surgical Journal*, June 7, 1900, p. 592; Muscatello with Gangitano (3), *Riforma med.*, 1900, ii, pp. 508, 519 and 530; Guillemot (1), *Compt. rend. Soc. de Biol.*, 1898, 10, s., v, p. 1017. A few other cases in which the gas bacillus was found are not reported with sufficient detail to be available for analysis. It is safe to say that *Bacillus aërogenes capsulatus* has now been found in at least 50 cases of gaseous gangren.

⁴⁵ Soupault and Guillemot's (*Compt. rend. Soc. de Biol.*, 1898, 10, s., v, p. 1017) three cases of gaseous abscess came to my notice too late to be included, and perhaps should not be classed under emphysematous gangrene. All were relatively benign.

⁴⁶ *Ueber Gasphlegmonen*. Inaug-Diss. Halle, 1898.

⁴⁷ *Quarterly Medical Journal (Sheffield)*, 1896-97, v, p. 237.

The injuries were as follows: Compound fracture, 18; bullet and gunshot wounds, 7; infusion of salt solution, 3; hypodermic injections, 2; ligation of the femoral artery for aneurism, 3; external urethrotomy, 2; traumatic rupture of the rectum, removal of the appendix, prostatic abscess following self-catheterization, operation for strangulated Littré hernia, incision of a foul submaxillary abscess, and nephrectomy, each 1. Of the 5 non-traumatic cases the gaseous gangrene followed erysipelas in 1, was consecutive to apparently spontaneous gangrene in 2, whether diabetic or not is not stated, and was without apparent explanation in 2 (Fraenkel, Case 2, and Passow).

Compound fractures, and next bullet and gunshot wounds, occupy by far the most prominent place in this list, each of the other various causes being represented only by scattered cases. Those injuries in which there are much laceration and crushing of tissue, comminution of bone and grinding of dirt, bits of clothing or other foreign bodies into the wound are the ones most likely to be followed by emphysematous gangrene. That, however, severe traumatism is not an essential factor is shown by the 5 cases (10% of the entire number) following hypodermic injections and infusion of normal salt solution. These latter, however, were all of patients whose vital forces were greatly depressed, namely, by Asiatic cholera, typhoid fever, surgical shock, or post-partum hemorrhage. There is good reason to believe that the intact tissues of human beings in health possess marked resistance to the gas bacillus.

In the great majority of cases it was evident that the gas bacillus was introduced through the wounded skin from without. In three instances (removal of appendix, strangulated hernia, and traumatic rupture of the rectum) the infection undoubtedly came from the intestine. This was also the probable source of infection in one of Muscatello's cases (gaseous phlegmon in the site of an extirpated kidney). With our present knowledge of the frequent, if not regular, presence of *Bacillus aerogenes capsulatus* in the intestine, there is nothing surprising in this mode of infection. In three of Dunham's cases the infection followed injury of the urethra, and here also the bacilli may have come from the intestine. In one of his cases (gaseous phlegmon at angle of the jaw) it was suggested that the bacilli gained entrance through decayed teeth.

Bloodgood thinks it probable that in one of his cases the gas bacilli were brought by the circulation to the seat of infection. In this case the femoral artery was ligated for traumatic arteriovenous aneurism in the popliteal space. There was no primary infection of the wound, but gangrene of the foot and leg ensued and on incision gas bubbles were found in the blood of the aneurismal sac and the tissues. With what we know about the entrance of intestinal bacteria into the circulation, there is nothing improbable in Bloodgood's opinion. The clot in an aneurism and tissues robbed of their nutrient supply would offer little or no resistance to the growth of bacilli which might reach them or their immediate neighborhood through the circulation, and the conditions would be anaërobic. It was indeed a case of aneurism in which I first found the gas bacillus, and here the clot was swarming with bacilli. It is interesting to note that three of the cases of emphysematous gangrene in

my list followed ligation of the femoral or popliteal artery for aneurism.

Pirogoff⁴⁸ distinguished clinically two groups of cases of traumatic emphysematous gangrene. He described under the name "primary mephitic gangrene" cases in which the emphysema appears within two days after the injury, the "local stupor" passing without inflammatory reaction into crepitating gangrene. Here the emphysematous necrosis spreads rapidly, the patient sinks into collapse with an icteroid hue of the skin, small, thready pulse and cold sweats, and death occurs usually within a few days after the onset. This type of the disease corresponds to Maisonneuve's *gangrène foudroyante*. In the second group, designated by Pirogoff also as "acute gangrenous edema," there is reaction from the primary "local stupor" of the tissues, the emphysema is preceded and accompanied by local edematous or purulent inflammation, is associated with febrile reaction, often appears later after the injury and spreads less rapidly, and presents in general a more varied anatomical and clinical picture than the first class of cases.

Hitschmann and Lindenthal consider that Pirogoff's first group corresponds especially to cases of pure infection with the gas bacillus, and his second group to mixed infections. Erdmann is also of the opinion that in the unmixed infections the emphysematous necrosis spreads more rapidly and is more likely to terminate fatally. On the other hand Muscatello and Gangitano, who also divide the cases into two groups — pure infections and mixed infections — hold that the mixed infections are characterized by the rapidly progressive form of emphysematous gangrene, while the pure infections, at least in their early stage, show little tendency to spread beyond the injured tissues. According to the last named authors the gas bacillus is incapable of exerting any pathogenic action upon healthy tissues, but attacks only tissues already altered in their vitality by injury, other pathogenic micro-organisms, toxins, or other depressing factors.

The study of our cases has not enabled me to adopt either of the two conflicting opinions just stated. Of the collected 46 cases, 30 were mixed infections, 14 were pure, and in 2 there is no clear statement on this point. The most common associated bacteria were the pyogenic streptococci and staphylococci. Other forms found occasionally were *Bacillus coli*, proteus, pyocyaneus, tetanus, Sanfelice's *Bacillus pseudo-œdematis maligni*, and uncultivable, often spore-bearing, bacilli. It seems probable that the bacillus of malignant edema, being a common inhabitant of the soil, must occasionally, like the tetanus bacillus, be present, but it was not isolated from any of these cases. My experience is that if reliance be not placed exclusively upon cultures, but careful microscopical examinations be also made, instances of unmixed infection with the gas bacillus are rare. It is by no means always easy to determine whether associated bacteria are exerting pathogenic action or not. Pyogenic cocci may be present without producing pus or marked inflammatory reaction.

We have found rapidly progressive forms of emphysematous gangrene both with pure infections with the gas bacillus and with mixed infections, and on the other hand we have observed with both types of infection cases in which the tendency to spread is much

⁴⁸ Grundzüge d. allg. Kriegschirurgie, p. 1006, Leipzig, 1864.

less marked. In all of the cases with much purulent inflammation mixed infection was present, but aside from this feature the division of the cases into pure and mixed infections does not, according to our experience, correspond to different, sharply marked, clinical features. Pirogoff's classification is doubtless of clinical value, but there is every gradation between the two groups.

I cannot agree with Muscatello and Gangitano, whose investigations of emphysematous gangrene are of great value, that the gas bacillus is incapable of attacking healthy tissues. Virulent cultures, even in small doses, can produce rapidly spreading gaseous phlegmons when inoculated into the subcutaneous tissues of susceptible animals, such as guinea pigs and pigeons. In human beings the emphysema may extend very rapidly into the healthy tissues, frequently outstripping in its advance the inflammatory edema. This may occur in pure, as well as in mixed, infections with the gas bacillus. It is true, as urged by Muscatello and Gangitano, that toxins derived from the bacilli may prepare the tissues for the invasion and action of the advancing bacilli, but the same explanation has been put forward for the spread of other pathogenic bacteria in healthy tissues. In asserting that the gas bacillus may attack healthy tissues, I would not be understood as minimizing the great importance of the various accessory causes of emphysematous gangrene which act by lowering the vitality of the tissues or the general resistance of the patient or as failing to recognize the marked resistance to infection by the gas bacillus offered by the healthy tissues, a resistance to which I have previously called attention and which I shall have occasion further to emphasize.

Gas may appear in the tissues as early as eight hours after the injury. In a case of gaseous phlegmon following a bullet wound of the knee joint, reported by Welch and Flexner, Dr. Bloodgood recognized gas in the joint⁴⁹ and surrounding tissues just twenty hours after the injury. In a case of Dr. Tiffany's which we have reported, death from emphysematous gangrene, due to pure infection with the gas bacillus, occurred forty-eight hours after a fall causing a compound comminuted fracture of the patella with grinding of the underclothing into the wound. There was no other injury of the body. Any one who has seen one of these rapidly fatal cases of spreading traumatic, emphysematous gangrene will receive an impression which he will never forget.

The anatomical and clinical study of uncomplicated emphysematous gangrene demonstrates that the disease is not, as many formerly supposed, simply an intense variety of ordinary phlegmonous inflammation or cellulitis, but is a disease sui generis. It may be combined with phlegmonous inflammation, but then some other micro-organism, usually the streptococcus, is associated with the gas bacillus.

In typical uncomplicated cases the lesions consist in necrosis of all the tissues, the presence of gas in the interstices, infiltration with blood, evidences of the mechanical action of the gas, and exudation of a variable amount of bloody serum. The amount of gas varies much in different cases. There may be only a few bubbles or the tissues may be everywhere blown up with gas. The nuclei disappear by karyolysis. The

notable thing in most cases is a nearly complete absence of leucocytes and of cellular reaction, although in a few instances, even of pure infection, I have found leucocytes in considerable number, and even purulent foci, but generally at a distance from the primary necrosis. As will be shown later, *Bacillus aërogenes capsulatus* in certain situations is capable of setting up purulent inflammation. In one of our cases, reported by Bloodgood, Dr. Cushing found gas bacilli without gas in a small subcutaneous abscess of a stump two months after amputation of the thigh for emphysematous gangrene of the leg, the amputation having been followed by uninterrupted convalescence.

After death there may be a rapid extension of the subcutaneous emphysema, and at autopsies made a few hours after death gas bubbles may be found in the heart, vessels, liver and other organs, but as to this occurrence there is no rule. As I have already explained, wide-spread distribution of gas in the blood and organs in early autopsies indicates entrance of the bacilli into the circulation during life.

As is to be expected from the etiology of many of the cases of emphysematous gangrene, emboli of fat and of bone-marrow cells are common in the pulmonary capillaries, but I do not know that in any case they contributed to the fatal result.

The prognosis of emphysematous gangrene is more favorable to-day than before the antiseptic period. The disease terminated fatally in 59% of the cases in my list. In the cases observed and treated at the Johns Hopkins Hospital — 10 in number — the fatality was 50%, but of these one was a gaseous phlegmon of the pelvis extending to the thigh, resulting from traumatic rupture of the rectum: a second was a gaseous phlegmon of the abdominal wall following removal of the appendix and complicated with diffuse gangrenous peritonitis, and a third case terminated twenty-five days after disappearance of a gaseous phlegmon of the thigh (treated by incisions) from a late streptococcus infection, gas and the gas bacillus having disappeared. Of the two remaining fatal cases, in one — emphysematous gangrene following compound fracture of the thigh — amputation was refused by the patient until the fourth day, when he was in a state of collapse and died fifteen hours later, and in the other — compound fracture of the skull and both lower extremities — the patient died thirty hours after the accident, having never regained consciousness. When the disease is accessible to surgical treatment, is not complicated by other grave conditions, and is promptly recognized and treated, the prognosis, according to the experience of my surgical colleagues, Professor Halsted and Dr. Bloodgood, is not very unfavorable.

The clinical evidence seems to me to favor the view that, at least in most uncomplicated fatal cases, death is due to toxemia. Norris was unable to demonstrate the presence of strong toxins in artificial cultures of *Bacillus aërogenes capsulatus*, but, as is well known, the same difficulty is encountered with many other pathogenic bacteria which are believed to produce poisons in the human body. Muscatello is also of the opinion that the constitutional symptoms are attributable to toxemia.

The suggestion that death may be due to gaseous embolism is not new. Pirogoff and other of the older observers knew that gas bubbles may be found within the heart and vessels very soon after the death

⁴⁹ It is to be regretted that in the cases reported by Prutz (Deutsch. Zeit. f. Chir., 1898, xlviii, p. 591) as traumatic entrance of air into the knee joint, no bacteriological examination was made.

of patients from emphysematous gangrene. In the discussion on Lungenbeck's paper on traumatic infiltration before the Society of German Military Surgeons in 1870, Senator⁵⁰ advocated the idea that death is caused by gas embolism. While the possibility of this occurrence as the cause of death may be admitted, there is at present no proof of this opinion. Gas bubbles are by no means always found in the blood and organs after death from emphysematous gangrene, and the clinical histories of those in which they are found post mortem do not appear to differ from those when they are absent. In experimental gaseous phlegmons in guinea pigs there is no evidence of the presence of gas bubbles in the circulation during life.

In 1 of our cases (Mann) death resulted from tetanus, and Verneuil⁵¹ has reported 3 cases, which without bacteriological examination he calls malignant edema, where also tetanus intervened. There is nothing surprising in this association when one considers that the home of the tetanus bacillus, like that of the gas bacillus, is the soil. The period of incubation for tetanus is longer than for infection with the gas bacillus, the former appearing rarely before the seventh day, and the latter usually within two or three days after the injury.

Prophylactic measures against emphysematous gangrene are sufficiently obvious from the etiological factors which have already been considered. It is important in wounds of the character most frequently followed by this complication to search microscopically and by cultures for the gas bacillus. The examination of cover-slips will usually suffice for a probable diagnosis. I have already cited instances in which this bacillus has been detected before the onset of emphysema and in which there is good reason to think prompt surgical treatment warded off severe infection. The possibility of infection from the intestinal canal, as well as from external sources, is to be borne in mind.

The cases were treated either by free incisions or by amputation or both. The results were better after amputation than after simple incisions. Of the cases of emphysematous gangrene affecting primarily the extremities, the recoveries numbered 68% after amputation, and 33 $\frac{1}{3}$ % after incision without amputation. Careful study of individual cases shows that amputation is by no means always necessary. Everything depends upon early recognition of the nature of the infection. Dr. Bloodgood⁵² from a relatively large experience says: "If the infection is recognized early, and the destruction of the soft parts and bone is not extensive, free incisions with immediate continuous bath treatment should be tried. If the general symptoms of infection are not immediately relieved, amputation should be done. If, however, the infection is recognized late, one should take no risk but amputate at once. . . . An early diagnosis will probably save life, and from many observations an amputation may not always be necessary."

A similar position as to prognosis and treatment is taken by Muscatello and Gangitano in their valuable paper on gaseous gangrene, in which they also emphasize the value of abundant irrigations with disinfectant and oxidizing solutions. In the service of

Dr. Halsted at the Johns Hopkins Hospital the continuous bath treatment has been found useful. Hirschmann and Lindenthal are certainly mistaken in their assertion that incisions are usually without favorable effect and that early amputations offer the only chance of recover. As pointed out by Thorndike and others, recovery may follow amputation, even when it is impossible to remove the whole of the diseased tissues.

UTERINE INFECTIONS.

Knowledge of *Bacillus aerogenes capsulatus* is of not less interest and importance to the obstetrician than to the surgeon. Infection of the puerperal uterus by this micro-organism leads to a variety of morbid conditions, some comparatively mild, others of the utmost gravity.

The wide distribution of the gas bacillus in the intestinal canal and the outer world renders as explicable the occasional presence of this bacillus in the female genital tract as that of the colon bacillus in the same situation. Lindenthal⁵³ found the gas bacillus in the vagina without the presence of gas or other pathogenic effects, twice out of 6 puerperal cases examined. According to the observations of others, Lindenthal's experience would seem to be exceptional. As with so many other pathogenic bacteria, the mere presence of the organism upon exposed surfaces does not necessarily signify infection.

I shall consider the uterine infections by the gas bacillus under the headings of emphysema of the fetus, puerperal endometritis, physometra, emphysema of the uterine wall, and puerperal gas-sepsis, although these conditions may be associated with each other.

Emphysema of the fetus.—The occurrence of emphysema in the dead fetus in utero has been known for centuries,⁵⁴ but it was not until 1897, when Dobbin published his paper on "Puerperal Sepsis due to Infection with the *Bacillus Aerogenes Capsulatus*,"⁵⁵ that the cause of this condition was determined to be invasion by the gas bacillus. In this case gas and the gas bacillus were both recognized during the life of the patient in the fetus, the placenta and the cavity of the uterus, and after death there was general gas formation throughout the body.

Dr. Dobbin has kindly given me the notes of a second unpublished case observed by him. He was called to see a woman in difficult labor, upon whom repeated attempts at delivery of a dead fetus had been made. Upon examination he recognized crepitation of the caput succedaneum while the fetus was still in utero. Upon delivery the fetus was emphysematous with foamy organs. The gas bacillus was found in pure culture in the fetus and mixed with other bacteria in the amniotic fluid. No gas was recognized in the uterus after delivery. The patient made a good recovery without evidence of sepsis.

Menge and Krönig⁵⁶ have observed three instances of fetal invasion by the gas bacillus and have brought strong evidence that usually the invasion is through the mouth of the fetus, the bacilli being taken into the lungs or stomach by inspiring or swallowing am-

⁵⁰ Wien. klin. Wochn., 1877, pp. 3 and 35.

⁵⁴ It is usually stated that this condition was known to Celsus, but he does not expressly mention the presence of gas, although this is to be inferred. In the chapter on extraction of the dead fetus, he says: "Solet etiam evenire, ut in infans humor distendatur, eaque eo profuata foedi odoris sanies." Milligan's "Celsus," p. 391, Edinburgh, 1831.

niotic fluid. In their cases the bacilli were not found in the part of the umbilical cord attached to the placenta, but in Dobbin's first case this, as well as the placenta itself, was infected with the gas bacillus. The amniotic fluid within the intact membranes, as is well known, is usually sterile, and only exceptionally becomes infected before rupture of the membranes, so that the infection of the fetus from this source is generally after this rupture. As shown by Menge and Krönig, all grades of invasion of the fetus by the gas bacillus occur, so that there may be only a small amount of gas, and this limited to the lungs or the alimentary canal or both. The medico-legal importance of not mistaking for air this gas in the fetal lungs produced by gas bacilli should be emphasized.

As is well known, fetal emphysema is usually unattended with danger to the mother. In 2 of the 5 cases due to *Bacillus aerogenes capsulatus* in my list the puerperium was even without rise of temperature, in 2 there was mild fever, but in Dobbin's first case there was rapidly fatal gas sepsis.

Puerperal endometritis.—Under the heading "gas-sepsis" will be considered cases of acute uterine infection with the gas bacillus followed by invasion of the blood and organs by this organism. Here it may be mentioned that *Bacillus aerogenes capsulatus* may be present in the uterus, usually in association with other bacteria, in both mild and severe cases of puerperal endometritis without the recognition of gas in the fetus or the uterine cavity or wall. An example of such a case is an unpublished one in the service of Dr. J. Whitridge Williams, of which the notes have been furnished me by Dr. Dobbin. A woman with rachitic pelvis, upon whom delivery by forceps had been attempted before admission to the Johns Hopkins Hospital, was there delivered by craniotomy. There was no gas in the fetus. Forty-eight hours later *Bacillus aerogenes capsulatus*, together with streptococci, was found in the uterine lochia. No gas was detected. The patient developed fever, but recovered.

In 2 cases, one reported by Dobbin⁵⁷ and the other by Blumer,⁵⁸ the gas bacillus, although not identified with absolute certainty, was probably present in the puerperal uterus in association with the typhoid bacillus.

Physometra.—Distension of the uterine cavity with gas (physometra, or tympany of the uterus) was present in Dobbin's first case, already cited, and is often associated with emphysema of the dead fetus, but may occur without the latter and even in the non-pregnant uterus. This curious condition was formerly ascribed to entrance of air or to ordinary putrefaction,⁵⁹ but it is now known to be the result of the activity of gas-producing bacilli.

Since the observations of Lindenthal,⁶⁰ reported in 1898, it cannot be doubted that *Bacillus aerogenes capsulatus* is the chief cause of physometra. He found this bacillus in five cases during life and reproduced the condition experimentally in guinea pigs. He is justly sceptical of the correctness of the previous reports of Gebhard⁶¹ concerning the agency of the colon bacillus in generating gas within the uterus. We

know from Theobald Smith's investigations that the colon bacillus can produce gas only from carbohydrates, whereas it is the most distinctive biological attribute of our gas bacillus that it can produce gas from proteids. Until it has been shown that the amniotic fluid and uterine contents may under any conditions contain enough carbohydrate to explain the development of gas by the colon bacillus, there is every reason to question the claims for this bacillus as a cause of tympany of the uterus.⁶²

My list of cases contains ten instances of physometra in which *Bacillus aerogenes capsulatus* was demonstrated. Although, as some of our cases show, this condition may be associated with invasion of the bacilli into the wall of the uterus and by acute gas sepsis, these occurrences are exceptional and the prognosis is in general a favorable one. Most of the cases furnish a good illustration of the resistance of living human tissues to the action of the gas bacillus. Doubtless in these cases the bacilli grow simply in the amniotic fluid after rupture of the membranes, and in the dead fetus, these offering no vital resistance, whereas we must suppose that the intact uterine wall offers ordinarily an effective resistance to the invasion and multiplication of the gas bacillus. That occasionally the bacilli may find other dead material in the uterus, as in sloughing myomata and cancers, is evident from the histories of some cases of physometra.

Emphysema of the uterine wall.—Far graver in significance is septic emphysema of the uterine wall, of which Halban⁶³ has recently reported an interesting case due to *Bacillus aerogenes capsulatus*. Graham, Steward and Baldwin and P. Ernst were the first to demonstrate this bacillus in this condition, their papers, to which reference has already been made, appearing simultaneously in August, 1893. Eleven instances of emphysema of the wall of the uterus, all puerperal, have been reported, of which 5 were recognized during life. In all but Halban's case there was also physometra, and this would seem to be a necessary accompaniment unless the cervical canal is open, so as to permit the escape of the gas from the uterine cavity. All of the cases were fatal, and in most gas was found at autopsy in the blood and internal organs.

Subperitoneal emphysema has been observed after rupture of the uterus, Dischler⁶⁴ having collected reports of 14 cases. In most instances this has been attributed to entrance of air, but I think that it is safe to predict that the gas bacillus will be found in similar cases in the future, if proper methods for its detection are employed. I know, however, of no instance of this condition in which it has been looked for.

Puerperal gas sepsis.—I have adopted from Halban the term "gas sepsis" as a convenient one, although perhaps open to criticism, to designate the important group of fatal puerperal cases in which gas bubbles are found at early autopsies in the heart and vessels and often also in the organs and tissues under conditions where we must suppose that gas bacilli and possibly gas have passed from the uterus into the circulation during life.⁶⁵ Here, in my opinion, belong most of the cases which have been reported as deaths

⁵⁷ American Journal of Obstetrics, 1898, xxxviii, p. 185.

⁵⁸ Ibid., 1899, xxxix, p. 42.

⁵⁹ The older hypotheses and records on physometra and emphysema of the fetus are fully presented by Staude: Zeit. f. Geb. u. Gynäk., 1878, lii, p. 191.

⁶⁰ Monats. f. Geb. u. Gynäk., 1898, vii, p. 269.

⁶¹ Zeit. f. Geb. u. Gynäk., 1893, xxvi, p. 480, and 1897, xxxvii, p. 132.

⁶² Halban (Monats. f. Geb. u. Gynäk., 1900, xi, p. 102) states that he has found lactose once in the amniotic fluid of a normal puerpera. Further studies of this subject are needed.

⁶³ Monats. f. Geb. u. Gynäk., 1900, xi, p. 88.

⁶⁴ Arch. f. Gynäk., 1893, lvi, p. 199.

⁶⁵ Gas sepsis in this sense occurs also in other infections with the gas bacillus than the uterine.

due to the entrance of air into the uterine veins. This opinion, which I expressed in my first communications on the gas bacillus in 1891 and 1892, received prompt confirmation in the papers of Graham, Steward and Baldwin and of P. Ernst, in August, 1893, and has since been strengthened by other similar observations. Cases described by Wendeler⁶⁶ as sepsis acutissima belong also in the same category.

My list includes 12 puerperal cases in which gas bubbles and the gas bacillus were found at autopsy in the blood or organs, but in only 6 of these does it seem to me conclusive or extremely probable that the infection occurred during life.⁶⁷

The most remarkable of these cases is that reported by Graham, Steward and Baldwin, of a woman upon whom abortion had been recently produced, who during the four hours immediately preceding death became emphysematous over nearly the whole body. At the autopsy gas and gas bacilli were found everywhere throughout the body. In Dalton and Bremer's⁶⁸ case, also one of criminal abortion, an emphysematous swelling of the arm and pectoral region was likewise recognized during life. These cases are of importance as demonstrating the invasion of the body by the gas bacillus from the uterus while the blood is still circulating. In Halban's and Dobbin's cases gas was recognized also during life within the wall or cavity of the uterus.

In the majority of cases of puerperal gas-sepsis there has been some operative interference preceding infection, such as criminal abortion, forced delivery for placenta previa or other causes, or the manipulations of an unskilled midwife. The fulminating character of the infection, death being sometimes very sudden, is a notable feature of many of the cases.

In a case of attempted criminal abortion reported by Perkins,⁶⁹ the patient, according to the statement of the practitioner in whose office death occurred, died suddenly, and at the autopsy twelve hours later in cold weather, gas was found in the vena cava, heart, and other vessels, with evidences of injury to the pregnant uterus. The case was reported by Perkins as one of death from air embolism, and certainly with as much and even more plausibility than most cases thus reported. After the publication, Dr. Perkins, upon the request of Dr. Dobbin, was so good as to send the uterus, well preserved in alcohol, to my laboratory, where Dr. Dobbin demonstrated in the uterine vessels and tissue bacilli morphologically and in staining reaction identical with *Bacillus aerogenes capsulatus*.⁷⁰

I would not be understood to deny the possibility of the occurrence of fatal air embolism from the uterus. A very few of the reported cases are difficult to interpret upon any other supposition, but I do claim that the foundations of this doctrine have been seriously shaken by our discovery and investigations of the gas bacillus, and that no case, however plausible, can be considered as positively proven without a satisfactory bacteriological examination. Did we not know how long it takes new knowledge, especially

that originating in this country, to penetrate throughout the medical world, it would be amazing that cases should still continue to be reported, as they are,⁷¹ of deaths ascribed to air embolism without any bacteriological examination or even any reference to the possibility of any other explanation. I am not aware that in any instance of alleged air embolism, a bacteriological examination has been made which would exclude the presence of gas-forming bacteria.

Whether, as suggested by Staude, in any of the cases with gas within the uterine cavity death is attributable to gaseous embolism is, I think, an open question. It is possible, although I know no proof of it, that in some of the cases of sudden death following immediately after some manipulation or operation on the pregnant uterus and attributed to air embolism, gas, generated by bacteria, may have existed under pressure within the uterine cavity and have entered wounded veins in sufficient amount and so suddenly as to have caused death.

To what extent the free gas found in the blood-vessels, heart and internal organs, even very soon after death from what has been described as puerperal gas-sepsis, is there during life is a question difficult to answer. I have already considered this subject, and in this connection will again emphasize the importance of caution in interpreting the presence of gas in these situations as a vital phenomenon, although there is evidence that it may be such.

INFECTIONS OF THE URINARY TRACT.

There is evidence that the urinary tract may not only be a portal of entrance for the gas bacillus into the circulation or adjacent tissues but also be itself the seat of infection by this organism. Unfortunately for the decisive interpretation of many of these cases, *Bacillus aerogenes capsulatus* has, so far as I am aware, hitherto been found in the urinary tract only after death, although in some instances so soon thereafter and under such conditions that its presence during life cannot be doubted.

I have already called attention to instances of emphysematous gangrene following external urethrotomy and other operations on the urinary passages.

Among the cases of general invasion of the blood and organs (foamy organs) by the gas bacillus observed by myself and others are several in which the portal of entry was the urethra, bladder or other part of the urinary tract.⁷² In a case of urethral stricture with cystitis, for which perineal section had been done, reported by Welch and Flexner, gas bacilli were found three-quarters of an hour after death in large numbers in the bladder, ureters and renal pelvis and a few gas bubbles and gas bacilli were already present in the blood of the right ventricle. In Howard's case of meningitis caused by the gas bacillus, to be cited subsequently, he considers that the portal of entry was the urinary tract.

Gas, generated by *Bacillus aerogenes capsulatus*, has been found in the urinary passages in 6 cases which have come to my notice.⁷³ The gas may be either free in the cavity of the bladder, ureters or renal pelvis, or contained within submucous blebs, or in both situations.

⁷¹ Zorn (Münch. med. Woch., 1898, p. 567) may be cited as an example. Gas limited to the right heart may occur from invasion of the gas bacillus.

⁷² Such cases are reported by Welch and Flexner, Goebel, Dunham, and Howard in papers already cited.

⁷³ These do not include some instances of very extensive post-mortem emphysema of the organs with gas everywhere throughout the body.

⁶⁶ Monats. f. Geb. u. Gynäk., 1896, iv, p. 581.

⁶⁷ These are the cases reported by Graham, Steward and Baldwin, P. Ernst, Krönig and Menge, Dobbin, F. C. Wood (Medical Record, April 15, 1899), and Halban, to whose papers references have already been given.

⁶⁸ American Journal Medical Sciences, 1888, xciv, p. 594. This infection, although attributed to the bacillus of malignant edema, was probably due to the gas bacillus.

⁶⁹ Boston Medical and Surgical Journal, 1897, cxxxvi, p. 154.

⁷⁰ Dobbin has reported his examination with further notes of this case in the Monats. f. Geb. u. Gynäk., 1897, vi, p. 375.

Welch and Flexner⁷⁴ have reported an instance of pneumaturia in a diabetic man in whom six hours after death, without trace of cadaveric decomposition, the urinary bladder was found filled with frothy urine containing *Bacillus aerogenes capsulatus* in pure culture. This case indicates that the colon bacillus and *Bacillus lactis aerogenes* are not the sole causes of pneumaturia in diabetics. Dr. Flexner has given me the notes of a second case of pneumaturia upon which he made the autopsy at the University Hospital, Philadelphia. This was of a patient with chronic cardiac disease who had been catheterized twenty-eight hours before admission and who died thirty hours after admission. At the autopsy, made one hour and a half after death, about 60 cubic centimetres of frothy urine were found in the bladder, from which *Bacillus aerogenes capsulatus*, together with *Staphylococcus aureus* and *Streptococcus pyogenes* (no colon bacilli), was cultivated. Neither gas nor gas bacilli were found elsewhere in the body. The mucous membrane of the bladder was edematous. There can be little doubt that in this case the gas bacillus was introduced by the catheter into the bladder.

In one of Welch and Flexner's cases (Case XVIII) of hypertrophied prostate with pyoureter and pyonephrosis, the renal pelvis and ureters were found at autopsy distended with gas and containing pus mixed with bubbles of gas. Small gas cysts were present in the mucous membrane of the renal pelvis. Neither gas nor gas bacilli were present outside of the urinary organs. In this case cocci and colon bacilli were associated with the gas bacillus.

In a case of Dr. Kelly's, of which the full records have been given me by Dr. Miller,⁷⁵ there was pneumonia demonstrated by cystoscopic examination and ureteral catheterization to come exclusively from the inflamed left renal pelvis and ureter. Among cocci and other bacteria were found on cover-slips bacilli morphologically resembling *Bacillus aerogenes capsulatus*, but unfortunately no anaerobic cultures were made. None of the bacteria which grew aerobically produced gas in lactose agar. This case is interesting as demonstrating that the gas may come exclusively from one renal pelvis and ureter, but the micro-organism producing the gas was not satisfactorily demonstrated. It seems certain that it was an anaerobic organism, and from the microscopical appearances may have been the gas bacillus.

The subject of submucous gas cysts will be considered subsequently, but here it may be mentioned that besides the gas cysts in the renal pelvis noted by Welch and Flexner in the case already cited, Goebel found gas blebs containing in pure culture *Bacillus aerogenes capsulatus* beneath the mucous membrane of the urinary bladder, without gas elsewhere in the body, and Dunham has reported a similar condition of the bladder in a case of emphysematous gangrene with general invasion of the blood and organs by the gas bacillus.

Bacteria have been found also in emphysema of the bladder (cystitis emphysematosa) by Eisenlohr,⁷⁶ Camargo⁷⁷ and Kedrowsky,⁷⁸ but it is impossible

from the authors' descriptions to identify their bacteria. Kedrowsky considers the bacillus isolated by him as allied to *Bacillus aerogenes capsulatus*, but less sensitive to oxygen. Perhaps it was Sanfelice's *Bacillus pseudo-œdematis maligni*, to which I have already referred, but Kedrowsky's description of his cultures hardly inspires confidence in their purity.

Welch and Flexner, and Howard have reported finding the gas bacillus in association with other bacteria in inflammatory lesions of the bladder, renal pelvis and kidneys, without the detection of gas. Howard considers that in one of his cases the bacillus was concerned in the etiology of suppurative lesions of the kidneys, but in this case the colon bacillus and *Streptococcus pyogenes* were also present.

INFECTIONS DERIVED FROM THE GASTRO-INTESTINAL CANAL.

Mention has already been made of the frequent, if not constant, presence of *Bacillus aerogenes capsulatus* in the intestinal canal, of gaseous phlegmons originating from this source, and of the readiness with which intestinal bacteria may gain access to the genitourinary tract.

The intestine is by far the most common source of the gas bacilli found together with gas bubbles in the blood and organs at autopsies. This invasion may occur either with or without definite intestinal lesions, and is probably in the majority of cases an agonal or post-mortem event. The mode of distribution and spread of the bacilli in these cases has been well described by Howard,⁷⁹ whose experience has been exceptionally large with this class of affections. Especially demonstrative of invasion of gas bacilli from the intestine, usually post mortem, is the occurrence of gas bubbles limited to the neighborhood of the intestine, as in the intestinal wall, within the portal or mesenteric veins or lymphatics, in the subperitoneal tissue, mesentery and omenta, around the pancreas, in the mesenteric glands, and especially in the loose tissue near the gall-bladder and in the porta of the liver, without gas in more remote situations. I have seen examples of each of these occurrences in very early autopsies without ordinary cadaveric decomposition.

Local gastro-intestinal lesions.—Interstitial emphysema of the gastro-intestinal wall will be considered subsequently.

Howard has described several cases with larger or smaller areas of superficial necrosis of the mucous membrane of the stomach and intestine, in which gas bacilli were present in large numbers. These areas, which may occur either with or without gas cysts, are found most frequently beneath the folds of the valvula conniventes and are characterized by absence of nuclear staining and disintegration of the cells and tissue, usually without marked inflammatory reaction.

Bacillus aerogenes capsulatus may undoubtedly be a cause of meteorism. Instances of this are reported by Welch and Flexner, and by Howard.

Pneumoperitonitis with and without perforation.—My records include 13 cases of diffuse peritonitis in the exudate of which *Bacillus aerogenes capsulatus* was found. Eleven of these were in autopsies made either by Dr. Flexner or myself, 7 having already

⁷⁴ Case XIII of our list in *Journal of Experimental Medicine*, 1896.

⁷⁵ This case is briefly reported by Kelly and MacCallum, *Journal American Medical Association*, 1898, xxxi, p. 376, whose paper may be consulted for the full literature of pneumaturia.

been published by us in 1896. The remaining 2 cases (both being perforations of gastric ulcers) have been reported by Page,⁸⁰ and by Pratt and Fulton.⁸¹ It was the observation of these cases which first called my attention to the frequent presence of the gas bacillus in the intestine.

Ten of the cases were perforative and 3 were non-perforative. Of the former, 4 were the result of perforation of typhoid ulcers, 4 of gastric ulcers,⁸² 1 of strangulated gangrenous intestine and 1 of a cancerous ulcer of the duodenum. In the last case (autopsy fourteen hours after death) the exudate was sero-fibrinous and the gas bacillus was found in pure culture⁸³ and abundantly in the peritoneal cavity and was absent from other organs and the blood. In the other perforative cases the gas bacillus was mixed with other bacteria, although in some instances it predominated. In all of the cases the abdomen was greatly distended with gas and usually there was great tympanites.

I attach especial importance to the case fully reported by Welch and Flexner,⁸⁴ in which we brought conclusive evidence of the occurrence of pneumoperitonitis without perforation, the first of the kind on record in which similar proof was obtained. Since our publication a similar case has been observed by Dr. Flexner in Manila, who has kindly furnished me the notes. At the autopsy, twelve hours after death, there was found hemorrhagic infarction of the lower part of the ileum and adjacent part of the large intestine, caused by the passage of this part of the intestine through a hole in the mesentery. The peritoneal cavity was greatly distended with gas which burnt with a pale blue flame. There was a large amount of frothy, bloody serum in the peritoneal cavity, together with a fibrinous exudate. The most careful examination showed no perforation. *Bacillus aerogenes capsulatus* was obtained in pure culture and abundantly from the peritoneal fluid. Gas was absent from the blood and other organs.

We have found the gas bacillus, mixed with other bacteria, twice in circumscribed, gas-containing, intraperitoneal abscesses resulting from perforation of the appendix vermiformis.

Hepatic and biliary infections. — The development of gas in the liver is so striking a phenomenon in most autopsies where the gas bacillus and free gas are found in the blood and organs that P. Ernst used the term "Schaumleber" for the title of his article on the gas bacillus, published a year after the paper by Welch and Nuttall, in which we first directed attention to the subject of foamy organs and the gas bacillus.⁸⁵ I have already considered the general subject of gas bubbles in the blood and organs, and wish here to call attention especially to infections of the gall bladder and biliary passages by *Bacillus aerogenes capsulatus*.

In cases of foamy liver gas may be found in the bile ducts and gall bladder, but my experience is that, when the gas bacilli reach the liver through the blood-vessels, the appearance of gas in these situations is a rather late occurrence and met chiefly in advanced cases. In contrast to these cases are the observations of gas in the biliary passages, associated sometimes with definite lesions of the bile ducts and liver, where the evidence is that the gas bacilli entered from the intestine directly into these passages. Two such cases have been reported by Howard⁸⁶ and I have observed 2 cases.

Pratt and Fulton⁸⁷ report a remarkable case of cancer of the common bile duct and pancreas in which cholecystotomy was performed, the opening in the gall bladder being stitched to the abdominal walls. At the autopsy the liver was found studded with minute abscesses with greenish translucent walls. In cover-slips, sections and cultures *Bacillus aerogenes capsulatus* was found in pure culture in these small biliary abscesses, but there was no gas in the abscesses, the liver, blood or other organs. A somewhat similar case, in which cholecystenterostomy for gall stones had been performed, was previously reported by Nicholls⁸⁸ from Adami's laboratory. Here also multiple miliary abscesses containing the gas bacillus were found in the liver, but in this case gas was present in the liver as well as in the blood and other organs, the autopsy being six hours after death. Larkin⁸⁹ has likewise reported a case of hemorrhagic pancreatitis with fat necroses and small, multiple hepatic abscesses with gas holes in the liver, from which *Bacillus aerogenes capsulatus* was isolated. The autopsy was eight hours after death.

Hintze⁹⁰ has recorded a post-mortem observation of gas in the inflamed bile ducts with cholelithiasis. He cultivated only the colon bacillus, but it does not appear that he made anaerobic cultures.

From the foregoing cases it is to be inferred that the gas bacillus may invade the bile ducts and gall bladder from the intestine, and sometimes during life, and that it may not only produce gas but also necroses and purulent inflammation. The presence of gall stones, cancer of the bile ducts and operations on the gall bladder appear to favor this mode of infection.

INTERSTITIAL EMPHYSEMA OF THE GASTRO-INTESTINAL, GENITO-URINARY AND BILIARY TRACTS.

One of the most interesting lesions produced by *Bacillus aerogenes capsulatus* is the formation of submucous or subserous gas cysts or blebs, of which the earliest examples attributed to this organism were reported by P. Ernst, Goebel and Welch and Flexner. They are sufficiently common to have been observed by nearly all investigators who have had much experience with the gas bacillus in human beings. My list of cases includes 25 instances of this condition, of which 5 were of the stomach, 11 of the intestine, far oftener of the small than the large intestine, 5 of the gall bladder and bile ducts, 3 of the urinary bladder, 1 of the renal pelvis, and 1 of the vagina. The majority of the cases were observed by Flexner, Howard and myself, and in all the gas bacillus was demon-

⁸⁰ Canada Lancet, May, 1900.

⁸¹ Boston Medical and Surgical Journal, June 7, 1900, p. 599.

⁸² Welch and Flexner have reported an instance of perforated gastric ulcer causing peritonitis in a rabbit, in which the gas bacillus was found.

⁸³ The purity of the culture in this case is explicable by the results of Cushing and Livingood's interesting bacteriological and experimental studies of the duodenal flora published in Contributions to the Science of Medicine, dedicated by his Pupils to William Henry Welch on the Twenty-fifth Anniversary of his Doctorate, p. 543, Baltimore, 1900.

⁸⁴ Case XIII of our list in Journal of Experimental Medicine, 1896, p. 35.

⁸⁵ Heydenreich's paper on "Emphysem der Leber" (Centralbl. f. Bakt., 1897, xxi, p. 305) may be mentioned as a curiosity. He had never heard of the gas bacillus or of any other investigation of the subject later than 1872. In contrast to this is the interesting article of P. Bernhardt on pneumoemathema and foamy organs, with full consideration of the recent literature. Deutsch. med. Woch., 1900, p. 83.

strated. The case of emphysema of the vagina was reported by Lindenthal.⁹¹

These gas cysts vary in size from microscopic dimensions to large blebs. They are most common in the submucous coat, but may be present in the mucous membrane, the muscular coat, or beneath the serous covering; in fact, in any part of the membranous wall. They may be few or in enormous numbers, in groups or scattered. In one of our cases the whole small intestine from the duodenum to the ileocecal valve was studded with small gas cysts. Gas cysts of the same general character may be found in the mesentery and omenta.

These gas cysts are in their inception simply such gas holes as we are already familiar with in the liver and other organs in cases of local or general invasion with the gas bacillus. They indicate a foamy or emphysematous condition of the walls of the stomach, intestine, gall bladder, bile ducts, urinary bladder and vagina, due to the invasion into these parts of the gas bacillus.

The condition of the walls of the blebs and of the surrounding tissues varies. Some of the cavities are round and their walls smooth, others are irregular in shape and have ragged walls. They may correspond to dilated lymphatics, but more frequently they do not represent dilatation of any preformed channels. There may be communication between adjacent cavities, but oftener the cysts are distinct from each other. The tissue in the immediate neighborhood of the cavities may present no alteration not explicable by the mechanical pressure of the gas, or it may show necrosis in varying degree and extent. Inflammatory changes or cellular reaction which could be reasonably referred to the presence of the cysts or of the gas bacilli causing them were not noted. Sometimes a little coagulated, homogeneous or granular material is present in sections of the cysts in hardened tissues, as indeed may often be found in gas holes in the organs.

In sections stained by Gram there is usually no difficulty in demonstrating the relation of the gas bacilli to the cysts. The bacilli may be in masses in the walls of the cysts, but sometimes they are not more numerous there than in the tissue at a distance from the gas blebs, and occasionally it requires some searching to find them. By anaërobic methods the gas bacillus can be cultivated from the cysts or the adjacent tissue.

All of the instances of submucous and subserous gas cysts in my list were observed post mortem. In the larger number of cases gas bacilli and gas bubbles were more or less widely distributed in the blood and organs, but without evidences of ordinary post-mortem decomposition. There are, however, several cases in which these gas cysts in various situations were the sole manifestation of the presence of the gas bacillus in the body. Howard has shown that if careful systematic search is made for areas of necrosis and minute gas cysts due to *Bacillus aerogenes capsulatus* in the stomach and intestine, these lesions can be found much more frequently than has been supposed.

It is with our present information a difficult matter to say in how many of these cases the emphysematous state existed before death. It is certain that, at least in the great majority of cases in my list, the emphysema was not the result of ordinary post-mortem decomposition. In a large number of the cases the

autopsy was made within a few hours after death. Howard in one of his cases of gas cysts, limited to the intestine, made the autopsy one hour after death. I have already emphasized the importance of great caution in interpreting as vital processes the various gaseous conditions of parts and organs not open to inspection during life, even when autopsies are made soon after death and there is entire absence of putrefaction, and I can only repeat this caution here. Mere absence of nuclear staining around gas holes, I do not regard as proof of their origin during life.

It would lead altogether too far to enter here into a discussion of the general subject of submucous gas cysts, concerning which there is a large literature, the principal references to which will be found in the articles of Eisenlohr,⁹² Camargo,⁹³ Winands,⁹⁴ Dupraz,⁹⁵ and Lindenthal.⁹⁶ It would appear from a study of the records of the subject that anatomically different conditions have been described under the designation "gas cysts" (*cystides aëriferae*). Some have been apparently of long standing and show chronic inflammatory changes in their walls and surrounding tissues. The most voluminous literature relates to the gas cysts of the vagina (*kolpolyperplasia cystica* of Winckel, *emphysema vaginae* of Eppinger).

At present we have no warrant to identify the more chronic gas cysts with thickened walls with the more acute emphysematous condition which I have described as referable to *Bacillus aerogenes capsulatus*. Nevertheless the former are probably of bacterial origin also, although I am unable to accept the bacteriological findings of Eisenlohr, Camargo and Dupraz as at all convincing, for they made no use of anaërobic methods of cultivation. It is quite possible that *Bacillus aerogenes capsulatus* is concerned also in the etiology of the gas cysts of long standing; certainly it is important to apply hereafter anaërobic cultural methods to their study. Lindenthal has no hesitation in identifying the emphysema of the vagina observed by him post mortem and from which in a single case he cultivated what he chooses to call *Bacillus emphysematis vaginae* (in reality our *Bacillus aerogenes capsulatus*) with Winckel's *kolpolyperplasia cystica*, but while he may be correct, further observations are needed before this anatomical and etiological identification can be accepted.

The only instance in which gas cysts of the human intestine have been recognized during the life of the patient is reported by Hahn,⁹⁷ who found them in large number upon opening the abdomen. It is to be regretted that no thorough bacteriological examination of this case was made.

In my original communication on the gas bacillus I ventured the surmise that the bacillus found by E. Fraenkel⁹⁸ in hardened sections from a case of gastritis emphysematosa might be identical with *Bacillus aerogenes capsulatus*, and this suspicion has gained in probability by Goebel's statements based upon an examination of the sections, his work having been done under Fraenkel's supervision.

Notwithstanding an effort at compression, so much space has been occupied in the presentation of the

⁹¹ Wein. klin. Woch., 1897, pp. 3 and 35.

foregoing subdivisions of our subject, which in less than a decade has grown to considerable magnitude, that I shall only summarize very briefly a few remaining topics, although all deserve fuller treatment.

Pulmonary and pleural infections.—To the two instances of invasion of the lungs by the gas bacillus reported by Welch and Flexner I can add the cultivation of this organism from a gangrenous lung by Dr. Flexner in my laboratory.

Of much importance is Levy's⁹⁹ demonstration of *Bacillus aerogenes capsulatus* as a cause of pneumothorax without perforation. This case and those of pneumoperitonitis without perforation to which I have already referred have settled affirmatively the long standing controversy concerning the possibility of the generation of gas within closed serous sacs during life.

Nicholls¹⁰⁰ has reported an instance of pneumothorax and pneumocardium without perforation, in which the gas bacillus was probably present. Finley¹⁰¹ and May and Gebhart¹⁰² attribute their 2 cases of pneumothorax without perforation to the colon bacillus, but in neither were anaërobic cultures made. It is important in all gaseous affections to search for anaërobic.

Gas bacillus in the blood during life.—Extremely interesting is the demonstration by Gwyn,¹⁰³ both by cover-slip specimens and by cultures, on repeated examinations, of *Bacillus aerogenes capsulatus* during life in the blood of a patient in the Johns Hopkins Hospital, with chorea insanians and acute endocarditis. I had the opportunity of examining his cultures, which were entirely typical. The patient died, but unfortunately no autopsy could be obtained. There was no evidence during life of free gas in the blood or tissues. The case is of importance as demonstrating that gas bacilli may be in the circulating blood for days in sufficient number to be demonstrable both microscopically and culturally without evidence of free gas. I have already expressed my suspicion that Achalmé's anaërobic bacillus, which has likewise been cultivated from the blood as well as from the tissues of several cases of acute articular rheumatism, is identical with *Bacillus aerogenes capsulatus*.

Presence of the gas bacillus without gas.—In this connection I may say that the gas bacillus may be present and even multiplying within the human body without the production of gas. Certain organs, above all the liver, offer much more favorable pabulum for the generation of gas than do others, but even in the liver the bacilli may be present without gas. I have found gas bacilli in small clumps within the spleen and kidney, surrounded by areas of necrosis, without recognizable gas. I have already cited the demonstrations by Cushing and by Pratt and Fulton of the gas bacillus in small abscesses without gas, the observation of the latter being particularly complete and satisfactory.

Dr. Harris in my laboratory isolated the gas bacillus in pure culture from an abscess containing blood and pus in the neck of a dog, following an operation on the jugular vein. There was no gas in the abscess. Aerobic cultures were entirely negative. These observations, however, are not the only ones demonstrat-

ing that the gas bacillus may under certain circumstances and in certain situations manifest prodigious capacity.

Meningitis: pyogenic capacity of gas bacillus.—Howard¹⁰⁴ in April, 1899, reported a case of acute fibrinopurulent meningitis, following operation for urethroperineal fistula. *Bacillus aerogenes capsulatus* was found in pure culture in the meningeal exudate. Hirschmann and Lindenthal¹⁰⁵ have recorded another convincing example of acute cerebral meningitis following fracture of the occipital bone, in which the gas bacillus was found unmixed with other bacteria. These authors call attention to the pyogenic power of the gas bacillus when it attacks the meninges, but, as already shown, the same power may be manifested elsewhere.

Cavities in the brain.—Finally, I would call attention to Reuling and Herring's¹⁰⁶ and Howard's studies of cavities in the brain produced by *Bacillus aerogenes capsulatus* and to the light which their observations shed upon certain obscure examples of cerebral cavities previously reported.

In this excursion into pneumatopathology I have invited you to the survey of fields comparatively new and little trodden. I can only hope that our journey has been not without some interest and some profit to you. To me the opportunity to present before such a body as the Massachusetts Medical Society the results of these investigations is one which I highly appreciate.

I desire in closing to pay my tribute of respect and to call to your grateful remembrance the founder of this lectureship, Dr. George Cheyne Shattuck. That the subject of this address would not have been without interest to him may be inferred from the title of his first Boylston Prize dissertation on the theme propounded in 1806 and entitled: "The difference between mortification produced by an external cause and that which is produced by a constitutional defect, the diagnostics and proper mode of treatment of each."¹⁰⁷ By his noble character, professional services and liberality Dr. Shattuck deserved well of the medical profession of his city and State and indeed of the whole country, and his memory is worthily perpetuated not only by the foundation of this lectureship but also by the endowment of the chair of pathological anatomy in the Harvard Medical School.

DURATION OF LIFE IN VARIOUS EMPLOYMENTS.—From the following statistics given in the *Medical Record* it will appear that average longevity apparently has little to do with employment which is not in itself dangerous. A general summary shows that the average duration of life has been about sixty-eight years and eight months. Forty-six poets average sixty-six years, 39 painters and sculptors sixty-six years, 30 musicians sixty-two years, 26 novelists sixty-three years, 40 men of letters sixty-seven years, 22 religious sixty-six years, 35 women sixty-nine years, 18 philosophers sixty-five years, 38 historians sixty-five years, 58 scientists and inventors seventy-two years, 14 agitators sixty-nine years, 48 commanders seventy-one years, 112 statesmen seventy-one years.

Address.

THE TRUE FUNCTION OF THE STATE MEDICAL EXAMINING BOARD.¹

BY ALLARD MEMMINGER, M.D.,

Professor of Chemistry and Hygiene and Clinical Professor of Urinary Diagnosis in the Medical College of the State of South Carolina; Visiting Physician in City Hospital of Charleston, etc.

MR. PRESIDENT AND GENTLEMEN OF THE SOUTH CAROLINA MEDICAL ASSOCIATION:—In presenting to the consideration of this august body the question of the propriety of the offices of the State Medical Examining Board as now organized, I trust sincerely my real and true purpose will not be misunderstood as a suggestion for lowering our medical standard, for its design is, on the contrary, to elevate and make that standard more practically useful.

As a teacher in our State Medical College, I hope you may and will regard the outcome of my views as suggested by a long course of observation, and not as in the least actuated by a desire to further alone the well-being of our institution to the detriment of the public good. With these excuses then, if indeed they be necessary, for the selection of my theme, I shall proceed at once to the subject matter of my paper.

(1) The offices of examination to constitute a graduate in medicine; (2) the offices of examination by our State board to constitute the right to practise medicine and surgery in our State.

The requirements for graduation are so well known by all of you here present that I need not take your time by a repetition of the same, but simply call your attention directly to the salient points that must always be kept in view, namely, that a student must have not only a theoretic, so-called, idea of the subject, but as well, a practical application of the same. To this end, the course or courses of our four year graded institutions is divided into two portions.

In the first the theoretic aspect of the branches taught is kept in view almost entirely, and thus the student is not only prepared for what is to follow, but his untrained mind is brought into better condition for the environment by which he is soon to be surrounded, and by imbibing which he is to become a graduate in medicine, and a practical medical man. Observe here, please, the words I use: graduate and a practical medical man.

With this idea then in view, our examinations are, or should be, directed, and for its accomplishment we have divided our course into what are termed junior graduating branches and senior graduating branches; the former dealing more with the theory of the underlying principles of medicine, and the latter with the application of the same. The junior branches are studied for two years, and at the end of this term an examination is held, and if the student attains a graduating excellency, he is allowed to discontinue his further study on these branches, and devote the remaining two years of his studies to the application of his theories gained by his two years' course.

This plan is deemed so advisable that our State Medical College allows the certificates of junior branches passed in other first class four year graded colleges to count, and exempt the holder of the same from standing the examinations on these branches in

our college, thus enabling these students to apply all of their time to the practical aspect of medicine. By this division of labor and study in our colleges, it is found that the students are better prepared to practise in a practical manner than when theory and practice were crowded into two years. Indeed if I mistake not, the trend of medical teaching is now aiming more at bringing our colleges into the line of post-graduate institutions, and thus giving to the public more practical and less theoretical physicians.

Now then let us glance at the offices of the State Medical Examining Board: What do they set out to do? (1) Examine, so as to keep out quacks and charlatans; (2) examine, so as to see whether the diploma of any particular college is upheld by the answers made to questions propounded the applicant for license to practise. Most assuredly with these two objects in view, the charlatan and graduate of a reputable college when he or she comes before the board, are on the same footing; true the board says you must show a diploma, but of what good is such a diploma when this State board is to decide upon the answers of the applicant and not on his credentials.

It is to this point I wish to draw particular attention, for we most assuredly think that the credentials should be allowed a full and just weight in the matter. The credentials or diploma give evidence that the student has studied medicine four years, has graduated in the junior or theoretic branches of medicine, and has also just before coming before this State board been considered worthy of applying this theory to the practice of medicine.

This board then does not show that comity which exists between four year and high standing colleges, but at once commences to examine on the senior and junior branches, which latter the student has put by two years ago, and which with the best of us grow dim in that time. No wonder then that some of the applicants show a less familiarity with these questions than with the senior and practical questions, and in the summing up of the examination may show a lesser total than that required. That such is the case is to be expected until the medical colleges all require a university A.B. or A.M. as necessary before entering the study of medicine.

I as a teacher know full well that questions which are put in chemistry to test the theoretic knowledge of the student, it would be unwise to ask two years after the student has passed, but this is what is expected by the board and which I contend is unwise, as it does not fairly subserve the purposes for which the board was created.

No doubt such an examination would be fair to put to one not holding a diploma, but then we should add this, that if one should pass successfully such an examination, he would be in our judgment fully prepared to practise medicine.

The diploma then of our four year graded medical colleges divided into junior and senior branches is surely deserving of some respect, and should entitle the holder thereof to some more deserving place than in the category of quacks and persons who have never studied medicine.

I would therefore respectfully suggest that the State Board of Examiners work along in the same line as that pursued by reputable four year graded medical colleges, accepting junior certificates as proper credentials of proficiency of having passed in

¹ Read at the Meeting of the South Carolina Medical Association, Charleston, April 19, 1900.

these branches, and paying more strict attention to practical medicine, limiting their examinations for those holding diplomas from four year graded courses to questions absolutely pertaining to the practice of medicine and surgery, and respecting to this slight degree the junior branches, which, as I have already said, grow dim after two years, and which hardly any of you who now listen to me would care to have himself tested on.

For example, would all of you gentlemen who have practised long and I hope well in the various sections you hail from care to answer the questions I now propound, and which have been well answered by many in the junior graduating class of chemistry this year.

QUESTIONS ON PHYSICS, TOXICOLOGY AND CHEMISTRY.

1. When does a liquid boil at 212° Fahrenheit?
2. Explain the upward draught or current in a chimney.
3. What is the effect of gravity, what the cause of pressure, and what is weight?
4. What is solution and upon what does it depend?
5. What is the universal effect of heat and how are heat and cold related?
6. When a moving mass is stopped by friction what takes place?
7. When heat falls upon a body what becomes of it?
8. Mention some of the cooling effects of evaporation.
9. Why is wet clothing injurious to wear.
10. What is the velocity of heat, light and electricity?
11. How is heat, light and electricity conveyed to our senses?
12. What would be the effect of removing the aqueous vapor from the air?
13. Describe the voltaic circuit.
14. State the difference between tonic and clonic contractions.
15. Give the order constituting the reaction of degeneration by the galvanic current.
16. Give the chemical properties of oxygen.
17. Give a like description of sulphur dioxide and chlorine gas.
18. Give one method of production for ammonia gas and phosphorus respectively.
19. Give the salts, with correct formulæ, containing one or more of the following elements: Oxygen, arsenic, potassium, calcium, carbon, iron, antimony, mercury, bromine.
20. Is the following formula correct, and if so, why?
 $As_2 O_3 + 6 HCl + Zn_3 = As_2 + 3 Zn Cl_2 + 3 H_2 O.$
 The atomic weights and valences are as follows:
 As atomic wt. 74.44. Valence, iii and v.
 H " " 1 " i
 Cl " " 35.5 " i iii v and vii.
 Zn " " 65.4 " ii
 O " " 16 " ii

Yes, gentlemen of this association, you all once answered questions of a like kind, but do not let us forget that which we have forgotten, and require this a second time of these students because we ourselves are safe. This lack of due appreciation, and what is deemed injustice to the four year graded course is, I believe, at the bottom of the *unrest* of the students in this and other States as to the rights of State examining boards; it is indeed a wave of discontent that must be met, not by harsh measures, but by just and wise acts.

Let us, therefore, keep ever before us the true office of a State medical examining board, which is neither to give a diploma nor revoke one, but, on the contrary, grant a license to practise — to stand between the honor conferred on the graduate and the exercise

of it on the people. The board, therefore, should busy itself with the clinic and hygienic aspect of the subject, and should feel that by close attention to this the public good is best subserved.

A course then such as I have hurriedly mapped out will not lower the scale of medical education in the State, but, on the contrary, tend to elevate and increase practical teaching, and give out to the State a better class of medical men. What we want is thorough and practical physicians, who will do the public no harm and much good; a State examining board organized then on such lines may aid much in this direction, and at the same time feel that in recognizing a graded course, they further and approve the good work already begun, and not in any way hamper nor render it less effective.

I repeat, I do not wish to abolish the State Board, far from it; I wish to make it, and by it the medical institutions all over our land, more effective, so that in the future a license to practise medicine in South Carolina will carry with it the assurance that the holder thereof is a good, practical physician who, having passed through the alembic of common-sense, is now fit to be a custodian of health in our historic State.

Medical Progress.

RECENT PROGRESS IN NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON.

REFLEXES.

IN a consideration of the more important clinical points in regard to the cutaneous and tendon reflexes in nervous affections, Strümpell¹ speaks first of the methods of irritation. By pricking a very small area of the skin quickly with a pin, whereby only a few nerve endings are excited, a reflex contraction of many muscles may be produced. If the reflex-excitability be diminished the contraction may ensue from long-continued pricking, — the time summation of a circumscribed reflex irritation. It leads us to imagine that the persistent irritation sends fresh waves of sensory impulse which finally break down the resistance. There is also a local summation of reflex irritation, where a number of cutaneous areas are irritated, as in the so-called stroking reflex. The abdominal and cremasteric reflexes among others are excited especially by this local summation from stroking a considerable area of the skin. Cold and pressure may also excite skin reflexes, and in some cases the reflex appears only on the cessation of the irritation. The place of the reflex irritation is also of importance; only certain regions, "reflexogenous zones," are excitable. The sole of the foot is the most excitable region. The reflexogenous zone for the cremasteric reflex may extend down to the foot, and that for the abdominal reflex to the thigh. True skin reflexes very rarely occur in the upper extremity. The reflex seems to vary with the strength of the irritation, and the muscles involved vary with the place of the irritation. The muscular contractions in the skin reflexes are usually of a tonic character. The tendon reflexes are regarded as true reflex processes, as is shown by the occurrence of reflexes in distant muscles and crossed re-

¹ Deutsche Zeitschrift für Nervenheilkunde, xv, 254, September, 1899.

flexes on the opposite side of the body. There is, however, this peculiarity about them, that they are excited only by brief, sudden concussion, which can cause vibration of the parts, and not by any other form of irritation. Time or local summation of the reflex plays no part, the contraction is short and never tonic, and often only a single muscle is affected. The old reflex diagram of a sensory fibre, motor fibre and inhibitory fibre coming from the brain is still useful. The inhibitory fibre, however, is probably not identical with the fibre for voluntary movement, for in certain cases with an enormous increase of the reflexes and muscular hypertonicity there may be very little paresis. The increase in reflex action due to cutting off this inhibitory influence does not affect the skin reflexes. In ordinary cerebral paralysis the skin reflexes are usually diminished, while the tendon reflexes are increased. The explanation of this contradictory behavior of these reflexes is still lacking. It is difficult to believe that there is a persistent irritation of some inhibitory fibres, while others have been cut off; nor is the supposition that the reflex are for the skin reflexes extends upward into the brain wholly satisfactory.

Furthermore, in a few cases of cerebral hemiplegia the knee-jerk is lost on the paralyzed side. In many cases of complete transverse lesion high up in the cord the knee-jerk is absent. The explanation of these facts is obscure, but it is not necessary wholly to abandon the old reflex diagram. The loss of knee-jerk may be due to secondary or co-existing changes in the lumbar cord. These changes may arise from concussion in traumatic cases, or to the secondary changes in the peripheral neurones due to cutting off all the nervous influences from above. The explanation of the different behavior of the skin and tendon reflexes, however, is not easy. The old reflex diagram, although probably correct, is insufficient at present to explain satisfactorily all the clinical phenomena, but we still lack sufficient knowledge for a satisfactory explanation. The object of the reflexes is probably originally protective, but with the higher mental development of man they have lost their importance, and many of them are now merely rudimentary functions.

PUPILS.

Marimò² has undertaken a careful study of pupillary conditions in young children and in a considerable number of hospital cases, and has come to the following conclusions: In about 600 healthy children the pupils are always normal in size and reaction, except that they react very little to painful stimuli. The pupils are very sensitive to toxic influences, such as alcohol and tobacco, even in small amounts, so that in adults these factors are to be considered, if specific causes for alteration of the pupils can be excluded. Anomalies of the pupils are very common in ordinary diseases, manifesting themselves not only in lesser degrees (mydriasis) but in inequality and in changes in the pupillary reflexes. The variations in the diameter of the pupils in the course of a disease and the changes in their reflexes are of considerable value in prognosis. Anomalies are very rare in tuberculosis, more common in anemia, and very common in digestive disturbances. In hysteria and neurasthenia the pupils are dilated or normal, never contracted; inequality and delayed reaction are very rare. In neuralgia the pupils vary greatly, but Marimò never found dilatation on the af-

ected side. In brain tumors there are almost always grave and complex anomalies, but these are less common in cerebral hemorrhage, although here myosis is often seen, and it is a constant symptom in hemorrhage into the pons. There are always marked pupillary anomalies in tubercular basilar meningitis. In cerebral syphilis the pupils are usually unequal. In syringomyelia and multiple sclerosis he found the pupils usually normal; in poliomyelitis there was inequality; in chorea, mydriasis. In epilepsy there was mydriasis in the intervals, and myosis or mydriasis with immobility during the attacks. In tabes myosis and Argyll-Robertson pupils were constant symptoms. Inasmuch, however, as Marimò has studied only a limited number of cases of the various nervous affections his conclusions refer chiefly to them and they can not be regarded as establishing a general rule, as pupillary changes are not uncommon in multiple sclerosis. In this connection reference may be made to a study of the pupils in the hysterical attack by Karplus.³ Most writers claim that the condition of the pupils during the attack is an important diagnostic sign between epilepsy and hysteria; a loss of reaction excluding the latter. In 18 cases of hysteria, where the diagnosis was established by prolonged observation, Karplus found immobility of the pupils during the attack and absence of reaction to light. The pupils are most commonly dilated, but they may be normal or even contracted. The immobility is observed in the first two periods of the grand attack, but it may last for a few minutes after the attack. The pupils behave in precisely the same way as in epilepsy. This immobility is sometimes seen in slight attacks without loss of consciousness. The loss of reflex is a cerebral phenomenon, but it is not psychical or dependent on idea. The psychical influence may start a nervous mechanism which is itself not psychical.

OBJECTIVE SIGNS OF HYPERESTHESIA AND ANESTHESIA.

Bechterew⁴ recognizing the frequency of local hyperesthesia or tenderness and local anesthesia in the various traumatic neuroses, and recognizing also that the ordinary tests depend upon the statements of the patient, considers the various objective manifestations of these conditions, which, in litigation cases where the suspicion of simulation is raised, become of great importance. Bechterew lays special stress upon the test suggested by Mannkopf, which he himself had employed previously—the increase of the heart's activity by pressure upon the alleged painful spot. This test, or variants thereof, such as changes in the pulse curve as taken by the sphygmograph, dilatation of the pupils, flushing of the face, changes in the respiration or the reflexes, following pressure on the tender spot, Bechterew regards as one of the surest objective signs, in spite of the objections which have been made to it. In local anesthetics a diminution of the cutaneous reflexes in the anesthetic area is another objective sign of great value. This anesthesia is often associated with spasm of the peripheral blood-vessels, causing increased coldness of the part and differences in the vasomotor reaction of the skin. In addition, the Mannkopf test may be used in a different manner. The reaction may be obtained in one or more of the ways indicated by painful stimulation of healthy areas;

³ *Jahrbücher für Psychiatrie*, xvii, 1, 1898.

⁴ *Neurologisches Centralblatt*, March 1, 1900.

² *Rivista Sperimentale di Freniatria*, xxv, 451, July, 1899.

the failure to obtain a similar reaction by the same stimulus when applied to the alleged anesthetic area proves the reality of the anesthesia.

Egger⁵ reviews the objections which have been made to this test of Mannekopf's, which objections he considers inadequate, and then gives the results of a series of personal observations made with the aid of a sphygmo-chronograph. Pain was produced by the faradic current. In a healthy person he found that marked pain thus produced increased the frequency of the pulse, usually in direct ratio to the severity of the pain. Muscular exertion and changes in the respiration have also an influence in healthy persons upon the pulse. Individuals vary according to their cardiac irritability. It is a simple matter, however, to exclude the influence of muscular or respiratory effort in testing the influence of pain. The same rule of increase in the pulse holds true in testing painful conditions not due to injury, pressure always increasing the pulse rate. In traumatic neuroses the same holds true. The frequency of the pulse is always increased by sudden pain, the increase depending upon individual peculiarities, especially the degree of cardiac irritability, and the amount of the pain. Where the pain is slight and the heart is not very irritable, the increase is slight. Psychological influences, even the application of electrodes to the tender spot without switching on the current, have much less influence than has been claimed. Muscular effort will increase the pulse, and this must therefore be excluded during the experiment. Respiratory effort, except in the extreme degree, as in Val Salva's experiment of inflating the middle ear, has slight influence. The test is of decisive value in all cases where it is our object to assure ourselves either that a procedure is painful in a healthy person or that there is actually a tender region in the patient under observation.

FACIAL ANESTHESIA IN SYRINGOMYELIA.

Schlesinger,⁶ from a study of five patients affected with syringomyelia, in whom the morbid process gradually ascended into the medulla and involved the nuclei of the trigeminal nerve, has established the relations between the different parts of the nuclei and the areas of the skin which send sensory fibres to these portions of the nuclei. The territories thus determined agree in the main with those described a few years ago by Head, and the distribution may aid in determining between central and peripheral affections. With an ascending lesion involving the trigeminal nuclei the anesthesia is at first noticed on the lateral border of the lateral portion of the forehead; later it invades the skin of the forehead up to the eyebrow and at the same time the lateral portions of the face near the ear. It then advances from the lateral portion to the cheeks and eyelids. The sensibility of the nose remains intact the longest. The first branch of the trigeminal nerve, therefore, arises from two nuclei, of which the most distal corresponds to the skin of the forehead and the most proximal to the skin of the nose. Anesthesia in the whole domain of the trigeminal may be caused by a lesion involving the region below the margin of the pons. When the affection is unilateral the anesthesia extends exactly to the median line. In the pharyngeal and buccal mucous membrane anesthesia first appears with an ascending lesion at the same time with anesthesia of the upper part of

the forehead, in the posterior parts of the mucous membrane of the cheeks, the anterior parts of the velum palati, and perhaps the posterior parts of the tongue. The mucous membrane of the buccal cavity is probably innervated by the distal portions of the spinal root of the trigeminal, but the mucous membrane of the pharyngeal cavity may remain normally sensitive when the buccal cavity is completely anesthetic and analgesic. This idea that there are two varieties in the distribution of anesthesia in the face, a segmental and a peripheral, according as the medulla or the peripheral nerves are affected, corresponds, of course, to the two varieties in the distribution of anesthesia in the trunk and limbs according as the cord or peripheral nerves are affected. Schlesinger's studies have been practically confirmed by the independent investigations of Sölder,⁷ who claims that in all diseases of the spinal cord, whether involving the spinal roots or the gray matter, the anesthesia is of the segmental type, as portrayed by Thorburn, Starr, Head and Koehler. Sölder holds that this segmental type of anesthesia is also found in affections involving the brain stem, and he gives diagrams corresponding in the main to some of the regions described by Schlesinger, showing the boundaries of the various areas. In this connection it may be noted that Hahn⁸ also confirms the existence of this segmental spinal type of anesthesia in the trunk and limbs in syringomyelia, but he has found an increase of the sensory disturbance toward the periphery of the limbs. This, however, is usually limited and is always subordinate to the segmental arrangement, but, in his opinion, it may afford an explanation of the claim made by Brissaud and other French observers, that the sensory disturbances of syringomyelia often assume the cerebral form, that is, that the boundary of the anesthesia is at right angles to the long axis of the limb, and the anesthesia presents the so-called "glove," "sleeve" or "stocking" type. Hahn himself claims that such a distribution is contrary to the facts afforded by the study of other spinal diseases and by anatomical research and, therefore, he doubts if it exists.

SENSORY DISTURBANCES IN TABES.

Frenkel and Fersler⁹ have made a detailed study of the sensory disturbances in tabes, of which only the conclusions have yet appeared as a preliminary communication. They find that disturbances of sensation are a constant symptom and are found both in the pre-ataxic and the ataxic periods. An absence of such disturbances is wholly exceptional and it was found only twice in several hundred observations; in both instances the tabes had been arrested by blindness. The disturbances affect cutaneous sensibility and the deep sensibility of the muscles and joints. Disturbances of the sense of touch are most constant, being found in every case. Disturbances of sensibility to pain are common in the pre-ataxic period and are the rule in the ataxic period; the same is true of sensibility to heat and cold. These disturbances are found localized in a constant fashion upon the trunk, and they may be regarded as an initial symptom of tabes. Even in advanced cases the sensory disturbances may be found only on the trunk. In the pre-ataxic period there may be hypoesthesia in two areas on the breasts and two corresponding areas on the

⁸ Loc. cit., xvii, 54, 1898.

⁹ Revue Neurologique, November 30, 1899.

back. Later on the sensory disturbance involves an area of varying extent encircling the body, often from the axillæ to the umbilicus. In the great majority of cases the tactile sensibility is alone affected, rarely the sensibility to pain. The anesthetic zone may be surrounded by a hyperæsthetic zone and hypo-æsthesia to cold, with delayed perception, is especially common. The arms are also affected as a rule; the disturbance is very common in the pre-ataxic stage and almost the rule in the ataxic stage. The anesthesia forms a band along the ulnar side of the arm, which is typical. This band may be large, involving all the fingers or the hand, but the radial aspect of the arm is only exceptionally affected. Disturbances of the pain sense are also common in the arms, but disturbances of the temperature sense are rare and atypical. Sensory disturbances in the legs are exceptional in the pre-ataxic stage, but they are the rule in the ataxic stage, but, even with marked ataxia, the cutaneous sensibility may remain intact. Disturbances of cutaneous sensibility, however, are the rule in the arms, even when there is no ataxia. The foot is first affected, especially on the plantar aspect of the toes; then the external border of the sole, the entire sole, the dorsal aspect of the toes, and finally the entire foot. The external and posterior aspect of the leg is next involved, and finally the entire leg. Sometimes this anesthesia is associated with anesthesia on the posterior aspect of the thigh and about the arms. The anal and genital regions may be affected without anesthesia of the legs. There is sometimes an area of anesthesia just above the groin, extending backwards to the buttock and in a band down on the scrotum. Rarely there are multiple patches of anesthesia on the legs and in advanced cases the entire leg may be involved. As a rule, the area of analgesia corresponds to that of anesthesia, and it is rare when it exceeds it. In very rare instances there may be sensory disturbances in the neck, face, mouth, tongue, or conjunctiva. It is a general rule, with rare exceptions, that the areas of skin affected by disturbances of sensibility are separated by normal areas, proving that morbid process in tabes is discontinuous and multilocular.

(To be continued.)

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE.

STATED meeting, January 18, 1900, the President, WILLIAM H. THOMSON, M.D., in the chair.

DR. JOHN H. MUSSER, of Philadelphia, read a paper on

MYOCARDITIS.

He mentioned a number of other affections with which myocarditis was apt to be associated or consequent upon, and said that the symptoms of myocarditis were constantly mingled with those resulting from other conditions. He first described the form of myocarditis met with after, and secondary to, pericarditis, and gave an illustrative case. In this instance the aortic and mitral valves were thickened, and the tricuspid valvular orifice was enlarged. The heart muscle was fatty, and the cavities were greatly dilated. In another case mentioned the myocarditis was secondary to valvulitis, and in a third dependent

on pernicious anemia. Myocarditis was classified in general under four heads: (a) Secondary to pericarditis; (b) dependent on endocardial conditions; (c) of toxic origin; and (d) resulting from coronary artery disease.

The general statement might be made that myocarditis is met with most commonly in males just past the prime of life who have probably had syphilitic disease in early manhood. The symptoms referable to the heart might take the form of either dyspnea, syncope attacks, or arrhythmic cardiac action, and whatever the form of these special manifestations, there were certain striking phenomena which the cases had in common. The patient appeared prematurely old, with gray hair and abundance of wrinkles, while the eyelids were heavy and there was an almost characteristic sallow pallor of the countenance. There was usually evidence of endarteritis in the vessels and the physical signs found on examination of the heart might be those of myocarditis alone or in association with dilatation and other phenomena. Reduplication of the second sound was sometimes met with, but less frequently than in valvulitis. There might at times be reduplication, "gallop" rhythm, murmurs and other manifestations, but the most prominent characteristic of the phenomena was their great variability.

The disease was usually progressive, and the fatal termination might come from uremia in connection with concomitant renal disease, from angina pectoris, from pulmonary edema, or from prolonged cardiac dilatation. Myocardiac angina was especially characteristic, and in all the cases of angina pectoris which he had examined post mortem he had found myocardial disease present. In the advanced stages of the disease any slight occurrence in life might bring on the fatal result. In one case where the patient died at the age of fifty-six the subject was under his observation for ten years, during which he underwent an operation for appendicitis under anesthesia without any unfavorable results. In this instance he was at first inclined to the opinion that the cardiac trouble was functional, resulting either from excessive use of tobacco or from gastro-intestinal disturbance, but the increasing frequency of the attacks, notwithstanding the most careful treatment, convinced him of its more serious character. In another case characterized by pain and dyspnea, with enlarged area of cardiac dullness, the only phenomena found on auscultation were reduplication of the second sound and an uncertain murmur.

The first special symptom mentioned as incident to myocarditis was angina; the second was dyspnea. The attacks of dyspnea were due to the rapid outpouring of fluid into the air-vessels and bronchi, and the patient presented the appearance of pronounced shock, with the face pale and the forehead bathed in perspiration. The heart's action was irregular and intermittent. The attacks at first occurred only at long intervals, but as the disease progressed became more frequent. They might be called attacks of pulmonary edema and should be carefully distinguished, especially on account of the treatment, from pulmonary congestion due to acute dilatation. The latter was attended with marked cyanosis, and was most efficiently treated by general or local blood-letting. Certainly in the paroxysmal dyspnea of myocarditis bleeding would be entirely out of place. In myo-

cardial dyspnea the frequency of respiration was not so great as in dilatation of the heart with congestion. In many instances the attacks of dyspnea alternated with attacks of pain. G. T., age forty-nine, addicted to tobacco, a free liver and moderate drinker. For several years has had dyspnea associated with angina-like attacks. Prematurely old; gray hair; temples standing out prominently. No visible cardiac impulse; palpable impulse not extreme. High arterial tension. Area of heart dullness increased; "gallop" rhythm over left ventricle. Evidently the heart muscle is weak. He had known of some instances in which patients suffered from great dyspnea from ordinary walking, but could ride a bicycle for considerable distances with ease.

The third special phenomenon commonly met with in myocarditis was the Stokes-Adams syndrome. In one case with vertigo, high tension and slow pulse, the pulse would fall to 40 or even 30. In another case there were nose-bleed, headache, vertigo, and loss of consciousness followed by sensations of numbness and tingling. In the attacks of syncope the pulse would sometimes fall as low as 28.

The last special symptom referred to was arrhythmia; the heart's action being irregular and intermittent. In one case that he had seen several years ago, this phenomenon was so marked that he felt positive that the patient was suffering from myocarditis, but as time went on he made a complete recovery, and the conclusion was reached that the heart trouble had been due to a toxic agency, probably tobacco.

While these four groups of symptoms might occur independently, it was to be borne in mind that they might be intermingled in the same case. In making a diagnosis we should not depend altogether on the physical examination, but should also take into consideration the patient's family and personal history and his occupation, habits and general appearance. In addition, the fact that the renal pathological process often goes hand in hand with the cardiac was not to be lost sight of.

Dr. HENRY KOPLIK read a paper on

MYOCARDITIS IN INFANCY AND CHILDHOOD.

He said that our present knowledge of myocarditis had been principally obtained from the study of the disease in children, and it was one of the most important of the grave affections of early life. In speaking of its pathological characteristics, he stated that Romberg had found that the diseased action occurred in foci, and was not generally diffused, as in nephritis. The cardiac muscle was peculiarly sensitive to toxic agencies, and myocarditis was liable to be caused by the special poisons of the various acute infectious diseases, as well as by high temperature alone. One of the most striking effects of the modern serum therapy was the action of antitoxin in strengthening the muscular fibre of the heart, as well as fortifying the general system.

He mentioned the case of a child four years old, who, at the age of nine months, had suffered from severe malarial poisoning. As it grew older it became subject to attacks of weakness. There was now no plasmodium in the blood, and as the signs of valvular disease of the heart were absent, he believed that the case was one of myocarditis. At the present time the attacks were less frequent than formerly and it seemed possible that the diseased areas might eventually be

replaced by healthy tissue, and the child entirely recover. He next referred to one case of myocarditis in connection with pneumonia with marked cerebral symptoms, and to another in a case of osteomyelitis in which a sudden attack of pneumonia intervened.

In whooping-cough the heart was subject to great strain, and myocarditis might result not only from the direct effect of the violent paroxysms, but also from the special poison of the disease. In rheumatic pericarditis adherent pericardium was a very common result, and it was not difficult to understand how myocarditis might sometimes arise from this cause. It was certainly very difficult to make a positive diagnosis of myocarditis during life, but a probable diagnosis could often be made, and it should always be borne in mind that the muscular fibre of the heart was liable to this serious degenerative disease. In the diseases of children it was of great importance to support the heart, as well as the general strength of the patient, remembering that even in myocarditis there are left areas of healthy tissue which may be sufficient to enable the organ to perform its functions adequately.

Dr. EDWARD G. JANEWAY thought that while in some cases the characteristics of myocarditis pointed out by Dr. Musser were sufficiently evident, there were others in which it was extremely difficult for even expert clinical observers to make a correct diagnosis. He recalled one case in which the patient had hydrothorax on the right side and was sent to Colorado under the impression that he had tubercular pleurisy. There was nothing about the color or appearance of the man to suggest myocarditis, and, with the exception of being somewhat enlarged, the heart appeared to be entirely normal on examination. In the urine there was no albumin and no casts. He was aspirated some twenty times. Later he became delirious and finally died. At the autopsy there was found myocarditis, with fluid in the right chest and a periarthral gumma constricting the coronary artery.

Myocarditis, he believed, was very liable to be mistaken for tuberculosis. It was well to remember, however, that there might be found a few bacilli in cases where there really was no tuberculosis. When attacks of angina occurred a mistake might be made in not recognizing the gravity of the trouble present. Such attacks, really due to myocarditis, were sometimes attributed to digestive disturbances for the reason that they were liable to take place after a meal.

Dr. ISAAC ADLER said that formerly two types of myocarditis were recognized, but he thought that this distinction could no longer be made. At a very early stage of the disease the muscular fibres gave way and became degenerate, and he had never seen any specimen of myocarditis under the microscope in which the two types, proliferation of cellular tissue and degeneration of muscular fibre, were not united. No heart was entirely degenerate, some areas always being found in which the tissues remained intact. There was one point to which he desired to attract attention. The condition of the auricles, he thought, had been neglected to a very great extent, and he was convinced that the cases of myocarditis with pulmonary edema, owe their clinical features mainly to the fact that the auricles are principally affected.

Arterial sclerosis was commonly regarded as a disease of senile life, but in a considerable number of cases it occurred soon after puberty, and such individuals were especially liable to myocarditis. It was

principally in males, and often depended on syphilis and other toxic conditions, particularly the use of tobacco. That tobacco heart was a sclerotic heart. Heredity was also a prominent factor, and in certain families distinct sclerosis and sometimes myocarditis were found under the age of thirty.

DR. MUSSER, in closing the discussion, said he regretted that he had not stated as positively as he might have done that quite a number of cases of myocarditis occur which during life present no evidence of the disease. The peculiar countenance which he had described was by no means always present, but when it was present it constituted one of the most suggestive aids to diagnosis. The occurrence of right-side effusion in myocarditis, as had been referred to by Dr. Janeway, was of great interest, and could readily be explained on anatomical grounds.

Recent Literature.

Food for the Sick and How to Prepare it; with a Chapter on Food for the Baby. By EDWIN CHARLES FRENCH, M.D. Louisville: John P. Morton & Co.

The author of this little book of 171 pages is not alone in believing in the importance of properly prepared and chosen food in the treatment of the sick. Certain simple physiological principles regarding the action of various foods are given, in connection with a limited number of diseases. What may be taken with advantage is given in detail, and what should be avoided is alluded to. Methods of cooking and preparing foods are discussed at considerable length in the latter part of the book. This portion smacks somewhat of a cook book, which, however, we regard as no disparagement. Infant feeding has a few pages devoted to it, a necessarily superficial consideration of an extremely important subject. We confess to a feeling of doubt as to the necessity of a book of this sort, and it is a little difficult to see to what class of readers it will appeal. The typography is sufficiently good and the subject matter conveniently arranged.

A Manual of Clinical Diagnosis by Microscopical and Chemical Methods. For Students, Hospital Physicians and Practitioners. By CHARLES E. SIMON, M.D., late Assistant Resident Physician Johns Hopkins Hospital, Baltimore. Third edition, thoroughly revised. Illustrated with 136 engravings and 18 plates in colors. Philadelphia and New York: Lea Brothers & Co.

This edition of Dr. Simon's Clinical Diagnosis is an octavo volume, with index, of 563 pages. We have dwelt upon the merits of the book in a previous notice. The aim of the book is to aid and elucidate laboratory diagnosis. This new edition has been brought up to date. The parasitology and bacteriology of the blood, saliva, feces, urine and vaginal discharge have been rewritten. New methods of chemical examination have been incorporated in the book.

Diseases of the Intestines. A Text-book for Practitioners and Students of Medicine. By MAX EINHORN, M.D., New York. New York: William Wood & Co. 1900.

This volume of about 400 pages is a companion and continuation of a similar book by the same author on "Diseases of the Stomach," the two together covering

the principal disorders of the digestive tract. The writer dedicates his book to Von Leyden, of Berlin, and follows in large measure in the track of the labors of the German school, of which Von Leyden and Ewald are perhaps the most distinguished representatives. There was room for a book in English on this subject, and the author has produced a very competent and conscientious work.

Diseases of the Stomach, their Special Pathology, Diagnosis and Treatment, with Sections on Anatomy, Physiology, Chemical and Microscopical Examination of Stomach Contents, Dietetics, Surgery of the Stomach, etc. By JOHN C. HEMMETER, M.D., Professor in the Medical Department of the University of Maryland, Baltimore. Second edition, enlarged and revised. With many original illustrations, a number of which are in colors. Octavo; 898 pages. Philadelphia: P. Blakiston's Son & Co.

This second edition of Dr. Hemmeter's excellent work contains a considerable amount of new subject matter. The whole text has been subjected to careful revision with the effect of greatly increasing the value of the last edition over that of the earlier one.

Care and Treatment of Epileptics. By WILLIAM PRYOR LETCHWORTH, LL.D., Ex-President of the New York State Board of Charities, Ex-President of the Eleventh National Conference of Charities and Correction, author of "The Insane in Foreign Countries," etc. Illustrated. New York and London: G. P. Putnam's Sons. 1900.

In this volume of 246 pages the author has embodied the results of a wide experience in dealing with charitable enterprises, and particularly with the medical and social problem which the epileptic class offers. The result is an eminently readable and practically useful book, full of information regarding the constantly increasing number of hospitals and colonies devoted to the care of epileptics. There is also a certain amount of discussion of the disease itself, which naturally is not original with the author, and hence is of relatively small interest to the physician, though no doubt of value to the lay reader. The detailed consideration of the problems of building and sanitation, and even landscape gardening, in the planning of a colony hospital is of very distinct value and should be widely read and pondered. A highly conscientious account of the various epileptic colonies both here and in Europe fills the greater part of the volume. In this connection, as is natural, Craig Colony receives particularly detailed mention. Mr. Letchworth is an ardent believer in the colony system; he points out the fact that both the community and the epileptics are benefited by segregating the latter in a village, where they can work, go to school and to church, have expert medical attendance, a special hospital and constant experienced care. His efforts in behalf of the epileptic in New York State make his book particularly significant and valuable. It serves as an ocular demonstration of the soundness of the principle of colonization for certain classes of defectives, a principle which we are glad to note is gaining a wider and wider acceptance. The appearance of the book as regards paper and typography is quite beyond criticism and its value is much enhanced by numerous illustrations, chiefly of buildings. We would, however, suggest that the binding be strengthened in later editions.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 26, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

THE ACCIDENTS OF SUMMER.

SUMMER undoubtedly has its pleasures for those whose circumstances permit of their enjoyment, but to others, and even to the pleasure-seekers, there are concomitant dangers which a reading of the papers almost daily forces upon us. This last week, for example, has seen an unprecedented mortality from the effects of heat. A certain number of deaths from this cause we look forward to, and are never disappointed, but when we read a statement like the following taken from a contemporary, we are forced to the conclusion that summer has its notable drawbacks: "In New York the list of fatalities was unusually large. On Tuesday, which was the third day in which the thermometer stood at 94° F. at the registration bureau and 98° F. on the street level, cases of aphasia, suicide and insanity, due to high temperature, were reported, and the bodies of 33 children were received at the Morgue ranging in age up to five years. Twenty-two of these came from institutions and 11 from residences. This takes no account of the many deaths that occurred among private families which were not reported at the Morgue." Boston, in proportion to its size, was almost an equal sufferer, as may be seen by the mortality statistics published in another column. Deaths from this cause are however to be placed in the category of the unavoidable. No doubt our floating hospitals and similar charities save many lives which otherwise would be sacrificed, but unfortunately our cities grow as rapidly as our charities, with the inevitable result that the number of deaths appears to suffer but slight diminution from year to year. Among the poorest classes this evil must no doubt remain, but among the more well-to-do in the community each year finds a larger and larger number who are able for a shorter or longer time to leave the centres of population for less thickly settled and more breezy localities. But here again a new danger threatens which it is highly desirable not to underestimate. Boards of health at summer resorts are not apt to be

vigilant, if in fact they exist at all, and the possibility of danger from defective sanitation becomes in certain cases a menace to be reckoned with. We have previously found occasion to comment on the neglect of proper sanitary precautions by hotel proprietors and owners, whose season is short and whose expenses are heavy. It no doubt frequently happens that the health-giving qualities of salt water and fresh air are vitiated by noxious gases and surface drainage. The crowding of summer resorts becomes therefore a danger different in kind, but even more to be dreaded than the stifling cities, the drainage of which fortunately is unaffected by the number of degrees of heat. It is an anomalous state of affairs and yet a fact that people live calmly and contentedly in the summer under conditions which would not be tolerated for a moment in the winter. That there is relatively so little disease is certainly a source of wonder when we contemplate in a perfectly unprejudiced manner the typical successful, and hence populous, summer hotel.

A certain number each year are drowned. This is the fair penalty for the pleasures of risk. The victims are sometimes careless, and sometimes over-matched by the element with which they are finding amusement. Here again, although these accidents are usually avoidable, they are to be expected, and must be put down as part payment of the debt we owe for the summer's gayeties. There is however one variety of accident, often most unpleasant in its consequences, with which we have small sympathy. We refer to diving in shallow water. Each summer brings records of one or more such cases. It seems difficult to impress upon a certain type of venturesome swimmers that diving, except for the trained expert, demands at least several feet of water. Were the depth of the water a difficult matter to ascertain, we should be glad to make allowances, but inasmuch as the requisite knowledge is so easily gained, we are inclined to pity but not to sympathize with the victim of a fractured vertebra or a spinal hemorrhage who did not know how deep the water was.

But after all, unless our mood be one of unusual depression, the dangers and accidents which the months of summer bring make no impression on our minds when weighed against the satisfaction of an out-of-door life. Most of us willingly put up with crowds and odors and the risks of sudden death if we can only remove ourselves from the safety and sanitary perfection of a hot and crowded city.

THE NEED OF PRACTICAL LABORATORY METHODS OF INSTRUCTION.

THERE has grown up such an array of special tests in the study and detection of disease that the average doctor feels swamped at their mere mention. And well may he, for time is too short for him to master many of them, or, having mastered them, to put them in daily use. Time is not his only obstacle: ex-

pense and laboratory space are no small items. All will agree that the modern doctor should give his patients the benefit of medical progress, but all will at the same time assent that even with the help of our public laboratories it is in most cases impossible to do so. Few doctors feel warranted in employing an assistant (too few unfortunately, for a good assistant is a good investment), and to send to specialists for the performance of simple tests is a needless and almost unwarranted expenditure alike to doctor and patient.

The medical school to-day, no matter what its deficiencies in other respects, does not fail in furnishing methods for the refinement of diagnosis. But the question arises as to whether sufficient attention is given to supplying students with methods which are practicable for their office work. We feel that this is not the case. Only too often a common and important test is shown, which though easy to perform in the laboratory would be extremely difficult to perform at home. The same test could be performed in another way and a simpler, and it is this way we think which should be impressed upon the students. Then again a multiplicity of tests all for the same end are often demonstrated, and the student is confused by their mere number. He is not made to realize that a single reagent will suffice for all his wants. It is a common experience to hear a house officer say that it was not until he entered the hospital that he learned practical laboratory work.

This object should be constantly before the instructor's mind — to make his methods so easy that his hearers will feel capable and desirous of carrying them out later in their own offices. Unless we teach our students practical methods, their needs as practising physicians are not supplied. They will be overwhelmed by the obstacles of time, money and space and so fail to detect plasmodia and tubercle bacilli and neglect examinations of gastric contents, stools and urine. The usefulness of a test is measured by its simplicity.

THE SANITATION OF BOSTON SCHOOLS.

THERE has of late been a considerable agitation regarding the sanitary condition of many of the Boston schools. The daily papers have published somewhat detailed reports, under headlines which do not tend to reassure the reader, that many of the buildings are in a condition actually menacing the health of the children attending them. Allowing for certain inevitable exaggeration, the general facts appear to be substantiated by the investigations of the Board of Health, which finds a condition of affairs absolutely demanding attention. Many of the school buildings need immediate renovation — of that there seems to be no question. No doubt the members of the School Board recognize the necessities of the situation, though possibly not with the completeness with which it forces itself upon experts in public sanitation. There is, however, no evidence of any antagonism

between the School Board and the Health Board, as one might be led to expect from a reading of the press reports. It is clearly the duty of the Board of Health to leave no stone unturned which will tend to uncover any possible menace to health, and it is equally the duty and the privilege of the School Board in this case, to lend its heartiest co-operation in an attempt to remedy the evils which have been demonstrated to exist. It is an expensive undertaking, again a fact which the Board of Health acknowledges, and it is not to be expected that the suggested improvements can be at once accomplished. As we understand the matter, all that the Board of Health and the public whose representative it is demand is a conscientious effort on the part of the School Board to rectify the defects which have been pointed out as rapidly and as efficiently as the circumstances of the case will permit.

MEDICAL NOTES.

THE RED CROSS. — A meeting of the incorporators of the Red Cross was held in Washington, July 10th. Miss Clara Barton was again elected President. The act of incorporation sets forth that, at Geneva, representatives of Italy, Baden, Belgium, Denmark, Spain, Portugal, France, Prussia, Saxony and Württemberg, and the Federal Council of Switzerland agreed upon articles of a convention for mitigating the evils of war, and providing for a distinctive flag for wounded and neutrals. This treaty was ratified by 43 nations, including the United States, and a permanent organization formed for the purpose of co-operating with the international committee. The act gives the corporation right to hold real estate, to sue and be sued, and to use the Greek cross, which was adopted by the several nations. — *Philadelphia Medical Journal*.

WATER POLLUTION. — The Supreme Court of Pennsylvania has handed down an important decision, as stated in the *Medical News*, relating to the rights of water companies and the pollution of streams. A water company is an individual and can obtain only a civil remedy against a person polluting its water supply. The defendant in the case was ordered by the Secretary of the State Board of Health to abate the nuisance, but it was held that the board must take action before the secretary could enforce the order.

YELLOW FEVER IN HAVANA. — Up to July 20th there had been 45 cases of yellow fever in Havana and 16 deaths. Two, however, were attacked in June. Surgeon-Major Gorgas anticipates about 25 civilian deaths this month, which has been the average for July for the past ten years. Nearly all the cases have been Spaniards who recently arrived. Most of the cases are in the old part of the city. The situation is regarded as natural under existing conditions, and no alarm is felt.

INTERNATIONAL MEDICAL CONGRESS. — Beginning Monday, July 30th, special rooms in the buildings of the Faculty of Medicine, Paris, will be placed at the disposal of the national committees of each country. These rooms are to serve as meeting places for those attending the congress from various countries.

APPOINTMENT. — The appointment of Dr. D. R. Brower, of Chicago, to the professorship of neurology and psychiatry at Rush Medical College is announced.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 25, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 39, scarlatina 2, measles 14, typhoid fever 11.

BOSTON MORTALITY STATISTICS. — There were 17 deaths from heat prostration last week in Boston, while a year ago there were no deaths from this cause. The deaths reported from cholera infantum for the week ending July 21st numbered 41, as against 52 a year ago, while the number of deaths of children under one year of age is 97 this week, as against 103 a year ago. The hottest day in July last year was on July 4th, when the mercury registered 94 degrees. There was an increase of twenty-four diarrheal cases as compared with the number a year ago for the same period of the year, while there was a decrease on the larger part of the other diseases tabulated at the Board of Health office. The total number of deaths reported to the Board of Health for the week ending July 21st is 271, as against 249 the corresponding week last year. Of this number 132 were males and 139 females, 52 of American parentage, 194 of foreign parentage, and 25 unknown. The number of children who died under one year was 97, the number under five years 125. The number of persons who died over sixty years of age was 46. The deaths in public institutions were 73.

DEATHS FROM HEAT. — The official reports of the Board of Health show that during the period of excessive heat last week there were 6 deaths due to weather conditions. Most of the deaths were reported through the agency of the police department, but it is probable that others occurred which were not officially reported. The number more or less overcome by the effects of the heat was exceptionally large.

MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH. — About 100 members of the Massachusetts Association of Boards of Health held their quarterly meeting at Gallup's Island, Boston Harbor, July 19th. Papers of a technical character were read by Dr. R. S. Weston and L. P. Kinnicut. Dr. Walcott, the president of the association, presided.

NEW YORK.

ANNIVERSARY OF ST. JOHN'S GUILD FLOATING HOSPITAL. — The twenty-fifth anniversary of the first trip of the St. John's Guild Floating Hospital was celebrated on July 19th. The exercises were held at

the Seaside Hospital of the guild at New Dorp, Staten Island, and the officers, members and invited guests sailed down there with the children on the original hospital boat, *Enma Abbott*, and returned to the city on the new one, *Helen C. Juillard*. Ex-Mayor Wm. E. Strong presided, and among those who made addresses was Sanitary Superintendent Charles F. Roberts, of the Health Department. Secretary John P. Faure gave an outline of the guild's summer work during the quarter century just closed. Since July 19, 1875, the *Enma Abbott* has carried 826,312 mothers and children, and together with those which have been cared for on the *Juillard*, which was built last year, the number now amounts to considerably over a million. For the first three years the *Abbott* made three trips a week from two landings. Now the two boats each make six trips a week from the two sides of the city, making numerous landings in Manhattan and touching at Harlem, Williamsburgh and Brooklyn. The trained nurse department was started in 1887, and the salt-water bathrooms the following year. Other facilities have been added from time to time, and Mr. Faure stated that for the first time in the fourteen years he has held the position of chairman of the Floating Hospital Committee no improvements were made on the boats this year, for the reason that there seemed to be nothing that could be done to make them more complete. The anniversary contributions amounted to \$1,300, \$500 of this sum being subscribed by Mr. Seth M. Milliken.

A LEGAL DECISION REGARDING CONTAGIOUS DISEASE. — When an outbreak of scarlet fever occurred at the Majestic Hotel on 72d Street, in January, 1896, Edward Eyre, then occupying apartments there with his wife and four young children, abandoned his rooms. He refused to pay further rent under his oral lease of \$4,050 a year, claiming that the prevalence of the disease, which endangered the lives of his family, justified him in surrendering the premises and terminating his liability for future rent. The hotel company, in a suit brought in the Supreme Court against Eyre, recovered judgment for about \$3,000, the referee before whom the case was tried holding that there was no eviction, and that the premises did not become untenable. The case was appealed, and the Appellate Division has now affirmed the decision. Justice Hatch, giving the opinion of the court after discussing the "Real Property law" and stating that the statute does not seem to cover the case, goes on to say: "There is nothing that appears which would justify a finding of negligence upon the part of the landlord in introducing the epidemic or in preventing its spread after it made its appearance in the hotel. On the contrary, every precaution which science or the Board of Health suggested was adopted. The finding of the learned referee has settled such questions, and it is abundantly supported by undisputed evidence. There is therefore no eviction, either actual or constructive, to be spelled out of the facts of this case, and therefore there is no defense to this claim."

DARK TENEMENT HOUSE STAIRS AND THE AWARD OF DAMAGES.—The Appellate Division of the Supreme Court on July 18th decided that persons injured in falling down stairs in a tenement house in which the hallways are unlighted are entitled to damages, and also that in case of its being a woman who is injured the husband may recover damages for the loss of the services and society of his wife. In a case in which a woman sustained serious injuries by falling down the stairway of a tenement house at night she brought suit and secured a judgment for \$2,750, and her husband also brought suit and was awarded damages. The landlord of the house appealed from the decision of the lower court, but the Appellate Division upheld the judgments, citing the law which requires that in the city of New York a light shall be kept burning in the hallways on each floor of all tenement or lodging houses from sunset until 10 p. m.

NEW JERSEY STATE BOARD OF MEDICAL EXAMINERS.—At a regular meeting of the State Board of Medical Examiners held at Newark, N. J., July 5th, the following resolution was adopted: **RESOLVED**, that this board will endorse the licenses of any State board of medical examiners in the United States, in lieu of an examination, provided, *First*, That the candidate for endorsement shall present satisfactory evidence of having the academic and medical education required by this board, and *Second*, That the license presented for endorsement shall have been issued after a State examination of the same grade and kind as that required by this board.

A CASE OF YELLOW FEVER.—One of the second class passengers of the Ward Line Cuban steamer *Havana*, which brought Gen Leonard Wood and his family to New York, died on Hoffman Island of yellow fever on July 18th. The disease did not develop until the vessel had reached quarantine, and the patient, who was a Syrian woman, was ill only about twenty-four hours.

MORTALITY FROM HEAT.—During the three days July 17th, 18th and 19th the first serious mortality from hot weather occurred, the number of deaths from the direct effects of the heat amounting to 68 in the various boroughs. Twenty-nine of the deaths were on July 18th, and 25 on the 19th. There was also, naturally, a considerable increase in the infant mortality of the city.

CÆSAREAN SECTION ON A DWARF.—Dr. Henry D. Nicoll recently successfully performed Cæsarean section at the Nursery and Child's Hospital in the case of a negro woman three feet eight inches tall. She and her husband, who is also a dwarf, are said to be acrobatic performers.

ARMY NOTES.

AMERICAN HOSPITAL IN CHINA.—The Ninth U. S. Infantry, now in China, has with it a regimental field hospital and an additional field outfit for 50

beds. The Fourteenth Infantry and artillery organizations now en route to China from Manila are similarly provided. In addition there has been shipped from Manila a division field hospital of 300 beds, with an allowance of medical supplies for 5,000 men for three months. This hospital will be under the command of Capt. Wm. Stephenson, Assistant-Surgeon U. S. Army, who has been provided with a fund of \$50,000 for contingent expenses. The smaller hospital will be under the command of Lieut. L. A. Fuller, Assistant-Surgeon U. S. Army, who has been provided with \$10,000 for contingent expenses. The transports *Grant* and *Sumner*, which sailed from San Francisco on July 3d and 16th, respectively, carried an aggregate of 18 medical officers and 78 hospital corps men available for service with troops in China. The transport *Meade* will sail on August 1st with 8 medical officers, a hospital of 50 beds and a large number of hospital corps men. Great care has been taken, in providing for the hospital service in China, to outfit for the cold weather met with in winter in the vicinity of Peking.

EXPERT IN MENTAL DISEASES TO BE SENT TO THE PHILIPPINES.—In view of the cases of insanity liable to occur in such a large force as is now stationed in the Philippines, Surgeon-General Sternberg has decided to station an expert in mental diseases at Manila to have charge of insane patients prior to their embarkation for this country. For this purpose he has given a contract as acting assistant surgeon to Dr. Charles H. Latimer, who has been a member of the staff of the government insane asylum at Washington (St. Elizabeth's) for the past twelve years. Dr. Latimer is a man of much experience and ability and will undoubtedly be of great assistance in the general hospital at Manila in his special line of work. He takes with him as assistants two attendants from the government asylum for the insane who have each had more than ten years' experience in the handling of cases of mental alienation.

WORK OF EXAMINING BOARD IN MANILA DELAYED.—An examining board which has been in session for some months in Manila for the examination of candidates for appointment in the medical corps has met with great delay, due to the scattered condition of the troops and the infrequent means of communication. Twelve candidates have so far been recommended for commissions and every steamer from the South is said to bring one or more applicants, who leave their stations as their services can be spared. An examining board recently in session in Cuba has passed four candidates; the one in session in Puerto Rico has not as yet rendered a report. All those recommended for appointment are either contract surgeons or medical officers of the volunteer forces. There are at present twelve vacancies in the regular medical corps.

AMERICAN OFFICERS WOUNDED IN CHINA.—Cable advices state that in the fight at Tientsin Ameri-

can medical officers were fired upon and wounded by the Chinese. As the present outbreak in China is largely of an anti-Christian nature, it is probable that the Red Cross badge of the hospital corps can scarcely be expected to afford protection, but, in fact, rather the reverse. It will be remembered that in the Philippines the medical officers and hospital attendants were a special target for Filipino bullets, and that it finally became necessary to arm the hospital corps men with Kräg-Jorgensen carbines. This plan will very likely have to be adopted with our forces in China.

HOSPITAL SHIP "RELIEF" DISABLED. — A recent cablegram states that the hospital ship *Relief*, which has been stationed in the Philippine Islands during the past year and which was ordered to Taku to receive the sick and wounded of the allied forces in China, has arrived at Nagasaki in a disabled condition and will require extended repairs. No details as to the nature of the disability were given.

Miscellany.

DR. A. CONAN DOYLE ON CONDITIONS IN SOUTH AFRICA.

DR. A. CONAN DOYLE, in the course of a letter on medical conditions in South Africa contributed to the *British Medical Journal*, writes as follows:

"When the nation sums up its debt of gratitude to the men who have spent themselves in this war, I fear that they will almost certainly ignore those who have done the hardest and the most essential work. There are three classes, as it seems to me, who have put in more solid and unremitting toil than any others. They are the commissariat, the railway men, and the medical orderlies. Of the three, the first two are the most essential, since the war cannot proceed without food and without railways. But the third is the most laborious, and infinitely the most dangerous.

"... How was this unforeseen and unprecedented crisis grappled with? [Referring to the outbreak of typhoid fever.] Entirely by the efforts of the medical men and by the devotion of the orderlies. When a department is confronted by a task which demands four times more men than it has, the only way of meeting it is for each man to work four times as hard. This is exactly what occurred, and the crisis was met. In some of the general hospitals orderlies were on duty for thirty-six hours in forty-eight, and what their duties were — how sordid and obscene — let those who have been through such an epidemic tell. He is not a picturesque figure, the orderly, as we know him. We have not the trim, well-nourished army man, but we have recruited from the St. John Ambulance men who are drawn, in this particular instance, from the mill hands of a northern town. They were not very strong to start with, and the poor fellows are ghastly now. There is none of the dash and glory of war about the sallow, tired men in the dingy khaki suits — which, for the sake of the public health, we will hope may never see England again. And yet they are patriots, these men; for many of them have accepted a smaller wage in order to take on these arduous duties, and they are facing

danger for twelve hours of the twenty-four, just as real and much more repulsive than the scout who rides up to the strange kopje or the gunner who stands to his gun with a pom-pom quacking at him from the hill.

"There is one mistake which we have made, and it is one which will not, I think, be repeated in any subsequent campaign. Inoculation for enteric was not made compulsory. If it had been so I believe that we should (and, what is more important, the army would) have escaped from most of its troubles. No doubt the matter will be fully threshed out in statistics, but our strong impression, from our own experience, is that although it is by no means an absolute preventive it certainly modifies the course of the disease very materially. We have had no death yet (*absit omen*) from among the inoculated, and more than once we have diagnosed the inoculation from the temperature chart before being informed of it. Of our own *personnel* only one inoculated man has had it, and his case was certainly modified very favorably by the inoculation.

"Of the courage and patience of the soldiers in hospital it is impossible to speak too highly. We have had 500 cases pass through our hands, and can speak now from a fairly large experience. I had always imagined that in every large army there must be a minority of skulkers and shirkers, but they are singularly absent in the South African Field Force. I have not had more than two or three cases in my wards which bore a suspicion of malingering, and my colleagues say the same. They are uniformly patient, docile and cheerful, with an inextinguishable hope of 'getting to Pretoria.' There is a gallantry even about their delirium, for their delusion continually is that they have won the Victoria Cross. One patient, whom I found the other day rummaging under his pillow, informed me that he was looking for 'his two Victoria Crosses.' Very touching also is their care of each other. The bond which unites two soldier pals is one of the most sacred kind. One man shot in three places was being carried into Mr. Gibbs's ward. I lent an arm to his friend, shot through the leg, who limped behind him. 'I want to be next Jim, 'cos I'm lookin' after him,' said he. That he needed looking after himself seemed never to have occurred to him."

It is of interest to note Dr. Doyle's and Dr. Wright's opinion given below regarding inoculation against typhoid, an opinion which apparently is not universally shared.

ANTITYPHOID INOCULATION.

DR. A. E. WRIGHT, Professor of Pathology at the Netley Army Medical School, sends a communication to the *British Medical Journal* (July 14th) on this subject. He gives some statistics in tabular form in regard to the results obtained with antityphoid inoculation in officers and men, and officers alone of the military garrison during the siege of Ladysmith. Dr. Wright's conclusions are that:

"In view of some points regarding which there is not at present any information available, it is at this stage impossible to determine precisely to what extent the inoculated were protected by inoculation. But the results set forth would appear to be distinctly encouraging, inasmuch as they show that the proportion, on the one hand, of attacks, and, on the

other hand, of deaths from typhoid was seven times smaller in the inoculated than in the uninoculated, and it may be borne in mind that if the number (no doubt a considerable one) of men who had previously suffered from typhoid had been subtracted from the number of the inoculated, as might quite legitimately have been done, the statistics would have borne an even more favorable aspect."

A PROLIFIC WOMAN.

DR. WILLIAM P. BURKE, of New Haven, Conn., reports in the *Medical Record* the following extraordinary case of fecundity:

"On the evening of May 23, 1900, he was called to attend Mrs. H — in her fourth labor. After a tedious and severe labor he delivered her on the morning of the 24th of triplets, two boys and one girl. The boys weighed eight and nine pounds respectively, and the girl seven pounds, making twenty-four pounds of children in all. There was but one placenta, which was attached in three places, arranged very much like a clover-leaf with membranous connections between the patches of placental tissue. One of the children, the second, a boy, presented by the feet and died in about fifteen minutes after birth. The others were vertex presentations. On May 1, 1898, he delivered this woman of twins, a boy and girl. She also had previously had two other labors with one child at each birth. Ten months before she gave birth to the twins and about the same time before giving birth to the triplets she miscarried at five months. All of this occurred within six years and one month. Of the seven full-term children but three are living. Her mother gave birth to eight children in all, and her grandmother to eleven."

Correspondence.

THE AVERAGE BIRTHS TO EACH CASE OF TRIPLETS.

Boston, July 24, 1900.

MR. EDITOR:— In the Massachusetts Registration Report for 1897, page 130, the average number of living births to one case of triplets is stated as 121,929.2 for the twenty years 1878-1897. In the Twenty-eighth Annual Report of the State Board of Health for 1896, page 738, the average number of births to each case of triplets is stated as only 9,629. for a nearly identical period. Why this tremendous discrepancy, and which is correct?

Deaths reported 2,750; under five years of age 1,346; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 1,003, diarrheal diseases 620, consumption 245, acute lung diseases 185, diphtheria and croup 54, typhoid fever 22, measles 21, whooping-cough 14, scarlet fever 13, cerebrospinal meningitis 12, erysipelas 2.

From measles New York 18, Washington 2, Boston 1. From whooping-cough New York and Washington 6 each, Worcester and Springfield 1 each. From scarlet fever New York 9, Boston 2, Washington and Lawrence 1 each. From cerebrospinal meningitis New York 10, Boston 1. From erysipelas Worcester and Chelsea 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending July 7th, the death-rate was 14.5. Deaths reported 3,220: whooping-cough 89, measles 84, diarrheal diseases 63, diphtheria 63, scarlet fever 27, fever 26, small-pox (Liverpool) 2.

The death-rates ranged from 9.1 in West Ham to 24.1 in Sunderland; Birmingham 16.3, Cardiff 11.5, Gateshead 18.1, Hull 14.2, Leeds 15.1, Leicester 12.6, Liverpool 19.9, London 13.5, Manchester 19.3, Newcastle-upon-Tyne 15.1, Nottingham 11.4, Portsmouth 13.4, Sheffield 18.0.

Original Articles.**ASPHALT PAVEMENTS; THEIR NATURE AND DESIRABILITY.¹**

BY CLIFFORD RICHARDSON, ESQ.,
Expert on Asphalt, New York.

I HAVE been asked by your governing board to present to you this evening some facts in regard to asphalt and asphalt pavements, from the point of view of the engineer, and to explain the advantages which are offered by such pavements for abating the dust nuisance, the matter which you have especially under consideration.

It may interest you, to begin with, to learn something of the origin and extent of the industry.

ORIGIN AND HISTORY OF THE PAVING INDUSTRY.

Although the application of asphalt to industrial purposes on a small scale dates back to the earliest times, it is only with the introduction of rock asphalt into Paris about forty-five years ago that the asphalt paving industry can be said to have originated.

In 1838 the first sidewalks were laid in Paris with bituminous limestone from Scyssel and Val de Travers. In 1849 Mereau, a Swiss engineer, noticed that at the quarries pieces of the rock which fell from the carts united under the influence of heat and traffic so as to form a concrete mass, and on this principle he constructed a road in the village of Travers upon a macadam base. M. Darecy, inspector-general of bridges and roads in Paris in 1850, made a report recommending the use of compressed asphalt, and after some experiments a pavement of this material was laid in the Rue Bergere in 1854. In 1858 another trial was made on a larger scale in the Rue St. Honore, and from that time on the Parisian asphalt pavements were laid. In London, the first asphalt pavement was laid in Threadneedle Street in 1869. In Paris there are about 450,000 yards of asphalt pavement and in London about 400,000. But the amount has not increased of late years owing to the slipperiness of this form of asphalt surface. In Berlin the first asphalt pavements were laid about 1873 or 1874, and since then very large amounts have been put down, reaching about 1,700,000 square yards. Pavements of this description have never been popular, however, in America.

The success of asphalt pavements in Europe led to much experimenting in this country, and at first coal tar was used as a cementing material. Between 1870 and 1873 a large area of such pavements was laid in Washington, a majority of which proved worthless, and grave suspicion was thrown upon coal tar as a cementing material.

In 1870, De Smedt began experimenting with Trinidad asphalt with a view to overcoming the defects of coal tar, and laid a sample pavement in Newark. He took out a patent for his invention. In 1871 or 1872 he laid an asphalt pavement around Battery Park, New York, and in 1873 one on Fifth Avenue in front of the Worth monument, which remained in use, with one or two resurfacings, until 1886. At about the same time Trinidad asphalt was laid in Philadelphia, on Sixth Street, in front of Independence Hall. In 1874 or 1875 Eighteenth Street was paved with

Trinidad asphalt between Fourth Avenue and Irving Place, as were several other New York streets. The pavements were successful and attracted much attention. In 1876 Congress passed an act providing for the paving of Pennsylvania Avenue in Washington, under a commission composed of Gen. H. G. Wright, Gen. Q. A. Gilmore and Architect Edward Clark, of the Capitol, with no restrictions as to price or kind of pavement. The two former gentlemen, of the Corps of Engineers, U. S. Army, had been stationed in New York and had noted the success of the asphalt surfaces. The board therefore decided to lay compressed asphalt, and divided the work into two parts, using rock asphalt from the Capitol to Sixth Street, and Trinidad for the remainder. The rock was imported from the Val de Travers mines, and the work done by the New York Neufchatel Asphalt Company, of which Matthew Taylor was president. The contractor for the Trinidad surface was the New York and Grahamite Asphalt Company, with which De Smedt was connected. The rock asphalt pavement was condemned as being "too slippery for practical use," and no more of it has been laid in Washington.

The Trinidad asphalt was a success, and was so satisfactory that when the permanent board of commissioners was organized in 1878, they decided to limit the pavement of streets to Trinidad asphalt except where grade or traffic were prohibitory. Since that time the asphalt paving industry has rapidly expanded. In 1882 pavements of this description were laid in Buffalo, N. Y., which are still in fair condition. In that year asphalt was introduced in Omaha, Neb., and Youngstown, O. In 1883 the business extended to Baltimore, Philadelphia, Boston, Erie, St. Louis and Louisville, and from that time on has spread to 105 different cities in the United States, in which over 31,000,000 yards of asphalt concrete pavements have been laid by the several companies which have been engaged in the business. This extent of surface would amount to 1,950 miles of streets 26 feet wide. Of all this surface 26,000,000 square yards have been laid with Trinidad asphalt, the remainder with other asphalts, including about 1,000,000 yards of bituminous limestone rock from the Continent.

On the entire Continent of Europe there are only 4,000,000 square yards, or 250 miles of streets, all of which is constructed with bituminous limestone.

On the first of January, 1899 (the figures for January, 1900, are not yet available), some of the prominent cities of the United States had the following areas of asphalt pavements: Buffalo had about 3,900,000 square yards; Washington, about 2,600,000 square yards; New York, about 1,600,000 square yards; Boston, only 195,000 square yards.

In the smaller cities of the West asphalt pavements are extremely popular, and I may cite the town of Shelby in Ohio, which, with a population of only 6,000, put down in 1899 30,000 square yards of asphalt, or about 5 yards to every inhabitant. If Boston were paved on this scale it would have nearly 3,000,000 yards, or about the same as Buffalo. Every year asphalt pavements are introduced into numerous towns and cities, and the popularity of this form of roadway is growing rapidly.

In this connection it may be of interest for you to know what asphalt is, how it is obtained, something of the technology of the industry, the forms of construction, the extent of these pavements here and

¹ Read at a meeting of the Boston Society for Medical Improvement, February 19, 1900.

abroad, and their success and popularity as shown by the increasing demand for them.

WHAT IS ASPHALT?

Asphalt exists in nature and is not a by-product of manufacturing processes, like coal tar, as is often erroneously believed. It is a mineral found widely scattered over the earth's surface, but only rarely in commercially available quantities. It is also known as mineral pitch.

Asphalt, or more properly asphaltum, the essential constituent of asphalt, is a form of native bitumen. Bitumen is a mixture of hydrocarbons, with their derivatives which contain sulphur, nitrogen and more rarely oxygen, and may be either gaseous, liquid, viscous or solid, softening or melting when solid on the application of heat, and soluble in chloroform and similar solvents. Asphaltum is that variety of bitumen which is solid, or nearly so, at ordinary temperatures, melts rapidly on the application of heat, and contains a very considerable amount of sulphur derivatives. Maltha, or mineral tar, is a similar bitumen existing as a very viscous liquid and containing less sulphur. It grades from heavy petroleum to the less solid asphalts and is often called soft asphalt.

Asphalt is a name commonly applied to any mineral matter containing a considerable quantity of asphaltum, this form of bitumen being oftener found combined with limestone, sand, clay, soil, and, as in Trinidad asphalt, with sand and clay rather than in a pure condition, where it is characterized as glance pitch, the name applied to the bitumen of Judea or the asphalt of the Dead Sea. Asphalt is a secondary, or transformation, product of petroleum, being the result of the changes to which this lighter form of bitumen has been subjected under certain environment and especially in the case of petroleum containing hydrocarbons of a particular composition.

SOURCES OF ASPHALT FOR PAVEMENTS.

On the Continent of Europe there are large deposits of limestone impregnated with from 6% to 11% of bitumen which are mined to quite an extent for paving purposes. This material cuts no figure in the industry in this country.

The chief sources of the supply here are the pitch lake of the Island of Trinidad, that in the State of Bermudez, in Venezuela, and smaller amounts from California.

DESCRIPTION OF ASPHALT DEPOSITS.

The Trinidad deposit.—The Island of Trinidad is the largest colony of Great Britain in the Antilles, with the exception of Jamaica. It lies but a short distance from the mainland of South America, of which it was plainly once a part, near the most northerly and westerly of the mouths of the Orinoco and the coast of Venezuela, being separated from the latter by the Gulf of Paria. On the Gulf Coast and at an altitude of 138 feet above the ocean and 1,100 yards from the shore is the celebrated pitch lake described by so many writers, including Kingsley in "At Last." The lake is a level expanse of 114 acres of black pitch, over which one can walk or ride in any direction except where interrupted by shallow water courses between the several areas of asphalt. The latter appear like the tops of a mass of mushrooms which have been gathered together at their edges.

They are prevented from remaining together or coalescing by the water between them. At the centre fresh pitch is continually being emitted in a very soft condition but at a temperature not above that of the air and there the weight of a man can also not be sustained.

The surface is bare except for a slight growth of grass near the edges and a few masses of larger bushes, small trees and grass floating on the inner part of the lake, whose movements can be detected from year to year. In fact, from an evolution of gas which is taking place in the pitch, the entire material of which the deposit is composed is in a constant state of motion. Stakes driven in the pitch in a straight line are after some days quite out of alignment, and substances left upon the surface are engulfed, perhaps to appear years afterwards. The pitch, although in a constant state of motion, is sufficiently brittle to admit of its being flaked out, like ice, in masses of 50 pounds or more and an excavation thus made will close up and disappear in a few days. Borings in the centre of the lake made in 1894 penetrated the deposit to a depth of 135 feet and were still in pitch. With the extensive area of the lake and this depth, the quantity of asphalt in this deposit must be enormous, in the millions of tons, while at the same time levels taken of the surface of the lake in connection with the accurately recorded amount of material taken from it since the material had been sought, more than 1,200,000 tons, shows that the surface has not fallen as much as it should have done were there no present supply of fresh asphalt, and it appears that from 18,000 to 20,000 tons run into the lake every year, in itself no small supply.

The crude asphalt of the lake is a peculiar substance. It is a mixture, or emulsion, of asphaltum, gas, water, mineral and organic matter not bitumen in the following proportions: Water and gas, 29%; bitumen, 39%; organic not bitumen, 7%; mineral matter, 25%; total, 100%. And it is still more remarkable that the composition of the pitch is so uniform that no matter on what part of the surface or at what depth it is taken it is always the same, ranging less than 1% in any constituent. This uniformity in quality is, of course, of great value in any industrial process.

On the Trinidad lake there is a cable railway in the form of a loop on which cars carrying buckets run and are filled with pitch. The buckets on reaching the edge of the lake are hoisted to an overhead conveyer, upon which they are carried to the sea and out upon a pier where they are dumped directly into the hold of the vessel lying alongside, as much as 750 tons being handled in a day. The flakes of crude asphalt settle together in the hold of the vessel and at the end of their voyage have become a solid mass which must be again picked into flakes to discharge cargo.

The Bermudez deposit.—On the opposite side of the Gulf of Paria from Trinidad and about 30 miles in an air line from the coast the asphalt deposit, known as the Bermudez Pitch Lake, is found at the point where a northern range of foothills comes down to the swamps. The Guanaco River, a branch of the San Juan, one of the large estuaries of this region, at about 65 miles, in its winding course, from its mouth, runs within 3 miles of the deposit, but it is 5 or 6 miles to a suitable wharfage site. The so-called lake is situated between the edge of the swamp and the

foothills in what might be termed a savanna. It is an irregular shaped surface with a width of about a mile and a half from north to south and about a mile east and west. Its area is a little more than 900 acres, and it is covered with vegetation, high, rank grass and shrubs, 1 to 8 feet high, with groves of large moriche palms, called morichales. One sees no dark expanse of pitch on approaching it, as at Trinidad pitch lake, and except at certain points where soft pitch is welling up, nothing of the kind can be found. In fact the deposit is nothing more than the exudation of a vast quantity of maltha from various springs which has spread over the swamp around and become hardened by exposure and the burning of the vegetation of the swamp.

At different points there is at most a depth of 7 feet of pitch, while the deepest part of the soft maltha is only 9 feet and the average of the pitch below the soil and coke only 4 feet. At points there is not more than 2 feet of pitch and in the morichale, or palm groves, it is often 5 feet below the surface. It is plainly quite a different deposit from the Trinidad lake, and on further examination the material is found to differ essentially from the Trinidad pitch. Analyses show it is far from uniform in composition. The asphalt, or matter as evolved, contains no water or mineral matter. Considerable amounts of these substances soon become mixed with the pure bitumen mechanically after it has appeared at the surface, so that the average composition of the original material and that which has become altered is as follows:

	Original Soft Asphalt.	Hardened Highest.	Asphalt Lowest.
Water or loss 212° F., Dried Material.	1.0	46.2	10.7
Mineral Matter0	3.7	.5
Organic not bitumen2	6.5	.6
Bitumen	99.8	98.5	90.1

The bitumen, too, in Bermudez asphalt softens and melts at a much lower temperature than Trinidad asphalt. This asphalt is shipped like that from Trinidad and refined in the United States. It makes a good pavement, but requires greater skill to handle it successfully, as it is so far from regular in composition.

CALIFORNIA ASPHALT.

There are vast quantities of bitumen scattered over a wide area in California, especially in Santa Barbara, Ventura, Los Angeles and Kern Counties. This bitumen is in the form of true asphalt and of maltha or asphaltic petroleum. The hard asphalts are not in large enough deposits to be available to any great extent commercially, although they have been used in an experimental way. The asphaltic petroleum and maltha are valuable materials when properly used, but must be handled with skill to give satisfactory results.

No asphalts as we know them to-day can compare with that of Trinidad for uniformity and ease of handling. In any case, however, skill in handling the particular asphalt is of as much importance as the material. An unskilled person cannot make a good pavement of the best material.

REFINING AND TECHNOLOGY.

Asphalt for use in the form of pavements laid in the United States must be refined to remove water, light oils, volatile at a temperature below 325°, and such organic or mineral substances as are undesirable.

This is done by melting and volatilization of the water and oil, and separation of the mineral and organic impurities by skimming and sublimation. Mineral matter if not present in too large an amount or in size too coarse to remain in suspension in the melted asphalt is not objectionable. Refined asphalt cannot be produced from any single deposit which will be satisfactory for immediate use in a pavement. It must be combined with other asphalts or fluxes so that the resulting mixture shall have a consistency which experience shows is suitable for the conditions to which the pavement is to be exposed. For this purpose the residuum left on distilling off the lighter oils from eastern or California petroleum is used. The material thus prepared is known as asphalt cement. This must be mixed with a suitable mineral aggregate consisting of sand and a fine filler or dust to form a bituminous concrete wearing surface for the pavement. As the mineral aggregate forms 85% to 90% of the surface it is just as important that it should be of satisfactory quality and properly selected as it is that the consistency and character of the asphalt cement should be right. In the early days of the industry this was neglected and often poor pavements were the result, but with the experience of years the best equipped companies are now in a position to avoid mistakes of this description, and it is probable that the best asphalt surfaces of to-day are far in advance of those of 1880 in their ability to withstand traffic and other conditions which tend to cause a disintegration of the surface. The gritty mineral aggregate and the asphalt cement are mixed at temperatures in the neighborhood of 300° F., spread upon the street and compacted in a way which you probably have all seen in Boston. Skill is of course necessary in all parts of this process also, and cheap workmanship must be avoided.

Attempts have been made again and again to construct pavements with artificial bituminous materials, such as by-products of manufacturing processes, coal tar, petroleum sludge, etc., as a cementing material, but always with more or less disastrous results. Nothing but native bitumen free from decomposition products of manufacturing processes can be satisfactorily used for this purpose.

FORMS OF CONSTRUCTION OF ASPHALT PAVEMENTS.

Asphalt pavements generally in use in the United States at the present day consist of three parts, a base, a binder and a wearing surface. Depending upon local conditions the nature and thickness of these courses vary.

Under pavements to be subjected to heavy traffic or upon a weak subsoil a hydraulic concrete base should be, and usually is, provided. Its thickness depends upon circumstances and may be from 4 to 6 inches. This base supports the weight of the traffic on the pavement and is a most essential feature. Upon the base a binder course consisting of clean broken stone of a size that will pass a 1-inch ring, heated and covered with a coating of bituminous cement, is placed and compacted to a depth of 1 to 1½ inches. This course prevents the surface from moving or creeping on the smooth base and is an important element in preventing its pushing out of shape, as happens so frequently with rock asphalt surfaces. Upon the binder the gritty surface is placed and compressed into its interstices until the whole is a mono-

lithic mass. The depth of the surface may range from 1 to 2 inches according to requirements. Residence streets are satisfactory with an inch of binder and the same of top. On business streets $1\frac{1}{2}$ inches of binder and 2 inches of top are more suitable.

Oftentimes it is possible to use as a base some form of old pavement which has been consolidated by traffic into an unyielding mass quite as suitable to support an asphalt surface as a new hydraulic base. For this purpose old granite block, brick and macadam have been used. In New York City between 1,000,000 and 2,000,000 of old block pavements have been covered with asphalt and the old macadam surface on Broadway between Fifty-ninth Street and 118th Street has been resurfaced in the same way, some of the asphalt having been in place with slight repairs since 1890. Worn-out brick pavements have also been successfully resurfaced in Ohio. In such cases a binder course is laid upon the old pavement to bring it to grade, and upon this the surface is laid.

THE PERFECT PAVEMENT.

There is nothing which offers such good evidence of the well-being and the good government of a city as the condition of its streets. Their first appearance to a visitor is the foundation of his impression of a town, which it is difficult to dispel if unfavorable. When paved with a perfect pavement which is clean, the initial impression is favorable.

The perfect pavement has been defined as one whose cost and that of maintenance is reasonable, whose surface offers the least resistance to traction consistent with a good foothold for horses, which is impervious to moisture, offers no irregularities for retaining dust, produces no detritus itself, is easily cleaned, kept cleaned and is as noiseless as is possible.

Asphalt, I believe, approaches these conditions more nearly than any other form of pavement, and I shall endeavor to show that at the same time it possesses qualities which render it desirable in other ways, some of which are common to all smooth pavements but which are more strongly developed in asphalt than in other forms.

It is unnecessary for me to tell you that the defects of macadam pavements are that they make the most detritus of any kind of pavement, and in consequence, when dry, are dusty, when wet, muddy; that their resistance to traction is high; that the cost of maintenance is higher than that of any form of roadway; that it cannot be kept clean, but that to keep down the dust it must be watered and made muddy; that the cost of the best possible cleaning is high, and that storm water washes quantities of detritus from it into the sewers which must be removed at great expense. The only claim for its excellence is that it affords a good foothold for horses and this is very much exaggerated in comparison with asphalt. There is no doubt that for fast and careless driving macadam offers the safer footing, but when used for ordinary traffic the difference is slight.

Granite pavements are rough, very noisy, difficult to clean and do not admit of perfect repairs, although in other respects satisfactory. Brick have the same objections as granite to a smaller degree, and wood is inadmissible in our climate.

Our final recourse must therefore be, and has

been, as will be shown, to asphalt, both as a necessity and a luxury. I trust you will allow me to explain the reason for this in more detail.

COST.

Asphalt is eventually the cheapest form of pavement that can be laid when it is considered that it is guaranteed to be kept in repair by the contractor for five years or more, when opened for excavations can be repaired with greatest ease and perfection and maintained for the city after the expiration of the guarantee for a long period of years at a reasonable price, can be more cheaply cleaned and causes less wear and tear upon horses and vehicles than any other form of pavement, thus benefiting the community in a very general way.

It may originally cost double the price of a macadam surface, but the repairs upon the latter are so expensive that often in three years the cost has been equalized, while the asphalt pavement may be maintained for many years at a cost of from two to ten cents per yard per annum, and finally resurfaced for half its original cost. In Buffalo asphalt pavements are in use to-day which, with a few minor repairs, have been subjected to traffic for twenty years, and the same is the case in other cities.

We have in the asphalt pavement, therefore, cheapness and durability combined, because economical maintenance, and not cheap first cost, is the best economy.

This, however, is true of asphalt pavements only if, as has been said, the highest grade of material is used and the most skilled labor employed, because nothing is more worthless or expensive to maintain than an inferior bituminous concrete. The prices paid must be large enough to warrant good work. Too cheap pavements are the most costly in the end because necessarily inferior.

The success of asphalt pavements early led, as has been said, a large number of irresponsible persons to go into the business with a resulting demoralization of prices, and many pavements or imitations of them have been laid upon which more was expended for repairs than would equal the cost of original high grade surface. Imitations of asphalt have been introduced at frequent intervals to the taxpayer, who has only learned of their inferiority by experience. Washington years ago went through this experience with coal tar and to-day there is still too much similar experimenting going on with by-products of manufacturing processes.

The chief cause of failure in asphalt surfaces is, however, lack of skill and experience on the part of irresponsible contractors.

ASPHALT PECULIARLY ADAPTED TO PERFECTION OF MAINTENANCE AND REPLACEMENT OF CUTS.

The necessity of prompt repairs is a fact that is self evident on a railway, but is not always so carefully regarded in connection with pavements. Too many pavements, whether stone, brick or macadam, are allowed to deteriorate until they are in a bad condition, because they are not actually dangerous and because satisfactory repairs are expensive and generally impossible. It is not possible to replace a stone block or brick pavement in such a way that the repairs are invisible, but with asphalt this is quite possible, and, as the latter surface shows the smallest defects, attention

is attracted to its condition at once and repairs are not so readily neglected.

Repairs to asphalt pavements for the first five years are guaranteed by the contractor for any deterioration of the material other than cuts and can be again contracted for with him for a subsequent period at a reasonable cost. Cuts made for gas, water or sewers can be replaced in an asphalt so perfectly that the place cannot be detected, and if it is necessary to renew the entire surface of a street, this can be done by softening the old surface with heaters to the depth of one-half to three-quarters of an inch, removing the inferior material and replacing it with new surface. It is quite unnecessary, as in former times with asphalt and now with other pavements like granite and brick, to tear up the old surface to the foundation. The economy in this direction is immense.

Of course the cost of maintenance of a pavement, asphalt or stone, depends upon the traffic to which it is subjected. But an asphalt pavement can be maintained under the heaviest traffic at a reasonable expense.

FOOTHOLD FOR HORSES ON ASPHALT.

The surface of an asphalt is a favorable one for horses as compared with other pavements. It is gritty from the sand used in its composition, except in the form laid with bituminous limestone on the Continent and to a small extent in your city. There is no grit in this surface and its use has been abandoned in Washington, New York and other cities where it has been tried.

An investigation of the relative number of falls of horses on the surface made with sand and asphalt as compared with other pavements was made in 1885 by Gen. (then Capt.) F. V. Greene. The results were presented to the American Society of Civil Engineers in a paper read December 16th of that year, which contains a large amount of interesting information as to different pavements. General Greene showed that in 192 days on 32 different streets of 10 cities, and including 807,552 horses travelling 81,051 miles, the average horse would travel the following miles before falling: On asphalt, 583; on granite, 413; on wood, 272; I am aware that to many persons who have only had a limited experience in driving on asphalt this seems doubtful, but the figures have been confirmed several times, and in cities like Washington and Buffalo, where all the pavements are asphalt, no such feeling would be found. It is true, however, that horses which have been accustomed to travelling on stone pavements are not at home on asphalt, but soon become so.

Again, persons are tempted to drive much faster and more carelessly on asphalt than on stone or macadam, their own personal comfort on the latter pavements controlling the speed. Falls on asphalt are generally due to careless driving. It has been claimed that asphalt surfaces are injurious to horses on account of the continual pounding on such hard surface. An investigation in Washington some years ago disproved this.

In 1892 one of the street railroads introduced a new motive power doing away with horses. In renewing their tracks asphalt was placed between the rails and in the interval between its being put down and the final discarding of horses they were driven for several months over the asphalt surface. It was

held by the Society for the Prevention of Cruelty to Animals that this would injure the horses seriously and that it fell within their province to look into the matter. Every opportunity was given its agent to examine the animals before they were used upon the smooth surface, while they were travelling over cobbles and during the time they were on asphalt and afterwards. Although prejudiced against asphalt pavements, the observer was obliged to report that the horses were in better condition at the time they were removed from the road than when they were in use on stone pavements.

A personal friend of mine in Washington, a breeder of horses and careful observer, said to me in this connection: "If one drives with as much care on an asphalt surface as one would do for his own comfort on a rougher pavement, no injury would ever be done to the horses."

The very general approval of asphalt pavements by the engineers of our city fire departments is striking evidence of their desirability and the increased rapidity with which engines can reach fires greatly increases the efficiency of our firemen.

EASE OF TRACTION ON ASPHALT.

A characteristic of a perfect pavement is ease of traction. Numerous experiments have been made to compare the resistance to traction of asphalt and other forms of pavements, and show that the relative force required to draw a load upon different surfaces was

On tramway	1
" asphalt	1.55
" best granite block	3 to 4.1
" macadam, best	3
" poorest cobble	14 to 25
" ordinary road cobble	8 to 13
" sleigh, on snow	7

The economy of the cost of the transportation of the very large amount of material annually hauled over our city streets upon asphalt instead of rough surfaces is therefore enormous. Calculations based upon the above results show that, if they are right, by the introduction of asphalt pavement into a city previously paved with stone, the same amount of work could be done by one-half to one-third less vehicles at a money saving in our large cities of many millions, a large sum in comparison with the cost of the pavement. Or, looked at in another way, three times as much work could be done with the same number of teams.

THE HEAVIEST TRAFFIC IS SUSTAINED BY ASPHALT SURFACES.

Asphalt surface will sustain as heavy aggregate traffic and single loads as any form of pavement. Asphalt has been maintained on several blocks of Fifth Avenue, New York, for four years without a particle of repairs, and for three years on the entire avenue from Ninth to Fifty-ninth Streets with no repairs to the main mass of the pavement, but only along rails or around steam boxes at local points. Asphalt has been maintained on Chambers Street since 1886. This street has an aggregate traffic hardly exceeded by any business street in New York, and one so concentrated by a car track in this narrow street that it is made additionally severe. On Fifth Avenue in New York a cable weighing 42 tons on a truck weighing 9 was hauled over an asphalt surface in 1893 without damage or even marked depression, and since that time similar loads have been hauled without remark.

In addition to the capacity for resisting traffic under circumstances, asphalt surfaces are not disappointing in an emergency. In 1898 in Rockford, Ill., a gravel train of fifty cars left the rails and ran back upon the asphalt pavement of one of the streets through an open switch. The engineer reversed his locomotive and hauled them all back on the track with no damage to the train and no more to the pavement than a slight crease which soon rolled out.

There can be no question, therefore, but that asphalt surfaces when properly constructed have a capacity as great as any form of pavement.

INCREASE IN THE VALUE OF PROPERTY.

Asphalt pavements largely increase the value of property when placed upon unimproved streets or upon streets previously paved with noisy or dirty pavements. Before 1891 Seventh and Eighth Avenues in New York were very similar in their character, but in that year Eighth Avenue was paved with asphalt. To-day the contrast between the two streets is striking. Eighth Avenue is now a flourishing business street, horse cars have been replaced by underground trolleys and the traffic through it is enormous. Seventh Avenue, with its rough granite blocks, has little business or traffic, horse cars are the public conveyance, and the street is deserted for the superior conditions found in the next parallel street. Rents are, of course, correspondingly lower.

ASPHALT PAVEMENTS IN THEIR RELATION TO CLEAN STREETS.

The dirt in our streets is a mixture of various forms of mineral and organic matter. It contains: (1) The detritus of the surface; (2) the results of abrasion of vehicles and horse shoes; (3) dirt forced up through the joints of certain forms of pavements; (4) horse manure; (5) house and other refuse. In this mixture, when moist, organic growths of various kinds flourish, and when it is dried their growth is merely inhibited and they are not killed. In the latter form as dust, the street dirt is carried aloft by the winds and distributed through the finest crevices in windows and doors into our houses. An examination of the dust of our houses shows that it is the dust of our streets, and to do away with the former means removing the latter before it is blown about by the winds.

It is asked what kind of pavement makes the least dirt; that is to say, the least detritus. There is no question which makes the most; that is, macadam, and asphalt undoubtedly makes the least, since it practically makes none.

It is a common idea that on streets paved with asphalt a fine black dust derived from the pavement is found in the neighboring houses. It is an error to suppose that this dust contains asphalt, because for structural reasons the entire asphalt surface would go to pieces at once if any particles at all were detached from it, while it has been found on the contrary that after twenty years' use the thickness of asphalt surfaces is not appreciably changed from that which they had when they were laid. Of course surfaces which wear into holes will make detritus, but this should not occur in a first-class pavement, or, in the rare cases where it may happen, immediate repairs should remove the cause.

Dirt and dust will collect on asphalt pavement as it

does upon our polished dining-room tables and it is of course more noticeable there than on macadam, granite block and other surfaces, where dust is compacted in the interstices between its separate parts. In consequence the cleaning cannot be neglected. It *must* be done. If asphalt is not properly swept half of its advantages are lost.

The smooth surface of this form of pavement can, however, be kept as clean as a house floor by sweeping or by flushing, and if dust is to be avoided this must be done. Too often the cleaning is neglected, and then, of course, dust has a free sway on being moved over the surface by the wind. It is not the form of pavement alone which must be considered, but the perfection of the methods employed in cleaning it and the opportunities which the latter offer for its being done satisfactorily, quickly and economically.

Statistics collected by Byrne show that the dirt collected daily from different pavements will average per 1,000 yards

Asphalt	:	:	:	:	.007 to .04 cubic yards,
Wood	:	:	:	:	.04 " .20 " "
Granite	:	:	:	:	.015 " .25 " "
Macadam	:	:	:	:	.10 " .35 (50 times asphalt),

and that the relative cost of cleaning different kinds of surfaces is: Asphalt, 100; granite 150; Belgian, 160; cobble, 400; that is to say, asphalt can be kept clean for two-thirds of the cost of granite block and at a still greater economy over other forms of pavement.

Cleaning of asphalt can be readily accomplished either by hand or machine methods. By hand the surface is kept clean at all hours of the day at a cost but slightly larger than that of machine work done but once in twenty-four hours or more. Hand cleaning as introduced by Colonel Waring in New York is undoubtedly the only satisfactory system in streets of heavy traffic, such as Fifth Avenue in New York and Beacon Street in Boston.

NOISE.

Of the effect of noise upon the nervous system it is useless for me to speak to gentlemen of your profession. With perhaps the exception of macadam there is no surface less noisy than asphalt. Wood gives out a rumble which is quite as distinct as the click of asphalt, while brick is perhaps more noisy than stone. In cities paved with stone there has been a great demand that asphalt surfaces shall be laid about hospitals and public offices.

A comparison of the Fifth Avenue in New York of to-day and that of a few years ago with its rough granite blocks will convince any one of the desirability of asphalt. In the hours of busy traffic in 1895, conversation could hardly be carried on as two persons walked up the avenue. To-day there is comparative quiet. Asphalt is the friend of every one with nerves.

As a matter of pure luxury we have to-day rubber shoes for our horses and rubber tires for the wheels of our vehicles. With these auxiliaries and asphalt pavements traffic becomes at once noiseless.

With the advent of the motor vehicles and the so-called horseless age, the demand for asphalt pavements will undoubtedly increase. The combination of the two will then of course give us a street which will be the ideal for cleanliness and freedom from noise.

REPAIRS TO VEHICLES.

In 1880 M. Darcy, then Director of Public Works in Paris, made quite an elaborate calculation of the saving which would be effected in the wear and tear of the 48,000 vehicles in Paris by changing all the rough stone into smooth-surface pavements. The result of the calculation was a saving of \$1,092,000 per annum. M. Barrabant, the chief engineer of Paris in 1884, in citing these estimates, states that "if made to-day they would give without doubt figures more striking." His average saving, it will be noticed, is only \$23 per vehicle, which certainly would seem to be moderate. In New York in 1888 there were 20,441 vehicles licensed for public hire; this does not include the trucks, wagons and carriages owned by individuals, firms or corporations and used for their own business or pleasure. The number of these is not of public record, but it is probably at least double the number of vehicles licensed for hire. If so, the total number of vehicles in New York is about 60,000, and the saving in wear and tear as a result of smooth pavements, according to M. Darcy's figures, would be about \$1,500,000 per annum.

A similar calculation, according to the *Philadelphia North American* of October 12, 1885, showed that repairs to vehicles necessitated by their use on the old-time cobble-stone pavements of Philadelphia amounted to enough every year to pay the interest on the bonds which it would be necessary to issue for paving the city with Trinidad asphalt, the entire saving to owners being determined as over \$100,000,000 annually.

I have been informed by carriage builders that in cities where all the pavements are asphalt, persons buying carriages are much more critical and demand a higher grade of workmanship, as the slightest defects are revealed on the smooth pavements which are concealed by the noise of the rougher kind.

SPRINKLING.

The sprinkling of streets to lay dust should not be tolerated. It is a makeshift, and merely covers up the lack of cleanliness, at least with asphalt pavements. With those forms of pavement having large interstices which cannot be thoroughly cleaned, sprinkling may become a necessity. The only way that water should be used on asphalt pavements is in flushing them from a hydrant, and this is the ideal way of keeping them clean. It may be done with either salt or fresh water without injury to the surface.

HYGIENIC DATA.

The best evidence of the desirability of asphalt surfaces from a hygienic point of view is offered by the death-rate in various cities as compared with the class of pavements which are in use in them and the degree of cleanliness practised. The following list of cities furnishes some interesting data:

Berlin: Almost all asphalt pavements; death-rate per thousand inhabitants per year	19.6
Amsterdam: Stone and asphalt, streets washed	20
Rome: Streets nicely cleaned, much asphalt, hard climate	21.2
Vienna: Little asphalt, much stone and macadam	24.3
Dublin: Granite, cobble and macadam fairly cleaned	29.3
St. Petersburg: Cobble and macadam, notwithstanding cold climate, which kills germs	30
New York: 1892, with little asphalt	38.37
1894, more asphalt	30
1896, more asphalt and clean streets because easily cleaned	26

In addition to the above data it is of interest to note that the death-rate from bowel complaints in New

York City decreased from 11.5 in 1892 to 6 in 1896 per 1,000. This decrease is directly connected with the pavement of the tenement house district on the East Side of New York with asphalt, and also to the increased cleanliness of the streets which was possible with this form of pavement.

RELATION OF ASPHALT PAVEMENTS TO ILLUMINATING GAS.

It has been claimed that asphalt surfaces prevent the escape to the outer air of gas which has escaped from leaky mains, and that on this account the escaping gas is forced into our houses. This is quite a mistake, at least as far as the asphalt portion of the pavements is concerned. The hydrocarbons of illuminating gas are readily absorbed by asphalt and through the ordinary surface gas works its way, readily acting as a solvent and disintegrating the material. Asphalt therefore cannot in any way confine coal gas. The hydraulic base under an asphalt pavement may prevent to a certain extent the egress to the air of gas from leaky mains, but as such a base exists under all well laid pavements any such disadvantage is common to all forms of pavements and is not peculiar to asphalt surfaces. The asphalt surface, on the contrary, is the most desirable in this respect, as it reveals the leak at once by the disintegration which takes place and makes possible its correction.

In the light of these considerations it would seem that it would be profitable for Boston to abandon her macadam streets and the enormous cost of maintaining and cleaning them, without effectually doing away with the dust nuisance, and to lay asphalt pavements at an outlay which, with a sinking fund to pay for them, would eventually involve the expenditure of no more money than is at present laid out for the expense of their maintenance, for cleaning and watering them, and for excavating from the sewers the material washed into them from the macadam. The advantage to the health of the inhabitants is of course one which appeals directly to the members of your association.

THE TRANSPORTATION OF DISEASE BY DUST.¹

BY HAROLD C. ERNST, M.D., BOSTON,
Professor of Bacteriology, Harvard Medical School.

The possible injury from such a dust nuisance as we have had this winter may be looked at from two points of view: the irritant action upon the respiratory apparatus, and the transportation of pathogenic bacteria. Of the irritant action there can be no doubt, as is illustrated by the photomicrographs of the dust from the street and the window-sill of the laboratory. The fields shown are not picked, but are from the first that were found to be thin enough for photographic purposes. They show a variety of minute jagged particles, of mineral and vegetable origin, that it is manifest would be injurious in their irritant action upon inhalation and lodgment upon any weakened spot.

That this material also carries living forms is illustrated by the slides, so far as the higher bacteria are concerned, and by the cultures that Dr. Coolidge has been good enough to make for me. In these the

¹ Read at a meeting of the Boston Society for Medical Improvement, February 19, 1900.

amount of gas production is very great, and the number of bacteria as represented by several counts is 80,000 to the gramme, at a conservative estimate and under favorable conditions. There has not been time enough to make a qualitative analysis of these bacteria, so that it is not possible to say whether any pathogenic forms are present in these particular specimens. Two inoculation experiments showed only local necrosis. The subject of the possibility of the transmission of pathogenic bacteria by dust has, however, been elaborately studied by E. Germano.² He first took up typhoid, and showed that the typhoid bacillus is not able to resist complete drying, and is not transmitted by dry dust to man. In this respect the typhoid bacillus behaves as does the cholera spirillum — and certainly most of the epidemics are not to be ascribed to transmission by dust. The infection of the air for many hundred metres about, as suggested by Froidboise, is entirely improbable.

The next bacterium studied was that of diphtheria, and the conclusions are: (1) That this bacillus can resist drying for a very long time, as well in the membrane as in the tissues and in dust; (2) an acceleration of the drying process does not influence the resistance of the bacillus either in tissue or in dust; (3) this bacillus retains its vitality longer the greater the amount of the surrounding dust (it may thus be better protected against oxidation); (4) in a condition of complete dryness the diphtheria bacillus can retain its full virulence until its death; (5) air can carry this bacillus in the living condition.

Taking up the possibility of the transmission of erysipelas, pneumonia and other streptococcus diseases, Germano demonstrated the following facts: (1) The resistance of the streptococcus to drying varies with the variety as well as the material in which the drying is carried on; (2) the resistance is always high and may last for some months; (3) the rapidity of drying does not affect the length of vitality in any way; (4) the resistance of the streptococcus increases with the mass of the imbedding material, as this prevents the direct access of the air.

The diplococcus of pneumonia belongs among the bacteria that can resist drying for a long time. (1) This property varies between wide limits, and a special variety may be of little resisting power. Kruse and Pansini were right in explaining the discrepancies of various authors upon this ground; (2) the form lying between the streptococcus and the diplococcus may be extremely resistant; (3) in Germano's experiments, the diplococcus kept its properties better in the dry than in the moist condition; (4) in low temperatures, the behavior is the same as in moisture; cold hinders drying; (5) the rapidity of drying in medium temperatures has no influence upon the retention of vitality of the diplococcus; (6) since the diplococcus may, under some conditions, resist drying for some time, even if it cannot do this to the same extent as the streptococcus, the possibility of its transportation in the air, and of infection of man through the air must be granted.

Germano then took up the study of cholera, plague and cerebrospinal meningitis, and came to the general conclusion that there is little danger of the transmission of these diseases through dust in the air.

He summarizes his final results by saying that there

must be a revision of opinion as to the transportation of important disease producers. In general it may be considered as settled that they must be dry to render their transportation by means of dust at all probable, and the experiments upon drying are only of value when conducted with fine dust. As the result of such experiments the conclusion is that the finer the dust the quicker the bacteria die.

In relation to resistance to drying, the bacteria he studied divided themselves into several groups: The first included typhoid, cholera and plague. Experiments with these showed that they often sank in number of resulting colonies from 100,000 to 0 in twenty-four hours. Therefore the chances of transportation by the air must be considered as very slight. His experiments were controlled by the use of several races of each, so that the fallacy of working with one especially susceptible to drying might be excluded. Similar results were obtained with influenza and gonorrhoea.

A second group was formed by the streptococci, the pneumococci, and the diphtheria bacillus, which in various races showed great variation in resistance to drying, some dying almost at once, some living days, weeks, or even a month; most of them died quickly, only a very small number resisted for any length of time. The so-called sporadic cases of erysipelas, diphtheria, etc., may be explained by the occurrence of these resisting types.

In a third group may be placed, as still more resistant, the diplococcus intracellularis, and with it the staphylococci of suppuration, and the bacillus of tuberculosis.

The fourth and last group includes the spore-producers, — which in this way may resist drying for an indefinite period, — anthrax, malignant edema, tetanus, etc.

Our knowledge of the acute exanthemata is not great enough to enable us to know in what group to place them; they certainly do not belong in the first, but it may be doubtful whether they belong in the second or third.

It would seem to me, then, that the conclusion to be drawn is that the danger from such a dust nuisance as we have had is greater from the direct irritant quality of the dust itself than from the chance of the transportation of any infectious disease; the winter has been so exceptional, however, that the Board of Health has an opportunity to furnish some valuable statistics upon the comparative occurrence of infectious diseases in the affected area this year as compared with last, when the same conditions did not exist.

EFFECTS OF DUST UPON THE LUNGS.¹

BY VINCENT V. BOWDITCH, M.D., BOSTON.

WHEN asked to make a few remarks upon the "dust nuisance," with special reference to its effect upon the respiratory organs, I gladly assented, delighted that the medical profession had again taken this matter in hand. The lethargy which seems to have let the people of Boston endure this state of things is as extraordinary as it is exasperating to those of us who know that the effect upon the health of the community is baneful, and who also know that the remedy is

² Zeit. f. Hyg. u. Infektionskrankheiten, Bd. xxiv, S. 403; Bd. xxv, S. 439; Bd. xxvi, S. 66, u. s. w.

¹ Read at a meeting of the Boston Society for Medical Improvement, February 19, 1900.

not difficult to find, if our citizens will only insist that a better state of things shall prevail. Will you allow me at first to recall a little of the work done by medical men upon the question of street watering?

Several years ago a committee composed of Drs. F. I. Knight, J. C. Warren, Henry J. Barnes and myself represented to the gentlemen then in power at City Hall the views of the Suffolk District Medical Society upon the wretchedly inefficient methods of street watering and the intolerably filthy condition of the macadamized streets, not only through the winter, but during the summer months. We received the rebuffs that invariably meet attempts to change existing conditions, by the remark that there was not money enough, and were asked what we proposed to do about it.

To make a long story short, the matter was agitated sufficiently to induce the subsequent mayor to allude to it in his first address. He instituted a much more efficient service by taking it out of the hands of contractors, who mulcted private individuals to fill their own pockets, and the street-watering service for nine months in the year, partly by dint of constant and persistent efforts of the committee, collectively and individually, has slowly and steadily improved, so that during the nine months of the year when the temperature has been above the freezing point, the Back Bay in the last year or two, even though very far from satisfactory at times, has been made a more habitable section of the city, as far as dust is concerned, than it was several years ago. Last year even a new departure was made by Superintendent Wells, by occasionally sending out a sprinkler in the winter months on the day when the thermometer rose above 32°.

In order to improve still further upon existing conditions, petitions for asphalt pavements on Beacon Street beyond Massachusetts Avenue, the only artery for heavy teams from the Back Bay to the Allston and Brighton districts, were signed by the residents in that street with very few exceptions.

Mayor Quincy and Superintendent Wells both cordially endorsed the idea, but lack of proper appropriation has thus far failed to accomplish what large numbers of the residents have earnestly desired. In consequence of this lack of proper pavements the citizens of Boston, especially those of the Back Bay, the most exposed section of the city, have had to endure in this open winter a vile atmospheric condition, which is a standing disgrace to any civilized community.

As a striking example of a not uncommon occurrence, I have at home a twenty-pound butter firkin nearly full to the brim of filth collected from my own doorsteps, in four hours, after a high northwest wind had caused the usual dust storm, in spite of a heavy rain during the preceding night.

It would seem almost unnecessary to speak, gentlemen, of so self-evident a truth as the baneful effect of such a condition upon the health of the community, yet it is necessary to emphasize this point. Apart from any possibility of carrying disease germs from the powdered filth lying in our streets and blown into our faces and forced into our houses, the mere mechanical irritation upon the nasal and bronchial tracts of such an atmosphere as we have had to endure this winter is sufficient to be a fruitful cause of trouble to many people. I have patients under my care now, with delicate throats and lungs, unable to leave town for various reasons, who have to be housed absolutely

during these days when, were our streets in proper condition, they could enjoy out of doors the comparatively mild and bracing air of this moderate winter. Even in the houses with the windows shut tight, my patients have bitterly complained of the effect upon their throats of the dust which sifts through the windows and doors. What a mockery it seems with the constantly growing knowledge that fresh air and open windows are essential for health, more especially for the prevention and cure of our great scourge, consumption; what a mockery it seems that we should go on enduring such a condition of affairs in our city, of which we naturally feel so proud, the many advantages of which we are apt to boast.

Our city government is not wholly to blame for this state of things. Mayor Matthews, with far-seeing policy, advocated strongly the plan of paving the whole of Commonwealth Avenue with asphalt, and of gradually extending this process to the whole of the Back Bay. This scheme was defeated by a number of people, largely those who own horses, because of the occasional slippery nature of asphalt, and in consequence the Telford pavement was substituted. From personal questioning, I know that many of those who signed that petition to defeat the mayor's plan now deeply regret their action. In consequence of this mistake it has been impossible to drive or walk on this great avenue with any comfort for a large part of the winter on account of the sweeping clouds of dust.

That asphalt is an ideal pavement or without drawbacks, none of its strongest advocates would claim, but with proper care and regulation to prevent its being constantly torn up and replaced by inferior material, it has thus far proved in our American cities the one which possesses the greatest advantages and the fewest disadvantages of all pavements used here. This is the testimony of Colonel Waring in a personal conversation held not long before his death.

Huntington Avenue and the upper part of Columbus Avenue are constant proofs of the superiority of their pavements, if one will take the pains to walk through Massachusetts Avenue and witness there the clouds of dust in winter on a windy day, almost reaching to the house-tops, and then note the condition of the atmosphere in the former streets.

In mild, damp weather, moreover, the collected filth of Massachusetts Avenue in the spring and autumn causes often a nauseating odor, most marked in the evening, which has not infrequently compelled me to leave the street from sheer disgust.

That Boston now, in comparison with many other large cities in our own country, still more with those in Europe, is, to say the least, in a most provincial condition as far as pavements are concerned, I think no one can deny.

Gentlemen, for the comfort and health of our community, I trust that this meeting may be a strong factor in bringing about the improvements which we all so earnestly desire.

TUBERCULOSIS IN PARIS.—According to the *Journal of the American Medical Association*, nearly 26% of the deaths in Paris in 1899 were due to tuberculosis—12,314 out of a total mortality of 46,988. The percentage of tuberculosis mortality at various ages was as follows: One to twenty, 37.2; twenty to forty, 60.2; forty to sixty, 30.5, and over sixty, 3.3.

THE EFFECTS OF DUST ON THE UPPER RESPIRATORY TRACT.¹

BY SAMUEL W. LANGMAID, M.D., BOSTON.

FOR many years I had been observant of the fact that whenever a dust storm occurred there was an outbreak of sore throats, until in June, 1889, eleven years ago, I incorporated into a paper which I read at a meeting of the Medical Observation Society an account of the deleterious effects of dust upon the lining membrane of the nose and throat, and ascribed to this cause much of the suffering which I was called upon to mitigate. It was evident that I was not alone in my belief and observation, since other members of the society expressed their concurrence, and the condition of our city streets and the evil effects of so much dust was made the special subject of discussion at a subsequent meeting. Action was taken to abate the evil. A committee was appointed to confer with the mayor, and a certain amount of good accomplished. But the evil was by no means eradicated. Dust storms are still frequent and the results are quite as marked as ever before.

In looking through the paper which I have referred to I found the statements as true to-day as when they were made, and I shall ask you to allow me to quote briefly a few paragraphs which it seems to me are as forceful as any I could make to-night. When it comes to the matter of how dust storms can be prevented, it might as well be said that absolute prevention is impossible, because some of the dirt is blown into the city from a long distance, from some miles of suburban macadam, or, as I prefer to call it, dirt roads. But it is certain that a great abatement can be obtained by a change of pavement. It might be said also that the ideal pavement does not exist in the world; objections there are to all, but better pavement than dirt road is used largely in other cities and to a small extent in ours. It is time that our beautiful city should be free from the criticism of visitors, who cannot understand why such a condition of mud and dust is allowed. In the paper referred to I said:

"Another factor in the production of obstructive swelling of the nasal mucous membrane is the presence of large quantities of dust in the atmosphere, and this cause, I am sorry to say, has greater significance in our city than in any other with which I am acquainted. The condition of our streets during a large portion of each year has called out many remonstrances on the score of uncleanness and inconvenience; but to what extent the *health* of the inhabitants and visitors to the city is affected has not within my knowledge been commented upon by laymen or doctors. For many years I have been able to predict an immediate increase in the number who present themselves for treatment of throat affections from my observations of the atmosphere and the conditions of the streets of the city.

"I doubt if in any other region east of the Mississippi River an atmosphere so loaded with irritating dust can be found as in this beautiful and *expensive* city of Boston. This dust, or gritty dirt, is not only encountered in the open streets, but escape from its irritating effects is not possible even in our houses. After one windy day the contents of our houses are covered by it; it lies in heaps upon the inner window sashes; it fills our halls and chambers. We live the

greater part of certain months among sifting sands, and in clouds of pulverized mud and excrement.

"Another cause of our discomfort is the plan pursued in the care of the streets. Most of our streets south of Tremont are of the variety called macadamized. These streets so made are, for a few days, after months of labor, in a clean condition; but the constant watering, with almost no sweeping, together with the attrition of the surface by passing vehicles, soon pulverizes the surface, and leaves a layer of dirt which is again wet down and so kept in a condition which makes it impossible to preserve a decent looking carriage which has been driven from the stable to the residence of the owner. The next scene is the transformation of this layer of mud and bestial excrement into clouds of 'dust' under the influence of a wind sufficiently strong to dry up the moisture faster than the life-preserving watering cart can make its round. The mud on Boylston Street is frequently two inches deep along the sides. Does any one ask how this concerns the *sanitary* condition of the city? I have said that I could predict with sufficient accuracy what the effect of such dirt storms would be as shown by the numbers of patients who would present themselves for treatment. Have we not, all of us, observed the frequency of sore throats during the months of November and March, the months when high winds prevail and the ground is no longer covered with snow?

"I do not mean to say that other causes which are productive of irritation of the mucous membrane of the respiratory organs would not produce their legitimate effects during these months, but I do believe that this condition of the atmosphere of our city is productive of incalculable inconvenience, suffering and invalidism. One of the first symptoms, and one of the most troublesome to rid patients of during these dirt storms, is swelling and abrasion of the nasal mucous membrane; one need not be a rhinologist to bear evidence to this fact; almost all of us become observers in our own persons at such times."

The effects of so much dust are not alone upon the throat, as we shall doubtless hear from others who are to speak this evening. Certainly neither ears nor eyes escape.

One of the most terrible diseases of the throat is tuberculosis. In many cases modern treatment is of great service in mitigating the suffering which results from swelling and ulceration of the larynx, and not infrequently cure of the ulceration can be accomplished. When this can be effected, life is always prolonged and unspeakable agony is abolished. I have several such cases under treatment this winter and I can testify that recovery was made more difficult and great suffering was produced by the irritating effects of the dusty atmosphere, which, in the absence of snow, has been more continuous than usual.

It has been my intention to speak briefly of my own observations of the effects of dust. I shall leave to others to suggest what steps ought to be taken to abolish some of the evil.

W. S. HALSTED, F.R.C.S.—It is stated in the *Philadelphia Medical Journal* that during the recent centennial exercises of the Royal College of Surgeons, England, Professor W. S. Halsted, of John Hopkins University, was made a fellow.

¹ Read at a meeting of the Boston Society for Medical Improvement, February 19, 1900.

RECURRENT LUXATION OF THE ULNAR NERVE.

BY F. J. COTTON, M.D., BOSTON.

THE following examples are presented as belonging to a class of cases which have been definitely described but apparently not often mentioned, perhaps not always recognized. The cases were seen by the writer while acting as out-patient surgeon at the City Hospital.

CASE I. A woman, age twenty-five, fell and struck her elbow. Following on this she had much pain on attempting to use the arm. This state of things continuing for a week, she came to the hospital. Examination showed an elbow slightly puffy and tender all about the joint, but without any evidence of bone-lesions or of effusion into the joint. Attempted motion caused a good deal of pain at the inner side of the elbow, and a tender cord was to be felt lying in front of the internal condyle. On extension of the elbow this cord slipped back behind the epitrochlea to the normal position of the ulnar nerve. The nerve seemed thicker than normal to the feel and when it was rolled under the fingers the patient complained of local pain and of pain referred to the last two fingers and the ulnar side of the hand. This referred pain was, however, not severe, hardly more than was caused by like pressure on the ulnar nerve of the sound side, while the local sensitiveness of the nerve trunk was much increased.

The forward luxation of the nerve occurred with each flexion when a right angle was reached; the nerve slipped back spontaneously with each movement of extension; slight pressure over the internal epicondyle sufficed to prevent the luxation on flexing. The nerve in luxation came forward well in front of the epicondyle. Motion of the arm was painful, the pain, curiously enough, being referred rather to the thumb than to the ulnar distribution, but the prominent subjective symptom was pain at the elbow itself on motion. There was no paresis, no numbness, no paresthesia. The arm was put up in a splint at an obtuse angle, and a pad placed over the internal condyle to guard against luxation of the nerve.

After a fortnight's fixation there was little pain and sensitiveness and somewhat less tendency for the nerve to slip out of place, while the excursion of the nerve in flexion was somewhat less. The pad and bandage were continued, the splint omitted. Massage was begun and light use of the elbow allowed.

The subjective symptoms improved slowly but steadily, and the patient soon discontinued treatment. When looked up four months later, she could use the arm nearly as well as ever and complained only of occasional darting pains in the hand. There was no numbness, no paresis. On palpation, the thickening of the nerve trunk proved to be entirely gone. The nerve still slips out of its normal place when the elbow is flexed, but slips only inward to the tip of the epicondyle, not in front of it. At times on active flexion the patient is conscious of a more decided snapping of the nerve. No further treatment was carried out.

CASE II. A girl of eleven fell and struck the elbow in falling. Three days later she came to the hospital with an elbow slightly swollen but showing no synovial effusion. The bones were intact. Motion of the arm was painful and there was some

spontaneous pain in the middle and ring fingers but no referred pain in the ulnar distribution. On flexion of the elbow the ulnar nerve slipped out of place with each flexion when an angle of 30° beyond the right angle (that is, an angle of 60° of upper arm and fore-arm) was reached, moving inward and forward to a point a little anterior to the internal epicondyle, but the range of the luxation was much less than in the previous case. The nerve trunk was not obviously thickened; on pressure on it there was distinctly increased sensitiveness of the nerve itself, but no referred pain or tingling. This rather unusual insensitiveness was equally to be observed on the sound side. Motion of the injured elbow was only moderately painful.

The arm was put up in an internal angular splint at a right angle, in which position the nerve remained in place. After three days there was practically no pain, much less sensitiveness on manipulation and perhaps slightly less range of the luxation of the nerve. The splint was continued and massage begun. There was a gradual improvement in symptoms till an approximately normal condition was reached, except that the subluxation still occurred in flexion.

In this case there was a history of a fracture at or near the elbow at two years of age, and though there was no deformity to be made out, yet there is no evidence that the recurring subluxation may not have existed prior to the recent injury, though the subjective symptoms were evidently due to the recent hurt.

CASE III was a boy of about ten. Here also the luxation was the result of a fall—three days before—and amounted really only to a subluxation, the nerve not passing beyond the tip of the condyle. The symptoms were only local sensitiveness and some pain at the elbow on motion—there were no signs of damage to the nerve itself. The patient did not return, and the course of the injury is not known.

In searching the literature for recorded cases the writer has found a considerable number, only a portion of which, however, belong to the traumatic class.

Blattmann described a case as early as 1851. Gruber, in 1867, described anatomically, but not clinically, a luxation of the ulnar nerve. The first adequate accounts of the recurring luxation seem to be those of Lutz in 1879 and of Zueckerkandl in 1880.

The cases recorded group themselves into two classes—practically distinct—the "habitual" luxations, where there is no known exciting cause for the dislocation, which may or may not be associated with symptoms, and the traumatic series, where there are almost invariably accompanying symptoms of greater or less severity. The trauma acting as the cause may be direct violence or muscular over-exertion or simply habitual over-use of the elbow.

In all these cases of either class the external anatomical condition is much the same; when a certain degree of flexion is reached the nerve moves inward to the tip of the internal epicondyle, and in the severer cases snaps over it to lie on its anterior surface a centimetre or less in front of its tip only to return to its normal position when the elbow is again extended.

The exceptions to this type—the permanent luxations of the nerve—seem to be very unusual. Schilling reports a case (non-traumatic) where the luxation on one side was permanent, on the other recurrent; a report of Poncet's seems to imply, though it does

not state, a permanent luxation, and the same may be said of Cunningham's report.

Of the congenital or habitual luxation many cases are reported. As to symptoms: in Schilling's case there was marked weakness and considerable atrophy in the muscles supplied by the ulnar; in MacCormac's case there was numbness and weakness enough to prevent work and to necessitate operation; in Zuckerkandl's, local fatigue on exertion; in Poncet's, numbness and pain, etc. On the other hand there are many cases without other symptoms than those following an occasional blow or pressure on the exposed nerve or without any symptoms at all.

Collinet examined 500 patients with a view to settling the frequency of the condition and found 13 in whom the nerve luxated forward in flexion, in 5 of them on both sides. Drouard carried out a like investigation on 200 subjects and found the complete luxation occurring in 3 cases only, though 15 others showed an abnormal mobility of the nerve in flexion.

Part of these cases showed no symptoms whatever, in some there was numbness and tingling in the third and fourth fingers when the elbows rested on a table or when the nerve was struck. In this connection it is interesting to note that wood engravers who rest the elbow in working sometimes develop, according to Bruns,¹ a partial paralysis of the hand muscles, etc., as a result of the pressure of the bench on the ulnar nerve, so it would seem that such symptoms as just described are not quite special to the cases under consideration.

The sum and substance of this list of non-traumatic cases would seem to be that the luxation per se usually gives but little trouble and may exist unknown to the patient, to be found out (as were so many of those described) only by a systematic examination.

To pass on to the traumatic class, we find usually, though not always, a more considerable train of symptoms, least in the cases in which over-use or a single muscular strain is the cause. Cases of this sort are reported by Blattmann, Jalaguier, Holden, Lutz and Lange, which showed no symptoms beyond some pain at the elbow and moderate tingling and numbness (on pressure, or spontaneously) in the parts supplied by the nerve. In Drouard's case, on the other hand, though the nerve was simply snapped out of place by forcible flexion of the elbow, numbness, atrophy, and contractures of the last two fingers developed, leading to almost entire uselessness of the hand. The patient in this case was an alcoholic, and this may have had something to do with the development of the neuritis from relatively slight injury.

Where the trouble has been the result of a fall or a blow, there are usually nerve symptoms, not necessarily severe. In cases noted by Cunningham, Plicque, Smith and Tronson, in Anger's case (the result of a dislocation of the elbow), as also in the writer's cases, the symptoms on the part of the nerve which persisted after the local damage had quieted were comparatively slight—occasional pain or tingling and sensitiveness of the nerve-trunk to pressure. In Wharton's case there was a good deal of pain in the distribution of the nerve; in Schwartz's, considerable numbness. In Felkin's case there was, beside the local pain at the elbow, neuralgic pain and numbness, lasting for some weeks, and flexion-contractions of the third and fourth fingers. Annequin reports

pareisis of both sensation and motion, Andral loss of sensation in the area supplied by the ulnar, atrophy, and flexion-contraction of the little finger.

In looking over the histories of these cases, we find the nerve symptoms following directly on the injury, and subsiding gradually, more or less independent of treatment. This is important as showing the nerve damage due to the original trauma, not to the irritation from the slipping of the nerve. As to the actual pathological condition which the symptoms represent, the data are scanty. The only autopsy is Schilling's; in this case the nerve and its sheath were considerably thickened for about 4 centimetres of its length at the elbow. In Schwartz's account of his operation he speaks of the nerve being locally thickened and reddened, and Croft found it in his case slightly thickened. In Drouard's case and in one of the writer's there was apparent thickening on palpation.

In Drouard's case, in that of Schilling just noted, in those of Annequin and Andral, and perhaps in MacCormac's, it seems fair to assume secondary degenerative changes in the nerve, but in most of the cases it is probable from the data given that the pathological process is essentially perineural, primarily a damage to the structures enclosing and fixing the nerve with possibly mild interstitial neuritis, rather than any considerable damage to the nerve-fibres.

There has been a good deal of theorizing as to the gross anatomical conditions in these cases as well as in regard to the pathology. As for the congenital or habitual cases, there must evidently be much laxness of all the fibrous tissues closing the groove in which the nerve lies, for Raymonecq's experiments on the cadaver showed that it was necessary to cut away a good deal in order to free the nerve so that it could be dislocated. Given this laxity or absence of the fibrous tissues, the experiments on the cadaver by Zuckerkandl and Raymonecq have shown that the triceps, unless very small, spreads inward enough on flexion to shove the nerve in front of it over the tip of the epitrochlea and this irrespective of the existence of a small epicondyle or of a cubitus varus to favor its easy transit. This spreading inward of the triceps on flexion can readily be demonstrated on the model or on oneself and seems to explain fully enough what causes the recurring luxation when once the nerve is freed.

As for the smallness of the condyle, and more especially the cubitus varus, alleged as a cause, it is evident that neither of these can more than present a favorable condition. There seem to be only 2 cases where there was actually a cubitus varus (Zuckerkandl, Poncet). The writer's second case had had a fracture, but there was no deformity.

As to the action of trauma in producing the condition, it may be assumed that some of these cases had naturally weak or lax fibrous attachments in this region, but in approximately normal elbows a good deal of tearing must accompany the loosening up of the nerve. Jalaguier says at least the fibrous arch of origin of the flexor ulnaris must be torn, and Annequin, in the description of his operation, actually notes such rupture and also the finding of torn shreds of fascia higher up. It would seem that the rupture may result either from the tearing of the tissues by muscular overaction or from the ripping force of a blow from without.

The treatment carried out in these cases has been

¹ Bruns; *Neurol. Centralblatt*, 1895.

either fixation with or without massage, or operation. Nine cases are reported in which an operation was carried out.²

The operation has usually aimed at the re-formation of the groove to contain the nerve. Either fibrous tissues have been trimmed out and loosened to make the groove in which the nerve was laid (Annequin, Poncet, Smith) or the edge of the triceps has been carried across and hitched to the internal epicondyle, leaving the nerve beneath the bridge so formed (Croft, Smith) or a slip of fascia, dissected up from the covering of the epitrochlear group of muscles, has been carried outward and stitched to the triceps (Schwartz). Croft, beside forming a groove, stitched the nerve sheath down and Jopson laid the nerve in a groove made in the triceps, stitching the fascia over it. Andral, for some occult reason, resected two or three centimetres of the nerve; the function of the nerve returned, but the luxation was not cured.

The other operations were all successful in curing the luxation. In some of the cases the surgical interference was followed by increased symptoms of nerve irritation; luckily these symptoms proved only temporary (Croft, Jopson).

It is impossible to study the recorded cases without coming to the conclusion that the operation is one for the luxation only, and can cure only such symptoms as are really due to the luxation. The chance of a cure of the luxation itself by conservative methods is poor; only one such success is reported (Plicque), but in many other cases, including the writer's, conservative treatment has brought about a relief of all symptoms, at least as soon, probably, as if the region of the damage had been stirred up by an operation, and the persistence of the luxation has not seemed to be of any moment. Where the nerve damage is directly due to the irritation of the constant dislocation, or where symptoms on the part of the nerve persist unduly long after the first effects of the trauma have worn off, the question of operation comes up. The operative treatment seems, so far as it goes—that is, for the luxation—to be without notable drawbacks and effective, but the writer is impressed with the notion already voiced by Quenu in his paper on the subject, that it is the nerve symptoms, not the luxation in itself, that should first be considered in deciding between conservative and operative treatment.

Medical Progress.

RECENT PROGRESS IN NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON.

(Concluded from No. 4, p. 92.)

MYELITIS.

HOCHE,¹⁰ recognizing that the term "myelitis" has often been applied to conditions which were not of inflammatory origin, has undertaken a series of experiments to determine more accurately the real nature of certain of the changes in the spinal cord. In the first series of experiments he produced embolism of the spinal arteries by the injection of aseptic substances into the aorta of dogs, using lycopodium, Kamala seeds, the pollen of typha japonica, etc. Such emboli caused hemorrhagic infarctions and necrosis of tissue in about thirty hours. This resulted in the formation of cavities which did not resemble those of syringomyelia. In the necrosed tissue were many granular cells, which were derived from leucocytes, neuroglia cells or connective-tissue cells, the large cells being always derived from connective tissue. The neuroglia showed a very sluggish tendency to produce new tissue to replace that destroyed, but the new tissue was chiefly of connective-tissue origin. The walls of the arteries plugged reacted to the mechanical and perhaps to the chemical nature of the emboli, and were thickened and infiltrated with small cells, which also invaded the perivascular tissue. The reaction varied with the substance injected. In a second series of experiments he injected cultures of various bacteria, Fränkel's diplococcus, staphylococcus aureus, bacterium coli commune, etc. The changes differed from those of the first series in the presence of mycotic emboli, and the more intense and more diffuse cell infiltration about the smaller blood-vessels, with many foci of round cells about the infiltrated vessels. There were also foci of leptomeningitis, especially after the injection of the bacterium coli commune. The alterations did not extend beyond the region of the cord reached by the bacteria, showing, therefore, that they were not due to the action of substances in the circulation produced by the bacteria. The changes were very similar to those of acute infectious myelitis in man. Acute myelitis, in the strict sense of an acute inflammation, is applicable only to a very limited group of cases of infectious origin. In the later stages of various pathological processes changes occur not unlike those of true inflammation, such as the formation of granular cells, the occurrence of swollen axis cylinders, etc.; and we very rarely have an opportunity to observe in man the early stages of any of these processes, in which stages alone can the true nature of the process be determined. We must exclude all cases of central softening from thrombosis in tubercular and syphilitic arteritis, the changes from compression, the rare changes from embolism, the cases of ischemic necrosis, as in caisson

¹⁰ Archiv für Psychiatrie, xxxii, 209, 975, 1899.

disease, and primary degenerative processes before we can speak of true myelitis. This is characterized in its earliest stage by alteration of the vessel walls, with or without hemorrhage, increase of the cell elements, proliferation of the glia and connective tissue and changes in the nervous parenchyma. In his experiments on dogs Hoche found that the central canal aided in the distribution of the inflammatory agents to various parts of the cord. In adults this canal is often partly closed by proliferation of the ependyma, but in children it is open throughout the length of the cord. This may be an explanation of the much greater frequency of infectious myelitis in children, since bacteria may through the patent central canal be more readily conveyed to the gray matter of the cord, especially the anterior horns, which lie nearest to the canal.

CHANGES IN THE SPINAL CORD IN CEREBRAL TUMORS.

Batten and Collier¹¹ have studied the changes in the spinal cord in 29 cases of cerebral tumor. In a preliminary review of the literature on the subject, they find that in 17 reported cases of cerebral tumor the cord was negative in only 2, and that in all the rest changes were found in the posterior columns. These changes were not due to early tabes, to secondary growths involving the posterior spinal roots, to meningeal thickening, or to secondary degeneration, and the changes were most marked in the lower cervical region. In their own cases 9 showed slight and 11 marked degeneration, and degeneration seemed more liable to occur with tumors in the temporo-sphenoidal region. Tumors situated behind the parietal region also seem more liable to give rise to degeneration than tumors more anteriorly situated. They conclude that degeneration of the posterior columns of the cord occurs in about 65 per cent. of the cases of cerebral tumor, and that it is more liable to affect the cervical region than the dorsal or lumbar regions, and is more marked in the postero-external than in the postero-internal columns. This degeneration is of root origin and arises from the point where the root enters the spinal cord; the posterior roots are always less affected than the posterior columns, and they may show no degeneration. The degeneration is due to traction on the posterior roots by distention of the arachnoid, owing to the increased intracranial pressure and especially such as tends to rapid dilatation of the ventricles and the subarachnoid space in the spinal cord. It is independent both of the situation and of the nature of the tumor, except in so far as their liability to give rise to the preceding condition is concerned. Optic neuritis bears no relation to the occurrence of posterior degeneration. Absence of the knee-jerks, except in the semi-comatose state, indicates posterior degeneration, but their presence does not negative such a condition, and the absence of the arm-jerks has the same significance. Degeneration may also occur in the direct cerebellar tract; such degeneration is due directly to pressure on the cervical region of the cord.

FREQUENCY OF EPILEPSY.

A statistical inquiry by Russell¹² in 5,000 patients as to the frequency of epilepsy gives some interesting results. Of these patients, 11.9 per cent., excluding

those attending directly for epilepsy or hystero-epilepsy, gave a family or personal history of fits, and 3.6 per cent. had themselves suffered from fits; of these, 5.2 per cent. gave a family history of epilepsy, and 1.8 per cent. had had epilepsy themselves. For various reasons, however, these percentages required some revision, so that he considers the average cases show 9.5 per cent. of fits in the family or personal history and 2.3 per cent. of fits personally, of which 4.3 and one per cent., respectively, were epileptic. Grouping the cases according to diseases, he finds an incidence of fits in patients who had little the matter with them of only 4.4 per cent., no personal fits being registered. This he regards as nearest the incidence in normal persons. Over one-half of the more definitely ailing patients show a fairly uniform average of epileptic incidence. Of the other cases, a group including acute (? also chronic) bronchitis, phthisis, chronic pneumonia, valvular heart disease, and acute and subacute rheumatism, shows a striking increase in the number of patients who have themselves suffered from epileptiform convulsions. Finally, the most marked epileptic incidence is to be found in the cases of chorea, functional headache and chronic nervous disease, in all of which the relationship reaches a high degree.

TREATMENT OF EPILEPSY.

At a recent meeting of the alienists of southwestern Germany, Fürstner¹³ spoke of the treatment of epilepsy. The results of treatment are difficult to estimate satisfactorily; in asylums severe and inveterate cases, complicated more or less with psychical symptoms, form the majority of the cases under observation, and in spite of favorable external conditions, such as constant medical observation, proper and long-continued treatment, and efficient dosage of drugs, the results are comparatively unfavorable, while in out-patient or private practice the patients are not sufficiently under control. The laity rarely have sufficient insight and perseverance to carry out a long-continued bromide treatment, they object to the alleged injurious effects of bromide and resort to secret remedies, thus lessening the chances of recovery. The dread of bromism, brought forward by many physicians, was regarded as exaggerated; in this Fürstner was in agreement with Binswanger. Using up to a drachm a day in children under ten and up to a drachm and a half in adults, he had seen only transitory symptoms of bromism. He holds that if these doses cause no improvement, larger doses will rarely be of benefit. We cannot predict in what cases bromides will be of benefit, and we must always experiment to see why it has no effect or in what cases it is especially beneficial. It is not always the old, severe cases in which bromide fails, but it may also fail in fresh cases. In such cases, however, diagnostic errors are possible. He had seen a considerable number of cases, chiefly in young persons, where the attacks apparently did not differ from epilepsy. They occurred chiefly by day, and four or five times in a day; the tongue was bitten and other injuries, although usually slight, were caused in an attack; the attacks were often excited by physical disturbances, constipation or external influences; after the attacks the patients were sleepy and irritable. There was often inequality of the pupils and increased reflexes. Under bromides the attacks were often increased in frequency, and on increasing the dose the patients be-

¹¹ Brain, xxii, 473, Winter, 1899.

¹² Loc. cit., 503, Winter, 1900.

¹³ Neurol. Centralblatt, December 15, 1899.

came dull and apathetic, and there were intestinal disturbances and acne. These attacks Fürstner regarded as not epileptic but hysterical, and by removal to different surroundings and isolation, with a cessation of bromides, the attacks diminished and sometimes wholly ceased. In another class of cases, observed chiefly in children, although only the symptoms of genuine epileptic attacks, including *petit mal*, were reported, there was probably some congenital or early organic brain disease. In many of these cases there had been a slight cerebral infantile paralysis with convulsions in infancy, then the convulsions ceased to recur between twenty and thirty. In these cases bromide is of uncertain benefit, and the attacks may increase in frequency under its use. Many of the cases classed as late epilepsy prove to be due to organic disease. Only those cases in which organic disease can be excluded should be so classed, but this may demand a long period of observation. In all these cases the effect of bromide treatment is an important aid in the diagnosis. Fürstner further holds that an improvement in the results of treatment for epilepsy may be obtained by a consideration of the convulsions of childhood. In 141 cases where epilepsy occurred before the age of eighteen there had been convulsions in infancy in 91; in 52 cases where it occurred between twenty and thirty there had been convulsions in infancy in 18. Attacks in childhood should be treated systematically with bromide, the treatment continuing after the cessation of the attacks. The best results were obtained where the treatment continued until after puberty. In the discussion Wildermuth confirmed the reader's opinions as to the value of bromide treatment for diagnosis, and the importance of early treatment.

SYMPHECTOMY IN EXOPHTHALMIC GOITRE AND EPILEPSY.

Considerable discussion has occurred, especially in France, in regard to the benefits to be derived from division or resection of the cervical ganglia or portions of the sympathetic nerve, particularly in epilepsy and exophthalmic goitre. Franck¹⁴ sets forth clearly the physiological conditions which might indicate such an operation. The cervical cord of the sympathetic acts as a propulsor of the eyeball, not by any vasodilator action, but by its action on Müller's muscle. Section of it diminishes exophthalmos. It acts upon the intra-ocular circulation both as a constrictor and as a dilator of the vessels; section diminishes intra-ocular tension, and thus it may prove useful in glaucoma. It does not dilate but it contracts the thyroid vessels; the dilator nerves are contained in the laryngeal nerves, especially the superior laryngeal. Section must therefore cause paralytic dilatation and increase the congestion of goitre. The sympathetic has no action upon the secretion of the thyroid. It has some influence in constricting the cerebral vessels; its section therefore increases the cerebral blood supply. As the influence of cerebral anemia in exophthalmic goitre and epilepsy is very problematical, the result of section must be equally problematical. It has no action upon the vessels of the pons, medulla or upper cord, which are supplied by the vertebral nerve. The accelerator nerves of the heart are derived only in small part from the cervical cord, the majority coming from the superior thoracic region; they are therefore suppressed only by total resection. The whole sympathetic apparatus is endowed

with direct sensibility and transmits to the medulla and upper cord the centripetal influences coming from the heart and aorta. Resection probably has as much action in suppressing the transmission of abnormal stimuli from the heart and aorta as in suppressing centrifugal impressions from the thyroid or brain. Aortic and cardiac irritation may provoke circulatory reactions like those of exophthalmic goitre, so that resection of the whole sympathetic may act by suppressing these centripetal irritations. This idea suggests the possibility of relieving angina pectoris by such an operation. Dastre¹⁵ rejects the idea that exophthalmic goitre is due to intoxication from hyperactivity of the thyroid, and goes back to the old theory that it is due to disturbance of the sympathetic—a theory which was abandoned because part of the symptoms were plainly due to vasomotor irritation and part to vasomotor paralysis. He and Morat claim that the sympathetic is complex, never containing both vasoconstrictor and vasodilator fibres. If we stimulate the right place we may obtain both irritant and paralytic symptoms. By stimulating the upper thoracic portion he obtained exophthalmos, acceleration of the pulse, thyroid congestion, etc. The operative results in cases of exophthalmic goitre seem to suggest these views. Gérard-Marchant¹⁶ has collected 37 cases, with 4 deaths from various causes in a few days, and 3 deaths later from nephritis, but without mention of the good results; in 7 cases of his own 2 were cured, 2 were much improved, 2 not improved and 1 died. In 2 other cases Schwartz reported considerable amelioration. Gérard-Marchant believes resection of the sympathetic is the best operative procedure, in view of the bad results of thyroidectomy, but he thinks that partial resection gives better results than total resection. Abadie¹⁶ also reports a complete and permanent cure in a case operated on in 1897. Jonnesco¹⁷ reports 5 recoveries. Chipault¹⁸ also reports satisfactory results in 1 case. On the other hand, Boinet¹⁹ did a partial thyroidectomy in a very severe case, followed by resection of both sympathetics with no benefit. Penguiez²⁰ practised resection of both sympathetics at a month's interval on a woman of twenty, with the three cardinal symptoms and profuse sweating. In a fortnight the goitre had disappeared, the exophthalmos was much diminished and the pulse had fallen to 116. Two weeks later she left the hospital nearly cured, but two weeks and a half later she returned, extremely emaciated, with so great exophthalmos that the lids could not cover the eyes, a temperature of 39.2° C., and suppuration in one eye. She became comatose and died in four days.

Sorgo²¹ still holds to the theory that exophthalmic goitre is due to an excessive or perverted action of the thyroid gland, and he considers that operation on the gland is justified in severe primary cases that do not do well under medical treatment. He has collected statistics of 172 operations; 48 were cured, 89 improved, 11 not improved, and 24 died. He considers that after resection of the sympathetic the exophthalmos is often much improved and that the other symp-

¹⁴ *Revue Neurologique*, September 30, 1899.

toms are not much changed. The operation he believes is more dangerous than its advocates admit, and its benefits are exaggerated.

While the benefits of the operation in exophthalmic goitre seem to have a certain physiological basis, they are still doubtful. In epilepsy, however, the justification of the operation is still lacking, in spite of Chipault's enthusiastic propaganda. Ferrarini²² resected the sympathetic on one side and caused permanent irritation by a ligature on the other side, in rabbits. Within three days the cortical cells on the side of the resection were profoundly altered, and somewhat affected on the other side. This alteration was due to the changes in the circulation from the vasomotor paralysis following resection. It is evident that a process which injures the cortical cells is hardly indicated in epilepsy. Laborde²³ produced epilepsy in the guinea-pig by hemisection of the cervical cord, and then practised resection of the sympathetic on one or both sides without the slightest effect on the epilepsy. Vedal,²⁴ however, in toxic epilepsy produced in the guinea-pig by tobacco, found that the quantity of poison required to produce convulsions depended upon the activity of the cerebral circulation. When the circulation was slow, after ligature of the carotid, a small dose sufficed; when it was accelerated, after resection of the sympathetic, a larger dose was required. Resection therefore had some efficacy. On the clinical side the most ardent advocate, as we have said, has been Chipault.²⁵ In 18 cases he claims that 5 were much improved, none were made worse, and 10 were unaffected. In a considerable number of cases the crises and mental troubles disappear or are permanently benefited. The results are better when both sympathetics are operated upon. The action is thought to be due to the acceleration of the circulation in the brain, washing out the toxic substances. The dangers and inconveniences of the operation are *nil*. Subsequently he reports²⁶ 4 other cases cured or relieved by the operation. They had been previously rebellious to medication, the improvement had lasted from four to twelve months, but bromides had been continued. Jonnesco²⁷ reports 9 cures, 4 improved and 2 unaffected in 15 cases where both sympathetics had been resected. On the other hand, Souques²⁸ and Ricard²⁹ each report failures. Jaboullais and Lanois,³⁰ after a study of 16 cases, decide that the operation is not warranted. It rests on the contestable hypothesis that the epileptic attack is accompanied by cerebral anemia, but the vascular change following sympathectomy is not permanent; the congestion of the face and mucous membranes ceases in two or three months after the operation, and clinical facts do not confirm the promises of the operation. In the discussion on Chipault's article, Dupuy and Gley protested in the name of physiology against the operation for epilepsy, and Dejerine dealt a heavy blow against the trustworthiness of Chipault's figures. In one of the cases reported by Chipault as successful the attacks had become much more frequent. The operation is useless and dangerous, several cases resulting fatally; the trouble may be made worse by it and men-

tal troubles may appear. In children the operation may lead to defective development of one side of the face.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting, Monday, February 19, 1900, DR. E. H. BRADFORD in the chair.

The subject of the evening was

THE DUST NUISANCE.

DR. HAROLD C. ERNST read a paper entitled

THE TRANSPORTATION OF DISEASE BY DUST.¹

DR. VINCENT Y. BOWDITCH spoke on the

EFFECTS OF DUST UPON THE LUNGS.²

DR. SAMUEL W. LANGMAID described the

EFFECTS OF DUST ON THE RESPIRATORY TRACT.³

CLIFFORD RICHARDSON, ESQ., of New York, read a paper on

ASPHALT PAVEMENTS; THEIR NATURE AND DESIRABILITY.⁴

DR. CLARENCE J. BLAKE: So far as the organ of hearing is concerned its trouble from dust is incident to the irritation of the mucous membrane which has already been described, and I desire from my observation in regard to ear complications under the conditions mentioned to very heartily second the remarks which have been made. Like Dr. Langmaid, my attention was drawn to this subject several years ago, and wishing to learn the source of the dust which was blown over the Back Bay I made a series of experiments in the house which I then occupied in St. James Avenue, a house with a swell front and three stories. The experiments consisted in fastening in the window, raised three inches at the bottom on the windward side of the bay, on each story, a strip of cotton wool, the window on the opposite side of the bay being widely opened and the door of the room closed, so that an indraught on the windward side should be facilitated. These pieces of cotton were on several occasions exposed in the first, second and third stories simultaneously to dust storms blown from the west. At that time the Back Bay was but sparsely built upon, and the surface consisted largely of fresh gravel brought from the Dedham hills. Notwithstanding this fact, and although the fine gravel furnished a large part of the accumulation in the cotton, there was found also fine dust, containing particles of carbon soot, fine gravel and the chopped straw from horse droppings. The soot and fine dust were found in larger quantities on the third story, the coarser gravel together with the soot and dust on the second story, and on the first story the same ingredients of the dust cloud and the largest proportion of straw from the droppings from horses. Some of the chopped straw was found in the second and third story windows also, but the straw on the first story was evidently

heavier, and an examination under an ordinary magnifying glass showed that the particles of straw on the first story were loaded down with dust and sand, the presumption being that the sand blown upon the horse droppings had loaded a portion on the outer part of the ball dropped, and so weighting the straw the wind had not carried it to the upper story. I had hoped to repeat these experiments just before this meeting, but the snow storm prevented. The extent to which even large pieces of gravel can be carried by a strong wind blowing from the westward down our streets is evidenced by the effect on the glass in some of the windows in this same house in St. James Avenue. In two windows with westward exposure there were holes through the glass made by large pebbles. I remember in the old Blake house on Washington Street a similar hole through a window pane, the result of a pebble blown through the glass during the "great September gale."

It has been said that one of the best testing machines for determining the condition of a road is a man on a wheel, and I have made some other observations during this winter while bicycling. The dust blown over the asphalt pavement on Beacon Street is of the same character as that which accumulated on Dr. Bowditch's doorsteps; the smaller particles come from a considerable distance, but a great deal of the heavier part is contributed from the upper end of Beacon Street itself. That portion of Beacon Street is in very poor condition, is muddy when moist, freezes into hard ruts, and these frozen projections between the ruts are ground down by the wheels of the large wagons and teams coming in from Brighton, so that, going over that portion of the road on a bicycle in the morning after a rain of the night before and a fresh freeze, care would have to be taken to avoid the ruts. Going over the same road in the afternoon the ruts would have been ground down to a comparatively smooth surface. This grinding down of the frozen projections between the ruts meant merely a distribution of their material over the lower part of Beacon Street in a strong westerly wind. It is very plain therefore that with outlying dirt roads cut up by heavy traffic and swept by strong currents of air carrying three qualities of dust—the very fine dust, the coarser gravel and the result of the droppings of animals—there is a very serious menace to health, and I am much obliged, Mr. President, for an opportunity to be present at this meeting and to bear witness.

DR. C. H. WILLIAMS: I can only add a word to what has already been said in regard to the irritation of the mucous membrane of the eye which is caused by this irritating dust. I have noticed during the past winter, for instance, a considerable increase after each of these dust storms of acute conjunctivitis caused by the irritation of the dust getting into the eye. I remember one child on Marlboro Street who cannot go out in such weather, because each time she goes out on the street, although she may have a thick veil over the face, yet when she comes back the eyes are red and there is considerable lachrymation, and the child herself complains of the dust as "biting" her eyes, so that practically whenever there is one of these dust storms in progress the child is confined to the house. This is simply a type of a great many other cases. I think in considering the question we ought to see what some of our neighbors are doing in regard to the same conditions. It would be interesting to have a

careful inquiry made in regard, for instance, to the results which they have obtained in Buffalo. In that city, situated at the end of Lake Erie, they are exposed to violent winds, and they have found practically that the dust nuisance has been abated to a very large extent by the improved pavement which they have been putting in, largely of asphalt. In that way they have been able to reduce the trouble caused by the dust, and have materially decreased the amount of dust in the air. I am very glad this matter is to be taken up by the society.

PROF. C. FRANK ALLEN, Professor of Railroad Engineering, Massachusetts Institute of Technology; President Boston Society of Civil Engineers: I do not know that what I have to say on the subject will shed very much new light upon it after the paper you have just listened to, but perhaps cumulative testimony may be valuable to some extent, and it is also possible that my point of view may be slightly different. Unfortunately I have not been able to hear the papers of the earlier part of the evening. I understand, however, that the subject of the evening has been dust, and that there is a desire to get rid of it, and it seems to me that the pavement most effective for that purpose is certainly the asphalt pavement. The gain would be very much greater if we had much larger areas of asphalt pavement. The asphalt pavement is found by some to be slippery. I presume that it would not be anything like as slippery if there were more of the asphalt pavement. One serious difficulty with asphalt pavement, as we have it here, is that there is so little of it, and that it is so close to the dirt pavements of various kinds. If you consider the macadam pavement as a dirt pavement, the dirt from the macadam pavement or the gravel pavement can be carried by the wheels for a considerable distance and left on the asphalt street. The statistics, however, certainly show that asphalt streets are not slippery to the extent that has generally been believed. A macadam pavement, as you know, is made up of comparatively small particles of stone compacted as thoroughly as possible so that there will be as small an amount of void spaces as possible, but these spaces must be filled with some cementing material, and the best cementing material seems to be the material that has been worn from the stones, part of it in its passage through the crusher, but part of it from the wear on the street. If you will find a piece of pavement which is not watered much and which has very little travel on it, you will find that after a heavy wind a good deal of the cementing material has been blown away from between the stone. On Saturday I observed exactly that condition in front of the Museum of Fine Arts. In places on the curve where the carriage wheels seem not to have frequently passed, some of the stones were loose on the surface, and it is undoubtedly true that the carriages in passing over a pavement are continually providing fresh material worn from the stones to help keep the stones cemented in place. If the fine material of that sort is kept wet it does not do much harm in the way of dust, but this meeting is held perhaps at a favorable time to get the worst impression from dust from the fact that recently, on account of temperature, it has not been possible to keep the streets watered and the winds have been high enough, so that the dust has had a good deal its own way. Where the grades are low it seems to me the inevitable conclusion is the asphalt

roadway if you want to get the best thing to be had. The asphalt, as has been said, wears little or, substantially speaking, not at all. As to how far you can carry your asphalt streets there may be a chance for question. Some engineers would lay an asphalt surface up the long hill on Beacon Street, and some engineers would not dare to put asphalt on a hill as steep as that. I suppose that there would be at least three or four engineers who would refuse to put asphalt on this long hill on Beacon Street to one who would be willing to take the chances of the comparatively smooth surface of asphalt on a hill as steep as that. You understand of course it is largely a matter of experience and a matter into which judgment must enter.

When you go beyond the asphalt street it is a little more difficult for me to tell what you should take next, but I am inclined to the opinion that you would find a brick pavement good. I am not ready to say that definitely. I have not looked into it far enough to know on what grades you can use brick pavement, how far you can go on steep roads with brick pavement. I understand it has been fairly successful on some steep streets in Worcester. Brick pavements have been used in many places in the West where good material of other sorts is not readily secured, and the testimony in relation to brick pavement has been very mixed. In certain cities brick pavements seem to have given the very best of satisfaction. Other cities have tried them and been much disappointed. On the whole, the experience with brick pavements in Boston has been less satisfactory than many people had hoped, but I think there is no question of the fact that brick pavements are better to-day than they ever have been before, and I personally expect that brick pavements will perform a very important function among pavements. Where you have a road steeper than you think is safe for brick pavement you very likely might use a granite block of good quality, and just where the limit is between the asphalt and brick, brick and granite block I do not know. When you come to a very steep road I am inclined to think that most engineers would feel it necessary to use either macadam or gravel; they would be unwilling to trust granite block or brick or asphalt.

It seems to me that the desirable thing is asphalt on the level roads; on the easier hills also, as far as by experience you think it safe to carry it; on steeper hills perhaps brick; perhaps on somewhat steeper hills granite block, neither of them so clean as asphalt, the granite block probably not so clean as brick. Probably in some cases you will find it necessary in spite of your desires to use the objectionable macadam or gravel pavement. It is claimed by some, and it is probably true, that the pavement of asphalt is very good if it is dry or if it is thoroughly washed. The intermediate stages are bad, and largely in proportion to the amount of dirt that has been brought on to the asphalt from the other streets, so that in order to get the full benefit of asphalt I believe that you should have large areas of it. In relation to the slipping, my understanding is that horses that have to pass between asphalt and granite block back and forth are more liable to fall than on either kind of pavement alone, and this also furnishes an argument for greater uniformity, and for larger areas of asphalt.

MR. WM. E. McCINTOCK, Chairman Massachusetts Highway Commission, Instructor in Highway

Engineering, Harvard University: I don't see that there can be a great deal for me to say after listening to the very complete and interesting paper by Mr. Richardson and the remarks made by Professor Allen. I think I can in the main agree with what Mr. Richardson has said with reference to asphalt pavement. It is certainly clean, but the key to the whole situation lies in the fact as he stated it, that the surface is so smooth that it must be kept clean, must be swept, and I will say there is no type of pavement I know of which can be kept clean without constant work. Hundreds and thousands of loads are taken from the firmest and most solid pavement every year. This dirt does not come from the joints in the pavement. The statement Mr. Richardson made with reference to the asphalt is true of any kind of pavement. If the material from the foundation works upward through the joints, the surface must show a settlement, and yet it does not show such settlement notwithstanding the fact that hundreds and even thousands of loads of dirt, made up of the various kinds of material referred to before, may have been removed. My experience has been largely with macadam roads. I have often made the statement, and still adhere to it, that probably outside of the city streets, where watering takes place several times a day, fully 90% of the wear on a macadam road is due to the weather. One of the most difficult problems in building and maintaining State roads in the country parts of the Commonwealth is to prevent the wear and tear due to wind and weather. The very method of building the road must convince you of the truth of this statement. The road is built of fragments of stone rolled in place and covered with about one-half inch of fine detritus obtained while breaking the larger stones in the stone-breaking machines. This is spread over the coarser stones, watered and rolled into place until it becomes hard and smooth. The water is quickly evaporated from the surface, and then the fine dust is carried in all directions. I know of no way of preventing it, while it requires a great deal of intelligent care to reduce the nuisance to a minimum and properly clean a macadam street. After it has been down in the heavier travelled streets for three or four weeks the mud and dust begin to appear. This mud must be taken off with scrapers. Within a few weeks it must be cleaned again, and then it should be swept with a broom. The sweeping requires great care to prevent the fibres of the broom from throwing out too much of the fine binder material and loosening the small fragments of stone. In the less travelled ways outside the city the loss due to wind and rain is made good by spreading coarse sand over the surface. On many of the State roads this has to be done two to four times a year, a thin coating not over a fraction of an inch in thickness being spread over a width of from six to nine feet. Under the action of the wheels this sand is gradually ground up and is blown off by the wind. The cleaning and maintenance of macadam roads must begin almost with the opening to the traffic and must continue while the road lasts. Then, of course, as the stones grind up and the dust blows off, it is necessary to make good the loss by spreading small stones over the surface. At certain intervals, the length of which depends upon the traffic, the surface has to be broken up and resurfaced again; so that on a heavy travelled mainway of a city like Boston it is neither economical nor satisfactory to build a

macadam road. According to figures I made four or five years ago, 17% of all the roads of Boston were macadam or gravel roads, most of them macadam. The reports from the Street Department of the city indicate that more money is expended on our roads and streets than in any other city of its size and population in the country. One reason for the better pavements in Washington and around the Lake cities is that the abutters in most or all of those cities pay the entire cost of the work, while in Boston the entire cost, or nearly the entire cost, falls upon the general taxpayer. This means a heavy tax—a high tax-rate, and successful opposition by a large party. So long as this state of affairs exists it will be impossible for us to extend asphalt or brick pavements to any great distance outside of the thickly settled part of the city.

DR. DURGIX: I have been greatly pleased to hear the remarks which have been made to-night, in regard to the nuisance. There has been no doubt in my mind for many years as to the effect of this continual dust or mud in our streets, and consequent upon the macadamized street. I think that if we did not each of us have that personal discomfort in the dusty streets we should be convinced by the expert testimony which has been given here to-night by specialists who have observed the effect upon the eye, ear and throat; wherever the mucous membranes have been exposed this irritation has been observed. I think there can be no doubt whatever as to the discomfort and as to its far-reaching effect. I do not think it should be necessary to prove that this dust may convey the germs of infectious diseases. We believe that it may convey these germs, but if it did not, I think the general irritation of the mucous membranes and the extensive discomfort which is endured by our people would be sufficient to warrant this society and the people in general in calling for a remedy. Having made out a case which demands attention we naturally turn to the remedy, and we have heard expert testimony to-night. There can be no doubt but that the most expensive street in Boston is the macadamized street, and it is certainly the dirtiest. To-day we have it in a state of mud, and to-morrow in a state of dust. As soon as the filthy mud begins to dry and the temperature rises, the odor is nauseating. Then comes the dust; so that we have a continual source of nuisance and discomfort. There is no question whatever as to its being the most expensive street, not in first cost, but in the everlasting care necessary to keep it in a half decent condition. A macadamized street cannot be kept clean; that is an impossibility. As to the kind of pavement which we should urge, it seems to me there can be no doubt about asphaltum being the best material for a street—at any rate for a sanitary street. If properly done it becomes a smooth surface, easy for traction, pleasing to the teamster and every person who drives over it. It can be cleaned with trifling cost by sweeping or a smart shower of rain will do the same service and leave no mud, dust or odor. I believe that the objections which have been found to the asphalt pavement have been greatly exaggerated. Of course the horse will be fearful of a smooth surface until he becomes accustomed to it, but he soon becomes so and when used to it he takes care of his feet all right. I was much interested in the remarks of Mr. Richardson as to the difference between the cheaper kinds of asphalt pavement and the better

class, the one being extremely slippery and the other not so much so.

Much has been said in regard to the grades. I believe we should be surprised to see how well the horse would keep his footing on steep grade on dry asphalt pavement, the same upon a brick pavement which has been laid with close joints. A smooth brick surface where the joints are close gives the horse a good footing. He does not slip except in time of ice, and this has been demonstrated in other cities.

DR. KNIGHT: One thing occurs to me which was not dwelt upon by the medical men and which deserves consideration. It is not important really to prove whether there is any infection or not from the dust; the discomfort is enough to say we must have a pavement of some kind. In regard to the inhalation of pathogenic germs, for instance, of tubercle bacilli, I have often been asked: Are there any in the dust of the streets, and do we inhale them? I am obliged to say it is difficult to find tubercle bacilli in the dust of the open streets, because they are quickly destroyed, especially by sunlight, but, as we know, they live a long time in rooms, cars and dark places, but the inhalation of street dust and its sharp particles wounds the epithelium so that points of infection are made when the patient is perhaps half an hour afterwards exposed to these germs.

PROFESSOR McCLINTOCK: In regard to the use of oil on a macadam road, I think the Park Department of the city of Boston used it on a short section of road near the reservoir, and our board used it on a short bit of road in Cottage City. The trouble was that if mixed with dust it ruined the carriages. It had the same effect upon the clothes of the occupants of the vehicles; it spoils the tires of bicycles, and would have the same effect on the tires of the automobile. Its use is short-lived, and, so far as my experience goes, it is a dismal failure upon a road surface. Sprinkling with salt water seems to be the best way of allaying dust that I know of.

DR. DURGIX: In regard to watering the macadamized streets, one watering with salt water will last longer than two waterings with fresh water. With the salt water it packs down immediately into a hard, smooth surface; with the fresh water it does not pack down at all, and will immediately loosen up and fly in the wind.

Recent Literature.

A Manual of Obstetrical Technique as Applied to Private Practice. With a Chapter on Abortion, Premature Labor and Curettage. By JOSEPH BROWN COOKE, M.D. Philadelphia and London: J. B. Lippincott Co. 1900.

This small book of 169 pages is devoted essentially to a description of the author's routine method of taking care of his obstetrical cases before, during and after confinement and also to the outfit in use by him. The author's methods are as a rule good but not by any means ideal. They embrace nothing new which is of any special value to obstetric art, and in fact many of the best modern methods are not mentioned in the book. His personal antiseptic precautions are excellent, yet he takes no notice of the practice of abdominal palpation in labor for the diagnosis of

position and the determination of progress, instead of frequently repeated vaginal examinations, a point now considered of great practical importance in the prevention of puerperal sepsis. The outfit described seems unnecessarily elaborate, much of which in the way of basins and solutions may as well be provided by the patient or prepared by the nurse as to be transported by the doctor. In the chapters on operative labor Casarean section is not considered, but craniotomy, a less common and important operation in modern practice, is given a place. The history cards which are described and illustrated in the appendix are of value for the careful recording of the histories of obstetrical cases and are worthy of commendation and of general use.

Practical Text-book of Midwifery for Nurses and Students. By ROBERT JARDINE, M.D. (Edin.), M.R.C.S., etc., Physician to the Glasgow Maternity Hospital, Glasgow. Pp. 245, with 36 illustrations. New York: The Macmillan Co. Edinburgh: William F. Clay. 1899.

This small book on midwifery, intended primarily as a text-book for nurses, is based on the author's lectures to the nurses in the Glasgow Maternity Hospital. The author expresses the wish that the book may be of use to others and especially to those students who take their cases before they have had their lectures on midwifery. The book is well adapted for nurses and perhaps for the first reading of young medical students, as the text is well written, condensed and elementary. It contains all that the nurse needs to learn from a book on the subject of obstetrics. The treatment of sepsis and the use of antiseptics are particularly valuable for the nurse and are perhaps the best part of the work. One fact which we note with pleasure is that he decries the use of the vaginal ante-partum douche as a routine measure and says that it should be used only in occasional cases where the vagina is septic before labor, as in gonorrhoea, but that in the majority of cases the douche does more harm than good, because it destroys or removes from the vagina the protective organisms.

A Manual of Obstetrics. By A. F. A. KING, M.D., Professor of Obstetrics and Diseases of Women, Medical Department of Columbian University, Washington, D. C., and in the University of Vermont. One volume, 12mo. Pp. 612, with 264 illustrations. Philadelphia and New York: Lea Brothers & Co.

The first edition of this book appeared in 1882 and the successive editions have appeared in rapid order and now another edition, the eighth, shows the continued demand for the work and testifies to its merit and popularity. The book has not been changed materially from the last edition. It still retains its elementary character and the author says that no attempt has been made to develop it into a systematic treatise on the subject. A considerable number of new illustrations has been added to the book, most of which, however, are not original, but have been selected from works of American authors, due credit being given.

The teachings of the author are plain and the directions for treatment are concise and to the point, as should be in a book for students, and yet the text is not so abbreviated as to be of value only in cramming for examinations, as unfortunately is apt to be the chief function of most manuals.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 2, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

PROGRESS IN THE TREATMENT OF INSANITY.

IN speaking of progress made by the medical profession, we are apt to associate it with something of a scientific nature, but it must be remembered that there is also a humanitarian side, and an improvement in this direction may quite as well represent real progress. This is especially true of the insane, who suffer from a disease which should be investigated scientifically, and yet is one which it is necessary to treat in a humane and sympathetic manner. We believe that there are now evidences of a real advance in both directions in the care and treatment of this most unfortunate class.

We have in mind what has been done in Massachusetts during the last few years. It will be remembered that in 1896 a commission was appointed by the governor to investigate the charitable and reformatory institutions of the Commonwealth. As a result of the labors of this commission, the Board of Lunacy and Charity was divided and the Board of Insanity, composed of five members (two being experts in insanity), created. In the act establishing this board it was specified that it should make to the legislature of 1900 a report on "State Care of the Insane." After much study this was prepared, and at hearings before legislative committees its details were carefully considered. It speaks well for the character of this report that it received the unanimous endorsement of the medical profession, and was reported favorably on by all the legislative committees. Almost at the end of the session a State Care Act was passed, exempting, however, the Boston insane from its provisions.

This brief recital of several years' work means a great change for the better, for it commits the State to a policy which will in the future make it impossible for an insane person to be confined in an almshouse, and recognizes the truth of what was said so many years ago by Horace Mann, that "the insane are the wards of the State." It seems rather strange that the legislature of 1900 has been the one to complete the work inaugurated by Dorothy Dix, but such

is the case. The new act does not go into operation until 1901, but its prompt acceptance by the legislature is significant of the greater enlightenment of the community in regard to the true nature of mental disease.

In the same act there is another important provision made for the establishment of a colony for the chronic insane, the Board of Insanity being empowered to purchase from 1,500 to 2,500 acres of land, and money being appropriated to erect buildings. Such a colony as this must be an integral part of our plan of provision for the insane both now and when the State Care Act goes into effect, for it will provide a means of overflow from the existing hospitals, which in the future should be used as much as possible for the care of the more acute cases. In any proper system of scientifically treating the insane in a community, classification is of the first importance. If in this State there are hospitals to receive acute cases promptly, with possibly detached buildings for the convalescent and small colonies of their own for old cases, boarding-out places, and the large colony already referred to, we shall have the necessary basis to accomplish the object in the most satisfactory manner.

It is the bane of insane hospitals that far too much of the time of the medical officers is taken up with purely routine duties. Notwithstanding this, however, there are indications that the spirit of scientific research is awakened among these men in this State. When the better system of classification is established, it will be possible without additional expense to increase the staffs in the hospitals for acute cases, as the chronic cases demand far less medical supervision. By thus concentrating the efforts of our ablest men on the study of the acute cases, we shall see one of the final steps taken in the advanced treatment of insanity, which will follow logically those already mentioned.

POST-GRADUATE STUDY.

THE idea is rapidly growing and taking form that the short period of undergraduate medical study is but the forerunner of a period of study which is coextensive with the physician's active life. We still occasionally hear a man say that he obtained his medical education at such and such an institution, with the implication that with the ending of those three or four years his time of study was permanently over. He is living, and what is more unfortunate, practising, in the remembrance of what was told him years before. This reproach of unprogressiveness is happily growing less; of that there is little doubt. The so-called country practitioner, with our improved methods of speedy transportation, is too near the large cities to permit of his adherence to methods of which his more progressive city colleague would disapprove. In spite of his comparative isolation he is living in an atmosphere which demands that he shall not place too much reli-

ance upon means of diagnosis or treatment which he learned in his medical course years before. In short, physicians everywhere are coming to the realization that success in any true meaning of the word implies a constant vigilance and an unceasing willingness to learn new things. The result has been that courses for physicians have been multiplied at our large medical schools, some of which have a separate department known as the graduate school. These courses, both in the summer and during the winter months, are attended by physicians who are quite willing to give up the time required in order to keep abreast, in a measure at least, of the development of medical knowledge. This tendency is unquestionably a most valuable one and one demanding every encouragement. A still further phase of the general movement is the establishment of post-graduate schools of medicine, primarily designed for the instruction of men who have received a medical degree. Several, at least, of our larger American cities are provided with such institutions, which no doubt do a valuable work in their insistence upon the principle that one's study in medicine is never done.

The *British Medical Journal* publishes an address recently delivered by Dr. Wm. Osler, in London, on the subject: "The Importance of Post-graduate Study." The occasion of the address was the opening of the Museums of the Medical Graduates' College and Polyclinic on July 4th, and Dr. Osler was at his best in his remarks on the necessity of post-graduate study from the point of view of the teacher as well as of the student. The address is partly reminiscent of the past history of medicine and of certain men who have made notable contributions to its progress, as Hunter and Mr. Jonathan Hutchinson, but the value of the remarks lies rather in the shrewd estimate of present conditions and the hopes for the future. He finds that there are two general types of practitioners—the routinist and the rationalist. With the first of these he has little sympathy; he says: "Into the clutches of the demon routine the majority of us ultimately come. The mind, like the body, falls only too readily into the net of oft-repeated experiences." The rationalist on the other hand, as we should expect, he highly approves:

The rationalist, on the other hand, always approaches a patient as a mathematician does a problem. There is something to be found out; in each case, however trivial, there is something novel; and the problems of causation and the question of relief, while not, perhaps, of equal importance, are of equal interest. He may be just as busy as his idle brother, but he finds time to keep up a technical dexterity in the use of instruments of precision, and the stethoscope and the microscope are daily helps in diagnosis. These men are the delight of the consultant. To go into the country and find the diagnosis made in a case of mitral stenosis, a Friedreich's ataxia, a case of leukemia, or one of myxedema, gives a man a thrill of pleasure, such as Comte says he always felt when a student gave him an intelligent set of answers in an examination. It is this class of practitioners for which the post graduate courses

are helpful and necessary. They alone feel the need of keeping abreast with the times, and men of this type will return every few years, finding that a three months' course of study not only improves and helps them personally, but is most beneficial in their practices.

Himself a teacher of wide experience and recognized success, what Dr. Osler has to say about the need of constant intellectual refreshment among this increasingly important class in medicine — the teachers — is of more than passing interest :

After all, no men among us need refreshment and renovation more frequently than those who occupy positions in our schools of learning. Upon none does intellectual staleness steal "with velvet step, unheeded, softly," but not the less relentlessly. Dogmatic, to a greater or less degree, all successful teaching must be; but year by year, unless watchful, this very dogmatism may react upon the teacher who finds it so much easier to say to-day what he said last year. After a decade he may find it less trouble to draw on home supplies than to go into the open market for wares, perhaps not a whit better but just a wee bit fresher. After twenty years the new, even when true, startles — too often repels; after thirty, well, he may be out of the race — still on the track, perhaps, even running hard, but quite unconscious that the colts have long passed the winning post. These unrefreshed, unregenerate teachers are often powerful instruments of harm, and time and again have spread the blight of a blind conservatism in the profession. Safely enthroned in assured positions, men of strong and ardent convictions, with faithful friends and still more faithful students, they too often come within the scathing condemnation of the blind leaders of the blind; of those who would neither themselves enter into the possession of new knowledge, nor suffer those who would to enter. . . . Progress is an outcome of a never-ending struggle of the third and fourth decades against the fifth, sixth and seventh. Men above forty are rarely pioneers, rarely the creators in science or in literature. The work of the world has been done by men who had not reached *la crise de quarante ans*. And in our profession wipe out with but few exceptions the contributions of men above this age, and we remain essentially as we are. Once across this line we teachers and consultants are in constant need of post-graduate study as an antidote against premature senility. Daily contact with the bright young minds of our associates and assistants, the mental friction of medical societies and travel are important aids. Would you know the signs by which in man or an institution you may recognize old fogyism? They are three: First, a state of blissful happiness and contentment with things as they are; secondly, a supreme conviction that the condition of other people and other institutions is one of pitiable inferiority; thirdly, a fear of change which not alone perplexes but appals.

Conservatism and old fogyism are totally different things; the motto of the one is, Prove all things, and hold fast that which is good; of the other, Prove nothing, but hold fast that which is old. Do not suppose that you have here a monopoly of the article, which is a human, not a national, malady, for we see a very virulent type in America. In its illuiveness and in the disastrous consequences which have often followed its hunting, old fogyism is a sort of Snark in the medical profession. Before the Boojum, in the form of an entrenched variety, many good men and true have softly and silently vanished away, like the beanish nephew of the bellman, sacrificed to in-

tellectual staleness in high places. One of the best correctives is the plan followed at Harvard, which compels (?) every teacher to take the Sabbatical year, ensuring in this way intellectual rest of the mind, if not refreshment. To maintain mental freshness and plasticity requires incessant vigilance; too often, like the dial's hand, it steals from its figure with no pace perceived except by one's friends, and they never refer to it. A deep and enduring interest in the manifold problems of medicine, and a human interest in the affairs of our brotherhood — if these do not suffice, nothing will.

This sound advice is certainly meant to be no disparagement of the advantages of advancing years. If we interpret it properly it simply means that experience, so glibly talked of as a possession which the elderly alone can enjoy, is a dangerous and a futile guide in a teacher, unless tempered continually with the progress of knowledge. We are nowadays hearing less of experience and more of knowledge, of which, after all, experience should be merely the handmaid. Nothing is more fatal in a teacher than that complacency occasionally met with which comes with the passage of the years, and the accumulation merely of personal experience. Against this Osler vigorously protests and we are confident that his views will not fail of a general acceptance.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 1, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 57, scarlatina 13, measles 25, typhoid fever 8.

PATROL WAGONS AS AMBULANCES. — A decided improvement has recently been made in the police service of Boston, by converting patrol wagons into auxiliary ambulances. The wagons are now provided with rubber tires, and the seat so arranged that room may be made for a stretcher if necessary. It is said that new wagons which from this time on shall be added to the department will have dropped axles similar to those on ambulances. At one of the police stations an emergency room, properly equipped, has been fitted up, an example which might well be generally followed. Particularly during the excessive heat of summer are such added conveniences desirable.

DEATH FROM GLANDERS — A death from glanders has recently occurred in Fitchburg, Mass., and a son of the deceased has been very ill with the same affection. The infection came through attention to a favorite horse sick with the disease. An autopsy performed by Dr. G. B. Magrath on the body of the father showed the principal lesion to be in the nares; there were also multiple nodules in the lungs and skin, some of them in a condition of suppuration or ulceration, and abscesses of the thigh, leg and knee joint. The bacillus of glanders was recovered from the body.

TETANUS AT LOWELL.—Several cases of tetanus have been reported from Lowell, Mass., since July 4th. One of the victims died July 30th, the infection having taken place through a cut made by a cleaver.

SMALL-POX AT LOWELL.—Small-pox has again reappeared at Lowell, and a number of cases are now under treatment at the hospital for contagious diseases. A general vaccination has been ordered.

NEW YORK.

AN UNLICENSED MATERNITY HOSPITAL.—The Appellate Division of the Supreme Court has affirmed the conviction of one Louisa Wagner upon the charge of having violated a provision of the Penal Code prohibiting the maintenance of a maternity hospital without securing a license. The case was before the court upon appeal from an order to the warden of the City Prison dismissing a writ of habeas corpus. Justice Ingraham, giving the opinion, states that such an enactment is clearly within the power of the legislature. The requirement of the license, he explains, is to enable the public authorities to make proper sanitary regulations as to such institutions, so that their inmates may not be exposed to infection or other dangers arising from improper medical attention, and also to ensure that they shall not be perverted to improper uses.

AN AMBULANCE RACE.—The newspapers give an account of an amusing race the other day on East 26th Street between two ambulances on their way to Bellevue Hospital. One of the ambulances belonged to St. Vincent's and the other to Roosevelt Hospital. Neither of these institutions maintains a lying-in department, but in each ambulance was a woman in labor. The Roosevelt ambulance won by a neck, and succeeded in getting its patient into the Bellevue reception-room before delivery, but in the case of the other the baby was born in the ambulance just as the hospital entrance was reached. Mothers and children are reported as doing as well as could be expected under the circumstances.

DEATH OF ADOLPH SIMIS.—Adolph Simis, Jr., Commissioner of Charities for the Boroughs of Brooklyn and Queens, died on July 22d at his summer residence near Newburgh. For several years before the consolidation of New York he had served as commissioner of Charities and Correction for Kings County. His record is that of a faithful and efficient official, and he introduced many improvements in the hospitals and other institutions under his charge.

DEATHS FROM HEAT.—In the three weeks ending July 21st there were 143 deaths in the city directly due to the heat. During the corresponding three weeks of last year, when the weather was much cooler, the number of such deaths was only 11. The deaths from all causes were 266 in excess of the mortality in the corresponding three weeks of 1899.

ARMY NOTES.

CONDITIONS AT NOME HARBOR, ALASKA.—A late report from Major Ebert, chief surgeon in Alaska, dated June 29th, deals of conditions prevailing at Nome Harbor. He states that within two or three weeks the population had increased from 2,700 to 20,000, with tents and buildings located irregularly along the shore. The sanitary arrangements, very crude at the outset, became much worse with the influx of the new population. He states that the sanitary condition of the place is shocking, as there is no provision for cleaning the town and no provision for the destruction of garbage and filth. Upon the recommendation of the surgeon an order was issued by the department commander directing the removal of filth, but as there was no fund save that derived from voluntary contributions it was difficult to accomplish any improvement. Common laborers receive \$1.00 per hour, mechanics \$1.50 per hour and teams \$10 per hour, and with such prices it is almost impossible to improve the condition of affairs. All the commissioners, save one, had resigned or ceased to act. Water is very bad and sells at from 7 to 10 cents per gallon. Reports of cases of enteric fever vary from 175 to 700, but reliable information as to the exact number of cases cannot be obtained. There had been 13 cases of small-pox, with 1 death, and measles also had broken out.

YELLOW FEVER IN CUBA.—Yellow fever has broken out among the soldiers of the First Infantry in Pinar del Rio Province, Cuba. Nine deaths have occurred and 11 cases are now under treatment. This regiment is now under orders to return to the United States. All the affected commands have been moved into camps and quarantine is being enforced. Arrangements have been made by which all equipments belonging to this regiment will be disinfected and stamped by the Marine-Hospital authorities at Havana before being placed on board transports for return to this country.

FEMALE NURSES FOR SERVICE IN CHINA.—About 30 female nurses of the Army Nurse Corps, now en route to the Philippines on transports stopping at Nagasaki, will probably be diverted for service with the expeditionary force in China, serving at base hospitals. There are now in service in the Philippine islands, or en route thereto, 212 female nurses in the government employ.

ADDITIONAL ACTING ASSISTANT SURGEONS.—In view of the projected operations in China and the necessity for dividing the troops in the Philippines into small garrisons, 100 acting assistant surgeons, in addition to the 400 at present in the service, are required. The pay is \$150 per month, with allowances of a first lieutenant, mounted.

HOSPITALS FOR TROOPS IN CHINA.—In addition to the arrangements for the care of the sick with troops in China, already noted, plans are being matured for a general hospital at Nagasaki, Japan, while Col.

J. V. R. Hoff, who has just been relieved from duty as chief surgeon in Puerto Rico, is to establish a hospital of 1,000 beds at some point in China not as yet definitely selected. Every possible precaution to anticipate any unusual strain upon the hospital facilities is being taken.

Miscellaneous.

A HOSPITAL FOR TROPICAL DISEASES IN LIVERPOOL.

A HOSPITAL devoted to the treatment of tropical diseases is about to be founded in Liverpool. The hospital is to be erected in memory of the late Miss Mary Kingsley. Many handsome contributions towards the fund have been promised; amongst others Mr. A. L. Jones has given £1,000 and Mr. Blaize £500. The creation of a hospital for tropical diseases in Liverpool marks a new era in medical education in this country. The Seamen's Hospital Society's Branch at the Albert Docks is largely devoted to this purpose, but it shows that the subject of tropical medicine is attaining a still greater hold on the country when a hospital is to be specially built and devoted to this important department of medicine.—*Journal of Tropical Medicine.*

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 21, 1900.

Deaths reported 3,924; under five years of age 2,025; principal infectious diseases (small-pox, measles, diphtheria and croup,

cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 1,472, diarrheal diseases 959, consumption 315, acute lung diseases 199, diphtheria and croup 58, typhoid fever 41, measles 34, whooping-cough 28, cerebrospinal meningitis 15, scarlet fever 13, erysipelas 9.

From measles New York 23, Philadelphia 6, Pittsburg and Washington 2 each, Lawrence 1. From whooping-cough New York 16, Washington 6, Boston and Pittsburg 1 each. From cerebrospinal meningitis New York 9, Baltimore 2, Worcester, Lynn, Holyoke and Gloucester 1 each. From scarlet fever New York 5, Philadelphia and Boston 2 each, Lawrence 1. From erysipelas New York 6, Philadelphia 2, New Bedford 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,295, for the week ending July 14th, the death-rate was 14.5. Deaths reported 3,476; acute diseases of the respiratory organs (London) 160, measles 104, diarrhea 102, whooping-cough 96, diphtheria 72, fever 27, scarlet fever 24, small-pox (Liverpool and Oldam one each) 2.

The death-rates ranged from 9.6 in Portsmouth to 20.9 in Liverpool: Birmingham 19.5, Bradford 12.7, Cardiff 14.8, Gateshead 20.0, Hull 15.9, Leeds 14.0, London 14.2, Manchester 20.0, Newcastle-on-Tyne 19.8, Nottingham 18.7, Plymouth 16.8, Sheffield 18.5, Sunderland 17.3, Swansea 16.3, West Ham 11.1.

METEOROLOGICAL RECORD

For the week ending July 21st in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer		Thermometer		Relative humidity.		Direction of wind.		Velocity of wind.		Wet'thr.*		Rainfall in inches.

SOCIETY NOTICES.

ROENTGEN SOCIETY OF THE UNITED STATES.—This society will meet in New York City, December 13 and 14, 1900, at the Academy of Medicine.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.—This association will hold its thirteenth annual meeting in the Assembly-room of the Galt House, Louisville, Ky., Tuesday, Wednesday and Thursday, September 18, 19 and 20, 1900, under the presidency of Dr. Rufus Bartlett Hall, of Cincinnati, O.

BOOKS AND PAMPHLETS RECEIVED.

Albany Medical College Register of Students 1899-1900. Announcement for Session 1900-1901.

Erysipelas, and its Treatment. By Albert E. Carrier, M.D., Detroit, Michigan. Reprint. 1900.

A Text-book of Practical Medicine. By William Gilman Thompson, M.D. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1900.

Nineteenth Annual Announcement of the New York Post-Graduate Medical School and Hospital, University of the State of New York, for 1900-1901.

Report of a Case of Tumor of the Cerebellum with Drainage of Fluid through the Nose. Neurasthenia: Some Points in its Pathology and Treatment. By G. W. McCaskey, A.M., M.D., Fort Wayne, Ind. Reprints. 1900.

The Thompson Yates Laboratories Report. Edited by Rupert Boyce and C. S. Sherrington. Illustrated. Volume I. Reprints. 1898-1899. Volume II. Reprints and Reports. 1898-1899. University Press of Liverpool. 1900.

XIII Congrès International de Médecine, Paris, 2-9 août 1900. Résumés des Rapports Présentés aux Sections de Chirurgie Générale, Pathologie Interne, Chirurgie Urinaire, Médecine de l'Enfance, Chirurgie de l'Enfance, Laryngologie et Rhinologie.

Addresses.**NORFOLK DISTRICT RECORDS AND REMINISCENCES, 1850-1900.¹**

BY C. ELLERY STEEDMAN, M.D., DORCHESTER, MASS.

I HAVE been asked by the authorities who rule our destinies to write for its jubilee a history of the Norfolk District Medical Society, from the earliest times to the present day. In looking over the records for this purpose, it seems that such a dissertation would furnish forth rather a dreary half hour to you who listen, however much it might profit the future analyst. I have preferred therefore to cull from the minutes some of the principal events, and to recall a few sayings and doings of the chief actors on this stage. In these fifty years there has been a goodly share of strong men in word and deed, who have had their part in attack of abuses, in defence of rights, in imparting of their wisdom to their fellows. They brought to the meetings a whiff of salt air from the South Shore, of hayfields from the country, and the dust and mud of the suburbs of Boston; all hard workers by day and by night, with definite notions, and not to be fooled by new practices and ideas till time had ripened them. They proved all things and held fast that which was good. Most of the founders went to their graves having done good work for their town, for the State, for the country and for their neighbors, and each one, I believe, was laid to his rest carrying some one bit of knowledge, or one bit of method, which, perhaps without his knowing it, was wholly his own and could not be transmitted. Few rose to honor, fewer to wealth, but they left memories which still keep green, and we, their successors, are wiser and better for their lives.

Before we quote the records, it is well to know something of the men who made them. A few of them I present you, I fear, in rather a dim perspective. Especially I recollect old Dr. Alden, whose class at Harvard was 1808, with Dr. Walter Channing and the first Richard H. Dana, and who had his M.D. from the University of Pennsylvania in 1812. He died in 1870, and the resolutions offered to the society on that occasion truthfully speak of the dignity, courteous bearing and felicity of expression with which he participated in the proceedings of the society, and his faithful service in its behalf during many years of his life. His Johnsonian manner was deeply impressive to us younger men. One day in the train, speaking of the government of the Massachusetts Medical Society, "Sir," said he, "it is an OLIGARCHY." I knew little and cared less about it, but it was many years before I had any other notion of the society than that it was an OLIGARCHY. What sense of humor he possessed was subordinated to duty and business. A young man who was appointed secretary could not keep his freshness out of the records. After noting that the president called for the appointed papers from Drs. A, B, C, D, E, F, G, and no one was present and prepared but Dr. Edes and Dr. Edwards, the secretary went on to say that the other gentlemen called on were lucratively engaged in the practice of their profession, and were consequently unable to attend. When the records

were read at the next meeting, Dr. Alden suggested that, as the secretary could not know that those gentlemen were prevented from attending a meeting on account of their being lucratively engaged in the practice of their profession, it was hardly admissible to record such a statement. Dr. Jarvis thought it well to allow the secretary to record the proceedings in his own fashion, as the society had so courteously permitted him to do for twenty years. I know no other than Dr. Alden who in a session devoted to hygiene could have enthralled us as he did with details of his study and his marvellous air-tight stove, its construction and performances, by which his blessed old body was kept warm, while superfluous heat was turned into the room above, and perfect ventilation reigned throughout; so that the gentleman who just before had bewailed the closing of old fireplaces with sheet iron and brick must have gone home himself to install an air-tight stove in his study after Dr. Alden's plans and specifications.

There were many stories told about good old Dr. Edward Jarvis, but they all illustrated his quaint manner and speech, his benevolence, and his attention to business. A specimen of his accuracy of method may be, I hope, not tediously exhibited by an entry in the record of the first meeting: "Dr. P., of W., forgot to bring his diploma, but was admitted so far as to join the society socially, sit with them, hear the address, pay his assessment, partake of the public dinner, with the promise on his part to show his degree to the president or secretary, sign the bylaws and be admitted a member of the society." This same gentleman from W., it is remembered, was absent minded, and being bored in a meeting at Dedham, went out to the stable and asked for his horse. It was a full meeting, and there were many horses. He was unable to select his own, resignedly returned to the hall, ate (and presumably paid for) his dinner, waited till all had departed and humbly took the last horse. Showing Dr. Miller his stable one day, he stopped short and asked, "Patrick, what horse is that?" "Sure," replied Patrick, "it's the mare you bought last month."

Dr. Munroe, of Medway, must not be forgotten, one of our strong and sagacious men, of wide experience and sound judgment. He could not, however, away with the doctrines propounded by Dr. Jacob Bigelow and so ably set forth by Dr. Cotting. He believed deeply in the curative power of drugs, and defended his position with close argument and tenacity. On one occasion, hearing that Dr. Cotting was to hold forth on the subject of disease as part of the plan of creation, he rose from a sick bed, and lay on a sofa in the hall of a meeting that he might lift up his voice in defence of his cherished convictions. With all this he was polite and kind, and would never consciously offend, however much he might differ from his adversary.

Then there was Major-General Appleton Howe, M.D., whose burly presence and strong personality remain in remembrance, as does the perfect luncheon he gave us in his dooryard in Weymouth, under the spreading trees, one hot, overcast day in summer.

Give me leave to speak of Dr. Erasmus Miller, of Dorchester, and his vast obstetric experience, his early practice in gynecology, his uterine scarifier, his intense shrewdness, his horse Stargazer and his cranberry bog in Franklin. He used to say that whatever

¹ Delivered at the Semicentennial Meeting of the Norfolk District Medical Society, May 8, 1900.

his ability might have been on his first coming to Dorchester, his real and speedy success was due to a superb gray horse with flowing white switch tail, so handsome as to make every one turn to look and inquire who was the owner. But a more efficient factor was his own early acquisition of snowy hair and sweeping beard, which made him a conspicuous figure in any landscape or company.

Naturally his best friend, Dr. Holmes, of Milton, must next be named. There are yet many of us who love to recollect his round, rosy face, his martial bearing, his cheerful presence, his ready sympathy, his talent in practice, which rendered him beloved equally by factory hand and dowager of Milton Hill. No amount of work tired him either on the road, in the sick room or at the head of the Cadets. Dr. Miller used to say that Holmes had rather be driving round the country all night than be in his bed. Music and his beloved Cadets were his recreations, for he hardly ever left Milton for a holiday. Rest his soul! Every one of us in Dorchester and Milton lost a friend when Christopher Columbus Holmes was laid to rest in 1882.

No more brilliant character shone on this stage than William Cranch Bond Fifield. After finishing his studies in London and Paris he came to Dorchester in 1860, where he died in 1896. He was a man of prodigious memory, who appeared never to have forgotten anything. He could tell you on what part of any shelf in the Athenæum you could find the book you wanted, and very nearly the page which recorded the fact, phrase or case you were in search of. Indeed his mind was so stored with authors, precedents, operations, that he could not always find the pigeonhole in which the subject in view was packed. He made some marvellous diagnoses, but often would not see into an ordinary case, because his gaze was fixed on a visionary possibility far beyond. It was a treat to hear him detail a case or tell a story about one of his European teachers. The graphic touches with which he embroidered his subject fixed its details in your mind, while wit and humor played around it, so as sometimes indeed, it must be owned, to obscure the judgment and make you wonder how much was fancy and how much was fact. Besides he was an omnivorous reader; a new book of fiction, history, poetry, travel had not been long published but he could give you its scope, with apt quotations, and his opinion about it. Withal he was a musician of no mean ability and of fastidious taste. Many afflictions overtook him and cardiac disease obscured his last days.

Those of us who were honored with the friendship of Benjamin Cushing will call to mind no physician whose example they would sooner wish to follow. The gaunt frame carried a great heart and through the large spectacles beamed a steady and confident gaze. No more upright man ever stood in our society. He seemed silent and reserved. You had to know him. When he could not praise or offer comfort he was silent. Once he told me of a family who had lost a child, and the parents thought him hardhearted. As he spoke his eyes filled with tears. No young doctor who was in trouble ever left his presence without wise counsel and just sympathy. His charities were wide and unmaned. To many of us his judgment seemed unerring. He spoke well of every one when he possibly could, but meanness, underhand methods, harshness, he could not abide; and he was not slow to let

the offender know it. He had a well-developed New England conscience. One nasty night he sent a poor patient to a young neighbor. After the messenger had gone, he could not sleep, and, as he said, pictured to himself that when he next drove by the house he might see a string of carriages before the door. So he rose, dressed, took his instruments under his arm, plodded to the place through the rain, heard the voice of the youthful accoucheur inside, returned home and slept the sleep of the just. His practice was large and wide. A relative looking over his books found one day's work, where he had made twenty visits, no great number to be sure, but one patient lived near Pine-tree Brook in Milton, another in Beacon Street, both of whom had to be seen twice that day. And his driving was like the driving of Jehu, the son of Nimshi. A lady once asked him, "Why, Dr. Cushing, do you drive so fast?" He replied, "I never drive fast, but I will admit that I like to ride behind a horse that wants to go fast." Upon a call for surgeons after one of the murderous battles of the Civil War, he did some service. He was deeply grieved that his name was not mentioned by the authorities, the only reward he would have accepted, but he would take no steps to publish his claim to recognition. With this right judgment and skilful, conscientious work went a delightfully dry humor, and he enjoyed a good joke in every nerve. Once a young doctor related a case with fatal issue where every remedy known to modern science had been faithfully employed. When he finished Dr. Cushing quietly remarked that he once signed a death certificate on the wrong line, "Cause of death, B. Cushing." At an annual meeting he had been appointed to read the address. It proved to be a very lively meeting indeed, with altercations and personalities which prolonged the session beyond the hour set for the address. When at last he was called on, he remarked that as the society had chosen to turn the meeting into a bear garden he considered it small honor to address them. It was never ascertained that he had any paper beyond notes scrawled on the backs of envelopes, and it was conjectured that foreseeing the possibility of disturbance, he had never got any further in his preparations. He was nicely exact—almost finically so—in his relations with other practitioners. Often has he said to the writer, "While you were away I saw your patients, Mr. A and Mrs. B. I didn't waste any politeness on them." He had no opinion at all of a physician who would do otherwise. Therefore he had disappointments. He died in 1895, aged seventy-three, leaving deep regrets and a shining example.

How pleasant sounds the name of Dr. Maynard, of Dedham! Into how many chambers did his alert step, his blithe and debonair countenance bring solace and cheer. How, when seated in the president's chair, did he beam upon us—like a benevolent monarch on the throne, encouraging his devoted subjects. His invention of collodion made him widely known and reflected honor on the society. It was charming to listen to his story of the process of his discovery, and of his journey to New York to demonstrate it in the presence of the great surgeons of that metropolis, who bestowed due praise on the young doctor's science and ingenuity. As modest as he was expert, his memory will not soon die in the hearts of those who knew him.

No notice of the Norfolk District Society is complete without reference to Dr. Cotting and Dr. Martin, who filled the eye of the society for many years. Most of us knew Dr. Cotting, and the young men who did not should lose no time in making themselves acquainted with his "Reminiscences," which were read to the society and afterwards published in a pamphlet. He began his professional life in 1838 as a poor boy, although he could have had the same help that carried him through college, but he had determined to be independent till he reached the head of the profession in the district by the hardest work, joined to ability and good judgment. It is no disparagement to other distinguished men to say that no president of this association and of the Massachusetts Medical Society ever accomplished so much as he did for both, in raising them to the high position they now hold. He was the first to visit all the district societies and to stimulate them to careful observation, and the recording and collecting of their experiences. The extent of his early indefatigable labors, when communication was so difficult, may be appreciated when we read that in the third year of his life in Roxbury he attended 115 cases of obstetrics, "and so on, till he had a very large fraction of the whole number in town." And in one summer day he made 43 visits. For many years he did most of the surgery in Roxbury, refusing no case among rich or poor. He had very small belief in the efficacy of drugs, in antisepsis, in the contagiousness of puerperal fever, and in other doctrines now received, and the contradiction he met with before the practice was relinquished of writing a new recipe at each visit, and filling up the sick chamber with eight-ounce phials, may hardly be estimated. I have already mentioned Dr. Munroe, who left his sick bed to protest against such unsoundness in doctrine, but there was other outspoken and violent opposition. It was seldom that one of us could detail a case and its treatment that Dr. Cotting did not cap it with a similar one of his own that had recovered with little or no help from drugs, all which made the meetings interesting and entertaining. Dr. Cotting was most good and helpful to young men, never forgetting his own youthful hard experiences. He used to say in later life that he had given away so many patients that he had hardly any left. He did expect that those whom he knew well would stand by him and help him carry his measures through; and those who enlisted under his banner were called "loyal." His hospitality was lavish and proceeded from a generous heart. I have known few men who conferred more benefit on the profession than Benjamin Eddy Cotting.

Dr. Henry Austin Martin was as different a man as could be imagined. His enemies said that he had facility and not ability. But he had both in marked degree. He was a deep student, not only in medical but in general literature. His knowledge, skill and resource in surgery were great. The inventions of his rubber bandage and his adhesive plaster were known in the whole medical world, but his distinction lay in the introduction of animal vaccine, which he popularized, and by which he became the recognized authority on vaccination. His mastery of the English language was exceptional, and his speech in public and in conversation was most fluent. He was afraid of nobody, and was a born fighter. He fully believed in the efficiency of drugs in the hands

of an experienced therapist. Therefore we may hazard the statement that he could not be said to agree with Dr. Cotting. When he did not like anybody he was not skilful in hiding his sentiments. To those who were congenial he was most delightful, entertaining and instructive, pouring forth a stream of wit, humor and information. When the followers of two such men clashed, it may be fancied that there was music in the air. And many of the sessions were too stormy to more than refer to. But they have left lively recollections with many of us oldsters. In the list of names of those present at the first meeting — the only one whom I know to be now living — is Dr. George Faulkner, of Jamaica Plain. Nothing would more disturb his quiet and happy retirement than to be spoken of as he deserves. But we may assure him of the respect and affection which his long and useful service and his high character demand.

There is temptation to go on indefinitely with reminiscences of those delightful characters which loom up in the mist of departed years, but they must be phantoms to you. We shall all be phantoms by and by — some of us at no distant day — and I trust the centennial orator of 1950 may have a good word to say of our wisdom, or our characteristics, or, as a student of my day used to say, "some one of our principal fortes." To relieve these obituaries of the wise and learned, and kind and good, let me acknowledge that there were others. Dr. Miller used to tell with glee of one valued colleague, who consulted him one day to glean some hints concerning a case of prostatic disease. "How old is the man?" asked Dr. Miller. "Bless you," was the reply, "it isn't a man, it's a woman." It was a neat and skilful pathologist in the society who having, with what difficulty we may imagine, secured a post-mortem in his village, having finished his task, left portions of his patient in corners of the room, and desired the womankind to sweep them up with dust pan and brush. There is no date of the second autopsy in that hamlet. And I had deep sympathy with the polished and self-reliant rural practitioner who told, at great length, of a case of tedious labor, the only interest of which was the fact that the patient was the wife of a distinguished man, whom he did not omit to name. There was silence when he concluded, and a kind-hearted member, to let the speaker down easily, inquired, "Pray, doctor, why did you not apply the forceps — shorten the patient's suffering, and save your own time?" "Well," returned the doctor, "I suppose I might have, but my time's wuth about as much as a settin' hen's."

The convention of physicians of Norfolk County, being invited by the councillors of the State Medical Society resident in this county, assembled in Temperance Hall (happy omen), Dedham, on the 18th of April, 1849. The first meeting of the new society was held at the Phenix House, in Dedham, the 19th of November, 1850. Dr. Jeremy Stimson, of Dedham, was the first president, and Dr. Edward Jarvis the first secretary, a post which he held for twenty years. As is proper, there are pages and pages of constitution, bylaws, signatures, agreements, elections, committees, motions, amendments, reconsiderations, propositions, resolutions, recommendations, and such precautions as should surround the launching of a craft of such burden and promise. Dr. Jarvis was invited to prepare a paper for the next meeting.

This gathering took place in Dedham, in May, 1851. Dr. Jarvis, being an expert in insanity, as well as in statistics and hygiene, naturally read an exhaustive treatise about the lunatic hospital. There was a grievance in that the judge of probate in Dedham, being a lawyer in Boston, took the first train for that capital and did not return till late in the afternoon; so that a doctor who wanted to have a patient committed had to get to Dedham before breakfast, or late in the evening. A minute in a later record witnesses that after a contest in the course of which the judge proved conclusively that no other method than that in practice could be employed, that functionary had to give in and appoint a convenient hour for such business, while victory perched on the banners of Dr. Jarvis, and the Norfolk District Society thus early proved that it had not been born in vain. It is also noticeable that the early records make little or no mention of professional matters, but are filled with the dry-as-dust formulae of minutes, elections, motions, and the other necessary throes of a new birth. But when a subject connected with insanity or hygiene came up the good and venerable secretary let us have it in full.

At the November meeting of 1851, it is reported that Dr. Robert Thaxter, of Dorchester, died the 9th of February, aged seventy-five. He was one of the old school of country doctors, observant, diligent, unselfish, conscientious and skilful, and in his fifty years of practice is related never to have spent a night out of Dorchester, except in attendance on a patient. Also at this meeting we find the note that a communication from the Essex North declares that unless the State Society disencumbers itself of empirics, the Essex North District Society withdraws from the parent association. After earnest discussion the memorial is agreed to unanimously.

At the meeting of May, 1854, seventeen queries about consumption were sent out, the fourteenth and fifteenth asking, "Is the disease communicable?" the first instance, so far as the reader knows, of the question of contagion being raised in this vicinity in a formal way.

In November, 1857, there is a pathetic inquiry about means to make the meetings more interesting and the attendance larger. At the next meeting certain rules are adopted requiring certain communications. This worked by the gentlemen appointed finding themselves too busy—as above intimated—to come at all. On July 16, 1858, Drs. Allen, Bartlett and Burgess read papers on "The Contagiousness of Puerperal Fever," but the statements and arguments are not reported. Dr. Cotting presents to each member a copy of Dr. Jacob Bigelow's work on "Rational Medicine."

In May, 1859, Dr. Miller first tells about his method of application to the os uteri of ethereal tincture of iodine for excessive vomiting of pregnancy—a practice which has helped out many of our patients more than once.

In January, 1861, Dr. Warren, of Neponset, reports a case of rupture of the uterus in labor. Dr. B. Cushing saw the patient in consultation and the reader recollects his story of the case. He was able to thrust his fingers through the rent and feel their tips against the interior abdominal wall, while his other hand grasped the fingers on the outside. Some time after, driving by the house, he saw a

woman standing at her door, and asked, "Can you tell me what became of a Mrs. McCarty who used to live here?" "'Deed, then, I am Mrs. McCarty,'" was the reply, vindicating the recuperative powers of nature without surgical aid in a way which must have warmed the very cockles of Dr. Cotting's heart.

In May, 1861, the society petitions the legislature to establish a board of health. At this time we find names of members serving in the army and navy during the Civil War, and papers read about gunshot wounds and camp and ship diseases.

In November, 1862, we discover that patriotic ardor begins to be tempered with a wise discretion. For the record has it that it is "Voted, That the vote passed May, 1861, to attend officers and soldiers of the army gratuitously, be repealed." After discussion it was suggested that that vote was restricted in the letter or in intent to the President's first call for troops, and had accordingly expired by its own limitation. This sounds sophistical, but I don't believe that any soldier or sailor of that war was ever unduly pressed by his doctor in Norfolk County.

The 9th of May, 1866, is rendered memorable by a record signed A. H. Nichols, secretary *pro tem*, giving the first full report of professional subjects treated at a meeting. It records a case of ovariectomy done by the secretary *pro tem* when the operation had hardly gained a foothold. The president, Dr. Cotting, as yet an unbeliever, remarked on the need of reporting such fatal cases, two of which had lately happened in Roxbury. Then Dr. Munroe, of Medway, read a case of opium poisoning cured by the continuous dropping of cold water from a height on the epigastrium. Next, Dr. Cotting announced his operation, now so well known and which he believed to have been first conceived by himself, for ingrowing toenail. After that Dr. Bullard showed portraits of French physicians. The president showed a copy of the Annual Dictionary of Garnier, of Paris, and read a critique upon it. Then came the annual address, by Dr. Salisbury, of Brookline, on "The Habits of Social and Domestic Life." Dr. Munroe criticised the school methods of Horace Mann, which had done harm from the continuous application required of young children. Dr. Alden, of Randolph, inveighed against long school sessions from 9 A. M. to 2 P. M. Dr. Arnold, of Roxbury, exhibited photographs of a case; Dr. Stedman, of Jamaica Plain, a case of neuralgia of stump of the forearm. Dr. Cotting read a letter from Dr. Wucherer, of Bahia, on "Obstetric Practice in Brazil," citing the injurious use of ergot and the cutting of the perineum by midwives, who carry a rude instrument for the purpose, to hasten labor. Dr. Miller described his uterine scarifier, which he detailed at length at a subsequent meeting. Dr. Cotting held forth on the uselessness of splints; that they had less power to prevent shortening and deformity than was supposed. Dr. Stone reported a case of compound fracture without splints—only extension having been used. Dr. Alden sought to prove that alcohol was not food. Dr. Cotting showed a large packet of papers published which had first been read before this society. He did not believe that quinine cured intermittent fever, or that mercury cured syphilis, and in the course of discussion this day mentioned that the surgeon of the *Dreadnaught* used to show a bottle full of chancres which he had excised without preventing constitutional symptoms. This excellently reported

meeting, you see, was full of interest, and the talk was quite abreast if not in advance of the times. How much wisdom and science are buried forever by the silence of the records heretofore, about anything except the machinery of the society, we dare not conjecture.

In November, 1867, we find the first mention of the annexation of Roxbury to Boston, and it is resolved that the removal of the physicians of Roxbury to the Suffolk District would be disastrous to the Norfolk District Medical Society.

In July, 1869, Dr. Scavens moved that the secretary be authorized to permit a full and impartial report of the proceedings of each meeting to be published in the *Boston Medical and Surgical Journal*.

In May, 1870, Dr. Jarvis resigns, having been secretary twenty years and having been present at every meeting except two when in Europe, one when a witness in the Supreme Court and a fourth on account of his brother's funeral. Dr. Martin remarked that such clever and original men as Dr. Tully had always been snubbed by the mediocre majority. Progress has never been made in medicine without opposition from the rich and comfortable in the profession whose battle had been fought and whose position was attained, and who disliked being disturbed in mind or person, and from teachers and professors who abhorred altering the outlines and principles of their lectures. He applauded Dr. Amory for his paper (on inflammation) rejoicing that he was faithful among the faithless, and unadverted (in passing) on the practice, but too common, of the gentlemen who offered or agreed to subjects for the meeting absenting themselves from the session. Dr. Miller had had such success in his treatment of uterine diseases and his methods being generally unknown, it had been reported that he was using secret means. So he came to this meeting, on the suggestion of friends, and exhibited his scarifier. The record says, being questioned about endometritis, he replied that he knew less about that affection than he did four years ago, though he had had large opportunities for making it a special study. Dr. Martin had called him the originator of the treatment by scarification: he had adopted it as a common-sense method of depletion; certainly never having heard of it before, but questions of priority were not to his taste. He had certainly found the repeated incision of the uterine mucous membrane to be the only way of curing old inflammations of that organ. He quoted the case of a physician's wife—painful uterine symptoms; had lived on opium and stimulants for six months; no local disease discovered; immediately relieved by four incisions three times in ten or twelve days, and so on.

In November, 1870, it is recorded that Dr. Fifield showed a handsome cast made by his house surgeon, Dr. Bolles. Dr. Fifield had just returned from Europe and this was one of his field days. Among other things he said that 5-drop doses of Collis Brown's chlorodyne cured his seasickness and helped so many on board that the ship's surgeon borrowed his two bottles and never returned them.

In January, 1871, we find Dr. Campbell remarking that the term "skeptick" was too often applied in this society to those persons who ventured to swerve from the beaten path. At this meeting Dr. Alden mentioned a case of harikari which took place one hun-

dred years ago. A butcher ripped himself open from sternum to pubes, in a swamp, during a paroxysm of insanity. He rolled about in agony among the leaves, making also fruitless efforts to reach a neighboring spring, crawling on the ground and dragging his bowels after him; probably fainting, the bleeding was staunch and he so remained during the night. In the morning he was found alive, and the town bier being furnished with a straw bed, he was conveyed on it to his house. Dr. Moses Baker was in attendance; bathed the protruding bowels in warm milk and water, carefully cleansing them from the dirt and leaves and replacing them within the abdomen, secured the opening with sutures, compress and bandage. Dr. Baker was most assiduous in his attendance. By his request, Dr. Joseph Warren, a distinguished surgeon, who afterwards fell in the service of his country at the memorable battle of Bunker Hill, saw the case, but made no change in the dressing, kindly saying that he could not have dressed the wound more skilfully himself. "On examining the account books of Dr. Baker, now in my possession," continues Dr. Alden, "I find the last charge for attendance and dressings was thirty-six days after the injury. The recovery was perfect and the patient was able to labor as before, living forty-three years, till 1811, when he died at the age of eighty-one." None of the bold and great surgeons of my acquaintance, or in my reading, have yet attempted autolaparotomy. It seemed to have been thought worthy of record that after this meeting the society proceeded to dinner, when the landlord was discovered in a condition of exasperation because his first notification of thirty or forty friends to dine with him was their appearance in the office. He was, however, soothed by having it pointed out to him that his diners were better when constructed at short notice, and he was served with a copy of the bylaws to study the times of meeting. The repast, it was noted, was set forth with the profusion and costly elegance which marks the Everett House.

In May, 1875, there was a long wrangle about the methods of Dr. Heaton, who was at that time supposed to have a secret method of curing hernia. A member, however, reported the whole procedure and technique, which was published.

In January, 1877, Dr. D. D. Gilbert, of Dorchester, reported a remarkable case of interstitial pregnancy, with operation and recovery. I will not dwell on the particulars, but will say that the diagnosis having been made, and pains coming on, and no time given for consultation, Dr. Gilbert incised the membrane enclosing the head, through the os, with a Miller's scarifier, and the next day a child weighing four pounds was born, who lived four weeks, the mother recovering. When we consider the state of knowledge and practice in this most dangerous condition twenty-five years ago, I think you will agree with me that Dr. Gilbert's promptness, resource, decision and skill are worthy of high commendation.

January, 1877, also gives the first notice of Dr. Martin's adhesive plaster: in October of the same year of his rubber bandage, both of which have had such extensive use.

In March, 1878, appears the first reference to the aspiration of the bladder, which used to be so frequently done, but which now is seldom heard of.

November, 1879, in a discussion about puerperal convulsions, Dr. Fogg related several cases where

convulsions were controlled by atropia, which he preferred to morphia.

On the 4th of December, 1879, the secretary is instructed by the President of the Massachusetts Medical Society that reasonable doubts having been presented by one of the boards of censors as to legality of action of the councillors at their last meeting regarding the admission of women to the society until its confirmation by the society at large, the Board of Censors of the Norfolk District is hereby directed not to examine women for admission until further official notice regarding the matter shall have been received by the secretary. This is the first notice of the great woman question on record in our reports. It would be difficult to divine the nature of the sensations and exclamations of Dr. Jeremy Stimson, of Dedham, the first president, and of Dr. Alden, of Randolph, were they to join us in the flesh this day and see ladies seated in the conclave and cheering us by their presence. Dr. Martin spoke of the want of knowledge of diseases of parts about the pelvis, and told of a patient first treated in Philadelphia after the method now fashionable for increasing "blood and fat," and later failing to be relieved at a water cure of "plethora," when the case was really one of piles cured at once by a proper operation. Dr. Joseph Stedman mentioned a case of his that had fallen into the hands of a "specialist," who said the patient had a "tumor" and should have it excised. Some few months afterwards the patient was brought to bed of a healthy child, and the "tumor" was no longer to be found. The "specialist" received an invitation to the christening.

In December, 1880, we find in spite of the excerpts which have been just read to you, an expression of want of interest in the society.

In the meeting of November, 1881, Dr. Martin gave glimpses of the International Medical Congress in London. He said the germ theory met with a cool reception in the congress, and, in the speaker's own mind, in less than twenty-five years that now popular theory would be one of the exploded fallacies. As to antisepsis Mr. Keith and several of his assistants had suffered from albuminuria from carbolic-acid poisoning. Mr. Lister was considerably disconcerted by Mr. Keith's remarks. Because the allotted time for speakers in the congress was limited by rule to ten minutes, and Dr. Martin found the rule inflexible toward himself, although frequent exceptions towards some others were not wanting, he preferred to accept the opportunity offered by the British Medical Association of an excursion to Ryde, Isle of Wight. The opinions about the germ theory and antisepsis were largely shared by leading surgeons of the period, and are only quoted as illustrating the fact that brilliant speakers and scholars are not exempt from the rule that it is safest to prophesy after the event.

In May, 1882, the election of councillors appears to have turned on the question of the admission of women, Dr. R. T. Edes being the champion of the sex.

The last date brings the history of the society within the memory of living man. I have already exhausted my time and your patience, otherwise material could be brought to light of increasing interest in the records of following years. I thank you for the forbearance with which the garrulity of age

has been listened to, and I know that you would all bear even greater hardships, if they would ensure the prosperity and duration of our Norfolk District Medical Society, and light it along for another half century.

THE PROGRESS OF MEDICINE.¹

BY HAROLD C. ERNST, M.D., BOSTON.

PROBABLY no period in the history of medicine has been so prolific of changes and, as we believe, of progress as the last fifty years, and it is my pleasant duty, at the request of your committee of arrangements, to place before you as clearly as may be an outline picture of how this progress has been accomplished.

The great period of medical advance beginning with the application of ether to the relief of pain in surgical procedures in 1846 at the Massachusetts General Hospital and almost co-existent with the life of this society has accomplished so much that a brief review of the changes is necessary to enable us to realize what has been done. These are changes, too, that are of the utmost practical value, and in medicine we are little liable to the reproach of the search after useless knowledge, for we should believe, and most of us do, that "The knowledge which a man can use is the only real knowledge, the only knowledge which has life and growth in it and converts itself into practical power. The rest hangs like dust about the brain or dries like raindrops off the streets."²

Now progress in medicine occurs by the increase in means for study; the growth of hospitals and dispensaries for the care of the sick and the study of disease on the one hand, and by the enlargement of the means for presenting the material thus brought together to the students of medicine, as well graduates as undergraduates, on the other.

How this has been accomplished in our own vicinity I shall endeavor to show you, and then to give you a very brief review of what similar changes all over the world have done for our knowledge and management of disease processes in the human race.

It is exceedingly interesting to find that of the 110 (approximate) institutions in Massachusetts devoted to the care and treatment of the sick, but 13 of them were in existence previous to 1850 (Massachusetts General Hospital, incorporated 1811, open for patients September 3, 1821; McLean Asylum for Insane [name changed by trustees in 1892 to McLean Hospital], Department for Insane authorized in charter 1811, opened for patients October 6, 1818; Boston Lying-in Hospital, organized 1832; Eye and Ear Infirmary, started by John Jeffries and Edward Reynolds, who hired a room November, 1824, in Scollay's Buildings; Boston Lunatic Hospital, 1839; Smallpox Hospital, 1817; State Lunatic Hospitals, — Worcester, authorized March 10, 1830; Taunton, authorized May, 1851, — Massachusetts School for Feeble Minded, organized 1848; Barre Institute for Feeble Minded Youth, organized 1848; Essex County Receptacle for Insane; Lowell Hospital, organized 1840; Salem Dispensary, organized 1824; Boston Dispen-

¹ Delivered at the Semicentennial Meeting of the Norfolk District Medical Society, May 8, 1900.

² Osler's *After Twenty-Five Years*, p. 11, rep. from *Montreal Medical Journal*, November, 1899.

sary, organized 1796; Lowell Dispensary, 1836); that some of these were merely talked of at that time and were not carrying on effective work, and that a very large part of them were intended for the treatment of mental degenerates of one kind or another. Also that one of the very first acts of the Norfolk District Medical Society was to pass a vote, "That a committee be appointed to prepare, in the name of the society, a memorial to be presented to the next legislature of Massachusetts setting forth the want of further and better provision of means and authorities in Norfolk County for the admission of lunatics into the State Lunatic Hospital from Norfolk County." It would be a difficult matter to interpret this latter fact correctly. To some it might seem to indicate what has often been asserted—that the hard New England life of early days had a double effect in providing for the survival of the physically strong, but in producing an undue amount of mental strain in those who survived the other hardships. Other students would place no such interpretation upon these facts.

Studying the times by decades, when the various institutions for the sick have been established in this Commonwealth, the enormous increase of late years is a very noteworthy fact. From 1850 to 1860 there were but 5 new institutions founded (the Boston City Hospital, which was incorporated in 1858, but not dedicated until May 24, 1864; the Channing Home, May, 1857, incorporated 1861; the House of the Good Samaritan, incorporated in 1860; Taunton Lunatic Hospital, organized in May, 1851; Northampton Lunatic Hospital, authorized May, 1855). From 1860 to 1870 there were 12, of which the most important were: The Carney Hospital, established 1864, incorporated 1865; the Children's Hospital, incorporated February 26, 1869; the New England Hospital, incorporated 1863; Tewksbury Asylum for the Chronic Insane, 1866. From 1870 to 1880, 24: Danvers Lunatic Hospital, authorized 1874, opened 1878; Worcester Insane Asylum, 1878. In the last twenty years there have been no less than 58 public and private institutions for the treatment of disease opened, with others projected or under way. In other words, there has been made more provision for the sick and infirm in these last twenty years than in all the preceding existence of the Commonwealth.

What appears to me to be the most notable fact about this increase is the many small local hospitals that have been started. I mean by this the small town and city hospitals that are springing up in such numbers all over the State. Sometimes their foundation is due to the liberality and public spirit of one member of the community, sometimes to the affection of an individual for the place of his birth, but whose life has been passed entirely away from it; and very commonly again to the civic pride of the governing authorities, who thus wisely use some of the funds at their disposal for the care of the unfortunate and the protection of the well. There is no doubt in my mind that this establishment of local hospitals in small towns and centres of population is a movement to be fostered and encouraged in every possible way. For, although it is true that great institutions for the care of the sick can be managed more economically on the average, and that the collected wisdom of the staff of such an institution is greater than can be reached by one of less experience, it is equally true that all these

advantages are often much more than counterbalanced by the fatigue, exposure and delay to which patients transported from a distance are often subjected. So, also, provision must be made for the growth of population, and great and freely offered as are the facilities of our older and larger hospitals, they cannot ever begin to cover the entire need for the whole State.

Another most notable incident in the history of hospital building in the last ten years is the opening of the State Hospital for the Cure of Consumption at Rutland, which shows by its presence the recognition of the duty of the government of the State to provide for this scourge of civilized communities, and, by its work, the great benefit that may accrue to those affected with this disease by proper management and care. Its benefits, too, are not confined to those received under its roof, but through them when discharged some knowledge of the proper management of persons sick with pulmonary tuberculosis and of the infectious material coming from them is disseminated slowly but surely among the neighbors. The pity is that it is not possible to take care of *all* those needing it, instead of only a small portion.

Finally, as regards hospitals, in the last twenty years the phenomenal growth of the Massachusetts General and McLean Hospitals, of the Massachusetts Eye and Ear Infirmary, and of the Boston City Hospital is especially striking. The McLean Hospital, opened, as few of us realize, *before* the Massachusetts General, has made its move to the magnificent situation and plant where its usefulness is to increase and spread for years to come. The Massachusetts General Hospital has not made a change in site, but has been in a constant state of unrest, in tearing down and building up again, and when its present plans are completed is likely to present an incomparable surgical hospital to the world. These two institutions, which are really one, present the spectacle of the superb results from private benevolence that follow with years of accumulation of funds and continued wise management. The Massachusetts Eye and Ear Infirmary has within a few years entered upon an enlarged career of usefulness in its buildings, beautifully arranged and constructed for its special needs, furnished for the hospital in large measure by private gifts, but also aided by the State. The contrast is great between the present great charity and institution of instruction, with its staff of over 30 medical men, its yearly treatment of over 22,000 new patients with eye and ear disease, and the rooms in Scollay's Buildings of its founders, Drs. John Jeffries and Edward Reynolds, in 1824, where "in sixteen months 824 persons applied for treatment."

Finally, as an institution of which all citizens of Boston may be justly proud, the growth of the Boston City Hospital shines before us all, an institution still on the site first chosen for it, but so different that except for the central dome its originators would hardly know it. Supported wholly by the liberality of the city government, and commanding this liberality at need by the continued excellence of its management and beneficence, it is truly a model which we can all point to with pride as a demonstration of what a municipal institution of the kind should be. That this hospital will also in the future receive its share of private benefactions needs no further proof than the beautiful Ann White Vose Home for its nurses, which forms the last addition to its equipment. These are

the most striking illustrations of the growth of great hospitals that we can see around us, but the money expended upon and superb results obtained in the Boston Lying-in and the Children's Hospitals must not be passed by without mention, for their work is of too great value in itself and for the cause of medical progress to be neglected. This is true also of the Boston Dispensary, that for over a century has been doing the good that came to it to do among the sick poor, without ostentation and without display, but first in the field for the care of the sick, first in the field of instruction for the improvement of medical knowledge, and first today in the number of persons that are yearly benefited by its ministrations.

Another of the institutions for the advancement of medicine that has been born to usefulness since that first meeting of the Norfolk District Medical Society in Dedham, on November 19, 1850, is the Boston Medical Library. The importance of a medical library to the medical profession is no less than that of a general library to the general public, but, on the contrary, is greater, and this need of the profession has been recognized and attempts made to satisfy it from an early date. In 1805 the names of Drs. John C. Warren and James Jackson are found connected with an effort to form a library, as in connection with so many other good works of their time, and while their efforts did not result in a permanent foundation, this failure must rather be ascribed to lack of pecuniary power and numbers than of appreciation of the need. This collection of books passed to the Boston Athenæum, giving certain privileges in return, and the next collection formed was at the Massachusetts General Hospital, from the gift of Dr. J. C. Treadwell, of Salem, in 1857. The present Boston Medical Library Association furnishes a means of study and research that grows more and more valuable as the years go by, and, when the present hopes are gratified, and plans carried out, will before long be housed as becomes the library headquarters of the profession in this State.

Finally, as the instrument of instruction in which we are most interested, and from which most of us derived our early knowledge of medicine; as the means by which, if at all, all the institutions already spoken of may be made to fulfil their highest functions — of teaching — we come to the Harvard Medical School. It is difficult for us to realize the condition of the school and the college at that time when we see the condition of things at present. It would not take long to read to you the entire announcement of the Medical School of fifty years ago, and it is extremely interesting to those concerned in medical instruction, but a few extracts and comparisons will serve the purpose without making too great delay. The entire faculty of the Medical School of the year 1849-1850 consisted of eight gentlemen, including the president of the college: Jared Sparks, President; Walter Channing, M.D.; Jacob Bigelow, M.D.; John W. Webster, M.D.; John Ware, M.D.; John B. S. Jackson, M.D.; Oliver W. Holmes, M.D., Dean of the Faculty; Henry J. Bigelow, M.D. (succeeding this year Dr. George Hayward). This is somewhat different from the announcement in the catalogue of 1899-1900, where are the names of 34 members of the faculty, and 87 instructors and assistants engaged in teaching, but without seats in the faculty. The summary (of the entire university) shows:

PROFESSIONAL STUDENTS AND RESIDENT GRADUATES.	
Theological students	17
Law students	100
Students attending medical lectures	127
Special students in chemistry and mathematics, and students attending lectures in the scientific school	38
Resident graduates	3
Total	285
UNDERGRADUATES.	
Seniors	65
Juniors	69
Sophomores	76
Freshmen	87
Grand total	297
	582

After detailing the instruction offered to students in the special branches, the following statement is found: "Taking into view the amount of instruction given in this school, the extensive apparatus with which it is furnished, its connection with the numerous cases and operations of one of the best conducted hospitals of the United States, together with the general thorough acquisitions and high respectability of its graduates, it may be doubted whether any seminary in the country offers the means of a more complete professional education than may be obtained in the Medical School of Boston."

The statute regulations relative to medical degrees of the time are very interesting, showing as they do how comparatively little in the way of general training was then deemed necessary. The medical school of that day was essentially a school of medicine in its clinical aspect, and the great questions of the sciences allied to medicine were either not taught, because not in existence, or were brought under some general heading. The statutes (in part) were as follows: "The faculty of medicine consists of the president and the medical professors and lecturers, one of whom, to be chosen by themselves, shall always be dean." The faculty shall hold two examinations annually for the medical degree, at which three members shall be a quorum for business. The following are the conditions on which students are admitted to examinations: "(1) Each candidate shall furnish evidence that he is twenty-one years old. (2) He shall have attended two full courses of the lectures in this college. Nevertheless, a similar course in any other college or university approved by the faculty may take the place of one of these. A third course may be attended without fee. (3) He shall have studied three full years with a regular physician, and be of good moral character. (4) If not graduated in the arts, he shall satisfy the faculty in respect to his knowledge of the Latin language and experimental philosophy. Certificates of competent persons will be received as satisfactory proof of these facts." "Each candidate having complied with these statutes shall be examined separately in anatomy, physiology, chemistry, materia medica, midwifery, surgery, and the theory and practice of medicine, and upon his dissertation." (Seven examinations as compared with twenty-eight or nine today.) "The decision in regard to each shall be made and declared to him at the close of his examination, by the votes of the major part of the members of the faculty present and, if favorable, shall be recorded by the dean, and by him certified to the president, to be laid before the *Senatus Academicus*." It will thus appear that two members of the faculty might have had the opportunity of conferring the degree of M.D. at that time. The severity of the

examinations of today as compared with those of fifty years ago needs no comment. A further announcement is made that, "The lectures for medical students on the various branches mentioned in the statutes are delivered at the Massachusetts Medical College in Boston. They commence annually on the first Wednesday in November and continue four months." (!)

This is practically the entire announcement of the Harvard Medical School for the year 1849-1850. The school was then in the building on North Grove Street, recently completed, and in not a great many years after was suffering from the same overcrowding, and agitating the same sort of ambitious plans for the future as is the case today.

In the early seventies the faculty of the school took the radical step of grading the course of study and requiring students to pass from one subject to another in logical sequence and after examination, a step that was taken with many forebodings, and that resulted in a tremendous pecuniary loss to the school (by cutting off the number of students), but that was so necessary that the struggle to carry it through cannot be realized today. In the early eighties the school moved into its present building, and it was then thought that many years would pass before its needs could even occupy the space it then had. On the contrary, even with the help of the Sears addition, the most effective work for the students has been hampered for some time past, and some of the departments are and have been crowded to the extent of often being obliged to refuse special students. Four years ago the faculty decided to raise the standard of admission to the school by the requirement of a degree from a recognized college in arts, letters or science, or examinations equivalent to entrance to the junior class of Harvard College, and this regulation will go into effect in 1901. It has been looked forward to with much trepidation by many of the teaching force, and with lively fears that the school will lose so many scholars that it will be pecuniarily crippled. It cannot be doubted, however, that if such an unfortunate result should temporarily occur, the friends of the school will support it through any such trying period as generously as has always been the case. That this is practically certain is shown by the encouragement to the efforts making to bring about the greatest advance that the school has ever thought of—a scheme for securing its future for generations to come, together with the establishment of what will be, if it can be carried through, the most perfect university of medical science that the world has yet seen, a place where students of medicine in all its branches may come to find an equipment perfectly adapted to its uses, and teachers prepared to foster and encourage research in all its directions for the demonstration of new truths, as well as to give instruction in all branches of present medical knowledge.

With this brief review of some of the changes that have occurred in what is concerned with medical teaching, let us turn now to what must be a still more brief review of some of the great changes that new facilities have made in medical knowledge. The changes have been many and of vast importance, and it would seem, if our just hopes are gratified, that more important changes are still to come.

Necessarily, since the discovery of ether, no event has so profoundly influenced medical practice and teaching as the realization by the medical profession of the tremendous importance of the theory of bacterial infection. Ether itself would not have proved the blessing it has if the knowledge of surgical fever, of septicæmia, pyæmia, and similar processes had not been made as clear as has been the case. Of course the knowledge of bacterial infection does not in any sense cover the whole field of medical advance, but it is of itself the great step of the century, and our exact knowledge of etiology is practically dependent upon it. It is to this part of medical advance that I shall devote the remainder of this paper.

As I have just said, it is the general knowledge of etiology and public hygiene that has most benefited by the increase in our knowledge of the bacteria, and this increase in knowledge has been dependent upon the destruction of the old theory of spontaneous generation. Until this could be definitely done away with, it was not possible to secure much support for a belief in the assertions as to the specific nature of the bacteria. When it was possible for one of the most acute students of the day (Nägeli) to affirm that he had seen such varying processes as the fermentation of milk and wine, the souring of butter, anthrax, septicæmia, and so on, all produced by the same micro-organism—which also changed its form, as well as its results, and that easily—very little belief could be secured for the theory that each of these processes was due to one form of living organism, and one only, and that that retained its shape and general characteristics, or at least returned to a definite group of characters when placed under proper conditions. It was the recognition of the existence of spores in certain of the bacteria and of their extreme resistance to destructive agencies that finally did away with any support of the theory of spontaneous generation, and enabled the modern ideas of infectious processes to gain form and strength.

Through this theory of the action of the bacteria in the production of disease we have gained a practical working knowledge that is of incalculable value in the management of these processes, even though our hopes in securing a specific means of treatment have not yet reached their full fruition. What better illustration of this can be given than the absolute disappearance of hospital gangrene or of puerperal fever from the hospitals in which these diseases used to be a curse to the attendants and a frightful menace to the patients? Neither of them were the object of *specific* treatment in the sense in which we understand the word now; in neither of them has any "antitoxin" been worked out; in fact, as to puerperal fever, it is well known that more than one bacterium may take part in its production. But in both, the gospel of cleanliness, according to bacteriological methods, has done its work thoroughly, and these diseases have disappeared as a menace to sufferers liable to their attacks, because of our knowledge of the bacteria and their methods of action, and for no other reason. Cleanliness as it was formerly understood was thoroughly applied, but it was ineffective as compared with the results of today, because there was then no conception of what to guard against. It is ridiculous to claim, as a well-known English surgeon has done, that his very excellent results in abdominal

surgery were due to common sense and cleanliness and not to the knowledge of the bacteria, based upon all the experimentation of recent years. This is the very greatest result of the work, the simplest proposition of all, that properly applied cleanliness — meaning the exclusion of pathogenic bacteria from wounds — makes it possible for any surgical procedure to be carried out with absolute certainty that no unfortunate results will follow, so far as surgical fevers are concerned. And what a field has been opened to the surgeon by this fact! Operative interference of all sorts is justifiable now and is daily carried out, as was never the case before, and operations are now performed daily that were hardly dreamed of a few years ago, and if performed, were done as a desperate and last resort for the sake of the life of the patient. All this is due not to the knowledge that cleanliness is important, but to the knowledge of what cleanliness means, and how it is best secured. Indeed so brilliant are the results in surgery, and with such comparative ease have they been obtained, that the more complex problems still to be solved in the domain of clinical medicine have been somewhat neglected because the results seen in them have not been as brilliant. If this be so, it is because the conditions surrounding the solution of these problems are infinitely more numerous and confusing. On the one hand is a general fact that the tendency of all healthy tissue is to heal, and that it will heal if the injury to the vital parts be not too profound, and if bacterial activity be excluded; the rest is merely a matter of mechanical skill. On the other hand is a problem in which are included as most important factors racial and individual peculiarities, with all of their infinite modifications, with changes from the normal induced by bacterial activity already under way. The two problems are hardly to be compared more closely than a simple formula in arithmetic and a most abstruse astronomical calculation; both are concerned with the vital functions, but one depends upon allowing those vital functions to act without disturbance, the other requires that these vital functions shall be encouraged to act, while already subjected to adverse influences, in such a way that they may finally return to the normal balance, and while this is taking place, that they may resist the future encroachment of the attacking force. It is little to be wondered at that the results in the management of special diseases have as yet been so apparently slight — and yet they have really been very great. For although it is true that the only specific of wide applicability in human diseases is the antitoxin of diphtheria, the solving of this problem alone is as great an achievement as all the triumphs of surgery together.

For the rest, the management of other infectious diseases may be intelligently conducted as never before, and if our knowledge be properly applied, the spread of these scourges may be largely arrested, if not prevented entirely. Thus we know in typhoid fever, as we did not know before, that the infectious material of the disease is contained wholly in the dejecta; we know further that the specific cause of the disease is a non-spore-bearing bacillus, easily destroyed by chemicals, and so we have the problem of how to prevent the spread of this disease from an individual under our care most perfectly solved; all that is necessary being the proper management of the dejecta and articles soiled by them, and the danger from that patient is done away with.

Typhoid fever being produced by a non-spore-bearing bacillus, the infectious material is easy of destruction. But the case is otherwise with pulmonary tuberculosis. Here is an instance of the enormous value of the knowledge gained by the study of the bacteria. In the first place, the determination of the fact that this is an infectious disease; in the second, that being an infectious disease, the active principle in its production lies wholly in the expectoration, and that this being properly treated the danger from the individual attacked is reduced to a minimum. But here the laboratory studies of the bacillus of tuberculosis show that the conditions of the problem are different from typhoid fever, in that the bacillus resists destructive agencies strongly, although not known to be a spore bearer, so that different and more strenuous methods must be adopted in its management than is the case with the bacillus of typhoid fever. The principle, however, is the same, and as in these two diseases, so in many others of the infectious processes, the knowledge already given to us teaches us an intelligent method of management that has never before been at our command.

Though briefly stated, these results have not been reached without many failures, mistaken inferences and stumblings on the path toward the truth. It cannot be doubted that finally we shall reach the goal toward which they all tend, of securing a means for the arrest of the processes when once begun, but in the meantime our present knowledge is too valuable not to be applied to its fullest extent, and as in pulmonary tuberculosis and typhoid fever, so it is our duty in pneumonia, cholera, tetanus, and other diseases in which we know the specific cause and its site, to carefully apply our bacteriological knowledge in their management, as the studies in the laboratory make this knowledge clear. By inference, too, such management is made more easy in the case of the acute exanthemata, in which the specific cause has not yet been clearly demonstrated. For, although we may not know the actual agent in their production, we do know much by circumstantial evidence, which enables us to manage these diseases with much greater safety to our patients and ourselves than was formerly the case. The benefits accruing from our knowledge of bacterial processes are not confined to the management and diagnosis of disease alone. In the latter domain of medicine — that of diagnosis — it is hardly necessary to more than call to your attention the means for diagnosis dependent upon knowledge of the bacteria that have been perfected within the last few years. Every one of them is of the utmost value, either for life-saving or protective purposes. Tuberculosis, diphtheria, typhoid fever, glanders, anthrax, actinomycosis, gonorrhoea, and so on, can not only be discovered with much greater accuracy, but can be treated with much greater intelligence and precision than before.

Lest the list given above seem meagre in numbers, others of the diseases less common in this vicinity should be mentioned, for they are as important in themselves as any of the others, and all serve to show the wonderful activity in medical investigation of the last generation, and the marvellous fruits that are the results of that investigation. Tetanus and rabies, malignant edema, cholera, some few of us know from personal contact with them, and the same may be said of bubonic plague, Malta fever, Madura foot and

leprosy, the scourge of localities infected by it; malaria, brought to our special knowledge by the sufferings of many of those returning from the Spanish War; influenza, that has apparently become a permanent resident among us, and pneumonia, always with us, have each and every one become better understood and better amenable to treatment, by reason of the improved knowledge of their causation, methods of diagnosis, or treatment, directly due to the study of the micro-organisms.

So, too, have the studies upon the bacterial flora of the intestines—first begun in this vicinity by the late Dr. John Jeffries, in my laboratory—been productive of enormous benefit in the way of feeding, and the beginning of an understanding of the processes of intestinal digestion. The first baby I ever heard of as being fed upon sterilized milk, and as I believe the first one ever so treated, was a patient of mine, and the idea of sterilizing that baby's milk came as a direct result of laboratory knowledge. We had then begun to realize that milk formed the very best of natural culture media for bacteria, and especially for those saprophytic forms that are especially found in indigestion and other infantile diseases, and the procedure was intended to destroy them, and thus prevent adding fuel to the fire already blazing in the digestive tract of *sick* infants. The destruction of these forms, that are easily killed, is all that is accomplished to-day, without so changing the character of the milk as to make it unfit for food. Given a pure milk supply, and proper care of the milk to the time it is consumed, even this is not necessary.

I should weary you if I should go on to speak further of the application of the knowledge of the bacteria and of fermentative processes to the matters of general hygiene and to commercial purposes. The disposal of sewage by bacterial action in filter beds, the brewing of beer with pure cultures of yeast, the ripening of butter, and the fermentation of wines by special cultures, are all matters of common occurrence illustrative of what I mean.

A review of the ways in which it has been sought to secure a specific treatment for the infectious diseases may, however, prove interesting and instructive. The inference to be drawn is apparently that each process is a problem by itself, and must be worked out for itself by the combined efforts of every one competent to do so.

First, there is vaccination against smallpox; this is really the substituting of a mild type of disease (cowpox) for a malignant form of a similar but different disease, without reference being had to the actual causative agent in either.

Then came the efforts of Pasteur to secure protection against anthrax, based upon the fact shown in the laboratory, that cultures of the bacillus of this disease could be *attenuated* in virulence upon being subjected to certain abnormal conditions, and that when thus *attenuated* they merely made the animal sick, but did not kill after being inoculated; when the animal had recovered, he was found to be in a condition to resist the action of cultures in full virulence. In other words, here was a method of protection against a malignant form of disease by subjecting the patient to an attack of a mild form of *the same disease* (not a different disease, as seen in *vaccination*). This successful production of immunity by an attenuated virus led to many efforts in the same direction, without

great success in disease attacking man, except in rabies. And here the result is somewhat different, for we do not in this case deal with the actual specific cause alone, but with an emulsion of the tissue in which this cause is known to be present.

Then came tuberculin and mallein, both dealing with the intracellular products of growth of the specific causes of the disease, as seen in the test tube, for both tuberculin and mallein are prepared by making glycerin extracts of the bodies of the bacteria grown in pure culture. Their use is therefore an example of the employment of the chemical products of the bodies of the bacteria, and not the vital activity of the bacteria, as a means for fighting the diseases against which they are directed.

Finally, we have the antitoxins of tetanus and diphtheria, the former not so successful clinically as was hoped, because the disease is so slow in becoming clearly defined that treatment is too long delayed; the latter the final triumph of the scientific method of laboratory study as applied to the actual treatment of disease. How this triumph has been carried out to its extreme in our own community the statistics of the South Department of the Boston City Hospital will tell more eloquently than any words of mine could possibly do.

So much for the past,—how much this is, I have but feebly pictured to you,—but what of the future? What will the next semicentennial of this society have to look back upon? Which one of us does not feel sure that we are but upon the threshold of greater advances than those with which we congratulate ourselves now? It requires but little enthusiasm to look for the disappearance of tuberculosis, diphtheria, and the rest from among us as completely as of smallpox in the past—and which one of us is not proud to have had some share in obtaining or spreading the knowledge necessary to this great saving of human suffering? Which of us, after a thought of what has been accomplished, is not more ready and eager for the struggle and sacrifices that are to come?

Original Article.

ACUTE DILATATION OF THE HEART IN INFLUENZA OF CHILDREN.¹

BY F. FORCHHEIMER, M.D., CINCINNATI, OHIO.

ACUTE dilatation of the heart has been observed in a number of infectious diseases either as the result of direct or indirect affection of the heart.

As direct affection of the heart may be considered those forms in which dilatation, and as a result myocardial insufficiency, is produced by primary disease or abnormal functional activity of the myocardium itself.

As indirect affection those forms may be considered in which the dilatation is the result of functional or diseased conditions of all those various apparatuses which in one way or the other have a direct influence upon the heart's activity—the respiratory apparatus, the nervous system, the blood vessels, the kidneys.

Under the first heading, then, we can take into consideration diseased conditions of the myocardium, its

¹ From Jacobi's Festschrift.

muscular or connective-tissue substance; and therefore, to a greater or less extent, the intracardiac nerve supply.

Under the second heading must be included the consideration especially of those conditions tending directly to change the intracardiac pressure as the result of increased resistance to the outflow of blood from the heart, and the changes that take place in the cardiac centres and the extracardiac nerves.

When the dilatation of the heart goes beyond certain limits, then we have produced symptoms of myocardial insufficiency. The appearance of these symptoms varies in individuals; and it is difficult in an individual case to state when the line of demarcation as between physiological and pathological dilatation has been passed. It has been my observation that children in most instances will recover from that which seems a pathological dilatation with incredible rapidity, in that respect differing greatly from the adult; again, this is largely a question of individuality, as we find some children who not only seem predisposed to this condition, but in whom not only all the symptoms of myocardial insufficiency develop as completely as in the adult, but also continue to do so upon comparatively slight provocation. While this is the case, yet the prognosis differs in the two periods of life, in that, once the great storm of symptoms has passed over, the child's heart recovers itself more quickly, and develops into what seems a normal heart, at least, without compensatory hypertrophy, while in the adult compensatory hypertrophy is the rule.

The clinical picture produced by acute dilatation of the heart in influenza has been known to nearly all the authors who have written upon the subject of influenza during the last twenty years; but it was left to Huchard (1890) to give a special name to this condition, *la grippe cardiaque*. For myself, I have always believed that terms like renal typhoid, or cardiac grippe, are of no especial benefit to us, in that, after all, in these conditions it is only a local manifestation of a general affection that we are dealing with; a fact that should be thoroughly appreciated and fully recognized at all times. For this reason I have preferred the title, "Acute Dilatation of the Heart," as it at least expresses the definite condition which is always present; one that we find in septicemias of all varieties, in the acute exanthemata, in whooping cough, diphtheria, influenza — in short, in nearly all the acute infectious diseases, either as the result of the specific, primary infection, or as the result of the secondary infections which we are so apt to find in all of these conditions. To the great Dublin clinician, Graves, is probably due the credit of having made a distinct clinical picture of the characteristic conditions, and which I am about to consider.² He says: "One of the most singular features of influenza is the extraordinary degree of dyspnea witnessed . . . and even in many cases when the bronchial mucous membrane is but slightly engaged, the amount of dyspnea is remarkably great . . . in many cases it is intermittent, or at least undergoes remarkable exacerbations and remissions at certain hours of the day and night. . . . It would appear that the respiratory derangement depends on the same general cause which produces the whole line of symptoms; and that it might exist even when there was no bronchial inflammation at all." This same condition is referred to with more or less detail by

the German authors, Biermer, Zülzer and Kormann, but it is to West³ that we owe a description of a more intense development of this train of symptoms. In the epidemic of 1856, West observed a combination of symptoms of which dyspnea was the principal one, disappearing in two or three days, followed by "extreme depression, cool, moist skin, a very feeble pulse, and labored respiration. . . . In this condition the children, though quite conscious when roused, lay generally dozing, while, though the somewhat livid hue of the lips and surface seemed to imply the existence of some serious mischief in the lungs, there was nothing to be heard but a large moist rale." He concludes by stating that "on several occasions," under increased depression, a fatal issue followed.

In this country we are now in the tenth year of successive epidemics of influenza; and the opportunity for study of its various manifestations and complications, both in private as well as in hospital practice, has been exceptionally favorable on account of the number of cases and the differing course of the disease in different epidemics. As a result, many of us have seen the conditions above described not infrequently. An infant or child is taken down, in the course of a house epidemic of influenza, with high fever accompanied by symptoms on the part of the respiratory or alimentary tract, possibly with a catarrhal or follicular angina tonsillarum, and within twelve to twenty-four hours there develops dyspnea, or, better, tachypnea, for it is perhaps more correct to refer to the condition of rapid breathing in this form of the affection as tachypnea, as all other evidences of dyspnea are wanting, such as cyanosis and movements of the accessory respiratory muscles. The child lies in bed, with congested skin, sleeps a great deal, yet is easily aroused; the tachypnea is represented by rapid breathing (60 to 70 or more per minute), without disturbance of the normal relation between inspiration and expiration, therefore neither inspiratory nor expiratory dyspnea. In some cases the breathing is not very much more rapid than the normal. The pulse is very rapid, depending upon the age of the patient, frequently intermittent, but otherwise normal. Physical examination of the chest reveals nothing, or possibly evidences of a bronchitis in the large tubes; the heart dulness is always found broadened, with no bruits as a symptom of this affection, although in one instance I found an endocarditis developing after the acute dilatation had run its course. The urine, which was examined in every instance, was invariably found to contain no albumin. In the course of from twenty-four to seventy-two hours all these symptoms disappear, the temperature, pulse, heart and respiration become normal, the whole condition of the child changes, it returns to its normal state, and then remains well; or the various symptoms of a more prolonged attack of influenza develop. I have never seen this mild form develop into the more severe one, as seen by West; all my severe cases have developed in a different way, as will be seen presently.

As to the etiology of this condition various and varying views have been expressed. Graves believes that the poison of influenza acts "on the nervous system in general, and on the pulmonary nerves in particular," and that the condition produced is one to be likened to the one following section of "the eighth

² Clinical Lectures on the Practice of Medicine, 1843, Influenza.

³ Lectures on the Diseases of Infancy and Childhood, Philadelphia, 1874, p. 281.

pair of nerves" in animals. Biermer⁴ thinks that the symptoms are due to a pulmonary congestion; Zolzer⁵ looks upon the condition as one akin to nervous asthma, more like a motor neurosis of the diaphragm and the bronchial muscles; Sansom⁶ says that "the cardiac crises during the acute stage of the disease might be due to involvements of the nerve elements in the bulb; the remote symptoms should be ascribed to a neuritis affecting the sympathetic ganglia, the vagus, and the sensorimotor nerve trunks."

Against the acceptance of congestion of the lungs as the cause of these symptoms speaks the fact that there are no physical evidences in the lungs which show the existence of this rather indefinite condition. These might have eluded detection on the part of one or more observers, but all those who have seen these symptoms remark upon the disproportion between physical signs in the lungs and the rapidity of breathing. It seems more satisfactory, therefore, to accept a nervous origin for these symptoms, although there is no direct evidence in favor of this view. Merklen and others, it is true, have found lesions in the vagus in cases of tachycardia; but we have here a condition producing especially tachypnea. Myocarditis can be excluded because of the transitory nature of the affection, although in the grave forms of dilatation this has been observed (Huchard). Neither does it seem possible that the cardiac branches alone are affected, otherwise the tachycardia would be the prominent symptom, while this is only relative, and the tachypnea the dominant symptom. It is, therefore, more reasonable to suppose with Sansom that there is some affection of the bulb affecting both the respiratory and the cardiac accelerating centres. The source of the irritation would be a toxin, hypothetical as far as the influenza bacillus is concerned, but positive as to some of the pus producers which habitually accompany influenza. It would be fully in accord with the nervous origin of these symptoms that we find broadening of the heart's dulness. The production of acute dilatation of the heart as the result of disturbance in innervation has been conclusively proven in many diseases. The second class of cases to be described demonstrates this more fully.

The grave form of the affection presents an entirely different clinical picture. Here there can be no question as to the origin of symptoms, at least, as all the manifestations can be satisfactorily explained by considering the heart. Huchard⁷ gives the following concise description of this condition (*la grippe cardiaque*): "The attack manifests itself by syncope and faintness, which may become fatal, by slow pulse, by arrhythmia, or intermittence, by grave symptoms of cardiac collapse, and sometimes by pains resembling angina pectoris." One of his patients had a very rapid pulse, with a feeling of suffocation upon making the slightest movement. How this form of acute dilatation of the heart presents itself in children will be best shown by the following histories of 2 of the 4 cases I have seen:

The first was in a girl twelve years of age, weighing about 130 pounds, who previously had had rickets, diphtheria, typhoid fever, pertussis and measles, from

all of which she had recovered without any sequelae. The family history is good. The child was taken sick with fever and sore throat on March 6, 1897, from which she recovered in a few days, and this attack left her with a cough which continued until I was called in to see her again on June 5, 1897. This cough, which I did not hear before the latter date, but heard too often afterwards, was the cough that we so frequently hear in influenza, and which has not inaptly been called pertussoid. On the morning of June 5, 1897, the child had fever (101°), and the cough, as far as number and intensity of paroxysms was concerned, had grown very much worse. In the evening the temperature had risen to 105°, with pulse and respiration in proportion; the cough was now so bad that with each paroxysm the child complained of pains about the lower region of the thorax and in the abdomen. Physical examination revealed the evidences of a bronchitis, large, moist and dry râles, and a large superficial heart, dulness almost to the right border of the sternum and to the mammary line to the left, the latter to be explained possibly by the obesity of the child. No evidences of consolidation in the lungs, nor were there any abnormal auscultatory phenomena to be found in the heart. The next few days passed in the same way, the temperature, pulse and respiration keeping up, the cough becoming worse, and vomiting taking place with nearly every paroxysm of coughing. As a result of this constant coughing, the abdominal pains became so great, constipation and vomiting being present, that a suspicion of abdominal inflammation arose, which, however, was soon dispelled; in other words, this child was now suffering from recrudescence of the influenza. On the morning of June 9th I was suddenly called to see the child, and found her in the following condition: She was in a state of collapse; she was lying in bed in a soporific condition, from which she was easily aroused; the skin moist, slightly cyanosed, the face swollen, breathing at the rate of 65 per minute without any effort apparently; the pulse had come down from 120 beats to 70 per minute, and was weak and intermittent. The slightest effort on her part, such as turning in bed, caused the frequency of respiration to be increased and the pulse to become more irregular and weaker. After an attack of coughing the pulse became almost imperceptible, and the breathing ran up to as high as 70 per minute. A thorough physical examination was not to be thought of on account of this condition; but auscultation of the heart showed nothing abnormal; while percussion, even in the recumbent position, showed the right border of the heart about one-half a centimetre to the right of the sternum. After two days the condition changed somewhat; large doses of colicia were added to the medication, as it seemed imperative to control the paroxysms of cough as much as possible, on account of their untoward effects upon the heart. Now the pulse gradually began to increase in frequency, going up to 140 beats per minute; the dyspnea was not so constant, there being a difference of between 15 and 20 respirations during the condition of being awake or asleep; but motion, swallowing or any excitement would make this difference disappear, and an attack of coughing would raise the number of respirations even higher than it was before (as high as 90 per minute). The pulse continued rapid all this time, never going below 120 beats per minute, and contin-

ued intermittent, although not quite so weak as on the previous days.

Physical examination of the lungs did not reveal anything more than at first, but the heart showed remarkable changes. The superficial dulness was increased to 1 centimetre to the right of the sternum; and after attacks of coughing to as much as 2 centimetres, depending upon the intensity of the paroxysms; no appreciable change to the left. Over the tricuspid area, as well as at the apex, was heard a soft systolic bruit, which also was increased in intensity after paroxysms of coughing. Bruits were also heard at the base, especially after the paroxysms of coughing, but they were more difficult to localize, and were conducted in such a way that it was impossible to ascribe them to one valve or another. Gradually, as the result of treatment, all these symptoms began to disappear; the pulse came down from this time until September, 1897, so that its minimum was 87, and its maximum 120 beats per minute; the latter upon exertion. As soon as it was possible, graded exercises were used, and the patient was discharged as well the middle of December, having been ill for five months, with diurnal changes for better or worse, but on the whole with a constant tendency towards improvement. On May 7, 1899, I examined the patient for the last time. I then found her, having lost her fat, having grown four inches, and with a normal heart which was no longer insufficient under any conditions of exercise or fatigue.

One other case did not materially differ from the preceding except that the manifestations were not so severe and did not last so long. In addition, this last child was younger and not fat, so that the contributing cause of obesity of the heart was absent in her. In the former case there were some peculiarities that must be taken into consideration. The child was unusually fat for her age; it is, therefore, not unlikely that there was some obesity of the heart, rendering the myocardium less resistant to strain than it would have otherwise been. Three months of continued coughing certainly did not add to the strength of the myocardium, so that when a renewed invasion of influenza occurred cardiac collapse ensued, which first manifested itself by great asystole, and afterwards by a decided and distinct acute dilatation of the right heart, with relative tricuspid insufficiency.

It is difficult to decide upon the real condition which first caused this cardiac collapse; but it was my distinct impression at the time of first seeing this patient that I had to deal with an uncomplicated case of myocardiac insufficiency, the result of heart strain, the factors producing the heart strain being the obesity and the whooping-cough-like paroxysms of coughing. It is outside of the province of this paper to discuss the rôle played by the influenza in producing the pertussoid; the mechanism of production of heart dilatation in this case was the same as that found in whooping cough, to which so many authors have called attention. That the toxin had something to do with the improper innervation of the heart it is impossible to deny, but just as impossible to affirm.

The following case again illustrates peculiarities, but seems to prove especially that the myocardium is the part of the heart that is affected. The patient, a little boy two years and three months old, of good antecedents, artificially fed as an infant, had had influenza when four months old followed by acute otitis

media; in October, 1897, when fifteen months old, he had another attack of influenza, which was followed by the peculiar and irregular fever so common after this disease, which lasted for two months, and which resulted in great depression, anemia and loss of flesh (no malaria, no typhoid). In June, 1898, he contracted whooping cough, which ran its course in a very mild manner (maximum, ten paroxysms in twenty-four hours).

In October, 1898, he had another attack of influenza; as the little fellow had three attacks of influenza, the fact must be emphasized that, in every instance, all the members of the family were affected with one or the other form of the disease, so that the diagnosis was perfectly clear. In this last attack the pertussoid nature of the cough was clearly demonstrable, as would have been the case, in all possibility, with any cough which would have developed so shortly after an attack of whooping cough. Early one morning after an unusually severe attack of coughing, "he turned blue in the face and fell fainting in my arms," as the mother expressed it. Two hours after this I saw him and found him cyanosed, sweating, breathing very rapidly and with a rapid, irregular, weak pulse. Physical examination of the lungs showed the evidences of bronchitis. Inspection of the cardiac region showed pulsation over the whole area; in addition there was epigastric pulsation. The heart impulse was diffuse, felt most distinctly in the fourth interspace to the left of the mammary line; percussion verified this as the left border of the heart. Toward the right the dulness extended to one-half centimetre beyond the right border of the sternum, and above began at the fourth rib. There was no bruit. The tachypnea was influenced by the slightest exertion, but the heart did not increase materially in size. The patient was kept in bed and under treatment for five weeks and then made what seemed from physical evidence a rapid recovery. During the summer he had another attack of tachypnea, which, however, lasted only a few days. When brought back to me in the fall there was no evidence of cardiac trouble.

The following winter (1898-1899) was uneventful; but the mother, preparatory to leaving for the summer, in June, 1899, asked me to examine the child again, which I did, and found the heart normal. The fatigue of a very hot journey and an attack of illness, accompanied by fever and gastro-intestinal symptoms, again brought on the same train of symptoms described above, the latter being diagnosed by the local physician as due to heart trouble. This attack lasted for two weeks.

My notes made on September 2, 1899, show the following as the condition of the heart: Apex beat immediately below the nipple in the fifth interspace; superficial dulness begins at the apex, the lower border of the fourth rib and the left border of the sternum; no bruit. Since the last attack the child has been well.

The peculiarities of this case are: That the myocardium undoubtedly was weakened by the previous attack of whooping cough, although no evidences of this weakness could be detected, and that this weakness has continued, so that when sufficient demand is made upon the myocardium, high fever with gastro-intestinal infection, for instance, the same symptoms return. On account of the long periods of rest which the child has enjoyed, it does not seem reasonable to sup-

pose that the nervous system of the heart, except as implied in the myocardial structure, plays any important rôle in the production of these symptoms. Again, at no time during the course of the disease was there bradycardia. It seems that here again we are dealing with a purely mechanical dilatation of the heart due to increased resistance to the outflow of blood from the right side of the heart. The fourth case had no predisposing conditions of myocardium as had the other three; and developed after the febrile stage when the pertussoid was at its height. Here the symptoms came on just as rapidly; physical examination revealed an enlarged right heart; but the whole condition lasted only ten days, leaving the heart normal. The dominant symptoms in all these cases were on the part of the heart, and the peculiar respiration which I have only seen in two other conditions — in pericardial effusion and the fugitive edematous condition of lung that frequently precedes pneumonic consolidation in influenza without cardiac changes. It is this latter observation that has induced me to explain all the cases of the milder form by taking into consideration the effect of a toxin upon the nervous system in producing acute dilatation.

As to the grave forms, observations made on 4 cases are not sufficient to form a definitive opinion, although in all of them the direct cause of the trouble seemed to be heart strain, in 2 of them there being a predisposing weakness of the myocardium. It is possible that in those 2 cases a myocarditis was going on at the same time, although the short duration of the attack in 1 of the cases and the complete *restitutio ad integrum* in all of them seem to preclude this. Under all circumstances, it seems to me that we are justified in calling this condition acute dilatation of the heart.

All the reflections on the subject of affections of the nervous system of the heart in influenza are purely theoretical; as yet, no changes have been described in any of the various parts of the nervous system of the heart, as has been done for scarlatina and diphtheria. Until this is done it seems safer to hold fast to that which we can verify, which has been expressed by Goodhart⁸ in a similar case, as follows: "The only conclusion that seemed possible was that an acute dilatation of the heart had taken place."

According to my own observations we are justified in assuming two forms of heart dilatation in influenza: One presumably produced by the action of the toxin upon the nervous system of the heart and possibly upon the myocardium; the second form occurring in such conditions in which outflow of the blood is materially interfered with on account of mechanical conditions.

The first form, according to the excellent observations made by West, undoubtedly may end fatally, although this has not been the case in my own experience. The second form is one that lasts much longer than the first, but in children has a tendency to recovery.

HYDROTHERAPY IN BERLIN. — An official chair of hydrotherapy, according to the *Philadelphia Medical Journal*, is about to be established at Berlin. A hydrotherapeutic department in the Charité Hospital will be opened in the autumn under the direction of Professor Brieger.

Medical Progress.

REPORT ON PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CURRIE, B.D., BOSTON.

GANGRENE COMPLICATED BY GLYCOSURIA.

WALLACE,¹ in an article on this subject, in which he cites a number of cases, comes to the following conclusions:

- (1) That it yet remains to be proved that true gangrene (excluding death from acute specific processes which may occur in any subjects and at any age) occurs in diabetic patients unaccompanied by such arterial disease as would of itself produce the gangrene.
- (2) That the glycosuria may or may not precede the gangrene, but is not usually accompanied by other signs of diabetes.
- (3) That septic wounds may produce a glycosuria which vanishes when the septic process is removed.
- (4) That individuals suffering from septic processes are often on the borderland of glycosuria.
- (5) That gangrene may aggravate a pre-existing glycosuria.
- (6) That the arterial disease is sometimes that which accompanies, or is produced by, chronic renal disease.
- (7) That it is yet to be proved that neuritis can produce any gangrene comparable to that of the so-called diabetic gangrene.
- (8) That the best chance of recovery is offered by removal of the limb near the trunk and that this measure should be undertaken before the patient is reduced by septic absorption.
- (9) That the presence of glycosuria may be an indication, instead of a contraindication, for operation.

ABDOMINAL SYMPTOMS IN PNEUMONIA OF CHILDREN.

A valuable article has recently been published by Dr. J. L. Morse,² Boston, in which he calls attention to those occasional cases of pneumonia in which the preponderance of abdominal symptoms (pain, tenderness, nausea, vomiting, dulness, constipation, etc.) may lead to serious errors in diagnosis. He has seen 2 cases where the abdomen has been opened by experienced surgeons, because appendicitis and not pneumonia was supposed to be the cause of the trouble. In these cases the physical signs may not be recognizable for several days. In the absence of physical signs the combination of symptoms should arouse a suspicion of the real seat of the disease. With an acute onset with high temperature and the rate of respiration increased out of proportion to that of the pulse, even in absence of a cough, Dr. Morse states the probable diagnosis will be pneumonia. By keeping in mind this combination of pulse, temperature and respiration, error may be avoided even when vomiting, abdominal pain, constipation, and at times also tenderness and distention, probably of reflex origin, are present. The cases accompanying the article are quite interesting, and seem to be illustrative of the subject under discussion. One, however, in which there was previous history of constipation and a blow on the abdomen, closely followed by the abdominal symptoms, would still be an anxious one for the attendant physician during the first forty-eight hours.

KOCHER'S OPERATION FOR CARCINOMA OF THE LARYNX.

Butsch³ reports 15 cases of carcinoma of the larynx treated by Professor Kocher since 1890. Twelve of these were operable. The first 7 of the series were operated upon by Kocher's former method; that is, general anesthesia, tampon canula, total or unilateral extirpation of the larynx by means of the so-called T incision, and subsequent feeding with pharyngeal tubes. This technique was essentially altered in the later cases of the series. In place of general anesthesia, local anesthesia by the infiltration method of a 1-100 solution of cocaine was employed. The patient was placed in the Trendelenburg position and the use of the canula dispensed with. A median incision was made from the hyoid bone over the larynx, exposing the thyroid cartilage. The thyrocericoid ligament was perforated and the thyroid cartilage split vertically with scissors.

The halves of the cartilage were retracted, thus completely exposing the interior of the larynx and the tumor. The parts to be removed are anesthetized by pencilling them with a 1-per-cent solution of equal parts of cocaine and antipyrin, and the tumor excised widely with the knife, or, better, with the thermocautery. If possible, only the soft parts are thus excised, but in cases in which the cartilage is involved Kocher uses the scissors to remove the affected cartilage superichondrially. The bleeding surface is cauterized and powdered with iodoform, and an ordinary tracheal canula introduced. The wound is tamponed and left open. Special position of the body, as well as feeding by the tube, is not necessary.

Of the 12 cases operated upon, 1 died as a result of the operation; 2 are considered cured, 1 four years and a half, the other two years and a half after the operation; 3 are free from recurrence, but have not been observed for a sufficient length of time to consider them definitely cured. These good results would not have been possible had not the diagnosis been made early in the majority of the cases.

The paper concludes by advocating simple mesial section of the thyroid cartilage, and circumscribed excision of the new growth in the Trendelenburg or in Rose's position without general anesthesia.

[Pieniazek⁴ removed a number of endotheliomata and also several carcinomata from the larynx without general anesthesia, employing essentially the same procedure as followed by Kocher. Rose's position is perhaps better adapted to these cases than Trendelenburg's.]

RESECTION OF THE CERVICAL PORTION OF THE ESOPHAGUS FOR CARCINOMA.

De Quervain,⁵ after a résumé of the literature and a careful study of 14 cases, including a report of 1 of his own cases, comes to the following conclusions:

(1) All carcinomata of the esophagus that have not involved the surrounding tissues, and the lower borders of which do not extend below the upper margin of the arch of the aorta, are suitable for extirpation through the neck. The lowest point of the upper margin should not be less than 20 centimetres from the teeth.

(2) Tracheotomy is seldom employed as a preliminary operation. If an opening into the trachea is found necessary, it should be made as late in the operation as possible.

(3) A preliminary esophagotomy is generally replaced by a gastrostomy.

(4) A gastrostomy is the best means of securing rapid healing after the esophagus resection. It is absolutely essential to operations upon deep-seated strictures, and advisable in those situated higher up.

(5) If it is impossible to fix the upper end of the lower portion of the esophagus in the wound, it can be ligated, where this is possible, and allowed to sink down into the thorax. A permanent gastric fistula is better for the patient than the dilatation of a constantly contracting scar-tissue stricture in the region of the aortic arch. Where it is impossible to unite the esophageal ends a salivary fistula is to be expected in the neck.

(6) In the after treatment the free changing of an aseptic gauze dressing is of the greatest moment, with great care to separate the pharyngeal from the mediastinal ends of the wound.

CANCER OF THE BREAST.

Abbe,⁶ in a paper read before the New York Academy of Medicine in February, states that progress towards the cure of mammary cancer has come from the recognition of the following anatomical distribution of the lymphatics:

(1) Those which drain the mammary gland directly towards the axilla, through parallel channels in the cellular tissue, coursing from the axillary edge of the gland to the axillary vein, interrupted by occasional lymphatic glands, finally concentrating in several channels lying upon the axillary and subclavian veins, mostly upon its anterior surface and entering the neck at the junction with the jugular.

(2) A series extending from the mammary gland directly outward to the overlying skin communicates with the lymphatics of the skin itself.

(3) A series from the deep aspect of the gland passes directly to the bed of cellular tissue between the gland and the pectoral muscle, where it is joined by lymphatics emerging from the pectoral muscle, and these together travel toward the axilla upon the pectoral fascia.

(4) Another series extends towards the sternum and is associated with the veins, penetrating the sternal part of the pectoral muscle and thus enters the mediastinum.

HERNIA OPERATIONS IN INFANTS.

Franckel's⁷ article on this subject, in which he recommends very early operation, and according to the Bassini method, attracted the attention of F. Kerewski in Berlin, and the latter has published his experience and conclusions relating to the same subject.⁸ He notes among his operations 13 reducible and 6 incarcerated hernie in infants with 1 death. No recurrences recorded. Duration since operation: Two cases over eight years, 3 over seven years, 2 over five years. He considers the Bassini method as too complicated and long for so young patients and in all children younger than three years simply frees the sac and ligates it as high as possible. The opera-

⁸ *Loc. cit.*, Bd. xxvi, S. 1337.

tion should be done as rapidly as possible and by the least complicated method. He states that he completes this operation usually in three to five minutes. He regards an operation indicated where a truss cannot be worn or when it does not hold the hernia, and the hernia is increasing in size in spite of truss treatment or becomes incarcerated. In the case of older children the probability of a spontaneous cure is much less, and therefore an operation is much more frequently indicated. The writer does not agree with Fraenkel that a spontaneous cure in an infant leaves the canal relaxed and patent, so that the hernia is liable to recur. He has failed to meet such a recurrence in all his experiences.

A NEW METHOD OF SUTURE IN OPERATIONS FOR INGUINAL AND OTHER FORMS OF HERNIA.

Freeman,⁹ in a paper read before the Wyoming State Medical Society in October, 1899, describes a new method of suture in operations for inguinal and other forms of hernia as follows: Previous to the operation, two or three needles are threaded with long loops of silkworm gut (silver wire may be used), and two pieces of stiff, silvered wire are procured long enough to reach the entire length of the inguinal canal, cut through the external ring and beyond the surface of the skin (small probes answer the purpose well).

The internal ring is exposed, the sac ligated and cut off or knotted upon itself,¹⁰ and the cord held out of the way. One of the silkworm-gut loops is passed from without inward through the muscular tissue on the umbilical side of the ring, well back from the margin, and fairly close to the point of exit of the spermatic cord. The loop is then carried through Poupart's ligament from within outwards, some distance from its free edge. Another loop is similarly inserted near the pubic limits of the opening.

One of the previously prepared wires is now run through the loops, which are pulled tight enough to hold it in place. The other wire is laid along Poupart's ligament between the free ends of the loops, which are firmly tied over it, thus approximating the wires and bunching a quantity of muscular tissue against the ligament. Before finally inserting the wires they should have been bent upward at their pubic extremities, so as to protrude through the external incision, thus facilitating their removal. The ends of the wires furthest from the pubes must be so placed that they leave the new internal ring neither too large nor too small.

The cord is now dropped in place over the line of union, and the aponeurosis of the external oblique united above it, the upturned ends of the wires passing through the external ring. As the aponeurosis is not subject to tension, its accurate union is not of so much importance, and Harris's removable suture may be employed if desired. Catgut, however, is not so objectionable as it is in the deeper portions of the wound, as it comes away more readily in case of suppuration. In uniting the skin, the free ends of the loops and the ends of the wires are brought out through the incision between the stitches.

In from ten days to two weeks, which is long enough to procure reasonably firm union, the wires are removed by pulling on their protruding ends. This frees the loops, which are likewise readily

extracted. It should not be lost sight of in this connection that after union has taken place sutures are of little or no utility; if there is no tension they are superfluous, and if there is tension they are equally so, because they will cut through the tissues.

The author has employed this method three times with satisfaction—in a boy of twelve, a man of fifty-five, and a young man with a very large internal ring. The technique is simple, and it is especially indicated when the internal ring is large or where tension is feared. The method may be readily adapted to umbilical or to ventral hernia, and would probably be particularly useful in cases where the opening is large and tension correspondingly great.

To the author's mind the procedure described presents the following advantages: (1) It is simple and quickly executed; (2) any reasonable amount of tension can be readily overcome, which is of paramount advantage when the internal ring is large; (3) the sutures cannot cut through, which must frequently occur in other procedures, especially if vomiting or coughing should supervene; (4) a large amount of muscle can be bunched up against Poupart's ligament, thus increasing the likelihood of permanent cure; (5) the sutures can readily be removed, leaving nothing to give rise to irritation or to a sinus.

(To be continued.)

Reports of Societies.

MAINE MEDICAL ASSOCIATION.

FORTY-EIGHTH ANNUAL MEETING, HELD AT PORTLAND, JUNE 13, 14 AND 15, 1900.

THE association met Wednesday, June 13th, at 10 A. M. in the Common Council Chamber, City Building, and was called to order by the president, DR. B. T. SANBORN, of Augusta. Prayer was offered by the RT. REV. ROBERT CODMAN, JR., Bishop of Maine.

After the reports of the treasurer and various matters of committee business, DR. C. B. SYLVESTER, of Harrison, read a paper on

SURGICAL PRACTICE IN THE COUNTRY.

The great need of the country physician is to be a good surgical diagnostician and able to do most of the surgery which now leaves the country for the city hospitals. Emergency surgery must be attended to in the country, and upon his ability to secure asepsis with ordinary facilities will depend his success.

DR. F. H. GERRISH, of Portland, thought the country doctor needed to be everywhere, on the whole, a better equipped and better informed man than his brother of the city, because he has not the same facilities of consultation and assistance. Dr. Gerrish commended the appreciation of the younger generation of country practitioners of the fact that no surgery which was not aseptic was good surgery; in that belief they were certain to have an advantage over their elders who were reluctant to accept it in detail.

DR. W. K. OAKES, of Auburn, was most impressed with the references of the paper to hospitals in competition. Present methods of receiving patients were unsatisfactory and unfair to country and city doctors

⁹ *Annals of Surgery*, March, 1900, p. 286.

¹⁰ Duplay and Cazin: *Semaine méd.*, November 11, 1899.

alike. Patients ought to be required to present some evidence of their inability to pay the same fees as others for the same service in private practice. These patients benefited by the lower rates of the hospitals ought to appreciate the fact that they are receiving charity.

Dr. SARAH W. DEVON, of Boston, read a paper on

A CASE OF REMOVAL OF THE SPLEEN.

AFTERNOON SESSION.

The session was held at three o'clock, Dr. S. C. GORDON, of Portland, in the chair.

Dr. J. J. HEALEY, of Newburyport, was welcomed as a delegate from the Massachusetts Medical Society and invited to participate in the discussions.

The President's Address followed. It dealt with the progress of the last decade in psychology and psychiatry, upon which his long experience as a superintendent of the Maine Insane Hospital qualified him to speak.

Dr. W. L. COUSINS, of Portland, read a paper on
A NEW OPERATION SUGGESTED FOR OBSTRUCTIVE
DYSMENORRHEA.

The operation consisted essentially of sectioning the bent cervix at point of constriction, dilating and maintaining the uterus in a straightened position by means of a shouldered glass tube.

Dr. J. D. COCHRANE, of Saco, read a paper on

LITHEMIA.

Salicylic acid and salicylates, phosphate and sulphocarbonate of soda were offered as the best solvents of uric acid, as well as hepatic stimulants. The lithia salts were condemned as forming insoluble compounds with ammonium and sodium acid at the expense of the alkalinity of the blood.

Dr. J. G. GEHRING, of Bethel, read a paper on
THE SUBJECTIVE CONSCIOUSNESS IN ITS RELATION
TO PRACTICAL THERAPEUTICS.

The report of the neurologist gave the following list of members deceased: Enoch Adams, Litchfield; A. J. Billings, Freedom; J. Gould Dyer, Portland; Theo. L. Estabrook, Rockland; Geo. Googins, Millbridge; Alfred Hitchcock, Farmington; Jerrie K. Phillips, Bangor; J. W. Turner, Gardiner; S. A. Patten, Skowhegan; Francis G. Warren, Biddeford.

EVENING SESSION.

The session was held in the rooms of the Portland Society of National History, on Elm Street, at eight o'clock.

Dr. GEO. HENRY FOX, of New York, exhibited by invitation a series of lantern slides illustrating

THE DIAGNOSTIC FEATURES OF CUTANEOUS SYPHILIS.

SECOND DAY.—MORNING SESSION.

Dr. EDW. J. McDONOUGH read a paper on

THE THERAPY OF THE FUTURE.

It was most hopeful for new possibilities in the physiological treatment of a larger number of diseases by serotherapy and the use of animal extracts.

Dr. A. E. BESSEY, of Waterville, read an exhaustive paper on

TUBERCULOSIS.

In discussion, Dr. A. G. YOUNG, Secretary of the State Board of Health, and Dr. D. A. ROBINSON, of Bangor, laid special stress upon the advantage of the Maine climate for sanitarium treatment of this disease.

Dr. CHAS. D. SMITH, of Portland, read a paper upon

THE MANAGEMENT OF CONTAGIOUS DISEASES BY
LOCAL BOARDS OF HEALTH.

It was the writer's opinion that the present law was adequate in its provisions, but that efficiency of administration could be improved by (1) better supervision of cases declared isolated; (2) medical inspection of school children; (3) the establishment of suitable isolation hospitals; (4) more efficient public disinfection by the use of improved methods.

AFTERNOON SESSION.

The association met at two o'clock. Drs. G. P. CONN, of Concord, N. H., and E. N. WHITTIER, of Boston, were introduced as delegates from their respective State societies.

The annual election of officers followed. The list for the ensuing year is: President, Dr. E. H. Hill, Lewiston; First Vice President, Dr. H. B. Palmer, Farmington; Second Vice President, Dr. J. F. Manning, Ellsworth; Treasurer, Dr. Aug. S. Thayer, Portland; Recording Secretary, Dr. Chas. D. Smith, Portland; Corresponding Secretary, Dr. C. A. Peaslee, Wiscasset.

Board of Censors: Drs. John F. Thompson, Portland; Arthur S. Gilson, Portland; Hiram Hunt, Greenville; G. M. Elliott, Brunswick; H. E. Snow, Bucksport.

Committee on Publication: Drs. Chas. D. Smith, Portland (*ex officio*); Willis B. Moulton, Portland; E. M. Fuller, Bath; E. J. McDonough, Portland; J. D. Cochrane, Saco.

Business Committee: Drs. S. P. Warren, Portland; W. L. Cousins, Portland.

Dr. H. T. CLOUGH, of Bangor, read a chapter on
ASTHENOPA AND GLAUCOMA OF THE CLIMACTERIC.

Dr. A. PALMER DUDLEY, of New York, read a paper entitled

THE MODERN CESAREAN SECTION AS AN IDEAL
METHOD OF TREATMENT FOR PLACENTA PREVIA.

He argued the possibility of detecting by vaginal touch the existence of placenta previa before hemorrhage takes place, by noting a less conical shape of the cervix, the feeling of dense tissue between the finger and the contents of the uterus and the placental thrill communicated to the finger. Gas and oxygen mixture was to be used for anesthesia, the uterus compressed by elastic rubber tubing and the operation to be made under constant hot saline irrigation without the use of sponges. The uterus to be closed by three rows of catgut sutures, closing separately the mucosa, the muscular wall and the peritoneal covering.

Cesarean section was urged as in every respect superior to rapid manual delivery, for the interest of both mother and child.

Dr. F. N. WHITTIER, of Brunswick, read a paper on

THE VALUE OF BACTERIOLOGY TO THE GENERAL PRACTITIONER.

Dr. S. C. GORDON, of Portland, read a paper on
GALL STONES.

At 4.45 o'clock the association adjourned to the Falmouth Hotel for the exercises attending the annual banquet. Dr. JOHN F. THOMPSON, of Portland, presided, and Dr. D. A. ROBINSON, of Bangor, acted as toastmaster. The speakers were Drs. S. C. GORDON, of Portland; PROF. F. C. ROBINSON, of Bowdoin College; Dr. G. P. CONN, Secretary of the New Hampshire Medical Society, and Dr. J. COLLINS WARREN, of Boston.

EVENING SESSION.

The annual oration was delivered by Dr. J. COLLINS WARREN, professor of surgery in the Harvard Medical School, upon

A REVIEW OF RECENT STUDIES ON THE NATURE AND ORIGIN OF CANCER.¹

THIRD DAY.—MORNING SESSION.

The association met at nine o'clock, and after the disposal of routine business, received the final report of the Board of Censors as follows:

The following recommendations and appointments were made. The next annual meeting of the association will be held at Portland, on the first Wednesday, Thursday and Friday of June, 1901. The selection of orator was left to the next Board of Censors with power. Following are the appointments:

Visitors to the Maine Insane Hospital: Drs. J. E. Walker, Thomaston; D. A. Robinson, Bangor; A. S. Gilson, Portland.

Visitors to Portland School for Medical Instruction: Drs. F. A. Chandler, Addison; G. M. Woodman, So. Windham.

Visitor to Medical School of Maine (two years): Dr. F. O. Thayer, Waterville.

Visitors to Eastern Maine Insane Hospital: Drs. G. M. Woodcock, Bangor; S. B. Hunter, Machias; John F. Manning, Ellsworth.

Delegates to American Medical Association: Drs. Alonzo Garcelon, Lewiston; M. C. Wedgewood, Lewiston; B. T. Sanborn, Augusta.

New Hampshire: Drs. J. F. Thompson, Portland; J. Z. Shedd, No. Conway.

Vermont: Drs. J. B. O'Neil, Portland; H. C. Bartlett, Norway.

Massachusetts: Drs. Chas. D. Smith, Portland; E. J. Marston, Bath.

Rhode Island: Drs. A. K. P. Meserve, Portland; N. M. Marshall, Portland.

Connecticut: Drs. S. R. Warren, Portland; S. B. Overlock, Pomfret, Conn.

New York State Medical Association: Drs. A. Palmer Dudley, New York; E. F. Clymer, Ithaca, N. Y.

New Brunswick: Drs. E. H. Bennett, Lubec; S. E. Webber, Calais.

Committee on Annual Banquet: Drs. H. F. Twitchell, Portland; R. D. Small, Portland; R. W. Bucknam, Portland.

Twenty-four new members were elected on recommendation of the board.

Recent Literature.

Tuberculosis; Its Nature, Prevention and Treatment.

With special reference to the Open-Air Treatment of Phthisis. By ALFRED HILLIER, B.A., M.D., C.M. Small 8vo. Pp. 243, with 31 illustrations and 3 colored plates. London: Cassell & Co., Ltd. 1900.

As the author states in his preface, this is "a concise manual, dealing with all the hydra heads of tuberculosis." It is largely a compilation but nevertheless a valuable and interesting summary of the whole subject, suggestive rather than exhaustive. There is little in it of the personal experience of the author except some references to his observations in South Africa regarding the climate and its influence upon consumption. The nature, pathology and transmission of tuberculosis are briefly considered, which is all that could be expected upon these subjects in so small a manual; for an exhaustive treatise one must look to Straus's and Cornet's great works. Under prevention the author advocates "the periodical application of the tuberculin test to all milch cows, and the *exclusion*—not necessarily the destruction—of all tuberculous cows from that portion of the herd from which the public milk supply is derived." In this opinion both the profession and the public for the most part coincide, and in view of the known facts it is the only safe and consistent course to pursue. Under this head also there are valuable suggestions regarding the care of children, in which is emphasized "the folly of so dressing children as to leave them with naked legs"; the prevention of atmospheric impurity by overcrowding in workshops; the disposal of sputa, and spitting, where the sensible suggestion is made that spittoons should be provided in workshops and crowded offices.

A chapter is devoted to Prevention by Legislation and Public Action, in which inspection of meat, milk supply, the housing of the working classes, and notification of phthisis are considered. Under the last head the author observes that "as public opinion becomes educated as to the true nature of tuberculosis it is quite probable that notification and supervision of cases will be insisted on." (In the United States compulsory notification already exists in several cities.)

The chapter on treatment is perhaps the most valuable one in the book, and is chiefly devoted to the open-air and sanatorium treatment. All phthisis therapeutists will concur in the author's conclusion that the benefit derived in every case (by the open-air treatment) is chiefly dependent on the extent to which the patient is continuously kept in pure air. Numerous interesting illustrations of sanatoria and various forms of open-air shelters are given, but, unfortunately, they are scattered throughout the book without regard to the text. In the description of sanatoria, Dr. Walther's at Nordrach, about which the English seem to be particularly enthusiastic, is given a prominent place and the author quotes a remark of Dr. Waltier's which is worth repeating: "Sanatorium treatment," he says, "should be largely educational, to teach what can be practised hereafter." The object to be attained in sanatorium treatment is well summarized as follows: "Pure and abundant open air by day and night, indoors and out; such good and

¹ See No. 2, p. 25, of the Journal.

plentiful food as the simple, open-air life may enable a patient to digest; rest—frequent and complete rest.” The majority of phthisis therapeutists will agree with the author that the sanatorium treatment of consumption gives results “equal to if not better than the health resorts of high altitudes, such as Davos.”

A short concluding chapter treats of the national movements against tuberculosis, and there is a valuable appendix in which are reprinted the leaflets distributed by the National Association for the Prevention of Tuberculosis, upon the prevention of consumption; fresh air and ventilation; rules for consumptive patients and those looking after them, from the Victoria Hospital for Consumptives, Edinburgh; the method of using the tuberculin test with cattle, and the recommendations of the second Royal Commission of Tuberculosis regarding meat and milk inspection, the care of milch cows and the elimination of bovine tuberculosis.

A Treatise on Surgery by American Authors. For Students and Practitioners of Surgery and Medicine. Edited by ROSWELL PARK, A.M., M.D., Professor of the Principles and Practice of Surgery and of Clinical Surgery in the Medical Department of the University of Buffalo, Buffalo, N. Y.; Member of the Congress of German Surgeons; Fellow of the American Surgical Association; Ex-President Medical Society of the State of New York; Surgeon to the Buffalo General Hospital, etc. Condensed edition, with revisions. With 625 engravings and 37 full-page plates in colors and monochrome. New York and Philadelphia: Lea Brothers & Co. 1899.

This condensed edition of Park's Surgery is a skillful cutting down of the two-volume edition, which is still on the market, and its compression into one volume. Practically all of the important matter of the two-volume edition has been retained and in its present form it makes a very practical single-volume work on modern surgery. It has been revised and considerable new material has been added. It is profusely illustrated, is an excellent piece of bookmaking, and makes one of the best textbooks on surgery.

The Modern Treatment of Wounds. By JOHN E. SUMMERS, JR., M.D., Surgeon in Chief to the Clarkson Memorial Hospital; Attending Surgeon, Douglas County Hospital; formerly Professor of the Principles and Practice of Surgery and Clinical Surgery, Omaha Medical College; Ex-President of the Western Surgical and Gynecological Association, the Nebraska State Medical Society, etc. Omaha: Medical Publishing Co. 1899.

This is a small octavo volume of 134 pages, which has a few illustrations of some value. The author has written a practical book, with but little theory; in fact, many of the statements are dogmatic, and are clearly the result of the author's strong conviction and the result of a large personal experience. As a whole the book shows that the views of the author are sound, but the meagreness of detail and technique gives the general impression that the book is written for lay instruction. Some of the mechanical devices that the author has brought forward are well worth knowing. The book can be safely placed in the hands of students and young surgeons, and many old surgeons will benefit by reading its pages.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 9, 1900.

MEDICAL LITERATURE.

THAT more persons, whether qualified or not, are writing for medical periodicals than ever before appears to be an established fact. If one is doubtful on this point, one needs merely to look over the files of our weekly or monthly journals, and then to realize that each year new ones are being added, with no diminution in the size of their longer-established rivals. Of the quantity there can be no question, but of the quality possibly something remains to be said. Various tendencies are observable, some of which are certainly good and others as surely bad and demoralizing. The idea is growing that a young doctor's reputation, if his lot be cast in a large city amid much rivalry, is determined largely by what he writes, and by his additions therefrom to the sum of medical knowledge. This tendency we must in general approve. It cultivates the mind of the writer, and if he be possessed of intelligence as well as of ambition, what he writes is likely to prove of some value to his readers. An early application to the demands of original work, however small the problem may be, is without question a most desirable frame of mind for the aspiring doctor. There is danger, however, that this otherwise admirable frame of mind may be perverted to unworthy ends. With the small opportunity for self advertisement allowed a doctor who is beginning his career, it is small wonder that he writes at times for no other end than to bring his name before the eyes of his colleagues. Such writing is extremely apt to degenerate into a conscienceless filling of space with facts already known, and details in which no one can or ought to be interested; nevertheless, the author is apt to derive, at least, a reputation for industry from the mass of his often too uncritical colleagues. This sort of writing should be persistently discouraged. Mere self laudation should not be permitted to fill the columns of our medical journals, however artfully it may be disguised. The better medical journals are now, however, in great measure free from this worst type of medical writing, and an educated public taste will hardly longer permit the repeated publication of such articles without

at least an inward protest against the author and his methods.

By far the larger class of those who write papers are actuated by higher motives than unqualified self laudation. They sincerely believe themselves to be adding, by their literary efforts, to medical knowledge. They are writing "scientific papers," which are intended to be a source of edification to others, as well as of advantage to themselves. These are the writers who show many propensities which are very much to be deprecated. They are apt to be under the impression that many words are better than a few; that length of exposition is a merit; that irrelevant details are essential; that tabulations are invariably more expressive than statements; that uncritical bibliographies are an indication of thoroughness, and so on through a long category of faults which should be apparent to any well-trained scientific mind. A German professor of high standing in his special line of work, when a foreign pupil about to publish a paper was bemoaning his inability to write idiomatic German, said that if the meaning could be expressed, the idioms would take care of themselves. In spite of this excellent advice, which was duly followed, the fact remains that the German method of superabundant detail expressed in language of complicated indirectness has done much to influence our American writing. The idea has grown that thoroughness and verbosity are in some mysterious way synonymous, and we are finding more and more our new medical literature overburdened with detail which tends to obscure the kernel of originality for which alone the paper is of value.

In view, however, of all we owe to the laborious work of German investigators, it might appear invidious to take them to task for any shortcomings, were we not supported by the opinion of that most respected of authors and editors, Professor Virchow. Virchow, writing in a recent number of his *Archiv*, sounds no uncertain note in his criticism of modern methods of medical writing. Coming from such a source, we need no excuse for referring to a few of the warnings and bits of advice, which not only have a distinct bearing upon the author and his work, but also upon the editor, who is responsible to his readers for what appears in the columns of his journal. Speaking of the length of articles, Virchow says: "Avoid everything which is not necessary for the presentation and proving of the subject. But this, experience shows, is very difficult to attain." The lengthy details of history and autopsy he deprecates as unnecessary and often prohibitive of a reading of the paper. What he alludes to as the new custom of introducing comprehensive and often un instructive tables, he regards as unnecessarily increasing the difficulties of the reader as well as of the printer. The careless writer who collects a worthless bibliography, which he has never properly verified, but which still occupies valuable space, Virchow has no sympathy whatever for. He also questions the growing custom of numerous illustrations and particularly of those in

colors. "If the contributors would only inform themselves what a single colored plate costs, they would then experience how exorbitant their demands upon an editor are, who is obliged to pay the cost." Finally, he positively declines to accept articles for his journal beyond a certain length.

All these complaints which Virchow from his long experience makes are no doubt shared in, to a greater or less degree, by editors everywhere. What we need now more than ever before to get at, for the benefit of all concerned, is brief statement of essential facts. To accomplish this means unremitting effort on the part of writers to introduce into their communications nothing extraneous to the main issue, and to apply, as far as possible, such forms of expressing their points as will most certainly, if not most showily, bring this about. At times numerous illustrations and elaborate tables may be the best means to this end, but we are inclined to think that the cases are not few in which no one would find fault with their omission. It is at any rate certain that the burden which often lies heavily on the editor's shoulders would be materially lightened if contributors would bear in mind the warnings which Virchow has seen fit to express.

THE RED CROSS IN CHINA.

THE advance of the allied forces on Peking means much more than the usual difficulties incident to a campaign through an enemy's country. Apart from the inevitable hardships and deaths in action and from disease, it may be expected that the arrangements for the care of the wounded will have to be considerably modified, owing to the fact that China is said not to have been a party to the Geneva Red Cross convention. This, of course, implies that the medical and nursing staffs accompanying the army will not be regarded as noncombatants, and will therefore be exposed to dangers from which the medical arm of the service of armies has been free almost from the time of the Crimean War. This naturally will not concern the base hospitals, to which we understand the female nurses are chiefly to be apportioned. It will, however, modify the situation on the field of battle considerably and necessitate far greater precaution than is ordinarily required in the care of the wounded. We have already commented on the lack of medical organization, and on the rudimentary medical knowledge among the Chinese. In view of all these facts, the possible situation of the wounded is not pleasant to contemplate, but it is particularly hard for us to look with equanimity upon the fate of those who through the accidents of war may fall into the hands of the Chinese. Even were the intentions of the captors the best, which unfortunately we have every reason for doubting, the lack of hospital facilities and medical knowledge would go far toward making immediate death preferable to the treatment the captives would be likely to receive. Recent experience in South

Africa, as well as in our own war with Spain amply testifies to the difficulties which the medical corps of an army is called upon to meet when an unexpected strain is made upon its resources. The complete absence of medical organization in the Chinese army is a fact which makes our hope the more ardent that no unfortunate foreign soldiers may fall a prey to the ignorance and fanaticism of their enemies in the momentous movement toward Peking which is now being undertaken.

MEDICAL NOTES.

AMERICAN FELLOWS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND. — At the recent centenary meeting of the Royal College of Surgeons of England, the honorary diploma of the Fellowship was conferred upon Dr. W. W. Keen, of Philadelphia; Dr. Robert F. Weir, of New York; and Dr. J. C. Warren, of Boston, as well as upon Dr. W. S. Halsted, of Baltimore, already announced. The Canadian physicians, Sir W. H. Hingston and Dr. T. G. Roddick, of Montreal, and Dr. I. H. Cameron, of Toronto, likewise received the diploma.

THE MEDICAL PROFESSION IN ITALY. — The statistics of the medical profession in Italy, as given in the *Philadelphia Medical Journal*, present something of the same state of overcrowding as elsewhere in the world. In 1876-1877 there were 2,035 students of medicine, in 1896-1897 there were 6,922. But it is puzzling to note that while the number of practising physicians in 1878 was 18,044, their number was only 20,000 in 1899. About 900 men leave the universities yearly, but only about 500 physicians are reported as dying in the same limit. In Italy there are some 9,000 town physicians (or health officers); of these about 5,000 have a yearly salary, which in only 500 cases exceeds 3,000 lire a year.

TOO ILL TO BE NURSED. — The following taken from a daily contemporary has in it an element of grim humor not without significance: "It is the *London Chronicle* that says, apropos of Mr. Burdett-Coutts's melancholy view of the South African hospitals, it is still lightened by humorous touches. A lady nurse rushing fervidly to her patients in a Cape Town hospital ward, found her favorite soldier fast asleep. Pinned to his coverlet was a scrap of paper on which he had laboriously scrawled: 'to il to be nussed today respectfully J. M.'"

THE RAVAGES OF PLAGUE. — It is stated in the *Indian Medical Gazette* that from the beginning of plague in Bombay, September, 1896, till May 11, 1900, there had been in all 392,578 recorded cases, and 308,172 deaths, in the Bombay Presidency alone. Out of this large number there had been only 202 cases and 59 deaths of Europeans in the same presidency.

LEWIS STEPHEN PILCHER, LL.D. — The degree of Doctor of Laws has been conferred by the University of Michigan and Dickinson College upon Dr.

Lewis Stephen Pilcher, of the Methodist Episcopal Hospital, of Brooklyn, and editor of the *Annals of Surgery*.

LANE LECTURES, COOPER MEDICAL COLLEGE, SAN FRANCISCO. — The fifth course of lectures for 1900 will be given by Sir Michael Foster, from August 20th to August 24th, inclusive, on various subjects connected with the history of physiology.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 8, 1900, there were reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 51, scarlatina 15, measles 26, typhoid fever 8.

SMALLPOX AT LOWELL, MASS. — Smallpox at Lowell still claims a certain number of victims. The disease is supposed to have been brought from Canada by a family of French Canadians, and is limited in Lowell to the French Canadian settlement. The patients are being cared for at the contagious hospital, and further means have been taken to hasten the work of vaccination.

NEW YORK.

A LUSTY CENTENARIAN. — John Paul Carroll, a centenarian residing in Brooklyn, has just been made a member of the Grand Army of the Republic, being mustered into the G. K. Warren Post, No. 286. He was considerably over age when the Civil War broke out, but he was accepted as a recruit of the Seventy-first Regiment, New York Volunteers, in May, 1861, because he was so robust, although he was then nearly sixty-one years old. He was born in the county of Meath, Ireland, on June 20, 1800, and the extraordinary vigor of his constitution is attested by his having passed the century mark, notwithstanding the fact that he still carries in the tissues of his neck a bullet received in the battle of the Wilderness and also that on his head is a silver plate covering the spot where a trephining operation was rendered necessary on account of another wound met with during the war.

NEW SUPERINTENDENT OF THE ELMIRA REFORMATORY. — Dr. Frank W. Robertson, of New York, who was recently appointed senior resident physician at the State Reformatory at Elmira, has now been appointed acting general superintendent of that institution, in the place of Superintendent Brockway, who was forced to resign on account of his reputed harsh treatment of the prisoners. While the latter has now retired, the resignation does not take effect until the end of the year, when it is probable that Dr. Robertson will be appointed permanent head of the reformatory. Dr. Robertson received the appointment of resident physician on the recommendation of a large number of prominent New York medical men. He is a graduate of the College of Physicians and Surgeons, and for five years prior to his going to Elmira was chief of the pavilion for the insane at Bellevue Hospital.

WORK OF THE CHILDREN'S AID SOCIETY. — The Children's Aid Society is doing admirable work during the summer. Since the 18th of June some 4,000 children from its industrial schools in the city have been sent to its summer home at Bath Beach. The girls remain for a week, and the boys go for one day, all alike enjoying the benefits of salt-water bathing. Nearly 1,800 mothers with sick children have been cared for at the Health Home at Coney Island, the larger portion remaining for one week; and a large number of crippled children have been afforded vacations of three weeks each at the Bath Beach Home. In addition to giving the day excursions for boys the society every Monday conducts a company of 100 little lads to the Farm School in Westchester County, where each company remains for one week.

A NEW CITY HOSPITAL. — On July 31st Deputy Commissioner of Charities Glennan, in the name of the city of New York and the Department of Public Charities, took formal possession of the old Brooklyn Homeopathic Hospital. This has hitherto been a private institution, but after the needed alterations have been made will be conducted in the future as a city hospital.

PRIZE AWARDED DR. KNOPF. — A dispatch from Berlin, dated July 31st, announces that the prize of 4,000 marks offered by the Tuberculosis Congress for the best essay on the subject, "How to Fight Tuberculosis as a Disease of the Masses," has been awarded to Dr. S. Adolph Knopf, of New York. Eighty-one essays are said to have been offered in competition.

INSANITY AMONG PRISONERS. — In the first two days of August no less than 6 inmates of the State Prison at Auburn, 3 men and 3 women, were adjudged insane, and they will be transferred to the hospital for insane criminals at Matteawan. No special reason is assigned for this sudden and unusual development of mental disease.

ADDITION TO ST. CATHERINE'S HOSPITAL. — St. Catherine's Hospital, in Williamsburgh, Brooklyn, is about to erect a new wing for the care of consumptive patients. The estimated cost is \$30,000, and of this amount \$18,000 has already been raised by the hospital society.

ARMY NOTES.

AN ISLAND FOR SEGREGATION OF LEPEES. — General MacArthur has convened a board of officers, of which Major L. M. Maus, Surgeon U. S. Army, is president, to select an island in the Philippine Archipelago for the segregation of lepers, to prepare plans and estimates for suitable buildings thereon, and estimates of salaries for the necessary officials and employes. The board is also charged with fixing the ration and other allowances for the support of this leper colony. This action was taken in view of the

large number of lepers in the Philippines, now under no restraint and a constant menace to the public health. It will be remembered that the army authorities are in Puerto Rico on a small key to the north of that island, while in Cuba the lepers have been carefully collected at the San Lazaro Hospital, near Havana.

ASSISTANT SURGEON LIPPITT WOUNDED. — Press reports state that Assistant Surgeon Lippitt, U. S. Navy, who has been serving with the detachment of marines guarding the United States legation at Peking, has been severely wounded.

Miscellany.

TABES DORSALIS IN INFANTS.

TABES DORSALIS is a rare disease in infants and the cases recorded in literature amount to 6 in all — namely, 3 cases published by Remak, 1 by Strümpell, 1 by Mendel, and 1 by Bloch. Dr. L. Dydynsky gives an interesting account of a seventh case — namely, that of a boy eight years of age, in whom the tabes had its onset at the age of five years and gave rise to bladder troubles. The patient has since then suffered from incontinence of urine and sometimes from retention of urine. He showed Romberg's symptom while standing, the pupils were of the characteristic Argyll-Robertson type, and Westphal's sign (loss of knee jerk) was pronounced. There were muscular hypotonia and feebleness but no atrophy or manifest inco-ordination. He had lightning pains and paresthesia in the lower limbs, as well as patches of hypoaesthesia and hypoaesthesia. The personal history of the patient showed a remarkable freedom from any infectious disease and there was not any direct sign of hereditary syphilis. The family history was as follows: The child's father had had syphilis when a young man, aged twenty years, and was at the time of recording of the child's present illness suffering from incipient tabes with characteristic knee symptoms and pupillary conditions. The child's mother had had five miscarriages before the present child was born. Following him were three other children (infants) who so far appear to be well. Dr. Dydynsky insists on the fact that in all the cases observed of infantile tabes and juvenile tabes (Raymond, Homen) syphilis has been noted in the parents, especially the father. Hereditary syphilis is undoubtedly the cause of infantile tabes dorsalis, just as it is also the cause of the characteristic cerebral degeneration, which may bring about juvenile general paralysis (Thiry, Alzheimer). It is interesting to note that in nearly all the recorded cases of infantile tabes the symptoms began with bladder troubles and troubles of micturition, after which ocular symptoms followed. Troubles of sensibility of the skin followed next in order of time, whereas ataxia and loss of the power of balancing and walking supervened late or did not appear at all. Considering the syphilitic etiology it is a question whether the prevention of both tabes and general paralysis in juveniles might not be effected were appropriate antisiphilitic treatment adopted in the case of every infant subject to heredi-

tary syphilis. The questions opens up one of the most important departments of preventive medicine. — *Lancet*.

Correspondence.

SPREADING OF DISEASE IN BARBER SHOPS.

BOSTON, August 3, 1900.

MR. EDITOR:—In view of the recent efforts of the Boston Board of Health to limit the spread of disease in barber shops, the following circumstances are of interest: D. H., age thirty-one, a laborer, early in June last was shaved for the first time in a certain Italian barber shop where the price of a shave is five cents. The barber cut his face and the cut did not heal. About three weeks later the cut became an ulcer, and at about this time a similar lesion appeared on the chin. On July 30th an eruption appeared all over the body. I saw him for the first time on August 1st. The sores on the face are typical hard chancres and the eruption is the secondary eruption of syphilis.

Yours truly,
H. F. R. WATTS, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 28, 1900.

Address.

SURGICAL PAIN.¹

BY G. RYDER, M.D., MALDEN, MASS.

"Every pain has its distinct and pregnant significance, if we will carefully search for it."—HILTON.

IN acknowledging the honor of this hour, the reader is reminded that we are living in the closing days of a glorious century, a hundred years that will forever be remembered by medical men as the period of their greatest conceptions, their finest discoveries and their most precious boon to humanity. The temptation in this valedictorian time to flush your cheeks with the pride that justly emanates from an enumeration of this century's achievements in medicine is indeed strong, and might, if indulged in, lead to an hour's agreeable entertainment; but the reader asks your indulgence in listening to a more painful subject, a subject which will for eons of time elicit, at least, the sorrowful attention of its victims, unless, forsooth, Christian Science finds some shorter cut than it now possesses to that Utopian state of curing "while you wait."

The child of the twentieth century will awaken at night, and toss in agony, thinking himself a living refutation of his father's fairy story about the nineteenth century being the one hundred years in which the bitterness of the primal curse was abolished and the horror of pain mitigated.

Pain will always exist. I invite you, then, today, to consider it as our ally, the one prominent symptom of all acutely dangerous processes within the abdominal cavity, rather than an enemy we would single out for destruction. To learn its import, to comprehend its value in the early discernment of disease, is our task and duty. The present drift of surgical thought since the triumph, during the last decade, over the terrors of appendicitis and pelvic disease is to apply the same reasoning and treatment to other similar, yet more dreaded, pathologies of the abdominal cavity.

And what is pain? Cicero believed it was a disagreeable movement in the body independent of the senses. Savage calls it one thing, Erb another. Whatever the neurologists may say, you and I believe the word to be sufficiently descriptive in itself.

Every increase of ordinary sensory stimuli above the physiological limit produces pain; excessive stimulation is the only prerequisite in its development. Beyond this the reader finds nothing clear and proven. There is no department in neurology which affords so unique a symptom in diagnosis, the relief of which requires discernment and ingenuity of so high an order. Very powerful nerve irritation, such as is produced by extreme shock, is painless, the higher degree of irritation destroying function.

The reader trusts he may not be thought to assume a too dogmatic tone in the presence of those whose experience overshadows his if in the following pages statements are made which challenge discussion.

We would not imply that pain *per se* is of sufficient importance to call it pathognomonic, except in certain few instances, but we would advance the suggestion that a more minute study of the subject may be the means of making an earlier diagnosis, and the saving of much time and life.

Gesture of pain.—In appreciating the value of pain

¹ Annual Address delivered at the Annual Meeting of the South Middlesex District Medical Society, April 18, 1900.

as a diagnostic symptom, which, we claim, is the most important and instructive of all subjective signs, we are thrown upon the sincerity and intelligence of the patient to accurately and truthfully depict his suffering. Any outward manifestation displayed by him in the description of his pain oftentimes affords the strongest clue to its seat, its nature and its character.

An investigation of a case characterized by pain should first elicit from the patient where the pain first began, where it is at present and what kind of a pain it is. Verbal descriptions of pain are often so indefinite in the ignorant, or so verbose, exaggerated or inconsistent in the hysterical and neurotic, that their gestures are more valuable as testimony than their word pictures. When a pain is due to inflammation of an external part, the patient will be observed to approach it in a very respectful way, if he does not actually avoid touching it, so that in a peritonitis his hand hovers over the part without touching it.

In mucous membrane inflammation like intestinal functional disturbances, the whole hand is laid upon the abdomen and passes over and across it to denote the diffuse general soreness. The localized pain of an appendicitis is indicated by the open hand, shielding it as it were from the observer's touch. There is an absence of gesture in meningitis, because such movement causes pain while in myelitis both hands pass from the spine to the umbilicus, indicating the sensation of pain or constriction.

In the gestures indicative of pain elicited only on pressure no such timidity of touch is noted as in inflammatory pain. Tumor, aneurism or abscess pains are indicated by pressure over the painful area. An extended thumb pressing into the back, indicating the area of a fixed pain, is said to be suggestive of aneurism. In the contractile muscular pains of a hollow tube, like the hepatic ducts, ureter or bowel, as in hepatic, renal or lead colic, the sufferer grasps or presses the part in contrast to his attitude in the inflammatory pains of pyelitis or cholecystitis.

Your attention is called to three great characteristics of inflammatory pain, with which this paper has largely to deal. The first is that pain is elicited or provoked by pressure and is greatest, as a rule, at the seat of the inflammation. This fact is of special interest in interpreting the diagnostic value of pain. You may move at will a limb the seat of pain without causing an objection on the patient's part, but pressure excited over the course of a nerve the subject of neuritis will provoke a distinctly painful sensation.

The second characteristic of inflammatory pain is that movement of the part even in the maintenance of its own function causes pain. Thus it is that an inflamed appendix is kept quiet by the contraction and rigidity of the overlying muscles, which act somewhat as a splint. If in the case of epigastric pain there be present no rigidity, one may exclude a gastritis or a localized peritonitis. Probably the best type of inflammatory pain which nature seeks to quiet, because thereby it keeps the part at rest, is the pain of vertebral disease. The child no longer bends his spine, but seeks to keep the spinal muscles at rest by bending the knees should occasion call for any stooping.

The third characteristic of inflammatory pain is that it is accompanied by a disturbance of the normal function of the part, as seen in the case of meningeal headaches, with the intolerance to light, delirium, etc

Such is not the picture of a neuralgic headache. But inflammatory pain, besides these characteristics, differs somewhat according to the part involved. Mucous membrane pain is rather a soreness, and when severe, it is styled burning; when griping, colicky pains ensue, it is because the inflammation is no longer confined to the mucosa, but has involved the muscular structures of the viscus. Serous membrane inflammation is more apt to be acute and stabbing. Fibrous tissue inflammation, of moderate, is of a dull, aching character, but violent and throbbing with each heart systole if the tissue is much inflamed.

Referred pains.—Inflammatory pain is either local or radiated along the course of nerves in direct communication with the seat of the inflammation, and this statement brings us to a consideration of referred pains, to whose study no better contribution has been made than the now aged but scientific and classical monograph of Hilton. A characteristic of these referred pains is the fact that movement and pressure do not elicit any objection on the part of the sufferer, or increase the pain, and so they can be proven not to belong to that part. You may press the sixth and seventh dorsal vertebrae without increase of pain, when, as it often happens, such pain is referred to that region from an ulcerative gastritis, the association having been maintained through the terminal ends of the sixth and seventh dorsal nerves. Likewise you may press, without increasing the pain, at the pit of the stomach, when such pain has been conducted there by these same nerves from a diseased vertebra.

Hepatic inflammation of the convex surface of the liver may send a nervous message along the right phrenic on the under side of the diaphragm, and then to the top of the right shoulder or the interscapular space, but pressure and movement do not affect the intensity of such pain. This brings us to an explanation of many of the pains situated between the scapulae dependent on visceral lesions. The fourth, fifth and sixth dorsal nerves are distributed over the inferior angles of the scapulae and the interscapular space, and are the particular nerves in question involved. If you will follow these sensitive peripheral filaments of the skin to their connection with the great splanchnic nerve, you will remember that the latter, passing down through the thorax, then enters the solar plexus, and that its abdominal ends are distributed to the liver, pancreas, duodenum and stomach, and hence supply us with a positive route for the transmission of inflammatory pain from these viscera to the scapular region of the back; such at least is one such nerve channel.

To the mid-dorsum may be referred pains of the kidneys, abdominal aneurism and the small intestines. In the lower back, likewise, we frequently find pains referable to the pelvis and lower abdomen. Referred pains from the pelvis come by way of the hypergastric plexus, travelling along the pelvic splanchnic, and enter the cord with the second and third sacral nerves.

Abdominal brain.—No definite or satisfactory comprehension of referred pains can be obtained without reference to that marvellous mechanism of the abdomen which presides over organic life, the abdominal brain. Although it was discovered by Galen, who was born 130 A. D., you could not spend a more delightful evening than by reading the recent works of Fox and Robinson.

The two great functions of the visceral mind are nutrition and rhythm. Here nutrition and secretion are controlled. Here visceral function and rhythm are begotten and sustained or prohibited. It receives sensation and transmits motion; it controls circulation and gland secretion; it presides over the organs of generation and has a master hand over the peripheral automatic ganglia of the viscera.

The abdominal brain is situated at the base of the celiac axis and the renal and superior mesenteric arteries. It lies, therefore, along the aorta, just behind the stomach, and consists of a meshwork of ganglia, comprising the splanchnics, the pneumogastric and phrenics. The abdominal brain, therefore, has brain centres, conducting cords, and a peripheral nerve apparatus, just as the brain proper has these parts. The abdominal brain can live without the cranial brain, but the cranial cannot live without the abdominal. This great visceral centre is connected with and is a part of the lateral chains of the sympathetic system, which range along the sides of the vertebrae, from skull to coccyx, and so gets its direct connection with the spinal and cranial nerves.

There are two interesting and practical features of this system instrumental in the production of the pain we are considering. Between the longitudinal and circular layers of muscle in the viscera lies a system of nervous ganglia known as Auerbach's plexus. This is the peripheral apparatus which induces intestinal peristalsis or vermicular motion. Overstimulation of this plexus causes colic, while insufficient stimulation is productive of constipation and paresis. Just under the mucous membrane there lies a still more delicate system of ganglionic brains, called Meisner's plexus, whose office is to preside over the secretions of its viscus; they induce a secretion of the digestive fluids and preserve a nice balance between over and under secretion.

The automatic menstrual ganglia of Robinson are situated along the ovaries and Fallopian tubes, and so preside over monthly rhythm. The uterine set of ganglia affect the muscle of the fundus only, the neck being supplied with spinal nerves, which inhibit rhythm, hence the powerful preservative action of the uterine neck against any undue stimulation tending to cause miscarriage.

Auerbach's and Meisner's plexus of the stomach, being the nearest and largest of the peripheral visceral apparatus, are generally the ones most readily responsive in all abdominal lesions, and hence we meet with nausea and vomiting so constantly as early accompaniments of abdominal pain, or of fermentation and indigestion in less acute abdominal disorders. When the peripheral apparatus of the small intestine becomes involved, constipation or diarrhea and tympanites result. If these little bodies are excessively stimulated, as in appendicitis, strangulation, etc., we get the colicky periodic pains characteristic of all abdominal tubular organs.

Pelvic stimulation is transmitted by way of the ovarian or hypogastric plexus, which latter, situated in the post-peritoneal membrane, is clinically the more sensitive and important as explanatory of the severe pain of tubal perforation.

Classification of pain.—Before proceeding to a consideration of visceral lesions themselves, the reader would refer you to a classification of pain by Lomer, of Hamburg, whose monograph on gynecological pain

appeared about a year ago, and which adds another most charming treatise on pain at a most opportune time, when pelvic surgery has become a question less of surgical technique than of sound surgical diagnosis. He divides pain into (1) traumatic; (2) contractile; (3) inflammatory; (4) neuralgic; (5) hysterical. This classification applies very well for practical purposes to all visceral lesions.

Simple uninfected *trauma* of the viscera is causative of comparatively little pain. It is recognizable as wound pain and soon subsides. Visceral nerves in the absence of inflammatory states are so little sensitive that pure and simple trauma of the peritoneum in these post-Listerian days is causative of little pain, as the reader has had occasion to notice in several cases when completing a section, with the patient in full consciousness. The tying of a pedicle, comprising the ovarian plexus, causes momentarily severe pain, and even under ether, you all have noticed the altered respiratory rhythm of the bowel reflex.

Contractile pain, of which examples are afforded by any abdominal viscus, as the hepatic and renal ducts, the intestine, appendix, Fallopian tubes, stomach, uterus and bladder, is typical in its recurrence, and is rhythmical in character, due to contraction and dilatation of the organ, and dependent on the peculiar peripheral nerve apparatus of Auerbach. At times it is the most intense in character, is paroxysmal and colicky, and ceases only when the obstruction which clogs the lumen is removed, or the muscles become overstretched, ruptured and worn out. An aborted ovum, a tubal pregnancy, an enterolith in the appendix, a stone in the renal and hepatic ducts, an intussusception, or an offending fecal mass causing obstruction, are all common illustrations in the causation of colicky pains. It is, therefore, the implication in diseases of orifices having contractile cavities behind them which is most calculated to make pain a prominent symptom in clinical histories.

Inflammatory pain is caused, we are taught, by the swelling of the tissues and the consequent pressure on nerve ends, but since the birth of bacteriology we know full well that the chemical action on the tissues of the toxins is by far the greater cause both of inflammation and its pain, and the reader believes it fair and essentially accurate to say that the colon communis and streptococcus cause more pain than most other germs, unless the nervous system is so steeped in poison as to be utterly demoralized.

Neuralgic pain is due to a neurosis of the sympathetic system, is paroxysmal with distinct intermissions, and, like the same pain elsewhere, is often accompanied by trophic disturbances, and lightning-like, lancinating pains. Enteralgia, as such exists, is a distinct lesion, but more often is an expression of some nerve reflecting a pain from a spine of ataxia, an inflamed ovary or an enteritis.

The most perplexing, annoying and interesting pain of the abdomen is the *hysterical*. Its seat and course are independent of any nerve zone or division of nerves, its course frequently forming geometrical figures. It depends on psychological changes, and is not influenced by rest or inflammation. It is subject to suggestion and referable to some central lesion. "It is generally a burning pain, and may occupy any part of the abdomen and its contents," says Charcot. Pains of the lumbar and sacral back, or of the abdominal wall, intensified by the slightest touch, are gen-

erally hysterical. As these pains have been the cause of much blundering in diagnosis, and the reason given for opening the abdominal cavity without finding a sufficient causative lesion, and, therefore, bringing calamity on the head of the operator, the reader would remind his hearers that Charcot's so-called *stigmata* are the essential means of differentiating them from genuine pains. In such hyperesthesia there is always present some other manifestation of altered nerve force, like the anesthesia of the conjunctival bulb, or the soft palate, or some anesthetic zone in the face, leg or back. Pinching the muscle and so locating the pain in the abdominal wall is a simple yet efficient method of discrimination. Thus the terrible pain of an hysteric, supposed to be suffering from gastric ulcer, perityphilitis, ovaritis, enteralgia, or gall stone, is soon converted into a skin hyperesthesia, whether due to a rheumatic myositis or a central hysterical lesion, and is amenable to other measures than the scalpel.

Clinical significance of acute abdominal pain.—He who starts out to elucidate the clinical significance of abdominal symptoms of an acute character, in which pain is the prominent one, meets at once on the threshold of his investigation the confession that the abdominal cavity is a veritable grab box, in which anything may be found from a simple innocuous cyst to a rare yet verified teratoma; while the number of mechanical instruments, wearing apparel, vegetable and chemical sundries that have been removed from the human intestines would suggest the propensities and capacity of a Harlem goat.

We acknowledge the impossibility of correctly diagnosing, before the abdominal incision is made, many even of the common forms of disease. Only the minute study of the early individual symptoms seems, at present, to promise much assistance in reaching a prompt diagnosis in that great class of diseases which suddenly threaten life from mischief brewing within the peritoneal sac. In the symptom complex—pain, vomiting, rigidity of abdominal wall, meteorism, collapse, etc.—called peritonism or peritonismus, pain is the one constant and foremost symptom.

Location of pain.—The more common localities of visceral pain are, first, the umbilical region, to which are referred all the early transmitted pains of the various types of obstruction, appendicitis, acute miliary tuberculosis, lead colic, twisting of tumor pedicle and thrombosis of the mesenteric vessels; the superior mesenteric plexus being the nearest box from which an alarm of intestinal fire is rung in to the central station, or abdominal brain. The second common locality of abdominal pain is the appendicular, in which region are found the secondary pains of appendicitis, obstruction, inflammation and right-sided pelvic disease, neuralgia of superficial branches of lumbar plexus and myalgia. The third locality is the hepatic and renal area, generally the localized seat of renal and hepatic colic, acute hepatitis, cholecystitis, aneurism of the mesenteric artery, aortic disease and subphrenic abscess. The fourth area is the pelvic, the peculiar seat of tubal pain; and finally the epigastric area, in which latter region are located the pains of gastric, duodenal and pancreatic ulcer with perforation, acute pancreatitis, malignant growth, diabetes, locomotor ataxia and reflex pelvic pain.

To further localize pain is impracticable without the

aid of pressure. Pressing the abdominal walls elicits frequently a localized pain, an expression of a localized inflammation, and is of the utmost importance.

Rigidity of muscle wall is the next important aid we possess in suggesting a localized pathology, it being the result of reflex irritation from involved viscera to the spinal cord, reflected back through the lower intercostals, governing the muscles, and hence frequently distinguishes purely abdominal from purely pelvic trouble, since the latter, for reasons before mentioned, has no such reflex before the peritoneum becomes involved.

Obstructions.—The great class of obstruction emergencies, which include bands, hernia, volvulus, intussusception, foreign bodies, stricture, tumor, fecal accumulation and perforation, are all characterized by sudden onset without apparently exciting cause, by severe abdominal pain, generally localized about the umbilicus, with at first little or no tenderness, but careful and attentive pressure by the first physician summoned very frequently evokes a localized tenderness of inestimable value to the surgeon who comes later.

The pain is colicky and constant, due to the disordered rhythm, provoking violent peristalsis, then comes vomiting with stomacheic, later bilious and finally brown, offensive products. It is copious, persistent and gives no relief; constipation is absolute from the first, with the single exception of intussusception; tongue furred, thirst intense, temperature subnormal, urine diminished; then appears collapse, weakness, pallor, sunken eyes, feeble and rapid pulse, cold sweat and sighing respiration. As the case persists unrelieved, the dry tongue becomes brown, the face has the aspect of horrible anxiety and the patient dies within three days from the start of these symptoms of septic peritonitis, which even modern surgery has failed to control. Vomiting is the more persistent, pain the more pronounced symptom, until exuded serum and lymph or pus bathe the roughened peritoneum.

The pain of intestinal obstruction depends on the futile, wild and irregular peristalsis and is measured in severity by the suddenness of the strangulation, the amount of bowel involved, the seat of the obstruction and the age of the person. The small bowel, when the seat of the lesion, causes greater pain and collapse than the colon, and naturally being severer as the jejunum is approached. The sigmoid flexure possessing a very susceptible and responsive nerve apparatus as compared with the rest of the colon, and being generally involved in its entirety when the seat of volvulus, causes great pain and collapse. The young adult, full of life and vigor, is the subject of more pain and collapse than the aged.

The periodic peristaltic waves may frequently be seen in a thin person hurling themselves against the seat of obstruction, like gallant Englishmen against Spion Kop, and with usually a like result. Tympanites arises in exact proportion to the peristalsis above the obstruction. The patient experiences a sense of fulness and of dragging at the bowels, and frequently says that he feels the movement in his abdomen arrested at the same spot.

In these cases of obstruction there is a feature of the pain which demands especial attention, namely, that when obstruction is complete the pain is constant though liable to exacerbations; while in partial ob-

struction the pain is distinctly intermittent, and the sufferer enjoys intervals between the attacks. If, for instance, an obstruction due to stricture becomes suddenly complete, the pain will as suddenly change and become continuous where before it was intermittent. Pressure frequently relieves the pain of obstruction at first, stopping the nervous telegram, but later aggravates it, a trustworthy sign of beginning peritonitis, or at least a peritoneal hyperemia. A diminution of pain toward the end of a fatal case is due to collapse, a sensorium steeped in the lethal septicemia, or upon extensive paralysis of the intestine, while its cessation is synchronous with perforation.

It is impossible to localize obstruction in the small intestine from pain alone, as the coils are continuously changing their position, but pressure aids materially. The stomach and colon being more fixed, it is quite possible to localize the painful lesion in them. The frequent site of abdominal pain in sigmoid obstruction is a point a little to the left of the umbilicus, the site of the inferior mesenteric plexus. In those rare cases of appendicitis and obstruction where pain is referred to the corresponding area of the left side, pressure over the right hypochondrium increases the referred pain of the left side. Icticanuria, as an accompanying symptom of pain, is of some considerable value in localizing obstruction to the small bowel, and is a pronounced symptom; when the small intestine is involved in obstruction cases the pain is more severe, begins earlier and is more persistent.

Strangulation by bands and apertures.—Strangulation by bands and apertures, one of the most difficult matters to diagnose as well as the most painful, constitutes about one-third of all intestinal obstruction. A history of previous peritonitis affords a strong presumptive proof of this variety. The subnormal temperature and weak, rapid pulse are not significant; the pain, agonizing at first, becomes more diffuse and continuous. There is no tumor. Pressure relieves. It may be said of such a status that a patient between twenty and forty years (the subject of previous peritonitis) presenting no evidence of stone, no gas per rectum, no tumor or hernial swelling, but a sudden, severe, colicky, abdominal pain with marked constipation and tympanites, with vomiting which does not relieve, demands surgical attention, for, with all these conditions, many feet of small intestine may exist as red as an autumnal sunset; and the reader ventures here a surgical axiom, that whenever a patient is suffering from any grave abdominal disease characterized by these symptoms, *without* a previous peritonitis, which cannot be accurately interpreted, an early exploratory incision is demanded, for in just these cases before pressure necrosis and peritonitis have set in surgery is the most successful.

Intussusception constitutes, also, about one-third of all intestinal obstruction. Here age is the primal consideration, for nearly one-third of this class occurs before the completion of the first year, and the majority of these, again, occur under six months. In 80% blood or bloody mucus occurs; vomiting is never severe at first, nor does it occur so early as in other obstruction, because the bowel is not completely blocked. Seventy per cent. of these obstructions are ileocecal. The sausage-shaped tumor is felt in only about one-half of the cases. Tympanites not reliable. Pressure at first relieves, afterward aggravates, the pain. (The invagination may be present at the anus.)

"After a few hours in a child, or a longer period in the adult, pain ceases as suddenly as it commenced, and there is an interval little suggestive of the continuance of the pathological condition." The pain returns with renewed energy and at shorter intervals.

Given a child under one year, especially a boy, suddenly seized with acute periodic pain, passing little else but bloody mucus, the subject of tenesmus, suffering from shock, and an incision to the right of the right rectus muscle would not be bad surgery, for, while undoubtedly many cases of invagination occur in infancy which nature herself relieves, and include many of the more persistent forms of belly colic, yet less harm is done by interference than by delay. A noteworthy feature of this pain is that while the invagination is increasing the pain is acute, but when adhesive inflammation sets in and fixes the part, or gangrene occurs, the pain subsides or is absent. The ileocolic variety is the most painful. The amount of intestinal contents has nothing to do with the amount of pain. As the invagination advances, and especially as a definite tumor appears, the pain becomes more localized, generally in the ileocecal region, and is increased by pressure. Vomiting is a less conspicuous ally of pain than in other forms of obstruction, and generally gives relief, contrary to the fact in complete obstruction.

Volvulus constitutes only about one-fortieth of all obstructive cases, and is generally located at the sigmoid flexure, occurring more frequently in the male between forty and sixty years. Its onset is sudden, pain referred to the umbilicus not increased by pressure, but there is no form of obstruction in which pain on pressure is elicited so early. It soon locates itself. The abdomen is early and frightfully enlarged, mostly from dilatation of the sigmoid itself, which facts, occurring in a case of marked chronic constipation, are so prominent in contradistinction to obstruction due to bands and invagination as to make a suspicion of *volvulus* quite probable. Hemorrhagic infarction may give rise to these symptoms.

In abdominal pain produced by the very infrequent obstructions of gall stones, salol enteroliths and other foreign material, it may be said that the seat of the obstruction is either in the duodenum, jejunum, or more usually in the lower ileum, with a previous history of hepatic colic, or the swallowing of foreign bodies, as in the insane. Their presence and location is usually detected by the Röntgen rays.

Stricture obstruction pain differs from these preceding dolores in that it is extended over a long course of time, and becomes progressively worse, until the complete occlusion of the bowel causes the typical symptoms of peritonismus characteristic of all obstruction cases. The pain becoming colicky announces the beginning of the last chapter of the patient's life unless surgically treated. Non-cancerous stricture occurs about middle life, cancerous beyond. The clinical fact of note in reference to the pain is that it comes on regularly some three or four hours after food, in paroxysms which occur at intervals, and is the constant feature of the disease. These attacks appear monthly, later weekly, daily, and finally the pain becomes continuous.

Fecal accumulation may cause obstruction and sudden acute abdominal pain, referable to the umbilicus, with absolute constipation. Tympanites and tenesmus suggest a *volvulus*, but the presence of a rounded fecal

tumor, the history of the prolonged constipation, and the aggravation of symptoms by the taking of food, the capability of the mass to be changed and flattened by pressure and the occurrence of these phenomena in the female neurotic present a much less obscure lesion than in other obstruction cases.

Twisting abdominal tumors, a not very uncommon form of intestinal obstruction, can usually be correctly diagnosed by the history and other examination, and do not differ in their symptomatology from that of other sudden obstructions.

Peritonitis. — Abdominal emergencies characterized by inflammation have all one common and timely feature, that pain is increased by pressure. Just at this point in the case history, if not before, a final decision must be made for or against interference, for to ignore it is to court disaster, to heed it may result in the saving of another life. The pain is localized at first, but soon becomes diffused and constant; nothing else simulates it but the pain of an acute enteritis. At this stage all the classical symptoms are present, and intervention is generally too late; even at this point, however, with an abatement of symptoms and an arrest of the inflammatory extension, a successful laparotomy is frequently possible. Pain ceases in the final stage of poison intoxication, and all succor is hopeless.

Let us simplify the manifold causes of peritonitis, and say they are due to extravasations of some visceral contents and abscesses or the escape of germ life. Of these, appendicitis, salpingitis, cholecystitis, gastritis and intestinal ulcers are the more common lesions in the order named, while traumatic, pancreatic, renal, tumor and fat necrosis inflammation are the less frequent.

Appendicitis. — Although much good ink and the futile display of functioning gray cells have been wasted in voluminous writings on this little part of our anatomy, yet as it is a type of inflammation yielding to improvement in recent surgical treatment, the reader ventures a few suggestions and the repetition of some established facts. Because at times this inflammation has been mistaken for every other possible lesion in the abdomen, and even for pneumonia, it does not detract from the importance of its initial symptoms. The initial pain, rarely elsewhere than over the solar plexus, is sudden, colicky and severe, and simulates at this stage renal and hepatic colic, acute pancreatitis, perforations of the digestive tract, functional colic, the crises of locomotor ataxia, embolism of deep, mesenteric artery and acute obstructions. This pain, the most important of the cardinal symptoms, settles into the right iliac fossa within thirty-six hours, generally much sooner. It is due, in the first instance, to overstimulation of Auerbach's plexus, by retained mucus, an enterolith, or by the swelling and pressure of the inner tube by interstitial serum, causing appendicular peristalsis, and is reflected to the superior mesenteric plexus, thence to the abdominal brain, causing umbilical pain and nausea. A few hours later, by an increasing stimulus, vomiting ensues, and a transmission of nerve irritation to the spine reflects back the muscular message of the external oblique through the intercostals, and so rigidity of the abdominal wall becomes the second most trustworthy symptom of this disease.

If it be remembered that beside the smallness of Gerlach's valve, the male appendix lies more closely

in contact with the psoas muscles, while in the female it is more dependent, one finds an easily understood explanation why the traumatism in a young male of the psoas muscles is more frequently provocative of trouble than in the female, and why an appendix is so frequently found agglutinated to a tubo-ovarian exudate.

Pressure in the neighborhood of McBurney's point elicits pain rather early and is caused by the ensuing movement of inflamed peritoneal surfaces. In only about one-fifth of his cases does the reader find the initial pain of appendicitis so referred to the seat of the trouble. Some writers lay considerable stress on the location of pain under the sternum, as significant of cecum inflammation or so called catarrhal appendicitis, rather than an appendicitis proper, and hence regard it as a favorable omen. The pain reaches its intensity in from twelve to twenty-four hours, while the appendix is trying to extrude its contents. It soon becomes more general over the right abdomen, which is hard and tense. Constipation is hard to overcome, except by salines, and combined with vomiting is apt in the first hours to suggest obstruction. Germ life and blood count aid much in the interpretation of appendicitis pain and its progress. In general it may be said that the streptococcus causes greater release of animal force in the form of heat, while the colon bacillus tends to depress the temperature even to normal, but they overstimulate the sympathetic nerves until the heart cannot well relax before each contraction, and thus we get, instead of an increase of temperature, a small, rapid, feeble pulse. The streptococcus and the mixed infections cause more temperature; the colon bacillus, a smaller pulse and greater pain owing to its more destructive nature.

The spasm of the external oblique muscles, near their costal attachments, when the region of the appendix is tapped in the early hours of trouble, is an accompaniment of pain that is very valuable in the diagnosis of appendicitis, and the progress of the case. The tonic spasm of these muscles, while continuing to guard the contents within, soon becomes tired and exhausted, and their relaxation before the normal decline of the disease, while other symptoms are increasing, is a bad omen for the patient's strength. Pain is continuous throughout the disease, colicky and spasmodic at first, but localized afterward, until the general diffuse pain of a peritonitis ensues. So long as nature can keep the Cronje of the abdomen within its surrounding defences, the ileocecal region becomes a veritable river of Paardeberg, where final surrender and starvation are sure, and the pain of the bombardment remains localized; let the enemy escape through the lines, and the surrounding country becomes the seat of a destructive conflagration, in which friend and foe are exterminated. The pain is everywhere; destruction general.

The pain frequently radiates to the testes and bladder, and indicates an entanglement of the hypogastric plexus, exciting bladder symptoms, or radiates down the leg and back, denoting an appendix posteriorly and deeply seated and difficult of enucleation. The persistent pains after the convalescence from an appendicitis are due, according to Morris, to nerve filaments being caught into the scar tissue, undergoing chronic sclerosis, following a neuritis, and therefore inhibiting the peristaltic movements of the

colon, and predisposing to constipation, intestinal fermentation and dyspepsia.

The secondary pain of appendicitis is to be differentiated chiefly from acute obstructions, floating kidney, renal and hepatic colic, the pains of pelvic disease with shock, and from cholecystitis, where the gall bladder is extended low down, an ether examination being frequently demanded in the latter case. When hepatic colic is epigastric in location, it frequently radiates to the midscapular region or the shoulder. It is not generally so violent or sudden, but is aching and tearing; when the calculus has entered the duct, it is tearing and cutting; is seated in the hepatic area.

The entrance into the duct of an hepatic stone starts a rhythmical or periodic pain, which begins slowly but rises to a maximum. When appendicitis pain becomes secondary, and thereby in close relation to the hepatic area, it generally becomes constant. Before the duct or bladder has perforated, patients are better able to locate a gall-stone pain than most other acute abdominal pains. Jaundice when present is decisive.

The referred pains of a renal stone, the course of the pain along the ureters and the tenderness on deep pressure in the kidney region are usually quite sufficient for a diagnosis of renal trouble. The pain of appendicitis increases progressively; nephritic colic, coming on suddenly, very rapidly attains its height. Appendicular pain ceases gradually; nephritic, suddenly. Suppressed or bloody urine decides a doubtful case. Ralph says that "aneurism of the aorta or mesenteric artery causes pain similar in amount and location to renal pain."

Pelvic pain.—Most pelvic pains, being more definitely located and more amenable to examination, are of less interest to us at the present time than the foregoing. The sudden, acute abdominal pain, however, of a woman of child-bearing age, referable to the pelvis, means usually a ruptured tube filled with pus or an ectopic pregnancy, is of extreme importance and is the one lesion of the pelvis most apropos to our subject. The sudden, severe colicky pain in a woman of this age, suddenly ceasing, followed by shock, rapid pulse, low temperature, usually means hemorrhage or pus escaping into the abdominal cavity and demands immediate relief, with a few exceptions where shock is extreme, in which case, after the filling of the vessels with normal salt solution, a rise of temperature and a falling pulse indicate the propriety of interference.

The question of interference in all abdominal hemorrhages, whether pelvic, post-operative, traumatic, cystic, gastric or intestinal, depends upon the early recognition of such a catastrophe and the state of pulse and temperature, the pulse being the better guide. "The combination," says Richardson, "of a temperature that does not respond to stimulants and artificial heat, with a pulse that still rises, calls for intervention in strongest terms, for it means the patient is bleeding to death." Sudden pelvic pain, at any age, accompanied by grave general symptoms of pyrexia and septicemia and followed by a rather abrupt cessation of the pain, points to purulent peritonitis.

Perforative peritonitis with sepsis occurs so suddenly, is so rapidly fatal, barring the few cases where Nature has been successful in her walling-off process, that the attendant has little time to lose. The pain is severe and constant, no longer colicky, followed by

symptoms of severe shock, local pressure, tenderness and rigidity. When extravasation and hemorrhage occur, the pulse begins to rise and we have then imperative indications for interference; a few hours' delay tips the scales unfavorably.

The call for surgical consultation is imperative in all cases of gastric perforation, for operations to be successful must, according to Lund, be performed within twelve hours of the accident, 79% recovering of these early operative cases.

The general conditions, according to Warren, under which surgery may become necessary in gastric and duodenal ulcers are perforative hemorrhage, persistent spasm of the pylorus with pain and dilatation, and, finally, perigastritis with the formation of adhesions and abscesses, the cause of death in these cases being septic peritonitis, retrogastric and subphrenic abscess.

In all perforative cases where pain is continuous, or when it revives after a period of freedom from it, the call for aid must be heeded immediately, Nature showing that she cannot resist the invasion.

General abdominal distention and immobility are the two other most important allied signs calling for outside aid. If the general distention does not pass away after the use of rectal tube, turpentine enema, etc., by the second day, it indicates a progressive case and a surgical one. In perforative appendicitis general distention with pain and pressure tenderness, but without localized tumor, is a grave condition; if in such a case the temperature constantly rises, the prognosis becomes worse and death is imminent within four days, unless surgically treated. Leucocytosis, as you know, increases and is marked before the perforation of an appendix or ulcer, but afterward suddenly drops, and when general peritonitis supervenes, it may disappear entirely. Its presence serves to differentiate appendicitis from typhoid, aneurism, simple obstruction, floating kidney, uncomplicated renal or hepatic colic, functional colic, fecal accumulation and ataxia. A steadily increasing leucocytosis in appendicitis is always a bad sign though other signs improve.

Typhoid perforations.—As from 10% to 20% of typhoid fatalities are caused by perforation, the majority of them occurring in the region of the cecum, a recent list of 103 operative cases, including Dr. Keen's, is of some interest, showing that 21 were saved when done within twenty-four hours. Semm writes, relative to his experiences in the Santiago campaign, that a bullet may penetrate the abdominal cavity at or above the umbilicus without causing lesions which demand surgical attention, but that if it penetrates below the navel, one to fourteen perforations will occur. Did time allow it would be profitable to discuss Professor Manley's aphorism: "When in doubt don't operate." We would rather say, first consult, then if in doubt, the patient being in fairly good condition but with symptoms growing progressively worse, give him the benefit of the only plausible course and operate. Of these cases of perforation it may justly be stated that the experience of Professor Semm at Santiago, and of Sir Wm. MacCormac in South Africa, points to the advisability of non-interference in visceral wounds below the umbilicus made by the modern bullet, while in civic life the traumatic cases of abdominal blows and crushes offer a much less successful surgical field than the purely pathologic.

When the term peritonitis can be relegated to the same oblivion as has the term bedridden in connection with pelvic disease, then will the physicians of the twentieth century have as much cause for just pride as we of today in the triumph of Lister, Tait and others, but as the decreasing mortality of operative cases progresses, with the intelligence and promptness of the family physician, it behooves us to abolish the fictitious line between medicine and surgery, and learn whatever we can of the early signs of abdominal disease. The bulk of all successful practice depends upon an early and accurate diagnosis.

From what has been said, one general conclusion may be drawn, best stated in the language of Dr. Richardson: "Is it not a duty, therefore, for those of us who see many of these cases to demonstrate again and again, as far as human error and frailties will permit us, those signs by which possible impending disaster may be recognized, to emphasize on every occasion the one great cause of disaster in these formidable lesions—the unnecessary loss of time; and to shorten, as much as possible, the interval which must elapse between Nature's first call for help and the surgeon's response?"

Finally, it may be said that while many a life can be spared by timely care and the knowledge of the just value of painful symptoms, we must confess to the large mortality of all acute, painful abdominal diseases. Those of you who will this summer visit that historic old pile, Westminster Abbey, will be reminded of the very common fate of this class of cases by reading the epitaph, in the Poets' Corner, of William Shakespeare:

"The cloud-capped towers, the gorgeous palaces, the solemn temples, the great globe itself, yea, all which it inherits shall dissolve, and like the baseless fabric of a vision leave not a wreck behind."

Original Article.

THE PSYCHIC FACTOR IN DISEASE.¹

BY ROBERT W. GREENLEAF, M.D., BOSTON.

A STUDY of the cases occurring in one's private practice leads to the conclusion that many of them present aspects of a mentoneural relation worthy of consideration. This relation, for want of a better term, we may call the *psychic*. The term is somewhat objectionable because it is burdened with diverse popular meanings. I use it simply in a plain medical, and in no sense a mystical, meaning.

We probably all remember the stories our teachers of physiology told us of the pranks the nervous system plays; of how a wise man on being asked to tell which of a set of servants was guilty of theft arranged them in a row, placed some rice in the mouth of each and then on calling for the rice found that one returned it dry. This one, perturbed by his consciousness of guilt, had failed to secrete saliva. It would be well if we paid more heed to such teachings of physiology, but in the interest attaching to pathology and to our diagnoses with instruments of precision, these less conspicuous factors easily escape our attention. What I have to say may seem commonplace

¹ Read before the Clinical Section of the Suffolk District Medical Society, February 21, 1900.

and trite, but it appeared to me desirable to have a discussion on certain topics relating to the rôle the nervous system plays in such diseases as ordinarily fall to the care of the general practitioner rather than of the neurologist.

It is my purpose to cite briefly a few cases illustrative of certain propositions, and I invite your discussion to these propositions rather than to the cases. The propositions are as follows:

(1) That some cases of illness are simply neuroses without appreciable pathological lesions.

(2) That causes capable of producing such neuroses may act while disease is present and should be guarded against.

(3) Purely psychic causes, as shock, grief, and the like, may pave the way for, if not directly cause, profound pathological disturbance.

(4) Attention to the psychic is capable under some conditions of so turning the scale to health that it may arrest, even perhaps cure, otherwise fatal pathological conditions.

(5) Attention to the psychic should be considered a routine measure in the treatment of delirium from toxic causes, as alcohol, belladonna, ether, and the like.

(6) Attention to the psychic should also be considered a routine measure in the treatment and in the prevention of delirium in febrile states, as of typhoid.

(7) Nurses should be able to enter into psychic relations with their patients; otherwise the value of their services is much lessened and may be harmful.

Taking these propositions in order, the first is that certain cases of illness are simply neuroses without pathological lesions. Such perturbations of function as that illustrated by the rice story are of frequent occurrence. Bad news may inhibit digestion and the resulting morbid waste products may produce their systemic train of symptoms. Muscular fatigue may produce cramps, mental effort insomnia, etc., and on removal of the cause the nervous system will go on its usual way as if nothing had happened, or possibly the disturbance may have been so profound that a "habit neurosis" will have been established where a train of perverted nerve functions will be set up by other than the original exciting cause.

I have selected the cases to illustrate my first proposition because they represent disturbance from definite causes. The whole relation of cause, effect and simple treatment is a little clearer in these cases than in those representing other varieties of this group. The principle is practically alike for all.

CASE I. A girl, fifteen years of age, had been in pain for hours on account of severe cramps in her leg, causing it to be strongly flexed on the abdomen. The cramps were due to overfatigue in dancing during the preceding evening. Efforts for their relief had thus far been futile. Gentle massage, careful extension of the leg, distracting her attention and aiding her self-control, were the measures which relieved her. The whole procedure took about ten minutes. Normal nerve control was re-established and no recurrence took place.

CASE II. A nurse of about thirty years of age was much overworked and debilitated. She had been subject to minor cramps. On this occasion both arms and legs took part in the excessive cramping. The toe, calf and upper leg flexor muscles all suffered. The arms were even cramped across the chest. Psychic measures were not equal in my hands to restoring the equilibrium, and not till the patient was etherized could the cramps be controlled. Rest, tonics and change of scene restored her to

health. Nothing was heard of the cramps again after the attack referred to.

CASE III. A phantom tumor in a woman of about thirty-four years of age. It came on after a severe fall. A mass suggesting a flattened orange could be obscurely felt in the left side of the abdomen. The case had been sent to the hospital for operation, but it was finally decided not to operate, as the mass disappeared when the patient's attention was diverted.

CASE IV. A girl of eighteen years, in excellent health, but of a nervous, excitable temperament, was much frightened by the noise and flames from the blowing out of a fuse in an electric ear. She, with others, jumped from the car and fell or was pushed down. She was, however, able to get up and walk about. On reaching home she became hysterical and complained of pain in her left leg. In three days this became anesthetic and partially paralyzed. This condition lasted about two weeks with sufficient distinctness to confine her to bed; then, on being up and about, it gradually wore away. Dr. James J. Putnam, who saw the case in consultation, considered it hysterical hemianesthesia and pointed out its similarity to those cases of pseudoparalysis following injury that are bedridden for months, or until a suit is settled.

The second proposition is that causes capable of producing neuroses in health may also operate when disease is present. The points I wish to call attention to are that we should be especially on our guard against such causes, first, to recognize them as not necessarily factors in the disease pictures at hand, and, secondly, to ensure measures to prevent their occurrence. When one is weakened by illness discussion of a business question may induce a sleepless night (for which the discussion and not the illness of itself is responsible). The visit of an injudicious friend may cause emotionalism, irritability or other depressant factor, hence should be guarded against in the sick room. It is surprising how slight a cause may sometimes disturb a patient. A creaky rocking chair, a starched dress, a whispered conversation, are familiar illustrations.

I have twice seen a temperature of 106° come suddenly from purely psychic causes and depart as suddenly as it came after remaining but two or three hours. One of these cases of psychic temperature, if I may so call it, was in a lad convalescent from typhoid fever and the other was in an hysterical woman who had had pelvic peritonitis. I have no doubt that some cases of post-operative febricula are of psychic rather than of infective origin.

My next proposition is that purely nervous causes, as shock, grief, and the like, may pave the way for, if not directly cause, profound pathological disturbance. I have never happened to have attended a case where such results as the whitening of the hair or the loss of the mind has suddenly followed shock or grief. But Case V illustrates other phases of the same possibilities.

CASE V. A young woman, who had been under treatment for enlarged cervical glands for several years, gave birth to a fine child, which survived the dangers of a breach presentation, also of a summer diarrhea when two months old. Otherwise the child was perfectly well till the tenth month. Then it had what appeared to be a slight cold, from which it was recovering. At this time, the great-grandmother, who lived in the same house, sickened and died. Grief so affected the mother that her milk entirely upset the child. Nothing that I advised was of any avail. In one week more the little one also died. This second fatality completely prostrated the mother. She declined visibly day by day. She became despondent. Her sleep was much broken. Muscular pains in the feet were so troublesome that she could not walk. The cervical

glands began to grow rapidly and she developed a severe bronchial cough. Tubercular trouble was feared, but as the signs in the lungs were not localized and as the sputum was negative, I felt justified in giving the assurance that such was not the case and that she could get well. This strong assurance combined with removal to fresh scenes and the invaluable iodide of iron then began to result satisfactorily. She was soon able to walk. The cervical glands diminished to one-third their size and the cough practically ceased. She, at the present time, a year from her twofold grief, is in fairly good condition.

Passing now from a consideration of the general topic of the psychic as a causative factor of disease, I will next briefly summarize certain cases which illustrate its power from a therapeutic standpoint. Cases VI and VII illustrate this in relation to my fourth proposition, namely, that the psychic is capable under some conditions of so turning the scale to health that it may arrest, even in some cases cure, otherwise fatal pathological conditions.

CASE VI. A gentleman, sixty-four years of age, who had suffered for several years with rheumatism and chronic bronchitis, was seriously ill with interstitial nephritis, to which was superadded an acute parenchymatous process. He was emaciated, having lost by estimate about seventy pounds. Edema, ascites and jaundice were present. He had a marked cachexia, which with the examination of the blood suggested malignant disease. The opinion of the three physicians who saw him was that he was not likely to live more than three or four weeks. In this illness the patient was remarkably calm. Following a well-known precept never to permit the news of a fatal ending to come directly from the physician, indeed not to allow such a disquieting thought to be discussed with the patient at all, I refrained from telling him how ill he was. On the contrary I availed myself of the psychic by keeping up his courage as best I could. In addition, which of course was a most important factor, though I do not believe it would have sufficed alone, I gave him nothing but the simplest of diet and medicaments, chiefly malted and peptonized milk, with *fel bovis* as a laxative medicine. Much to my surprise the scale began to turn. The acute symptoms gradually disappeared and he practically recovered. In the two years since that attack he has regained some fifty pounds; is able to devote several hours daily to business and is hardly aware of the renal disturbance, which has subsided to a moderate amount of interstitial process.

CASE VII. A gentleman, age forty years, was ill with advanced pulmonary tuberculosis. One lung was everywhere invaded and had an extensive cavity in the upper third. The other lung was moderately affected. The patient's digestion was much disturbed. He was emaciated and had a daily hectic. This patient had been under the care of skilful physicians in his own town. He had consulted specialists in our city, but his condition had gone on from bad to worse. My relation to the case was a very limited one. It seems that shortly before I saw the patient the family had transferred their allegiance to a mental healer. Friends had then made such an outcry that the family were induced to have at least one more opinion from a Boston doctor. I happened to be the one asked to see him. I made a critical examination, and on stating that I knew of no measures of any avail towards prolonging his life beyond six months at the outside, the family concluded to reinstate the mental healer, who, if nothing else, had already given the sufferer a sense of calm he had been a stranger to for months. Much to my surprise the man lived a year. His wife told me that up to a few weeks before his death, when suddenly he became seriously ill as if with an acute attack of grippe, he had been doing very well, that his dyspeptic symptoms had entirely subsided, that for a while he had gained in weight, and that he had been outdoors for months. The point is that he lived twice as long as I expected he could and had been kept in a fairly comfortable condition most of the

time, the only therapeutic measure in his case being the psychic, which had favorably influenced his nutrition.

While it is only in a most general way that anything approaching definite rules can be formulated to govern cases like those thus far cited, and while details as to measures for the avoidance of fatigue, or, on the other hand, words of encouragement, must from the very nature of the case be largely questions of tact on the part of the physician and of the mental habit of the patient, in the next set of cases a more definite line of action may be formulated. The proposition is that attention to the psychic should be a matter of routine in toxic cases with delirium.

CASE VIII. A typical case of alcohol delirium in a young man is here represented. Among his delusions were those of water bugs in his coffee cup. His efforts to remove them were absolutely true to life. If left to himself he would have starved rather than have taken any food.

In such cases the psychic may be advantageously and definitely applied as I applied it in this case. One should fall in with such delusions. Instead of arguing that no bugs are present when the patient is perfectly sure his cup is teeming with them, help him empty them out, then give him a fresh cup of beef tea and get him to take even a sip while he has the assurance that his cup is bug free.

Authorities are agreed, I believe, that restraint in such cases is not as well as the calming control of a judicious nurse. Though this man was of a turbulent disposition and a boxer there was not the slightest difficulty in leading his delusions, so that he was kept quietly in bed. Then with the aid of sedatives and eliminants he passed safely through the attack. Without the psychic factor in his treatment there would have been much increased risk of physical harm to himself or others.

CASE IX. Here is represented a somewhat similar condition in belladonna poisoning. A young woman had taken five A. S. B. pills. Besides having the dry throat and dilated pupils, she was completely unbalanced. She had a busy delirium. Prancing horses were trying to catch her. Every noise as of a passing train would startle her into efforts to escape fresh terrors. There was constant risk of her being seriously harmed, as she was ready to dash through a window or anywhere. She mistook her physician for her mother and his efforts quieted her. Her mother, usually most welcome, was mistaken for an acquaintance for whom she had an aversion and the mother could not approach her without adding to her fright. In this case availing one's self of the psychic by maintaining a protective calm was an important factor in the treatment. Nerve sedatives, eliminants and systemic tonics were also important factors, but their action was certainly much aided by the psychic.

The same condition is also shown in the following case of salicylic acid poisoning, and emphasizes the importance of sympathetically falling in with the delusions incident to delirium as a means of controlling the victims of such delirium.

CASE X. A man, of about forty-five years of age, entered the Boston City Hospital, where I was house officer, with acute articular rheumatism. He was given the usual routine dose of salicylate of soda, which consisted of — if I recall correctly — five-grain hourly doses till the physiological effect was produced. I never felt satisfied that it was a case of pure salicylic poisoning or whether previous alcohol was not a factor. The point for this paper is with relation to the peculiar transitory delirium and its psychic as-

pects. About midnight I was hurriedly summoned to the ward (Ward T) and a most bizarre spectacle was presented, one not soon to be forgotten by those who witnessed it. The patient had been given permission to continue wearing his precious red flannels. These were in full evidence as he, in his delirium, undertook to escape his fancied foes. He imagined the woods (that is, the ward) were full of devils; the ward master was their chief. All the lights were on, and the patient, quite unmindful of his previously painful joints, was dodging about from bed to bed. The ward master, usually a most efficient nurse, was quite unable in this case to meet the psychic relation necessary for its successful treatment. Expressed in terms of electricity he exerted only negative or repellent attraction. Fortunately for the sake of the patient and the peace of the ward, I happened in this case to illustrate "positive affinity." The patient at once recognized me as his doctor and came to me for protection. I fell in with his delirium, told him I would take him to a place of safety (namely, his bed) and gave him a quieting dose of bromide of potassium and chloral. The psychic was of great importance in this case. It was very easy to exercise if one happened to be the right one for it. It was positively pathetic to see this strong man yielding in his delirium implicit obedience to my simplest command. He helped himself into a camisole as trustingly as a little child would get into a nightgown. Sleep soon came, and nothing further was heard of the delirium.

Ether delirium deserves a word of mention, not on account of the gravity of the condition, for it is neither severe nor prolonged, but every case of etherization has a period when attention to the psychic means the difference between struggles, unseemly speech, etc., and a calm, quiet, almost natural falling to sleep. This latter condition is readily obtained if the operator has the confidence of the patient at the outset and takes care to exert his own control when the patient is going through the stage of anesthesia of the inhibitory centres. This is the moment when trouble may be apprehended, and when it will surely come in injudicious hands.

The delirium of fevers bears a close resemblance to that of many drugs and it is natural to infer that such delirium is due to toxin poisoning. The presence of toxins, chemically much like certain of the alkaloids, also suggests this relation. Whatever the exact processes involved in the causation of such delirium, it is certain that it frequently accompanies high fever, and that among the best measures for its prevention and its mitigation are the psychic. The following cases will illustrate this proposition.

CASE XI. A young man, ill with typhoid, distinguished himself early in his stay at the City Hospital by jumping out of the window and dashing about the grounds. Fortunately he was not harmed by the experience. For safety he was placed in a guarded room. One evening when the lights were put out he became very much alarmed and aroused us all by his frightful screams. He did not know the other physicians and they simply intensified his fears. He recognized me and a word sufficed to give momentary quiet, which was continued by the help of bromide and chloral.

CASE XII. This case illustrates the possibility of preventing delirium of fevers by attention to the psychic. A young woman, ill with typhoid fever, started out as if she were to be extremely ill. The temperature reached 105° and she had a moderate delirium. She was very averse to going to a hospital, and on finding a suitable nurse she remained at home. This nurse was a treasure. She exerted a wonderfully soothing effect on the patient; delirium did not come again. To be sure, baths were used and these tended to avert the liability to delirium. But quite apart from this I am of the opinion that the calming, quiet atti-

tude of the nurse was of great value in the treatment of this case. Besides being free from delirium throughout the seven weeks of her illness, a pregnancy of three months went on satisfactorily and the woman has since been delivered of a fine healthy boy.

The cases thus far instanced also illustrate the next proposition, namely, that nurses should be able to enter into psychic relations with their patients; otherwise their influence is much lessened and may be positively harmful. Do we give this factor enough attention? Are our nurses sufficiently trained in it? No amount of training can qualify the unfit. But training can greatly improve the fit. I am continually hearing of nurses who delight in telling of their experiences in other cases; how this pneumonia died, or that typhoid had hemorrhages.

CASE XIII. One type of trained nurse is here illustrated, unfit though possessed of the best of training. The patient, a young lady of an especially refined and sensitive nature, was ill with empyema. Medicines were all given on time, the clothing was duly changed; in other words, the nurse was perfect in technique. But she offended the patient in numberless little ways. She was constantly chattering uninteresting stories. Her hands were not always clean when serving food, and though clothed in spotless white she would not think of any harm in coming into the room at the patient's meal time when her clothing was redolent with odors from adjoining rooms. The patient, rather than offend by word of hers, endured it for days and days. Her appetite suffered and her spirits fell, nobody could quite see why, but I believe it was largely because the nurse failed to enter into helpful psychical relations with the patient. Had this relation been well met at a time when good nutrition was in process of establishment the fatal result in this case might have been averted.

Why one person should repel and another attract is a problem. Explain it as we please the fact remains that such relations exist. Moreover, a person when in good condition or at a particular time may attract and at the next occasion exert just the reverse relation. As a rule, however, a nurse with the proper fitness for nursing should exercise this quality in most instances. When illness has overtaken her or she is too fatigued, the sick room is no place for her. A sick doctor is bad enough for the patient. However, he may be able to give a moment's trustworthy judgment under such conditions, or be endured by the patient for that brief length of time, but with a sick nurse the case is different. If one looks over his successes and failures, while we all gladly recognize our great indebtedness to the nurses who have helped us towards success, yet we can also probably point to some failures where the psychic was important and the nurse utterly failed to meet it. I make it a rule never to accept a sick nurse if I can help it, no matter how much I may otherwise value her and wish to see her employed. Moreover, I believe that where a nurse cannot get into an acceptable psychic relation with her patient so as to be able to soothe and make everything tend to health, that she is not the nurse for the place and should be exchanged.

It is a question whether the average graduate of a small hospital is likely to be better than the average from a large one. Few nurses can rise above the tendency to routinism engendered in the large hospital. So that even if they escape the bane of overwork it is difficult to have acquired all the little delicacies and refinements of nursing which add so much in private practice. Where large hospitals do not give abundant

opportunities for service as "specials," and where they do not take proper care of their nurses' health, I am sure their graduates cannot compare with those from the smaller hospitals.

Our attention to the importance of the psychic is forced upon us today from another quarter, namely, the comparative success of various kinds of pseudo-practitioners. I foresee one good result, if nothing else, from the present craze for Christian Science, mental healing, homeopathy, and the like. They emphasize the importance of the psychic. There are a sufficient number of persons in our midst today, once ill, now well, who owe their recovery to the psychic relation, however blindly exercised, of some pseudophysician. It is an encouraging sign of the times that we, as physicians, no longer cry out, "This fad is totally bad; have nothing to do with it." Instead, when occasion permits, we say, "Yes; this is a fad. It owes its existence to certain well-recognized medical principles, is capable of much good within certain limitation, but is also capable of much harm through ignorance of other laws."

It would be interesting in connection with the subject of this paper to discuss the relations of electricity and hypnotism to the psychic. These agents have already demonstrated their value in certain limited lines as therapeutic agents, but it seemed to me that such discussion would unduly prolong this paper. I therefore thought it better to confine my remarks simply to two main thoughts, namely, the psychic as a causative agent, and the psychic as a remedial measure.

Clinical Department.

A BRIEF REPORT OF A CASE OF CEREBRAL ABSCESS OF OTITIC ORIGIN; OPERATION; DEATH.¹

BY GEORGE L. RICHARDS, M.D., FALL RIVER, MASS.,

Otologist and Laryngologist to the Fall River and Emergency Hospitals; Fellow American Laryngological, Rhinological and Otological Society, etc.

M. D., male, twenty-eight years old, was admitted to St. Luke's Hospital, New Bedford, September 16, 1899, at 8.30 p. m., with a temperature of 100.4° and the following history: Two years ago had earache in the right ear followed by a discharge. Since that time has not been conscious of any trouble with the ear up to September 3d of this year, when he had his hair cut. This was followed by pain in the head, loss of appetite and general weakness. For the last ten days has suffered from severe pain in the right ear, and there has been a slight discharge from this ear; has not been able to work.

On examination a small perforation was found in the drum of the right ear, while the left was normal; watch tick not heard in right ear. The ear was poulticed and boric-acid solution applied in it.

On September 17th his temperature was 99.2° and pulse 88; he was perfectly rational and general condition seemed good. On September 18th, the day following, he was allowed to go home, his temperature being normal and pulse 76. This was at his own request. He was told to present himself at the office of

Dr. Whitney for examination of the ear. He did not go to the doctor's office or to his home, but was found late in the evening in a dazed condition in a swamp some distance from his home. During the night he became unconscious, and Dr. Whitney saw him at his home early the following morning, at which time he was semiconscious and partly paralyzed on the left side. He was taken back to the hospital in the ambulance, less than twenty-four hours after he had walked out.

I saw him at 2 p. m. of the same day by invitation of Dr. Whitney and of Dr. Hough, in whose service he was admitted, and we operated on him at once. At this time he was absolutely unconscious, and his pulse was 104 (I do not find any temperature record on the hospital chart until after the operation), the right pupil was much dilated, the left normal and the whole left side paralyzed, not responding to any stimulus. I made a probable diagnosis of cerebral abscess, advised operation and gave an unfavorable prognosis. It seemed better to give an anesthetic, and ether was used, though I afterwards wished that we had either used none at all or else had used chloroform. I first did the usual mastoid operation. A very hard mastoid was found with no pus in the cells; the lateral sinus was then uncovered and found to be all right; the attic wall was cut away and a little foul secretion and purulent debris found, which was thoroughly removed. Not having found sufficient to account for the patient's condition, I next removed with a small trephine a button of bone, making the cut one inch above and behind the bony auditory meatus. The dura was wounded slightly, but no bleeding followed. A probe was passed along the point of wounded dura and the underlying tissue lightly explored, when a foul smell of gas easily apprehended some feet away followed. The dura was then slit and a director pushed down into the soft, nowhere bleeding, brain substance. At the depth of a quarter of an inch, perhaps a little more, a large pus pocket was reached, and two ounces of as foul pus as I have ever smelt evacuated. The cavity was washed out with sterile water, drainage tubes inserted, and patient put in bed, and a decidedly unfavorable prognosis given. The temperature four hours after the operation was 105°, pulse 140, respirations 72.

Directly after the operation, that is, within a few hours, there appeared a severe bronchitis which Dr. Hough regarded as due to the ether, but which may perhaps with as much justice be ascribed to the exposure of the day before in the swamp. He was given strychnia and other heart tonics hypodermically, with alcoholics, and the wound was frequently washed out of the accumulated purulent secretion and debris. The day following the operation he was unconscious, with temperature of about 106°, a pulse of 150, and a respiration of 48. The temperature being so high, antipyrin was given, and under this the temperature was kept from 101° to 103°. On the second day the bronchitis became a bronchopneumonia, and oxygen, which had been administered from the start, was given more frequently, and the dressings were changed three or four times a day, the discharge continuing considerable in amount. He was by this time partially conscious, the inequality of the pupils less marked and the paralysis not absolute, and had it not been for the pneumonia it seemed as though there might have been a chance of recovery. As it

¹ Presented at the Annual Meeting of the American Laryngological, Rhinological and Otological Society at Philadelphia, May 31-June 2, 1900.

was the temperature went higher, he grew rapidly worse, and died on the third day following operation, with a temperature at the time of death of 107.8°. Every effort was made to obtain an autopsy, but permission was denied.

The special point of interest in connection with this case lies in the fact that a man with destruction of very nearly the whole of the middle lobe of his right brain was able to go out from a general hospital at his own request, and with the house officer thinking him in sufficiently good condition, within less than twenty-four hours of his being brought back to the same hospital unconscious and paralyzed and with two ounces of fetid pus in his brain. When it is recalled how the very slightest hemorrhage into the same area will produce symptoms as marked, it is remarkable that nature in this case bore so great destruction for so long a time before she showed any positive signs of its presence.

PURGATION WITH OPIUM.

BY J. W. WAINWRIGHT, M.D., NEW YORK.

A VERY interesting case of intestinal obstruction came under my observation some years since, which I have often thought to report because of the treatment adopted, and the satisfactory termination of an illness which promised to demand operative procedure as the only means of affording relief.

R. W., age five years, male, very active, nervous, well nourished and with good family history, was found to be suffering from obstruction, but without distress. Inquiry revealed the absence of bowel movement for forty-eight hours. Laxatives were administered, but after twelve hours and no results cathartics were given together with enema. These measures not bringing relief, intussusception was diagnosed. There was no fever, tenderness or nausea. Broths and milk, which had been allowed, were now forbidden, and the patient placed under chloroform anesthesia, an enema with a long flexible rectal tube given, together with massage over the abdomen. Still results were *nil*. There was no escape of gas, no vomiting, other than could be ascribed to chloroform, and still no pain, circumscribed or otherwise. The case by this time—as ninety-six hours as near as could be ascertained had elapsed since the last stool,—was thought to be serious, and consultation sought. Consultants were not agreed as to diagnosis or line of treatment. Another effort to relieve the little patient was to be made before resorting to abdominal section.

Just at this point the patient's father, himself a physician, upon questioning him, learned that he had eaten a handful of small squares of American cheese, about two ounces. The servant was questioned, and remembered that upon entering the dining room just before announcing dinner, she had caught the little fellow "hooking" some cheese from the table, and that upon being caught, he forced what he had in his hands into his mouth and left the dining room, and this episode was traced to the day previous to the discovery that his bowels were not acting.

It was now believed that the cheese had lodged at the ileocecal valve and was causing all the trouble. The patient was again anesthetized with chloroform,

held up by the feet, and as much of an enema administered as the bowels would retain. While being held head down, completely anesthetized, massage was again used over the valve, but without effecting dislodgment of the obstruction. At this time—five days after a movement of the bowels and after every effort had failed—an operation was thought imperative in order to save the patient, and his father was so informed. The father, however, declined to have an operation at that time, believing that even were the operators able to remove the obstruction, the patient would succumb to shock. All this time there had been no nausea or fever. The patient had not complained nor once cried. The manliness of the little fellow and his perfect willingness to submit to anything his father suggested appealed to all the consultants, six in number. At the request of the father of the patient, a surgeon residing in a distant part of the city was now brought into the case, who, after hearing the history, making an examination and listening to the father's reasons for objecting to an operation, suggested one more effort to dislodge the obstruction before operating. His instructions were carried out to the letter by the father, and were as follows: A quantity each of *tinctura opii deodorati* and *tinctura belladonnae* was procured and two drops of the *tinctura opii* given on the tongue with a medicine dropper every half hour. This was kept up until there was complete coma with stertorous breathing, and this condition maintained for two hours, during which there was contracted pupil, insensible conjunctiva, threatened paralysis of the muscles controlling the tongue, etc. At the expiration of the two hours the patient was allowed to recover from the effects of the drug, taking about four more hours, with the aid of small quantities of *tinctura belladonnae*, which had been held as an antidote to the effects of the opium if needed. His first words upon regaining consciousness were to ask for "his chair" (stool), when there was a free stool. Upon examining this, a knuckle-shaped mass was found which proved to be cheese. The patient made an uninterrupted recovery. The cathartic action of the opium was rather the complete muscular relaxation which chloroform had not succeeded in bringing about, extending to the muscular coat of the intestines, thus allowing the mass to pass through the ileocecal valve by gravitation.

A CASE OF VOLVULUS COMPLICATED BY PERITONITIS; OPERATION; RECOVERY.

BY W. P. GIDDINGS, M.D., GARDINER, MAINE.

THE case here reported I have thought of sufficient interest to merit attention of the profession.

S. P., of Richmond, Maine, age fifteen, on Monday, February 2, 1899, at 4 P. M., was playing "snap the whip" in company with a number of his schoolmates. He being at the end of the line lost his hold on the hand of the next boy and was thrown some distance, but did not then realize he had received any injury. About five o'clock on his way home he began to have some pain in his abdomen, which was described as more diffused than localized. During the night his suffering so increased that early on Tuesday morning the family physician was called in. The doctor immedi-

ately recognized the case as one of intestinal obstruction and made search at the usual sites for hernia; but finding none was inclined to view the condition as due to impaction. Through the day attempts were made to induce an action of the bowels by saline cathartics and high enemata without other results than rejection of the remedies by the stomach and expulsion of enemata minus feces. Efforts were continued at intervals up to Wednesday night to get a movement of the bowels, when marked peritonitis supervened and the vomiting, which had occurred only occasionally, became almost constant and the pain greatly increased.

On Thursday morning, the case having become extremely grave, I was sent for by Dr. C. W. Price, the attendant, to do laparotomy. At 11 A. M., when I arrived, I found the patient's condition as follows: Countenance pinched, pale and anxious; pulse 108, rather thready; arrhythmic; temperature $97\frac{1}{2}^{\circ}$ F.; abdomen quite fully distended, tender and tympanitic with capillary stasis; vomiting occurring every few minutes, mostly bile and mucus; pain constant, with paroxysms centring around umbilicus. It being an emergency case aseptic precautions were made as thorough as circumstances permitted, the only delay being a wait for boiled water. Fortunately sanitary conditions were excellent. The whole abdomen was scrubbed with hydronaphtol soapsuds; shaved and rinsed off with boiled water and finished with an ether bath. The field of operation was surrounded with clean — not sterilized — towels. On opening the abdomen a bloody fluid poured out freely; estimated a quart. The whole peritoneal investment of intestines and parietes was deeply injected and lymph deposits scattered over surface; no agglutinations. It was found necessary to remove fully one-half of the small intestine upon towels hastily wrung out of boiled water before the twist was found, which was finally located a little below and to the left of the navel. There was no apparent redundancy of mesentery so common in cases of volvulus. The twist was easily corrected and intestines returned. The toilet was first made by washing out the cavity with a normal salt solution and fully a pint of it left inside. The abdominal incision was closed by three tiers of stitches and usual dressing applied.

Report made to me the following day: "Patient rallied rapidly from the operation; passed a comfortable night; no nausea or vomiting. Pulse 84, temperature 99.5° . Bowels moved naturally and he had a desire for food."

From this on recovery was rapid and uneventful. The interest in this case consists in the rapid subsidence of the peritoneal inflammation and establishment of convalescence. Query: What part, if any, was played in resolution by the salt solution left in the abdomen? Was the inflammation influenced by and absorption of its products promoted, or was the natural shock lessened in any degree and better circulation stimulated by its resorption? These are questions I am unable to answer satisfactorily to myself, but having pursued the same course in quite a number of serious abdominal operations from which the patients made unusually quick rallies, followed by rapid recoveries, I am persuaded that the normal salt solution does have decidedly stimulating qualities when so used, and that the favorable symptoms so soon manifest are something more than a mere coincidence.

Medical Progress.

REPORT ON PROGRESS IN SURGERY.

BY H. L. BURBELL, M.D., AND H. W. CRUSH, M.D., BOSTON.

(Continued from No. 6, p. 141.)

HERNIOTOMY UNDER LOCAL ANESTHESIA.

H. CRUSH¹¹ presents interesting data on herniotomy under local anesthesia. General anesthesia is still preferred, but there are certain cases in which it would be a source of danger, as in advanced age, chronic bronchitis and emphysema, pulmonary or laryngeal tuberculosis, marked cardiovascular changes, chronic nephritis, and, above all, shock and vomiting in strangulated hernia. Previous to the use of local anesthesia many patients with hernia were discouraged from seeking operative interference because of the immediate danger of the anesthetic. Bull and Coley¹² regard sixty years of age as, in general, a contraindication to operation. During the past few months at Johns Hopkins Hospital there have been 14 cases of herniotomy done under local anesthesia on patients ranging from sixty to eighty-four years of age. For strangulated hernia local anesthesia is specially adapted, for, by avoiding the dangers of the general anesthetic, both primary and secondary, one may keep the balance in favor of an organism almost overcome by shock, by toxins from the bowel, by depletion from repeated vomiting and lack of nourishment. Under a local anesthetic, with danger to the patient, the sac may be exposed, the constriction relieved, and the gut treated according to its condition. If it is viable and the patient's general condition warrants it, a radical cure may be done; otherwise the radical cure may be left until a later day. If the gut is not viable the establishment of an intestinal fistula is the safest procedure. This is readily done under the local anesthetic, and intestinal suture is done later, with far less risk. To succeed in major operations with local anesthesia, an accurate knowledge of the course and situation of the nerves to be encountered is essential, since accidental division of an unexpected sensory trunk often overcomes the inhibition to pain and renders complete narcosis necessary. The hernia skin incision divides filaments of the twelfth dorsal and first lumbar nerves above and of the iliohypogastric nerve below. Of the deeper nerves, the ilio-inguinal and genital branch of the genito-crural nerves are usually found as one trunk in the deeper part of the canal, and the early cocainization of this after splitting the aponeurosis is perhaps the most important step of the operation. The usual anesthetic result is a complete loss of sensation of the entire scrotal contents, cord, sac and testicle, and the inner side of Scarpa's triangle. There is no surface anesthesia of the scrotum itself. Sometimes there is sensation left in the lower attachments of the testicle, supplied by the superficial perineal nerve. If the lower border of the internal oblique muscle is to be cut it must first be injected to anesthetize the trunk of the iliohypogastric nerve which is found there. Schleich's solution No. 2 (cocaine mur., .10; morph. mur., .02; sodii chlor., .20; aq. dest., ad 100) was used. It is practically non-toxic and may be sterilized

¹¹ *Annals of Surgery*, January, 1900; *Medical News*, February 3, 1900, p. 181.

¹² *Annals of Surgery*, 1898.

without dissolution. For the undivided nerve trunks one-half to 1 per cent. cocaine was used. Preparatory to operation, patients of advanced age are kept in bed several days to see if they can endure recumbency, and to train them to void urine in bed. Three-quarters of an hour before operation one-tenth to one-eighth of a grain of morphine is given hypodermically and repeated shortly before going to the table. The patient is cleansed, the line of incision infiltrated with the cocaine solution and the incision immediately made through the linear wheel, the bleeding points clamped and the field kept dry. Only the upper end of the incision is carried down to the aponeurosis, which is opened, and the ileohypogastric and inguinal nerves cocaineized with 1-per-cent. solution. The lower end of the incision may then be painlessly completed. No further use of the anesthetic is needed. The ilio-inguinal and genital nerves should not be damaged because of resulting cremasteric and scrotal paralysis. The remainder of the operation may be completed according to the preference of the operating surgeon.

When, in large hernia, the two rings have become concentric and the conjoined tendon therefore absent, Bloodgood (Johns Hopkins Hospital) opens the rectus sheath and transplants the muscle to form a posterior wall to the inguinal canal. No additional cocaine is needed. If, as occasionally happens, the patient begins to feel pain and loses self-control, a few whiffs of chloroform relieve the pain without the loss of consciousness. There have been no "after pains," and healing has been absolutely unaffacted. The advantages of the method are: (1) No post-anesthetic sequelae; (2) urinary disturbances are less frequent; (3) diet is unchanged; (4) dressings may be applied originally to suit the comfort of the patient; and (5) above all, the dangers of general anesthesia are avoided. Disadvantages: (1) The operation is a little more prolonged and difficult; (2) some pain is inflicted, but this does not compare with the discomforts of recovery from ether anesthesia.

OPERATION FOR GASTROPTOSIS.

Several operations have been proposed for the treatment of gastroptosis. Gastro-enterostomy and various means of infolding the anterior wall of the stomach by a single row or many rows of sutures have been advocated. Rosving¹³ has hit upon a method of suturing the stomach to the anterior wall of the abdomen at the same time that he puckers it upon itself. He does this by making a median incision, stretching the lips of the wound apart and passing the needle first through one side of the wound, then with it catching up several points of the anterior wall of the stomach, and finally bringing it out through the other side of the abdominal wound. Several sutures passed in this manner will not only shirr up the anterior wall of the stomach, but will hold the whole organ firmly up in its place and so help it to empty itself. Two of 3 patients operated upon in this manner recovered their normal weight promptly. The third, whose symptoms had lasted for four years and who had wasted from 140 pounds to less than 60 pounds in weight, improved for a few days after the operation, and then died without reaction seven weeks later, an illustration of the serious character of gastroptosis if

allowed to go too long, for no other pathological lesion could be found to account for the death of this patient.

SURGICAL TREATMENT OF HEMORRHAGE FROM GASTRIC ULCERS.

Andrews and Eisendrath¹⁴ discuss this subject from its historical and clinical aspects and report two successful clinical interventions in addition to experimental work, which lead them to the following conclusions:

(1) The result of the practice of the best modern surgeons warrants the statements, previously made on theoretical grounds, that only operative interference can save the lives of a part of the patients affected with bleeding ulcers of the stomach, namely, those not improved by internal medicine.

(2) Surgical intervention is to be recommended, (a) in small, repeated hemorrhages; (b) in severe ones occurring more than once, especially if more than 500 centimetres are lost at each hemostasis.

(3) A single copious hemorrhage is not necessarily an indication for operation.

(4) In ulcers at or near the pylorus pyloroplasty (Heineke-Mikulicz) is ideal. It makes local treatment possible and gives all of the benefits of gastro-enterostomy and is safer.

(5) Canterization and curetting of the ulcer should give place to resection whenever the stomach wall can be reached from without.

(6) If adherent posteriorly and at the end of the stomach, canterization, curettement and ligature *en masse* are the best substitutes for excision.

(7) Ligature *en masse* is shown by their experiments to endanger perforation except when supported by external sutures.

THE WISDOM OF SURGICAL INTERFERENCE IN HEMATEMESIS AND MELENA FROM GASTRIC AND DUODENAL ULCER.

Armstrong¹⁵ reports 2 cases, 1 successful, 1 in which he operated and 1 in which he assisted in the consultation, but in which he believed the patient was left too long before the operation was undertaken. This latter case leads him to the conclusion that operative interference is often too long delayed. He makes the following clinical division: those in which occur frequently repeated small hemorrhages, and those in which the loss of blood is in large quantities; and it would seem that each class has a distinct pathological lesion, and this should be borne in mind in the consideration of the treatment of hematemesis, medically or surgically.

If we can exclude aneurism, which should generally be possible, and leukemia or cirrhosis or other cause of portal obstruction, he holds that the surgeon should interfere in these cases (1) of frequently repeated small hemorrhages which persist in spite of medical and dietetic treatment, and which threaten to destroy the life of the patient, and (2) in all cases of hemorrhage which, in spite of medical and dietetic treatment, recur. In these cases he advocates operation after the second hemorrhage. For hemorrhage occurring in cirrhosis and portal obstruction he does not think that the surgeon can accomplish any good. In

¹⁴ *Annals of Surgery*, October, 1899; *American Journal of the Medical Sciences*, January, 1900, p. 95.

¹³ *Arch. f. klin. Chir.*, Bd. ix, S. 812; *Medical News*, February 3, 1900, p. 176.

these cases the hemorrhage is generally from a varicose esophageal vein, a part difficult of access and secondary to a pathological lesion, but little amenable to any form of treatment.

In cases of gastric and duodenal ulcer, however, the conditions are totally different. The lesion is primary and local, and in addition to securing the bleeding point a more smooth and rapid convalescence is secured, the likelihood of perforation removed, and if found advisable the performance of a gastro-enterostomy or pyloroplasty secures to the stomach the rest which favors the healing of the ulcer and insures against subsequent occurrence of narrowing and obstruction at the pylorus.

APPENDICITIS.

Richardson,¹⁶ in an article on this subject, gives the following summary:

I. Should every case be operated upon as soon as the diagnosis of appendicitis is made? As a rule, the appendix should be removed if the diagnosis is made in the first hours of the attack.

After the early hours operation is advisable: (1) If the symptoms are severe, and especially if they are increasing in severity; (2) if the symptoms, after a marked improvement, recur; (3) if the symptoms, though moderate, do not improve.

The wisdom of the operation is questionable: (1) In severe cases in which an extensive peritonitis is successfully localized and the patient is improving; (2) in cases which are at a critical stage, and which cannot successfully undergo the slightest shock.

II. Should the appendix be removed in every case? It should not be removed: (1) In localized abscesses with firm walls; (2) when the patient's strength does not permit prolonged search. It should be removed whenever the peritoneal cavity is opened, unless the patient's condition forbids. The appendix should be removed in all cases as soon as the inflammatory process has had time completely to subside — in from two to three months after the attack. In cases simply drained the scar tissue should be excised, the appendix removed, and the wound securely sutured.

ACUTE PERITONEAL EFFUSION AS A SYMPTOM OF INTESTINAL STRANGULATION.

Bayer (Prague) in 1898 called attention to this fact, which has also been noted by Braum,¹⁷ who claimed that the effusion present in cases of internal strangulation was analogous to that which occurs in a hernial sac. Bayer¹⁸ has again called attention to the clinical significance of this condition and now emphasizes two points.

(1) That the effusion is a valuable aid in the diagnosis of strangulation and peritonitis and is direct proof of strangulation. Peritonitis may be present and increasing, and the initial dulness may be concealed by the increasing distention of the well-known paralytic character. If, however, a rapid increase in the area of dulness should be noted, becoming more marked hour by hour, and clearly shown by percussion, the presence of internal strangulation is demonstrated. If the case is a recent one this rapid increase of the effusion indicates strangulation.

(2) The importance of the acute nature of the

effusion as indicating strangulation. The writer publishes a case illustrating the correctness of his views on the diagnostic value of this symptom.

TREATMENT IN PERFORATION OF THE BOWEL IN TYPHOID FEVER.

Keen, in a paper on this subject read before the New York State Medical Association,¹⁹ states that since Mikulicz in 1884 performed the first operation for perforation of the intestines from typhoid ulcer, up to the end of 1898, 83 cases were operated on, and 19% of them were saved. During this last nine months 67 additional cases have been operated on, and 26% of them have been saved. The author states that if doctors would but remember that the healing process during typhoid fever is quite as good as in health, surgeons would get more chance to operate, be called sooner to the cases, and very soon the statistics would show at least 1 in 3 saved.

He states that the surgeon should operate in practically every case. The better the general condition the better the chance. One case was operated on three times and survived. Two cases have been operated on twice. One case was operated on successfully for post-operative obstruction. In cases under fifteen years of age, where operation has been done, 50% have recovered. From fifteen to twenty-five years of age is the most unfavorable period. Women have perforations less than half as often as men, and recover twice as often from operation, according to the statistics. The later in the disease that perforation occurs the better is the prognosis.

The surgeon should not operate during the primary shock. This means usually not during the first twelve hours. The author states that he has seen fit to correct this original expression of opinion, and to say not during the first eight hours. There would seem to be two rules: (1) Operate as soon as possible; but (2) do not operate during profound shock. The improvement of the statistics in the future will depend not so much on any perfection of the technique, but on advance in diagnosis. If the perforative stage can be recognized with any assurance, then perhaps it will be possible to prevent perforation entirely. In any case a surgeon should be called in consultation as soon as any abdominal symptoms appear that point even to impending perforation. An exploratory incision may be made under cocaine anesthesia with very little inconvenience to the patient. After this exploratory incision, bacteriologic specimens may be taken and examined to see if there is any peritonitis.

The Halsted mattress suture should be used rather than continuous suture. If the perforation is very extensive, a resection of the intestine may be done. Two recoveries have been reported after such an operation. If at any point there seems to be impending perforation the spot should be sutured. Such points should be looked for carefully, as a number of cases have terminated fatally after operation, owing to the occurrence of a second perforation. The abdomen should be closed without drainage. Speed is an important factor in the success of the operation. There are cases in the literature of the subject now which show that the surgeon need never despair of any case, no matter how low the patient may seem in vitality, and no matter how many other complications have

¹⁶ American Journal of the Medical Sciences, December, 1899, p. 629.

occurred before. Most unpromising cases have ended in recovery.

A NEW METHOD OF TREATING GENERAL PERITONITIS WITH DRAINAGE IN CASES OF DIFFUSE PERITONITIS.

Bode²⁰ reports a new and thorough method of treating cases of diffuse peritonitis. He employs large quantities of normal sterile salt solution. The intestines are delivered *en masse*, and while they are covered with sterile towels soaked in hot sterile salt solution, the abdominal cavity is thoroughly scrubbed and flushed. The intestines are then all carefully washed and any wounds sutured. When they are replaced, a drainage tube having perforations in the middle is introduced, and the ends carried over the colon on either side and out through openings in both lumbar regions. Through these openings drainage tubes are carried into the pelvis or any other portion of the abdomen that has been the seat of a focus of suppuration. Drainage is also inserted through the laparotomy wound as in ordinary methods. A peculiarity of the after treatment is that the cavity is flushed out through these drainage tubes in the daily dressings by means of large amounts of normal salt solution. When the symptoms of peritonitis subside, usually after three or four days, the tubes are withdrawn gradually and the wounds allowed to heal. The success of the treatment has been very marked, patients with very grave symptoms having recovered rapidly.

COLOSTOMY, WITH THE FORMATION OF A SPHINCTER FROM THE LEFT RECTUS MUSCLE.

Von Haecker²¹ (Innsbrück), has attempted to improve the Witzel method in the following manner. The preliminary steps of the operation are the usual ones, the inner angle of incision exposing the outer border of the left rectus muscle. The loop of intestine is stitched to the parietal peritoneum and fascia to close off the peritoneum. The rectus muscle is now split from left to right, into an anterior and posterior portion to such an extent that the loop of intestine can be passed through the opening thus formed, after being slightly twisted. The skin is incised over the point where the loop emerges at the median border of the rectus and the latter is then brought out through the cut and supported in place by the rod. The main incision wound is then sutured in layers. Continence equal to a normal sphincter has never been obtained by any method, and perhaps would cause discomfort, since it could not be voluntarily relaxed. Von Haecker's method from the results reported as observed in 3 cases is such as might justify a trial of it. It requires that the mesentery shall be of sufficient length, hence it is not adapted to all cases. In 1 case where it was too short the loop was passed through the rectus anteroposteriorly instead of laterally.

FECAL IMPACTION AND ATROPIA.

Batsch²² has called attention to the very satisfactory result obtained in intestinal obstruction from impacted feces from the action of atropia. He injects the drug subcutaneously. In 2 cases the result was quite striking. His explanation of the action of the

atropia is that it overcomes the spastic-like contraction of the muscular fibres caused by the inhibitory action of some of the fibres of the splenic nerve and at the same time stimulates the motor fibres of the paralyzed intestinal muscle.

EFFECT OF IMPLANTATION OF THE URETER INTO THE INTESTINE ON THE INTESTINE AND KIDNEY.

J. Kalabin, Moscow, has studied the results of the above procedure by experimenting on dogs. The details have been reported.²³ He operated on 4 dogs in the spring of 1898. Through an abdominal incision he implanted the ureter into the intestine. Three dogs died, 2 from peritonitis, 1 from uremia. The fourth lived one year and was apparently well and in a normal condition. He was killed and examined in May, 1899. The results of this examination have been recently published.²⁴ Macroscopically nothing abnormal was noted in the kidney, ureter or intestine. The ureter had remained fixed in its new position and its implanted end was patent. The mucous membrane of the intestine was normal. The microscopic examination showed also that the ureter and intestine were apparently unchanged, but that marked changes in the kidney had taken place, the details of which (appearances suggesting cirrhosis, cellular infiltration, degeneration, etc.) are specified in the writer's report. If the above results are corroborated by other investigators, the facts so obtained will have an important influence on this operation, which of late years has attracted considerable attention.

ON THE PROPER WIRE FOR INTRODUCTION INTO AN ANEURISMAL SAC.

Reeves, Jr.,²⁵ in an article on this subject, gives a series of experiments which he made with various kinds of wire to ascertain which would be the most suitable wire for introduction into an aneurismal sac, and he concludes that a silver or gold wire, about .0085 inch in diameter and of sufficient temper to retain its coil, would seem to be all that is required to fill, when carrying the positive galvanic current, an aneurism with clots, and is not so thin as to be in danger of breaking. He suggests that the easily obtained music wire — a fine-tempered steel wire made for musical instruments and called Hartmann's combination spool, No. 00 — be taken as a sample.

AN EXPERIMENTAL INVESTIGATION OF THE TREATMENT OF WOUNDS OF THE HEART BY MEANS OF SUTURE OF THE HEART MUSCLE.

Charles A. Elsberg,²⁶ has contributed a most interesting paper on this subject. It is divided into three parts: I. Introductory, consisting of the history and literature of the subject; II. Experimental Investigations; III. Historical Changes that Occur in the Process of Healing of the Cardiac Wounds. He draws the following conclusions, which are summarized as follows:

(1) Suture of a wound of the heart as a final resort is an operation worthy of consideration in some cases and often justifiable.

(2) Suture of wounds of the heart in animals and

²⁰ Centrbl. f. Gynäk., September, 1899.

also in man is devoid of the danger of sudden arrest of the heart, due to the manipulation of the heart incident to the procedure, unless Kronecker's co-ordination centre be injured.

(3) The suture should be an interrupted one of silk, applied in most cases so that the epicardium and superficial layers of the myocardium should be the only ones penetrated, and tied, when possible, during diastole.

(4) No stated indications can be given as to the cases that are operable or the time when the operation should be done. Each case must be considered by itself for symptoms which would justify operative interference.

CERVICAL SYMPATHECTOMY IN THE TREATMENT OF EPILEPSY, GRAVES'S DISEASE AND GLAUCOMA.

Jonnesco (Bucharest) has been investigating the effects of this operation on the above enumerated conditions, to which he first called attention in 1897. Since August, 1896, he has operated on 63 patients: Epilepsy, 43; epilepsy and chorea, 1; epilepsy and Graves's disease, 1; Graves's disease, 8; Graves's disease and glaucoma, 1; glaucoma, 1. There was no mortality from these operations. The transitory symptoms which followed the operation were congestion and increased surface temperature on the side from which the sympathetic was removed, increased lachrymation, increase of nasal mucus, sweat, saliva, slight conjunctival congestion. The permanent effects were stenosis and paralysis of the pupil, ptosis of the upper lid and retraction of the eyeball. No remote evil effects or trophic disturbances were recorded. The writer's report of his work²⁷ describes the character and extent of the operations performed, the rationale of the procedure, the physiological and pathological reasons for its results, and finally the permanent effects of his operations. The technique of the operation is simple and is as follows: The operator should incise the free anterior border of the sternomastoid, draw it aside, cut through its deep fascia so as to expose the carotid sheath, open the latter and separate the jugular vein from the carotid and vagus. The ganglion will be found in the space between; it should be excised above and below and detached. The operation is practically bloodless, and can be finished in about fifteen minutes. For full details the reader is referred to the original article or an excellent review by Dr. R. S. Fowler.²⁸ In general the results have been favorable enough to attract careful attention to the operation and its effects.

THE REMOVAL OF THE LYMPHATIC GLANDS IN THE INGUINAL REGION AND THE ILIAC AND OBTURATOR VESSELS IN ONE OPERATION.

Lennander²⁹ has described an operation which he believes is essential to any radical intervention in cases of malignant disease which tends to involve these lymphatic regions. He believes it to be indicated in case of carcinoma or sarcoma of the lymphatics in the inguinal region on the condition that the primary tumor can be readily dealt with and where no other inoperable lymphatic involvement is present. In the second place, it is valuable in cases

of severe tubercular lymphadenitis in this region and the iliac fossa, where there is no contraindication to a severe operation. In the latter instance the extent of the operation differs in that only diseased lymph glands and surrounding tissue are removed. Sound tissues and fat are allowed to remain, in order that later, by the development of the lower lymphatics, a collateral lymph circulation can be established. The same is true in cases of operation for suppurative lymphadenitis.

The operation which the author has developed and employed commences with an incision from the symphysis pubis along Poupart's ligament to the anterior superior iliac spine and then along the crest of the ilium for one-third or one-half its length. An incision from this over the femoral vessels gives access to the lymphatics of that region. This incision is carried through the muscles and fascia, and by retroperitoneal dissection gives access to the glands in the iliac fossa along the iliac arteries and into the true pelvis. Poupart's ligament is severed from its attachment to the pubic bone. Drainage is provided from the iliac vessels through the posterior portion of the wound. Poupart's ligament is carefully sutured in its original position and the muscles and fascia united except where left open for drainage. This operation does not in the least endanger the integrity of the abdominal wall, as it is entirely freed, and its bony and fascial attachments are afterward reconstructed. No motor nerves are in any way injured.

The author has employed the operation successfully in 2 cases. In cases of suppurative adenitis this incision cannot be carried to its full extent, since primary union of the attachment of Poupart's ligament cannot be depended on.

THE OPERATIVE TREATMENT OF EPILEPSY.

Schar³⁰ comes to the following conclusions as to the result of his study of the literature of this subject, and his observation of the cases occurring in Koch's clinic:

Operation is to be undertaken in cases of epilepsy whenever internal dietetic treatment has failed to produce results in a short time. The slight mortality from such operations makes the danger inconsiderable. It is better to operate too often than too seldom. The surgeon who treats a case of traumatic epilepsy by internal medication for a long period, and only resorts to operation when he finds he cannot produce a cure by other means, does not do the best for the patient. Epileptic patients should be examined by the surgeon as well as the physician at an early period. It is best for them to make the examination together. In asylums the surgeon should from time to time examine the cases and determine which require immediate treatment.

The surgeon should not forget, however, that internal medication and dietetic treatment are of great value, and that without them, even after operation, the patient could not recover. Alcohol must be avoided, and special care given to the diet of children who have suffered from traumatism. Epilepsy due to traumatism can be greatly benefited by operation at the site of the trauma.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

J. BERGEN OGDEN, M.D., SECRETARY.

REGULAR meeting, Wednesday, February 21, 1900, DR. H. F. VICKERY in the chair.

DR. ROBERT W. GREENLEAF read a paper entitled

THE PSYCHIC FACTOR IN DISEASE.¹

DR. E. W. TAYLOR: We are certainly very much indebted to Dr. Greenleaf for bringing forward in this tangible fashion this really important subject. So far as I am aware a paper of this exact description has not been presented at the medical societies of Boston before, a paper which takes up the matter candidly and discusses it from various points of view. I think all of us would be in practical agreement as to the general propositions Dr. Greenleaf advances regarding the possible effect of the mental element in the production of disease, and, in the second place, in the efficiency of the mental element, properly applied, to alleviate various symptoms of disease. What Dr. Greenleaf said in regard to the treatment of delirium struck me as of particular interest. What we certainly need in this whole question of so-called mental therapeutics is system. The matter has been brought to the attention of the medical community in Boston through various papers of late, through Dr. Putnam's oration at the Massachusetts Medical Society, through the numerous writings of Dr. Prince and through the admirable work of the late lamented Dr. Russell Sturgis. All these men have attempted to outline in more or less definite form the effect of the mind upon the body in its practical aspects and the possibility of treatment of the body through the mind. We need more than the mere recognition of the fact of the possible relationship of these two forces. It is not enough to say the mental factor is an important factor and must be used in all cases. What we must recognize, and what is an exceedingly difficult matter to recognize, is how we are going to use this particular agent in individual instances. It is a great mistake to think it is a simple thing to do. Dr. Sturgis had an idea which appealed to me very much, and which I think in certain cases in my experience has acted well. He felt it was always necessary to get at the cause and the associated conditions, and that if this was impossible his treatment was often unavailing. In a number of cases I have found by careful questioning that one could find a certain cause so far back in the life of the individual that it has practically become subconscious. When found it is often possible to trace from that original cause a long series of circumstances which through association have built up a definite neurosis. I remember a young woman who for years had not slept on her side. This was a comparatively simple matter in itself, but the consequence of it was unfortunate, namely, that she had gradually developed a condition of insomnia with all its accompanying nervous disturbances. On careful questioning it transpired that a physician on one occasion had said that a certain pain in her side which

she complained of was induced by the stretching of a nerve. That statement had sunk deep into the patient's mind, with the result that she was always conscious of the stretching of that nerve whenever she attempted to lie on the side. The inability to sleep on the side was easy to remove when she was assured that it was an anatomical impossibility to stretch a nerve in that fashion.

Another point is our lack of courage in these cases. We frequently hear physicians say they must give this or that patient something if only as a placebo. It is a mere tradition of medicine that it is necessary to give some tangible drug in order to relieve the condition. If we had more of the courage of our convictions we should frequently feel justified in declining absolutely to give any drugs, confining ourselves solely to the mental treatment of the case, with unquestioned benefit to the patient.

In regard to what Dr. Greenleaf said of nurses I should entirely agree. The success of the nurse depends largely upon the element of personality, as the success of the physician depends more upon that element than any other. We speak of the personality of the physician as being efficacious in bringing him success. We fail to see in a great number of cases that it is a matter which may be to a great extent cultivated by a recognition of the matters which Dr. Greenleaf has brought out.

It seems to me desirable, as Dr. Putnam very strongly stated in his address at the Massachusetts Medical Society, that more attention should be paid to this matter in our medical teaching. Unquestionably it is a very much neglected subject, and the reflection of medical teaching as seen in textbooks bears this out. We find scarcely any systematic method advised of treating persons through the mind in any of our books on medicine. This should be changed, and there is considerable evidence to show that a change is coming. A certain amount of teaching to meet this indication unquestionably should be conducted in our medical schools. That this want is felt not only by certain practitioners but by students is becoming more and more apparent of late. A number of students have spoken to me and expressed this opinion. They felt that here was a subject about which they had no definite knowledge, which they recognized was important, but which was neglected as a distinct branch of their medical training. It is, no doubt, possible to introduce a practical course in the psychology of the treatment of disease or whatever term you wish to apply to it, the object of which should be an attempt to give the student a systematic idea of the possibility of mental treatment. I do not mean to say these matters are not alluded to in the medical school. They are discussed at considerable length in the course in neurology, but we want a broader application of the principle. We should have it taught from the chair of therapeutics. It should be presented from the general point of view and not from the point of view of a special branch. It is not to be limited to a certain group of diseases, but is a method to be applied whenever we are brought in contact with a person who is ill, exactly as in all relations in life we must constantly bear in mind the fact that we are individuals who have certain definite mental relations with our fellow beings.

DR. PUTNAM: Dr. Greenleaf's interesting and practical paper has certainly touched upon a subject

¹ See page 155 of the Journal.

of immense importance which, as Dr. Taylor says, ought to come before us far more frequently than it does, and I look forward to the change in the requirements for admission to our medical school as likely to afford us a class of students who have been better trained in the essentials of psychology, and therefore will come better prepared to look these subjects clearly in the face. The best physicians have not paid this matter the attention it deserves. This is due to many causes, but I think the chief of them are two which Dr. Taylor and Dr. Greenleaf have both partly indicated. On the one hand, they feel the great difficulty of systematizing their ideas upon the subject; on the other hand, they have shrunk from the use of methods which have been in the hands of classes of practitioners in whose company they did not like to find themselves, not only the Christian Scientists, strictly speaking, but the large class of medical practitioners who have shown a willingness to impress and hoodwink their patients in objectionable ways. But physicians ought to go to work and substitute better methods for those they disapprove, while not failing to learn what they can from such as already exist.

Many of the mental influences which lead to disease and many of those which are used in the cure of disease are particularly difficult of recognition both of the doctor and the patient, because they seem to belong to a part of the mental life which lies outside the ordinary consciousness. Every person is evidently under the influence of a lot of memories, for example, which he cannot control and the source of which he no longer knows with his personal knowledge. It is, of course, very important to bear this fact in mind in treatment, and often essential to use special means to seek out and meet these hidden memories, many of which originate with "accidents," or special illnesses, or painful experiences which have been ostensibly but not really forgotten. At the same time I must admit that I think the treatment based on hunting out hidden causes, although very important, may be overrated. There are certain of the foreign writers who have dwelt upon it a good deal, and others, on the other hand, who have found their method of much less utility. I am inclined to think that if we can get the patient to adopt as a cause something we suggest to him it is almost as good as if we find the real cause. There is one practical notion which was suggested to my mind in reading an extremely interesting book by the physician and psychologist Janet, namely, that many of the notions which lead to so much trouble in the mind and seem to be associated with feelings of such intense and serious character may really come to be maintained by comparatively slight "mechanical" tricks of mind. The particular case I have in mind is one mentioned by this writer where a woman was filled with terror at the idea of infection by cholera to which she thought she had been exposed. This followed her and became a spectre. He became convinced after a time it was more the word than the idea which was controlling her mind, and so he changed this word to others of similar sound but different meaning, got her out of the habit of saying "cholera" to herself and succeeded in breaking up this sort of spectral notion which had filled her mind, and I feel quite sure that many classes of terrible morbid fears can be treated more or less successfully by an ingenious physician on similar principles. If a patient, instead of calling himself a

"wreck" or a "degenerate," can be got to look at his illness in a commonplace way, and if his sense of humor can be excited, success will often be gained.

I think that the evening should not close without a few more words being said about the subject of hypnotism. Although I have no special gift in that direction and have not practised it very much, still I have done so to an increasing degree, because I have found it to be very important. At the Massachusetts Hospital we have used it with great benefit in certain cases. We all do hypnotize whether we will or not. It is a matter of degree between these things we have spoken of and the influence of hypnotism. There are, however, certain classes of cases where we ought to do our best to use hypnotism pure and simple, to get the full effect of the necessary sort of influence. We have had at the hospital a very successful case of enuresis—difficulty of controlling the sphincters of the bladder and rectum—in a well-grown boy, and I had a similar case in my office which was very successful as long as I could keep control of the patient. At the present moment I am treating in a similar way a case of restless sleep in a somewhat nervous young woman who for many years has twitched all night long. I can easily get her into a hypnotic sleep in which she also at first twitched. Now she does not twitch in that and I confidently hope she will get to sleep more quietly and restfully at home also.

DR. VICKERY: I feel that there is a great deal that can be done in the daily treatment of all our cases. We can treat them in a sort of dry, perfunctory way or make a continual effort to impart a buoyancy to their feelings. I know a man who goes through his professional career with that in his mind. I think he is loved as much as any man I know, and I believe the secret of it is that influence, exerted not merely upon persons who have the misfortune to be a little queer in their mental condition, but toward all suffering humanity with whom he comes in contact. Watching him has certainly been an inspiration to me.

DR. LINCOLN: The mental influence in delirium was spoken of by the first speaker, which I desire to extend with the idea that there are possibilities in the case of insanity. I should like to repeat an instance which was given me by Dr. Stephen Smith, of New York, at the time he was commissioner of lunacy in New York State. At one of his visits to an insane hospital he found a man in a state of violent apparent mania. Dr. Smith saw something in that man that did not fully justify the diagnosis of insanity that had been made. He took the case in hand, got near the man and succeeded in attracting his attention and putting himself in the light of a friend. He took the man one side and said he had something to tell him. He said: "If you will be quiet and listen I know I can get you out of this place." The man's confidence was awakened, and by degrees his self-control was also awakened. Dr. Smith took him into a private room, and by quieting him and by putting him down from time to time whenever his violence reasserted itself, he finally got at his history. He suspected his wife of improper relations with a priest, the fact being that the priest was acting from the best of motives as family counsellor. Dr. Smith told him he knew from his knowledge of human nature and the knowledge of his wife's character that such a thing never happened, and after a certain amount of asseveration the man broke down in tears. All his violence and oppo-

sition was gone in an instant, and he submitted himself to Dr. Smith's advice. Dr. Smith said: "First write a letter of most abject apology to your wife, then to the priest, then to your creditors telling them the circumstances, and that you will make arrangement with them that will be satisfactory. Now, if you want to get out soon, be ready tomorrow morning early, get your best clothes on, wash your face, comb your hair, present yourself in a cheerful, smiling attitude when the warder knocks at the door and ask him if you can do something for him." Dr. Smith called again later and found the man in his best clothes with every symptom of mania gone. Here is an instance of a state of nervous excitement diagnosed as insanity, and which would probably have run into insanity in a short time, cured by this form of suggestion in the hands of a man who possessed a great deal of that form of self-consciousness which goes so far with patients. The man got well and was discharged in a week. My object in saying these things is to apply what has already been said in a suggestive way to the treatment of insanity, and I would leave with you all the question in your minds as to what extent in certain cases suggestive treatment is applicable. Some authorities think very strongly in the treatment of paranoia of getting at the root of the matter and eradicating it. The practical application is to the incipient stage of insanity and you doubtless are acquainted with Dr. Peterson's plans to put patients under the charge of men who are specialists. I can conceive no measure that is likely to increase the number of cases of cure of insanity more than that. Dr. Smith, twenty or thirty years ago, made the suggestion that every patient on entering the hospital should for a number of days be under the charge of a special attendant selected for the purpose, a nurse able to enter into the mental state of the patient and become intimate and if possible get at the root of the matter. I can conceive of nothing more rational, only it costs a little more at the beginning.

Dr. GREENLEAF: The discussion has brought out certain points that I hoped would be emphasized. Dr. Taylor referred to one which, it seems to me, is quite important—the fact that these nervo-mental conditions are incident to cases of ordinary illness as well as to purely nervous states. We should recognize this more generally than we usually do. Another point Dr. Taylor made, it seems to me, should be emphasized, namely, the need of calling attention to it in our student days. Most of us have learned it as far as we are acquainted with it through the brunt of experience. It would certainly help our early efforts in medicine to have our attention called to it more distinctly in our school days. I do not recall a single statement to this effect except from the teachings of the physiological and neurological departments when I was a student.

In regard to hypnotism there is no doubt that benefit in certain classes of cases is to be derived from this agent. It is a surprise to many of us to learn of its power. Its usefulness, however, is limited to certain lines, requiring especial training for their proper interpretation. I have tried to confine my remarks to conditions within the province of the general practitioner, and cases requiring the use of hypnotism, as well as cases like those referred to by Dr. Lincoln, I should be inclined to refer directly to specialists in these directions. I am glad, however, to see that the

neurologists who have spoken agree with me as to the importance of such remedial measures along psychic lines as I have presented in this paper.

Recent Literature.

Therapeutic Electricity and Practical Muscle Testing. By W. S. HEDLEY, M.D., M.R.C.S. (Eng.), in charge of the Electrotherapeutic Department of the London Hospital. With more than 100 illustrations. Philadelphia: P. Blakiston's Son & Co. 1900.

This book of 278 pages is an excellent treatise of sufficient conciseness to be of generally practical use on a too much neglected phase of therapeutics. It is safe to say that an exceedingly small proportion of intelligent physicians has anything more than a most rudimentary idea of the indications for electrical treatment, and of the means of carrying it out. This book is designed to give just such information. It is divided into three parts, with an appendix on means of testing for faults in a circuit, and is provided with a good index. Part I deals with the theory of electricity and the laws governing its action. This is sufficiently simple for the general reader and comprises only such knowledge as should be commonly known. Part II concerns itself with the more practical aspects of the subject, the electrotherapeutic outfit and various anatomical and physiological matters in relation to the action of electricity on the human body. The special treatment of a large number of diseased conditions concludes the volume, with the exception of the appendix, to which we have alluded above. This is done in considerable detail and for the most part in a judicial spirit, though often we think an undue importance is attached to the treatment by electricity. In general the book is a safe guide to the more or less inexperienced practitioner, and taken with a certain degree of conservatism we have no doubt the measures of treatment advocated will prove useful and efficient. The illustrations are abundant and well chosen and the binding and presswork entirely satisfactory.

Normal Histology. By EDWARD K. DUNHAM, M.D., Professor of General Pathology, Bacteriology and Hygiene in the University and Bellevue Hospital Medical College, New York. New (second) edition. Octavo. Pp. 319, with 244 illustrations. Philadelphia and New York: Lea Brothers & Co. 1900.

This second edition of Professor Dunham's textbook on normal histology, which this volume alone concerns itself with, will be welcomed by teachers and students. The advance of knowledge has rendered certain changes in the text necessary, and the author has seen fit to add a chapter on technique, which certainly is never amiss in these days of laboratory instruction. The book is well printed and illustrated.

THE BLIND IN RUSSIA.—It is stated in the *Medical News* that there are more than twice as many blind persons in Russia as in the whole of the rest of Europe. They number 190,000, which is equivalent to 2 in every 1,000 of the population. In France and England the proportion is not quite 1 per 1,000.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 16, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

AMERICAN ROUTINE; GERMAN ORIGINALITY.

THE words American and German in our title have not been misplaced by the typesetter! The state of things indicated by this phrase may sound odd to our ears, it may be erroneous in other professions, but in laboratory work and medical research the phrase conveys a large element of truth. Much of the evidence goes to support the general statement that originality is the distinguishing characteristic of the German work and a too persistent routine of the American.

On the other hand, the American clinic undoubtedly presents many points of superiority. It is usually conducted with more system, the practical welfare of the patient being kept more steadily in view, the patients receive more personal and medical attention and the refined methods of diagnosis are more generally employed. The sense of duty to the patient is certainly stronger with us, but besides this the American doctor has cultivated to a high degree what he believes to be his duty to science. In pursuit of this end, however, he has made the mistake of confusing a vast amount of drudgery conscientiously performed with real scientific work. Indeed, at first, such labor may be granted the rank of second-class scientific work, but later it degenerates into the third class and finally into mere mechanical routine.

It is positively pathetic to look at the records of thousands of "blood counts" which have been made on people a glance at whose blood under the microscope would assure any ordinary practitioner that it was normal. The excuse is always the same. "It is the routine to make a blood count in every case." When in addition to the blood count in such patients a differential count is insisted upon, that only too often is empty routine, but it now ceases to be pathetic; it is a futile waste of time. Still the young doctor at our medical centres is so anxious to do good work that he will count blood corpuscles "till he can't see" — all the time under the impression that he is making a contribution to science. And the same thing holds good of much of the urinary work. In the most pains-

taking manner he estimates earthy and alkaline phosphates, sulphates and uraphein because he wishes to learn all he can of his patient and such determinations are in the routine "complete examination." That this work is of any practical value is more than doubtful.

But it may be answered that this work does no harm — that it trains the house officer, student or young practitioner. We reply that it does do harm, and great harm, too. In the first place, the worker forms the pernicious habit of putting this slavish method in the place of active work when he should tax his own unaided mind with the demands of each case as it comes. Again, the routine method not only offers no stimulus to original thinking, but its influence is positively deadening to the mind already wearied with its monotony. Thirdly, it consumes an enormous amount of time on researches of slight value.

The German refuses to do such work day in and day out. He may put heart and soul into it for a short time, until he has dug to the roots of a subject, after which he drops it except in those special cases where it seems indicated. In its stead he is working out fresh problems, enlarging the grasp of his mind to take in obscure causes and effects. Routine occasionally is neglected, but this is atoned for by mental keenness and an occasional original discovery. While we Americans are occupied with our wonderful routine, the Germans are producing Widal reactions and anti-toxin.

ORAL SEPSIS A POSSIBLE CAUSE OF DISEASE.

ATTENTION has of late been directed to the mouth cavity as a focus from which various septic conditions may arise, not only in the immediate neighborhood, but also at times affecting the body as a whole. We have been, perhaps, rather too apt to consider that the bacteria of the alimentary tract are, under all conditions, harmless. It goes without saying that many of these bacteria are wholly innocuous and no doubt positively useful to the bodily economy, but this fact in no way proves that under certain conditions most serious consequences may not arise through a careless hygiene of the intestinal tract. We are glad therefore to see that more careful work is being done upon the bacteriology of the mouth, and we have no doubt the results in this difficult field of research will amply justify all the time that may be spent upon it. An interesting paper has recently appeared in the *British Medical Journal* from the pen of Dr. William Hunter, senior assistant physician of the London Fever Hospital, on the subject of "Oral Sepsis as a Cause of Disease." Dr. Hunter has long been much impressed with the importance of the subject and is inclined, no doubt with justice, to reproach the medical profession for its neglect of it in practice. In his opinion, many of the disorders to which the stomach is subject are attributable to the irritative action of swallowed pus.

The origin of the infective material is by no means always due to the commonly attributed cause, pyorrhea alveolaris, but in the great majority of cases to other dental and oral conditions of sepsis. Apart from various diseases of the gums, stomatitis due to septic toothplates, and to the bridge and crown work now much in vogue among dentists, must be taken into account. The fact that these various septic processes due to the presence of pus organisms are in many cases associated with dental caries adds to their virulence, for Dr. Hunter's experience has been that no pus organisms are so virulent as those grown in connection with necrosing bone. No physician or surgeon, he says, would tolerate for a moment that a patient with a foul septic ulcer, say in his forearm, should from time to time apply his lips to the ulcer to clean it. Yet this is — pathologically — precisely what happens in the case of patients with necrosed teeth and stomatitis. Moreover, the swallowing is constant, and goes on for years, unheeded both by patient and doctor.

The matter is important, however, not only in relation to gastritis, but in relation to the whole group of infections caused by pus organisms — *local*, for example, as tonsillitis, glandular swellings, middle-ear suppurations, maxillary abscesses; *general*, for example, ulcerative endocarditis, empyemata, meningitis, nephritis, osteomyelitis and other septic conditions. Whence do they gain entrance into the system? They are not ubiquitous, as was formerly thought. Nor are they necessarily disease producing from their mere presence; for example, on skin, in the mouth or in the intestinal canal. But given the suitable conditions, namely, diminished resistance on the part of the tissues, or increase of dose on the side of the organisms, they are disease producing. These are precisely the conditions brought about in long-continued necrotic and septic conditions of the mouth.

It is, of course, acknowledged to be an impossibility to keep the mouth absolutely free of pathogenic germs, but Dr. Hunter insists that the possible danger should be recognized and far greater care taken than is ordinarily thought necessary to prevent the conversion of the mouth, as he expresses it, into a perfect hotbed for the development and propagation of bacteria. The paper concludes with the following statements and suggestions: "In relation to the whole group of internal conditions caused by pyogenic organisms, I consider there is a wide field of preventive medicine open by the exercise of oral antiseptics, a field that can be worked in, with the most surprisingly satisfactory results, alike by the physician, surgeon, dental surgeon and patient. And by oral antiseptics I mean no mere rinsing of the mouth with mildly astringent and antiseptic mouth washes, but (1) the direct application to the diseased tooth or inflamed gum of carbolic acid (1 in 20), repeated daily for just so long a period as the patient will persist in keeping his necrosed tooth or fang; still better (2) the removal of all diseased, useless stumps; (3) the most scrupulous daily sterilizing by boiling of every toothplate worn and (4) on the

part of dentists the avoidance of too much conservative dentistry and the use of contrivances like 'bridges' which cannot possibly be kept aseptic."

It is at least probable that Dr. Hunter goes rather too far in his apprehension regarding the significance of oral sepsis and its far reaching consequences, but the vigorous expression of such a view will certainly do no harm and should direct renewed attention to conditions, the treatment of which is too often deferred, if not wholly neglected.

MEDICAL NOTES.

DEATH RATE IN HAWAII. — It is reported from Honolulu that the health statistics for the months of June and July show alarming increase in the death rate, especially among native Hawaiians and Japanese of the Island of Omaha, which alone has complete records. In June the number of deaths per thousand was 45; in July, 49.68. In 1896 the deaths numbered 48. Since then the figures have jumped to 59, 75, 93 and this year 114. Consumption heads the list of diseases, causing deaths in almost every month, and there is agitation for strict measures to quarantine patients. The Board of Health is discussing a quarantine against consumption, owing to the visits of tourists in search of health. Typhoid fever has also claimed a number of victims.

ANTIRABIC INOCULATION IN GREECE. — The number of patients who underwent the treatment for hydrophobia at the Pasteur Institute of Athens from the foundation of the institute in 1894 to the end of 1898 was, according to the *British Medical Journal*, 1,300. Of these 1,200, or 92.8%, had been bitten by rabid dogs, 58 by cats similarly afflicted, 7 by asses and mules, 4 by pigs, 2 by cows, 2 by wolves and 1 by a horse. In 18 cases the disease was transmitted by human saliva and in 1 by the bite of a man suffering from hydrophobia.

SIR WILLIAM MACCORMAC RE-ELECTED PRESIDENT OF ROYAL COLLEGE OF SURGEONS. — For the fifth time Sir William MacCormac has been appointed President of the Royal College of Surgeons of England. This is the longest term of service which has ever fallen to the lot of one man. Sir William Savory was at one time president for three successive years.

A PHILADELPHIA DENTAL INSTITUTE. — It is reported that by the will of the late Dr. Evans, the Paris dentist, \$3,000,000 is left for the establishment of a dental institute in Philadelphia.

RESIGNATION OF DR. EDWIN KLEBS. — It is reported that Dr. Edwin Klebs has resigned the professorship of pathology in the Rush Medical College, Chicago.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 15, 1900, there were

reported to the Board of Health of Boston, the following cases of acute infectious diseases: diphtheria 57, scarlatina 10, measles 13, typhoid fever 13.

NEEDS OF THE FLOATING HOSPITAL.—Owing to the somewhat exceptionally hot weather, the Floating Hospital has been crowded to its utmost limit with patients, and in certain instances it has been necessary to refuse treatment for want of room. The need of larger accommodations is becoming more and more urgent. The season is so short a one that it should be possible to give all those who require it the benefit which such a method of treatment affords.

NEW YORK.

MORTALITY STATISTICS.—The reports of the Bureau of Vital Statistics show that, notwithstanding the intense heat of a portion of the month, the death rate in July was slightly lower than last year. In July, 1899, the mortality represented an annual death rate of 23.01, and in July, 1900, a death rate of 22.98. For the very hot week ending July 21, 1900, the rate ran up to 27.75 against 22.91 for the corresponding week last year; but with this exception the mortality was materially smaller than in 1899. The weekly average number of deaths from diarrheal diseases in the four weeks ending July 28th was 313.75, and from this class of affections in children under five years of age, 290.5, against 73 and 68.25 respectively in the four weeks ending June 30th. The culmination of the deaths from diarrheal diseases was in the week ending July 21st, when they amounted to 398. In the following week the mortality from this cause fell to 270. It is noticeable also that the excessive heat had a marked effect in increasing the number of deaths from phthisis. In the week ending July 21st the deaths from this disease reached 181, against an average of 139 for the other three weeks. This increase brought the weekly average of the month up to 149, against 143.5 in June. The weekly average of deaths from pneumonia declined to 101.25 from 139.5 in June, and the weekly average from diphtheria to 30, from 40.25 in June. During the four weeks ending July 28th, 154 deaths were reported from sunstroke, and 94 of these were in the week ending July 21st.

COSTLY EXPERT TESTIMONY.—On August 9th, Controller Coler made public the bills of the medical, chemical and handwriting experts for work on the Molineux murder trial, the total amount reaching \$50,476. Of this sum, claims amounting to \$8,687 have been paid after reductions of \$1,800 were made by the controller, and the other accounts still remain to be settled. The largest claim is that of Prof. Rudolph A. Witthaus, who made the principal analyses, and on whose testimony the conviction of the prisoner was secured; its amount is \$18,550.

ADDITION TO INFANT ASYLUM BUILDINGS.—The Board of Managers of the New York Infant Asylum have filed plans for the construction of an addition to the buildings of their institution on Amsterdam Avenue which will practically double its capacity. It is to

cover an area of 100 by 56 feet, and the estimated cost is \$100,000. It will be four stories in height and is designed in such a way that three additional stories may be added in the future. The additional accommodations have been greatly needed since the old Second Avenue Lying-in Hospital was consolidated with the asylum about a year ago.

A NOVEL SUIT AGAINST THE STATE.—A militiaman of Poughkeepsie has brought rather a novel suit against the State, having filed a claim for \$30,000 for the loss of a foot in consequence of injuries received while participating in a sham battle when he was on duty at the State Camp of Military Instruction at Peekskill in the summer of 1899. He fell into a hole and the injury was so severe as to call for amputation.

Miscellany.

THE FINSEN TREATMENT OF LUPUS.

THE *Medical Press* comments as follows on the recently introduced Finsen treatment:

“It was long the practice to laugh at John of Gadesden's treatment of disease by the use of the red rays of the solar spectrum, nevertheless from 1492, when his ‘*Rosa Anglica*’ was published, the treatment held its ground in public favor until the middle of the eighteenth century. Defoe refers to it in his novels as a usual domestic method of cure. The curative property of both the heat-giving red rays and of the chemical rays is strongly corroborated by Dr. Finsen, of Copenhagen, whose hospital is attracting patients suffering from lupus from every country in Europe. He has found that the chemical rays of the solar spectrum, blue, violet and ultra-violet, have a marked bactericidal power, and on this he bases his treatment. The technique adopted is thus described: On bright, sunny days the patients are carried into the garden. They each have a nurse of their own, who during the hour they are under treatment presses an odd-looking little apparatus on the part of the face or hand that is diseased. It consists of a plate of quartz and a plain convex lens of quartz, both framed in a conical brass ring, and with two tubes fixed between them. Cold water is kept running in one of these tubes and out at the other. The use of the apparatus is to force the blood from the skin on which it is pressed, and thus enable the chemical rays to penetrate it more readily, while the water is there merely to keep the skin cool. By the side of the patient there is another apparatus, a large movable lens, fixed in a stand in such a position as to be in a direct line between the sun and the piece of skin requiring treatment. This lens is composed of two glasses, one plain, the other curved, framed in a brass ring, the space between them being filled with a weak solution of sulphate of copper. It condenses the sun's rays that fall on it, while the water it contains, together with the salt solution, intercepts the ultra-red, red and yellow rays. Thus, practically, the only rays that pass through the lens, and therefore the only rays that reach the area of the skin requiring treatment, are the chemical; and, as they are highly condensed, they destroy the bacteria on which they fall.

In the absence of sunlight, Dr. Finsen falls back on the use of electric light. He has found that the chemical rays intensify inflammatory skin diseases; and he confirms, from his own experience, the value of the red rays in the treatment of smallpox. Thus after five hundred years, he confirms the accuracy of that conscientious observer, John of Gaddesden, and by an extension of his principle of light treatment confers a distinct blessing on suffering humanity."

LEPERS IN FRANCE.

It is estimated, according to the *Medical Record*, that there are about four hundred lepers in France, many of whom are missionaries and nurses who have contracted the disease caring for sufferers in distant countries and also soldiers and officials from the colonies. They are now scattered about in Brittany, in the Pyrenees, on the shores of the Mediterranean and in Paris, where there are one hundred and fifty. A committee has been formed at the instigation of Dom Santon, a member of the Benedictine community of Liguge, and also a doctor of medicine, to further measures for the care of lepers in France and to prevent further spread of the disease. Dom Santon has studied leprosy for a number of years in the course of his travels about the world for this purpose and his plans to deal with the disease in France have received the approval of the French Government. He has acquired property in the Vosges, where he purposes to establish an asylum for lepers, to be called the St. Martin Sanatorium.

Melrose . . .	14,721	6	4	16.66	—	—	—	—

Deaths reported 2,417; under five years of age 1,129; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 921, diarrheal diseases 512, consumption 251, acute lung diseases 131, diphtheria and croup 60, typhoid fever 40, cerebrospinal meningitis 18, whooping cough 17, scarlet fever 11, measles 7, erysipelas 5.

From cerebrospinal meningitis New York 7, Boston, Baltimore and Lynn 2 each, Worcester, Somerville, Lawrence, Newton and Waltham 1 each. From whooping cough New York 10, Pittsburg and Washington 2 each, Boston, Providence, Worcester and Melrose 1 each. From scarlet fever New York 6 and Boston 5 each, Pittsburg 1. From measles New York 6, Washington 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,206, for the week ending July 28th, the death rate was 19.4. Deaths reported 4,313: acute diseases of the respiratory organs (London) 196, diarrhea 662, whooping cough 88, measles 76, diphtheria 66, fever 27, scarlet fever 24, smallpox (Blackburn) 1.

The death rates ranged from 11.1 in Derby to 28.0 in West Ham; Birmingham 19.0, Bradford 13.6, Cardiff 14.0, Huddersfield 11.5, Hull 13.8, Leeds 22.0, Liverpool 28.0, London 21.0, Manchester 16.8, Newcastle-on-Tyne 17.8, Nottingham 14.6, Salford 24.1, Sheffield 23.1, Swansea 12.9, Wolverhampton 16.9.

RECENT DEATH.

JOHN FRANCIS BURNS, M.D., of Long Island City, died on August 9th, in St. John's Hospital, of meningitis, after an illness of one week. He was born in New York on December 5, 1863, and was a graduate of the Medical Department of the University of the City of New York. He afterwards served on the house staff of the City Hospital and of the Maternity Hospital, Blackwell's Island, and later was associate superintendent of the Asylum for Inebriates at Fort Hamilton. At the time of his death he was one of the attending surgeons at St. John's Hospital.

Address.

MEDICINE AS A SCIENCE AND MEDICINE AS AN ART.¹

BY PHILIP H. FYE-SMITH, M.D., F.R.C.P.,
Consulting Physician to Guy's Hospital, London.

MR. PRESIDENT AND GENTLEMEN:—It has sometimes been disputed whether medicine should be regarded as a science or an art; but there is no doubt that the original meaning of medicine, and of the corresponding terms in other languages, is the art of healing. Medicine is so defined by Aristotle, and the art of curing, to which we may add the art of preventing disease, has all the characters of an art. It depends upon experience and skill; it deals with individual cases, and the perfection it aims at is practical, not speculative; the knowledge how to do and not the knowledge how things happen. Nevertheless, as practical navigation is founded on astronomy, meteorology and physics; as the art of agriculture rests on botany, geology and vegetable physiology, so the art of medicine depends on the science of pathology, the practice of physic on the principles of physic.

On the other hand, then, we must never forget that we practise an art; we must never allow theories, or even what appears to be logical deduction, or explanations however ingenious, or statistics however apparently conclusive, or authority however venerable, to take the place of the only safe rule of practical medicine—observation and experience. We must never treat the disease without considering the patient, for the art of healing is the art of healing individually. Nor need we wonder if vast knowledge, profound learning and the best scientific training sometimes fail to make a successful practitioner; for beside adequate knowledge to save us from gross blunders and a strenuous endeavor to do our best for each individual patient, however uninteresting the case or however irksome and thankless our toil; beside these first requisites for our art, there is ample room for those personal qualities which ensure success in every department of life—power of observation and insight, the personal influence by which a strong character will secure obedience and inspire hope, the judgment which divines what kind of remedies are suited to each patient, what kind and of what strength, and the sympathy which puts one in the patient's place, and not only meets, but anticipates, his wants.

If, however, medical science without art is inefficient, medical art without science is not only unprogressive, but almost inevitably becomes quackery. As soon as we treat our patients by rule of thumb, by tradition, by dogmas, or by metaphysical axioms, we do injury to ourselves as well as to them. The bone setter who is ignorant of anatomy, the wise woman who cures by charms, are not more irrational or less successful than was the physician of the seventeenth century who, in obedience to the doctrine of signatures, advised an infusion of roses for hemorrhage, and saffron for jaundice, and lungwort for consumption; or the astrologer who prescribed salts of silver, of iron, lead, or mercury in accordance with the horoscope of the patient and the planet under which he was born. Not less mischievous and in the true sense of the word unscientific were the systems of medicine known as

the iatromechanical and the iatrochemical, which in their turn had their vogue. The Brunonian system, explaining all diseases as due to laxity of fibre, was no better; for indiscriminate use of "corroborants," or, as they would now be called, tonics, is as irrational as that of hydropathy, of alcoholic stimulation or of electricity. There is no such thing as a tonic or strengthening medicine, the only source of strength is oxidizable food, and bitter medicines can only give strength by improving the appetite. The last of the systems of medicine founded on a dogma is homeopathy, of which the theoretical absurdity is somewhat concealed by the more obvious nonsense of infinitesimal doses. It, like the other systems which preceded it, is not a rival to rational medicine; they are not mistaken answers to a legitimate question, but attempted solutions of a problem which does not exist, attempted answers to a riddle which has none.

Apart from these exploded systems of treatment, our profession has often suffered from lack of the scientific, inquiring, sceptical spirit, and has often been led too easily by authority, by tradition, and by fashion. The reckless abuse of venesection in the last century and the former half of this led to almost complete disuse of a valuable means of treatment; the misabuse of mercury in the treatment of syphilis led to denial of its unquestionable efficacy. Have we not seen the value of stimulants in a contest with fever lead to their indiscriminate use in almost every ailment? Has not the immense value of careful and thorough nursing sometimes ended in its exaltation to an independent place, as if good nursing was anything more than an intelligent carrying out of the physician's directions? Have not the remarkable powers of electrical stimuli led to a blind, unscientific and mischievous employment of this remedy, as if it had some mystic efficacy apart from its demonstrable physiological effects? May we not say the same of hydropathy, of massage, and of hypnotism?

It is significant that the irrational exaltation of any of these particular modes of treatment into a panacea, while it begins in want of scientific intelligence, invariably ends in imposture and deceit. Our only safeguard against the spirit of quackery and the deserved loss of public confidence in the profession which it brings with it is continued recurrence to the scientific basis on which the practice of medicine rests. Our art is most satisfactory and efficient when most closely resting on science. The surgeon is continually guided by anatomy and mechanics in dealing with injuries or deformities. The physician is often able to apply his knowledge of chemistry and natural history to the direct and satisfactory treatment of disease. Generally we can appeal to the same test as that which proves astronomy or chemistry to be a true science; we can predict and our predictions are borne out by the event. But to take examples, the detection and treatment of plumbism, the diagnosis and cure of scabies and ringworm, the treatment of poisons by chemical antidotes, and of specific diseases by attenuated inoculations are all instances of strictly scientific medicine. Nor can I refrain from citing the most recent and one of the most remarkable advances of our science in the discovery of the origin of malaria. This heavy tax upon national as well as individual vigor and happiness has been known and treated from the dawn of medicine; but although by a happy accident its efficient treatment was discovered, it is only

¹ Address delivered at the Annual Meeting of the British Medical Association at Ipswich, July-August, 1900.

lately that by the combined labors of scientific physicians, Frenchmen, Italians, and our own countrymen, that the origin of the disease has been discovered, the mode of its transmission traced, and the diagnosis of its several forms established.

We know that treatment of symptoms without a diagnosis is always unsatisfactory and frequently worse; but we know also that diagnosis must rest upon accurate knowledge of morbid anatomy and of the natural history of the disease. Scientific medicine based on observation and experiment is always practical as well; but empirical medicine, whether based upon fanciful speculation or working by rule of thumb, is the most unpractical thing that can be.

ETIOLOGY AND PREVENTIVE MEDICINE.

That important and constantly growing branch of medicine which deals with the prevention rather than the cure of disease depends no less upon science, for tracking the dependence of one event upon another is the essence of inductive science. All efficient measures for the preservation of health, whether by individuals or communities, rest upon exact knowledge of the natural course of diseases. In fact, disease may be defined as the reaction of the human organism under conditions which make for its destruction. We must never forget that no irritant will cause inflammation in a lifeless skin; that no bacteria can produce fever without a nervous system to play upon; that no meal, however gargantuan, and no potatoes, however deep, can produce their wonted effect without a stomach to react. The infection of smallpox, of diphtheria, or of tubercle exerts a very different influence upon vaccinated or unvaccinated subjects, upon one who has received and one who has not received the prophylactic serum, upon an organism which is predisposed to or refractory against the invasion of the enemy.

How closely natural science is related to preventive medicine is shown by the history of Jenner, who was a naturalist, and Pasteur, who was a chemist. How dependent we are upon science is well illustrated by the history of myxedema. The cretinoid condition in adults which was discovered by the clinical acumen of Sir William Gull, unintentionally produced by the surgical skill of Professor Kocher, and reproduced in animals by Mr. Horsley, is now cured by the eminently scientific method due to Dr. Murray, of Newcastle, and to Dr. Hector Mackenzie, of St. Thomas's Hospital.

Such examples of accurate tracing of causation by observation and experiment admonish us to give up the perfunctory explanations which so often do duty for investigation. If we ascribe every inflammation to cold, and every doubtful symptom to gout; if we acquiesce in the popular ascription of disease to overwork, mental strain and the nervous tension of modern life, we shall make no progress in true etiology. I see many patients suffering from idleness, few, or none, from hard work. "Nerve prostration" from "worry" and "brain tension" generally proves to be a decent veil to the effects of gambling and drink. Contrary to popular belief, I hold that modern life is easier, safer and smoother than it was a hundred years ago, that our young men and maidens are healthier, stronger, better grown, less emotional, less hysterical and sounder in mind and body than their great-grandparents; and I hold that the duty of a physician is not

to flatter the selfishness of neurotic patients, but to inspire fortitude and to prescribe regular and steady work as the best cure for a thousand nervous ailments.

As another point in scientific etiology, allow me to warn against the temptation to assume that because many diseases are now proved to depend upon the presence of bacteria that this must be true of all. Science does not anticipate but waits for proof. We have complete scientific evidence, according to the criteria so well formulated by Koch, of the absolute and constant cause of anthrax, of relapsing fever, of tubercle and of several other diseases in both men and animals; but we must not forget the preliminary difficulty of identifying the specific bacillus, as in the case of enteric fever and diphtheria; nor the difficulty of finding one of the lower animals which is susceptible to the disease, as again in the case of typhoid fever and of cholera; nor the difficulty in the same anatomical and clinical conditions being produced by different organisms, as in the case with pneumonia and ulcerative endocarditis. Moreover, while in some diseases which are undoubtedly infective and specific no constant pathogenic microbe has yet been determined, as in typhus, measles, smallpox and syphilis, we have on the other hand in the case of leprosy and of lupus examples of disease unquestionably specific and bacterial in origin, but very unlike other infective maladies in clinical course and natural history. At present it is surely undesirable to speak of "the undiscovered microbe of rheumatism." Science has to do with proved facts and our language should never outrun our knowledge.

PROGNOSIS AND STATISTICS.

Another important branch of medicine — prognosis — depends as an art upon experience and insight. In making an individual prognosis, shrewd powers of observation are needful; and in this, of all branches of our art, it is true that

"Old experience doth attain
To something like prophetic strain."

Yet here also rational prognosis rests on the science of statistics.

It is to Louis and the French school of the second quarter of this century that we owe the application of this important method for learning the natural history of disease, a method which not only supplies a foundation for prognosis but also a criterion of treatment. We know, however, how many pitfalls there are in deducing conclusions from statistics. The morbidity or incidence of a particular disease upon the whole community is often confused with the mortality or the fatal cases of it compared with the population, and this last confused again with the case mortality. The return of deaths from a certain disease in a town or kingdom has been applied to the population which existed eight or nine years before. The success of treatment of a disease occurring in barracks, that is to say, among picked subjects, all in early manhood, under strict discipline, and sent to hospital as soon as they are unwell, has been compared with that of other measures carried out in totally different circumstances. As examples of statistical misuse take these facts: The numerical returns of the lying-in charity of a London hospital led to the conclusion that more women are delivered of a second child than of a first. A physi-

cian, to inspire confidence in an anxious patient, assured him that the mortality of the complaint from which he was suffering was only 1%; and in answer to the further inquiry whether he had seen many cases, said: "Yes; I have looked at my notebooks and find I have seen 99 and they all recovered."

But, apart from the corrections and limitations of statistical science, we are sometimes in danger of forgetting that to be of any value statistics must be based upon cases which are both numerous and accurate. A small number of cases is useless. It led to the conclusion that myxedema was peculiar to women and that insular sclerosis was rare in men. It was only after hundreds of cases had been observed that we learnt that infantile paralysis sometimes befalls adults and that osteo-arthritis may occur in children. This defect may be remedied by time, but the defect of inaccuracy is without remedy. If diagnosis is perfunctory or careless and nomenclature arbitrary and inconstant, the more cases observed the less do they teach. It is disappointing, after the immense labor, time and trouble devoted to the compilation of the official *Nomenclature of Diseases* of the Royal College of Physicians, that, although adopted in the navy and army and by the registrar-general, it is constantly neglected, not only in conversation but in systematic treatises. How can statistics be anything but misleading when made up of cases of one and the same disease under such different titles as chronic rheumatism, rheumatic gout, rheumatoid arthritis, arthritis deformans and osteo-arthritis? Of what value are statistics when such different diseases as acute lobar pneumonia, bronchopneumonia of children after measles, pulmonary tuberculosis, cirrhosis and septic suppuration of the lung are all labelled "pneumonia"? One difficulty is put in the way of the practitioner in making an accurate return by the well-meant but, I think in practice, unfortunate provision for returning a primary and a secondary cause of death. Sometimes this corresponds to facts and gets over a difficulty, but if a patient dies of enteric fever there is nothing gained by adding congestion of the lungs as the secondary cause, still less do we learn from a return of primary cause a chill, secondary cause debility; or primary cause an accident, secondary cause dropsy. As a matter of fact, in looking through hundreds of death certificates, one arrives at the valuable conclusion that a frequent cause of death is "exhaustion" or "cardiac failure."

Another and opposite mistake is often made by attempts at too great precision in diagnosis. To say that a man died of apoplexy or of paraplegia is to state a fact within any competent practitioner's knowledge, but, in the absence of a post-mortem inspection, to say that he died of cerebral hemorrhage or of myelitis is not a fact, but a more or less doubtful inference. It is surely better to be satisfied with a statement that there were ascites and enlargement of the liver when the cause of enlargement is altogether uncertain, than to be more exact and less true. I have again and again seen diseases the existence of which no experienced physician would assert without a necropsy returned as if they were common and easily recognized conditions—pernicious anemia, syringomyelia, cancer of the lung. It would, I venture to submit, be a great improvement if the return of one cause of death only were demanded; if certainty and definite statements were aimed at rather than speculative minuteness of vague generalities; if a query were allowed to qualify

deductions as distinct from observations; if the fact or the absence of a necropsy were always stated, and, lastly, if the authorized nomenclature were always used.

SCIENTIFIC MEDICINE AND EXPERIMENT.

There is one aspect of scientific medicine so important that it must not be wholly omitted: the necessity of experiments for the progress of pathology, and through it for the prevention and cure of disease. It requires no argument to convince any one who is the least acquainted with the principles of inductive science that experiment is no less necessary than observation. In physics and in chemistry this is obvious and universally acted on. The same method is indispensable for the progress of animal and vegetable physiology, and to such practical applications of science as engineering, agriculture, and medicine. Nor can experiments be restricted to rare, occasional and solemn occasions; they must be carried on in large numbers by many different experimenters and under every variety of conditions. Any attempt to abolish, to check, or to limit this experimental work is, in the degree that it is successful, fatal to progress. Happily it can never be successful, for the impulse to increased knowledge of the works of creation is too deeply implanted in man. Investigation must and will go on by the only path which it can follow. The method which was preached by Bacon and followed out by his great contemporary, William Harvey, which was continued by Lower, Hooke, and Mayow, in the early days of the Royal Society, by Aselli, Malpighi, and Haller, by Hunter and Hewson, by Hales, by Edward Jenner, by Sir Charles Bell, by Johannes Müller, by Claude Bernard, by Ludwig, and by the many eminent physiologists and pathologists in Germany, in France, and throughout the civilized world—this method of investigation must and will continue. As its objects and methods are better understood, it will secure the enlightened patronage of all who desire the effusion of human knowledge and the further spread of human happiness. Fortunately this very progress of science has brought with it the removal of the one drawback which every right-thinking man must have felt as a grave disadvantage to these experiments upon living animals. Inflicting pain upon the humblest of God's creatures is repugnant to our feelings, though no one, unless maintaining a thesis, would contend that it would be wrong to exact the most painful efforts, or even the death from exhaustion, of a horse, in order to carry help to a human being. The discovery of ether, chloroform, and other anesthetics, and the improved methods that we owe to the genius of Lister, have not only relieved the surgeon of the most repulsive part of his duties, but have relieved the experimenter also. Except in the investigation of the action of new remedies or in the inoculation of infective diseases, both of which inflict discomfort of a limited degree and duration rather than anything that can be described as pain, the experiments of the laboratory, whether physiological, pathological, or therapeutical, are conducted without inflicting suffering. The opposition to them has not succeeded, and is sure to diminish. However mistaken our opponents, we are glad to find there is exaggerated jealousy to avoid anything approaching to cruelty. This legitimate object our more candid critics may be assured is already amply provided for.

THERAPEUTICS AND SCIENCE.

Lastly, how far is the final end of our art — the cure of disease — immediately and directly dependent upon science? It rests, we know, on that sure basis, but even in its practical carrying out we are bound to take with us a scientific spirit. The administration of digitalis for cardiac dropsy, of mercury for syphilis, and of thyroid extract for myxedema is as truly scientific as prescribing a chemical antidote for poison, or nitroglycerin for angina pectoris, for it rests on a sure basis of observation and experience. But because in many cases we cannot as yet explain how remedies act, we should never prescribe them without watching the effects of the experiment. The foolish cry against hospitals as places where they experiment on patients is meaningless just because it is true. Every prescription we give either to rich or poor is an experiment and ought to be watched with critical and scientific eyes. And here let me say that our practice is often ineffectual, not for want of an accurate diagnosis or an adequate means of treatment, but merely for want of the needful treatment being thoroughly carried out — a want which inevitably prevents success, and therefore leads by a vicious circle to scepticism and want of thoroughness on the next occasion. A man who believes everything he is told of the action of remedies not only in the serious treatises of Garrod or Wood or Binz, but in the partial assertions of advertising druggists, is sure to be unsuccessful; and, beginning with credulity, is apt to end in unbelief of such remedies as colchicum, salicin and opium. Such a man will prescribe and will never see that his prescription is carried out; by the habit of giving multifarious mixtures of drugs in ineffectual doses he allows what he has prescribed to be taken three times a day for a fortnight to be really taken twice or once a day for a week, and still less often for the second week. He will prescribe exercise or lying down, abstinence or feeding, and never trouble himself to see that his directions are carried out. Who shall blame the patient if he ceases to believe in remedies to which the physician obviously attaches no importance? If we would sometimes prescribe no drug at all, but insist upon abstinence from certain articles of food or drink, or upon more frequent or less frequent meals, upon regular exercise or absolute rest, should we not secure more obedience from our patients when we prescribed really necessary drugs — just as a clergyman who desires to get a liberal collection would do wisely to begin by insisting on the sin of giving to charities which one believes to do more harm than good? How can we expect success in treating an obscure nervous affection if we apply galvanism to the spine without making sure of any physiological effect, nay, sometimes without making sure that a current is passing through the electrodes; or if we send the patient to drink the waters of such and such a fashionable watering place without remembering that there are two or perhaps three springs, one of them inert and the other very possibly injurious? What success can be anticipated if we order ointment for a weeping eczematous patch where it floats on the secretion and never reaches the inflamed tissue; or if we prescribe a lotion to be applied twice a day to skin well protected by its sebaceous secretion? We all know this half-hearted, ineffectual mode of action in everyday life; the man who wipes his shoes as a cere-

mony never looks to see if he has got rid of the mud; the groom who feeds his horse but never sees whether the oats are eaten; the nurse who washes the child and still leaves dirty places. Now much of this weak and therefore useless treatment is only the indolence to which we are all prone, and against which we must struggle as a temptation; but much of it, I am sure, is the offspring of incredulity and this again springs from half belief in quackery and imposture. Much of our ineffectual treatment again depends upon want of belief in our diagnosis. Until we make up our minds whether a certain eruption is psoriasis or a scaly syphilide, we shall never deal with it successfully. If we only suspect syphilis, we shall give our remedies in inadequate doses, and relinquish them if we do not see immediate benefit; whereas if our diagnosis is real and thorough, we shall use our remedies with confidence, increasing the doses, varying the form, but always persevering until we obtain their physiological effect, and then we may reasonably hope to cure our patient.

Another source of failure in therapeutics is the legion of new remedies, the eulogiums of which fill our waste paper baskets and light our fires. It is astonishing to find apparently rational men forsaking the drugs which have been proved effectual by the experience of long past time and of all civilized nations to take up with remedies the very composition of which is often unknown, the use of which they have never learned and of which the value rests upon the interested or credulous assertions of those who try to sell them. It takes a man long years of practice to learn how to prescribe an opiate. Why throw away this priceless knowledge to dabble in quack cures of which the very praises inspire distrust? New remedies are no doubt discovered from time to time — in this generation we have had several — and all probable claimants should be tested in pharmacological laboratories and in hospital wards. But I am speaking of drugs which have never passed either of these tests. Surely in this age of advertisements which disfigure and defile the beauties of land and sea, of town and country, of literature and art, the most credulous must be convinced that costly and pertinacious advertisement is evidence of the lack, rather than the possession, of genuine worth. No, sir; so far from our profession being carried away by this noxious and degrading habit, let us hope that we may not only stamp it out from among ourselves, but spread our own standard of conduct to other pursuits, until some day an honest tradesman shall be ashamed to push his sales by self-laudation and the wealthy manufacturer shrink from offending the eyes and deafening the ears of his fellow creatures by scribbling his name on blank walls and screaming it in every street.

In another popular branch of treatment it seems very desirable that the scientific spirit should be somewhat more freely admitted — I refer to treatment by baths and waters. That both are valuable modes of treatment no one will deny, but will any one be so bold as to assert that it makes any difference whether patients take a bath of water heated as it comes from the soil or heated to the same degree in a kettle? Who would pretend that so many grains of laxative or alkaline salts will act differently when occurring in natural solution and when dissolved in the same proportion in the druggist's shop? That benefit is obtained by change of air and scene, by early hours,

regulated rest and exercise and copious draughts of water is beyond dispute; but it is surely a pity when, instead of rational explanation of a "cure" treatment, we suffer our patients to be deceived by unscientific and more or less untruthful statements.

Is it not a mistake for so many of us to prescribe the made-up drugs offered us by wholesale manufacturers instead of our own combinations? It leads our patients to ascribe their recovery not to our skill, but to this or that pill or tablet. It would be an excellent task for this great association to set some of our skilled analytical chemists to strip the veil from mysterious remedies and tell us the exact composition of the many patent medicines, some of which are inert and some injurious.

RATIONAL MEDICINE AND ITS WAGES.

Lastly, we may ask whether our profession obtains the recognition that is due at the hands of the public. I believe that on the whole it does, or if in any degree it fails, that the failure is due to ourselves. We cannot expect that any but the most educated and enlightened should look at our science or our art from a rational point of view. The popular notion of a doctor among our patients is a man who has got some wonderful cure in a bottle which will make them well. The more educated patients suppose that, knowing what is the matter with them, or, as we say, having made their diagnosis for themselves, their next business is to choose the doctor who has devoted his exclusive attention to the malady of which they suppose they are the subjects, or if they chance to suffer from what they call a complication of diseases they will consult a heart specialist to cure palpitation, a throat doctor to cure hoarseness, and a rising young surgeon to "a special hospital for diseases of the knee," to cure weakness in that joint. If they should find no relief after these consultations—*Flectere si nequeo superos, Acheronta movebo*—they denounce legitimate medicines as useless and go to the lowest impostor, and will afterwards tell their friends that after being "given up by the faculty" they found instant and miraculous relief in a single box of wind pills, a galvanic belt, or a pad of "oriental herbs" worn on the pit of the stomach. Among the more enlightened the rule seems to be that they believe in surgery, they believe in nursing, in change of air, in tonics, and in stimulants, but they have long since given up faith in doctors or in medicine.

The fact is that we cannot expect our patients should understand the scientific basis of medicine, the meaning of etiology, or the possible degree of efficiency of treatment. What they frequently ask of us is to allow them to continue the very course of life to which we have laboriously traced their symptoms, and to give them some medicine which, as if by a charm, will break the inevitable sequence of cause and effect. They are slow to understand that this world gives nothing for nothing, and that we can only subdue Nature by obeying her laws.

There is, in fact, only one way in which we can obtain what we call our just recognition. Our services, however great, are services to the individual, not to the community. It is therefore absurd for us to expect the honorific or more solid rewards justly assigned to statesmen, to generals, or to judges, but from individuals we may expect—and I venture to say that as a rule we receive—the trust, the honor, and the grati-

tude which we have earned. Few of our patients will ever understand our principles or our methods, the reason for our successes, or the explanation of our failures; what they do understand is personal character, honesty and sense, kindness and sympathy, liberality and benevolence to rich and poor. These are the qualities which have always gained and still gain the respect of our fellow men; and I venture to say there is not a town in the three kingdoms where such respect is not widely and deservedly earned. In every cathedral, in almost every parish church, we see tablets bearing witness to the esteem in which the local practitioner lived and died. He spent his life in the constant exercise of his best faculties, intellectual and benevolent—a sure path to happiness; every day brought fresh interest and left no time for melancholy; he earned not only money but money's worth, in respect and influence; and when the practitioner became the patient—as we all must one day be—he had pleasant memories of a life spent in the service of God and man. He lives in the hearts of those who knew him,

"And there sepulchred in such pomp doth lie
That kings for such a tomb might wish to die."

REPEATED ECTOPIC GESTATION IN THE SAME PATIENT, WITH OPERATION IN EACH CASE.¹

BY MALCOLM STORER, M.D., AND M. T. THURBER, M.D., BOSTON.

I. PREVIOUS HISTORY OF THE CASE, BY DR. THURBER.

IN bringing to your notice this evening the interesting features of the following case I will endeavor to give only a brief clinical picture from the commencement of the abnormal conditions up to the time of the patient's entrance to the hospital. I am indebted to Dr. Joyce, of Kingston, N. H., (formerly of Dorchester) who had the patient under his charge during her first illness, for many particulars of the case.

A young woman, twenty-three years of age, small in stature, weight 110 pounds, of a nervous temperament; born in Canada, of the physical development characteristic of the French-Canadian girl, and married three years; never pregnant; ceased to menstruate October 20, 1898, having begun on the 17th. Her period was expected again November 14th, but was missed and, as she had always been on time, she concluded she was pregnant. She had nausea during the morning at different times, which was quite unusual for her, and this confirmed her belief.

Aside from "morning sickness" she felt as usual up to the early morning of November 26th, when immediately after coition she began to flow profusely. Soon severe pains began, located low in the pelvic region. She feared she was about to miscarry and at eight o'clock she was seen and examined by Dr. Joyce about half an hour after the hemorrhage began. Believing that a miscarriage was threatened, he administered remedies with the hope of checking the flow and to continue if possible the pregnancy. One visit only was made, as the above conditions soon passed away and the patient was as well as before.

¹ Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, March 28, 1900.

The doctor was again called December 7th for pain, but no hemorrhage. Relief was soon obtained by morphia given hypodermically.

Five days after this visit, December 12th, Dr. Joyce was called for the third time and as he was out of town the husband asked me to see her. When I arrived I found the patient, to use her own words, "suffering agony." Her temperature was $99\frac{2}{3}^{\circ}$ F. and her pulse 104. Hemorrhage was profuse. There was marked tenderness over the lower part of the abdomen, especially on the left side of the median line, where the slightest pressure produced sharp, cutting pain. She had had several chills, each leaving her in a more nervous condition than the preceding one. For three days previous to my visit she had had a bloody discharge which had an offensive odor. In attempting to pass my finger into the vagina the rectum was found to be loaded with a hard fecal mass, which was removed by a copious enema. Proceeding with the examination I found the parts very hot and exceedingly painful to the touch. The uterus seemed to be unusually low in the pelvis and was somewhat enlarged. The os was not dilated at all. In the cul-de-sac an oval, painful mass could be felt. This mass was soft and seemed to fluctuate like pus in an abscess. Rational signs of pregnancy were present. I could not satisfy myself with a positive diagnosis.

I gave an anodyne, ordered absolute rest in bed, with liquid diet. On the following day I found her quite comfortable.

Two days later her condition was worse than ever. I thoroughly sterilized a sound and carefully explored the uterine cavity, finding nothing. Dr. Joyce returned in the afternoon, and in consultation with him, everything was ruled out excepting ectopic gestation, which we believed must be the true condition, and operative interference the proper way to treat the case. She was sent to the Carney Hospital, December 19, 1898, just nine weeks from the date of her last menstruation.

REPORT OF FIRST OPERATION, BY DR. STORER.

On December 17, 1898, I was asked by Dr. F. L. Johnson to see at the Carney Hospital Mrs. J. L. Examination under ether showed the posterior pelvis filled by an apparently solid mass, with only one small area of doubtful fluctuation, the size of a ten-cent piece, directly behind the cervix. In the left pelvis a harder mass was to be felt that was adherent, while to the right was a movable tumor, rounded and somewhat smaller. The mass was so densely adherent to the uterus that it was extremely difficult, without the sound, to be sure that the fundus lay forward. The uterus was only slightly enlarged.

My diagnosis from the pelvic examination—not having heard the clinical history, and not seeing the patient until she was under ether—was that it was a case of old salpingitis with much exudate. Examination without ether must in this case have been quite hopeless. As at that time I was trying to persuade myself that the vaginal route offered advantages over the abdominal, and also perhaps because I did not have the patient's consent to a laparotomy, I determined to attack the mass by the vagina. On incising the posterior vaginal wall I came at once upon black, shining peritoneum, which when opened gave vent to several ounces of sweet blood. The finger then came upon a hemothecoele nearly filling the pelvis, and a

rounded mass that was apparently the gestation sac. I met great difficulty in bringing this down, as the patient's vagina was extremely small and the hemothecoele very much in the way, and as now manipulations were causing free hemorrhage and the patient beginning to be in very poor condition, I packed the pelvis with gauze and opened the abdomen. A large amount of fresh and old clots were turned out and the left tube, which was somewhat adherent, was found to be ruptured and bleeding freely though not alarmingly. The tube and ovary were removed. The fetus was not found. In spite of the entire lack of previous preparation for an abdominal operation, and in spite of the immediate preparation being of the most superficial nature owing to the probability of active hemorrhage being present, convalescence was as uneventful as if the most elaborate aseptic precautions had been observed.

I regret very much that I cannot show you the specimen of this pregnancy, but as I had no reason to suppose that the case would be one of especial interest it was not preserved. As I remember it the sac was about the size of a walnut, situated near the middle of the tube. I examined the other tube and ovary very carefully, having in mind a paper I had read a few days previously in which the writer advised that the other ovary should always be removed to avoid the possibility of an ectopic pregnancy on the other side. But as the right appendages were apparently perfectly healthy, except that the large old blood clot was adherent to the ovary, I decided to leave them for two reasons. I felt that being a young woman recently married she was entitled to at least the chance of giving birth to a child, and furthermore, I did not have her permission to sacrifice both ovaries.

HISTORY OF SECOND ECTOPIC PREGNANCY, BY DR. THURBER.

Mrs. L. came to my office on the 20th day of May, 1899. She informed me that menstruation had been regular after the operation, but that she had now passed her period about one week and thought she must be again pregnant. Presumptive signs of pregnancy were present, morning sickness, etc. She was feeling well and had no complaints to make, but wished to place herself under my care as soon as she found herself to be in an interesting condition. I felt quite sure I could make out Hegar's sign, and ventured a positive opinion that she was pregnant, and asked her to notify me at once if anything went wrong. Two days after her visit to the office, the 22d, she sent for me. She had a slight pelvic pain which soon passed off after administering an opiate.

On May 24th I received another call. At this time there was a slight hemorrhage but no pain, although there was some tenderness over the lower part of the abdomen, and, as in her previous illness, the left side was the more tender to pressure. I could make out nothing satisfactorily. She stayed in bed, and by the next day the hemorrhage had ceased. She was comfortable on the following day.

My next visit was in the early morning of the 27th, and I tried again to find the cause of the trouble. Her temperature and pulse were normal. In the cul-de-sac there could be found a small mass, very tender when pressed. This mass was soft and oval, and did not feel much unlike the fundus of a retroflexed uterus. I presume my previous experience with similar condi-

tions in this patient led me to believe that ectopic gestation was repeated.

The next day, the 28th, Dr. Storer, in consultation, confirmed my diagnosis and advised her immediate removal to the hospital for operation. She was admitted to the Carney Hospital that afternoon, six weeks from the date of her last menstruation.

REPORT OF SECOND OPERATION, BY DR. STORER.

On May, 1899, five and one-half months after the previous operation, Dr. Thurber asked me to see Mrs. L. again, as she thought that she had another extra-uterine pregnancy. Examination now showed a somewhat enlarged, retroflexed and rather soft uterus with a prolapsed and somewhat thickened tube. There was no exudate or boggy mass. The diagnosis of an extra-uterine pregnancy was made more from the history of the previous attack, the recent symptoms and the foul flow rather than from what I felt in the pelvis, which without the history to guide us suggested a retroflexed gravid uterus as much as anything. I have often noticed a similar hardness of the cervix in gravid retroflexions, from disturbances with the blood supply probably. I advised immediate removal to the Carney Hospital. After my previous experience with the vaginal route in this patient I had no desire to try it again, and so opened the abdomen at once. The uterus was found retroflexed and adherent with rather fresh adhesions, and the prolapsed tube showed a fusiform enlargement at about its middle. A considerable amount (half a basinful) of free blood and clots was found in the pelvis, all of which was perfectly sweet. The tube was found to be practically unadherent, and on bringing it up carefully it was found to be intact, but blood was coming from the ostium in rapid drops. I removed the tube, but left most of the ovary stitched close to the stump of the tube, not wishing needlessly to remove the only remaining ovary in so young a woman. Although there was in my mind some question as to its subsequent nutrition, Nature had no trouble in attending to that. I tied this tube off with chronicized catgut; and the many cases in which tubes have become patulous, no matter how carefully they have been tied off, will naturally cause me to ask Dr. Thurber to watch this case with great care to see whether a third pregnancy ever takes place. There is really no great reason why she should not become pregnant again, and from the shortness of the tubal stump the chances are that another pregnancy would be uterine rather than interstitial. Menstruation, I may say, took place after the patient left the hospital in normal amount, and has continued as usual and without pain, although she has no tubes.

According to Dr. Whitney's report upon this second specimen, it will be seen that he is unable to state with any certainty that he found any evidences of an extra-uterine pregnancy, but the clinical picture of the case given by Dr. Thurber fits in so perfectly with the gross conditions present in the abdominal cavity that I think we are justified in regarding it as one, especially as some cells were found recalling very strongly decidual cells, and as there were no symptoms of any previous inflammatory condition in the pelvis. Dr. Whitney's report was as follows:

MARCH 25, 1900.

DEAR DR. STORER:—The specimen of the tube and portion of the ovary consisted of the fimbriated end of the tube for about 4 or 5 centimetres, which was opened and

to the inner surface was adherent a small, firm clot of blood about 5 millimetres in diameter. The outer surface was also roughened and a few clots adherent. Microscopical examination through the wall and attached clot showed the papillary folds of the tube of about normal size, but with enlarged lymph spaces, prominent blood vessels and here and there a little hemorrhagic extravasation. The blood clot seemed to be in the outer part of the fold and looked as if it could have originated from the rupture of some of these vessels. At one place on the wall, just beneath the adherent clot, was a little clump of large mononucleated cells with rather clear protoplasm, recalling very strongly decidual cells. But this was the only place that pointed to a change that could have been produced by pregnancy. Nowhere was there the slightest trace of chorionic villi, nor were the folds of the tubal mucosa infiltrated with small cells, as is frequently the case. A rather loosely attached piece of hemorrhagic tissue proved to be full of very many thin-walled blood vessels, which were also present in the adhesions on the outer surface. Aside from the one little group of large, decidual-like cells, there is nothing which proves the condition of pregnancy. The hemorrhage can be explained by the rupture of the enlarged vessels in the folds of the tube and from the thin-walled ones associated with the chronic inflammatory process of the peritoneum.

Yours very sincerely,

W. F. WHITNEY.

That repeated extra-uterine pregnancy is of more frequent occurrence than was formerly thought is attested by the cases reported in recent years, but authentic ones are still sufficiently rare. Zangenmeister in a paper published last year has gathered together some 40 cases. A careful examination of the literature shows, however, that in only 17 was the condition proved by actual operation [J. Veit, 1889; Olhausen, Hermann, Abel, Beck, Harrington, Bennington, Frankenthal, Ross, Brosin, Kokman, Schoolfield, Falk, Dührssen, Zangenmeister (2 cases), Thomson]. To these may be added the cases of Winckel, who in 1888 demonstrated the specimens from a patient in whom he had destroyed an extra-uterine fetus in 1885 and again in 1888, and the case of Tait in which an operation for extra-uterine pregnancy was followed three years later by the death of the patient from the rupture of another extra-uterine sac. The number of surgeons to whose lot it has fallen to have had an opportunity to operate twice upon the same patient for this interesting condition is naturally extremely small, limited as far as I can find to the following: Veit, Olhausen, Hermann, Harrington [1893 (the first, and with the exception of Ross the only one in this country)], Ross, Brosin, Dührssen, Zangenmeister (twice), Thomson and myself. My case is also noteworthy in that she was in each case under the care of the same physician as well as of the same surgeon. In this case the diagnosis was naturally easy with the history of the first ectopic gestation to aid us, and I would emphasize the importance of a previous extra-uterine pregnancy as rendering more probable the recurrence of the condition should in a second suspicious attack any or most of the classical symptoms be wanting.

A patient who has been operated upon for extra-uterine pregnancy and in whom the other ovary has not been removed should be carefully warned of the extreme importance of reporting herself to her medical attendant should she go a single day over her normal period. The earlier the diagnosis can be made the better are the chances for the patient, and in a case in which extra-uterine pregnancy is suspected before rupture has occurred, the fact that the patient

had previously been operated upon for this condition would with me turn the scale in favor of immediate operation. I feel that nothing is gained by waiting for symptoms to develop. The removal of a tubal pregnancy before rupture of the sac offers no dangers in comparison to an operation after rupture has taken place with probable inflammatory results.

With the history of this case in view we are met with the question of whether or no it is the surgeon's duty in operating upon an extra-uterine pregnancy to remove the other tube or not, lest it later become the seat of another ectopic gestation. This question cannot be answered offhand, as many writers have done, that the other tube should be removed. Of course it by no means follows that pregnancy will ever take place in the other tube, although it is probable that the same conditions that produced a tubal pregnancy in the one tube also exist in the other. Any greater degree of mutilation than is necessary should be avoided. Should the woman be a nullipara (which is the case in about 1 case in 5 of extra-uterine pregnancies), and children be greatly desired, we should at least leave her to decide (should she be in condition to do so) whether she is willing to run the risks of a second extra-uterine pregnancy on the bare chance of giving birth to a living child. We can encourage her by citing the cases of Tait and Kokman, in each of which a normal pregnancy intervened between two tubal ones, and that of Dührssen, who reports 2 cases of normal pregnancy after operation for extra-uterine.²

It is, of course, possible that should the extra-uterine pregnancy be due to kinks, etc., in the tube, caused by inflammatory adhesions, as, according to most writers (Virchow, etc.), is generally the case, they may exist only on one side, or if bilateral they may in the course of the manipulations incident to the removal of the one tube be so broken up as to permit the free passage of ova from the ovary to the uterus. Our willingness to leave the other tube may, however, be modified by other considerations. Inflammatory bands which we may possibly break up satisfactorily are not the only causes of extra-uterine pregnancy. It may also be caused, according to Freund, by the persistence of the infantile convolutions, or by diverticula in the tube, or, according to Klob, in a failure in the normal peristaltic wave towards the uterus, or even in default of other cause upon which we can lay our finger, to a failure in the proper working of the cilia lining the tube due possibly to a catarrhal salpingitis. To be sure Webster argues very ingeniously that the site at which pregnancy takes place in these cases is determined by its being the seat of greatest receptivity — showing the greatest decidual reaction — probably because of some fault in development, but I think most observers still cling to mechanical causes as the most plausible explanation of ectopic gestation. Such cause may or may not be amenable to treatment; the tube may possibly be laid open and everted and straightened out if necessary or diseased portions resected. A case of mine shows well to what an extent plastic operations upon the tube are feasible:

R. G., twenty-two, one child two years previously; ill since then. In June, 1898, I resected a cyst the size of a small orange from the left ovary, together with about a third of that organ, and after removing the outer half of the catarrhal and cystic left tube

built a new ostium for it by suturing its mucous membrane to the peritoneum and divided the various peritoneal bands that bound it down so as to leave what was left of it a straight tube instead of being much twisted and kinked. The remnant of the ovary was stitched close to the ostium. On the other side the tube was apparently perfectly normal at its two extremities, but in its middle for the distance of an inch and one-half it was much thickened, convoluted and entirely impervious. This impervious portion was excised and the small proximal end of the cut tube introduced into the lumen of the larger distal part, and the peritoneal coats stitched together with two anchoring sutures from the proximal end running up through the wall of the distal part of the tube from within. Five small cysts of the right ovary were punctured with the cautery, and a ventrosuspension completed the operation. About a year later she became pregnant and last month gave birth to a child at St. Elizabeth's Hospital.

The question of the treatment of the other appendages, then, must in each case stand by itself, and the surgeon must decide from the conditions present whether he is willing to allow the patient, even knowingly, to run the risks of another extra-uterine pregnancy. In my case the tube that I left in the first operation had certainly no macroscopical appearances that would have suggested its likelihood to become the seat of another ectopic gestation. Should, however, it seem best to remove the other tube I would urge that at least one ovary be preserved, or a part of it, to avoid the discomforts of the premature menopause.

This case is also I think of some interest as bearing upon the vexed question of whether to approach an ectopic pregnancy in the early weeks from below or from above. In the first operation I had to abandon the vaginal route on account of free hemorrhage, stirred up by possibly unskillful manipulations. Be that as it may, I found I had to open the abdomen to stop the bleeding. In general terms I would confine the vaginal operation to women with a large pelvis, yet even in them should there be urgent symptoms of active hemorrhage I should personally prefer the abdominal route, being confident that with the aid of the eye I should be able to find the source of the bleeding and control it much sooner than if working in the dark. Under some conditions every drop of blood saved is of value. When the diagnosis has been made before rupture the vaginal route may have its advantages, and after rupture, when actual suppuration has taken place, it lessens the risk of sepsis and therefore may be preferable, especially as in such late cases the danger of active hemorrhage is not so very great, but even then I think that in every case of extra-uterine pregnancy in which the operator prefers to begin by the vaginal route he will be extremely wise to have everything ready for a celiotomy in case he should find it necessary to abandon the vagina in a hurry, and a celiotomy without proper preparation is not conducive to a surgeon's peace of mind.

THE MORTALITY OF HYSTERECTOMY FOR FIBROIDS.¹

BY F. H. DAVENPORT, M.D., BOSTON.

THE question of the mortality of any operative procedure has an important bearing upon the advice we give a patient who consults us for the relief of disease. It modifies very materially the advice given. How important it is depends upon the character of the disease present, as, for instance, in the case of ovarian tumors, where the outlook, if nothing is done for the patient, is absolutely unfavorable. In such cases we are therefore justified in taking great risks for the sake of cure. That was the state of affairs from twenty-five to fifty years ago, when abdominal operations were in their infancy. Then, even though the physician could not assure his patient that the operation was practically without risk, as he can today, he could still urge it, knowing that the risk of the operation was less than from the disease left untreated. The same is true of cancer today. Any operative measure, however severe, which holds out the least chance of success is to be advised.

The case stands differently with fibroid tumors. In themselves they are benign, that is, they do not necessarily endanger life. In their early stages they rarely give rise to any serious symptoms except hemorrhage, and even when they attain considerable size the symptoms may be unimportant. The frequency of their occurrence, their slow growth and the fact that in a large proportion of them hemorrhage is not an essential feature, has, in my opinion, led the profession to put too light an estimate upon their importance. The fact, too, that the operative measures for their removal were in the early stages of operative work accompanied by a considerable mortality has led to a very conservative course of action on the part of a good many surgeons. It could not fail to have a marked effect upon the opinion of the profession when so prominent an abdominal surgeon as Dr. Keith, of Edinburgh, only ten or eleven years ago, made the following statement: "Hysterectomy is a hazardous operation for the removal of a tumor that of itself rarely shortens life. For myself I have always had grave doubts if I were justified in performing such operations at all, especially hysterectomy, for the mortality attending this operation is out of all proportion to the natural history mortality of uterine tumors, and the results of it are out of all proportion to the benefits received by the few." These sentiments expressed the grounds which led Dr. Keith to abandon all operative treatment of fibroids in favor of the electrical treatment after the method of Apostoli, of Paris. There is no question but that the technique of hysterectomy has made great strides in the last de-

cade, and yet the mortality even then must have been, in the hands of Dr. Keith, a comparatively small one. He speaks of a fibroid tumor as one that of itself rarely shortens life. It seems strange that an observer of so large an experience could look upon fibroid tumors as such innocent affairs. In a series of cases, such as would naturally fall under the observation of a practising gynecologist, there must occur a certain number which would clearly demonstrate that fibroid tumors bring with them distinct dangers and not infrequently threaten life.

Before discussing the question of the mortality of hysterectomy for fibroid tumors, I desire to point out causes of danger which are operative in case the tumor is left alone. These are, first, hemorrhage. This may become a source of danger no matter what the size of the tumor, and it not infrequently happens that insidiously, and almost unconsciously on the part of the patient, a condition of anemia is produced which may affect the prognosis in case of operation, or exceptionally may be fatal. The second cause is the size of the tumor. A large tumor may so press upon the other abdominal organs as to induce serious disease. A third cause is death of a part of the tumor, from what is known as anemic necrosis. A fourth cause is the development of malignant disease in connection with the fibroid. It may be said that these are rare conditions, so rare that they need not really enter into the calculation in considering the prognosis of these tumors, yet, as will be seen later, they are found too often to be ignored. In the light of the occurrence of these various conditions, it seems almost absurd to speak of a fibroid as almost never shortening life. Such being the case with regard to these tumors if left to themselves, is it not our duty to revise our opinions with regard to their early removal? It is just here that the question of the mortality of operative measures is of importance. If, with the improved methods of operating now at our command, it can be shown that the mortality, if the operation is done in the early stages and at a time which the operator can select, is practically nil, should not we advise our patients to submit to such operation, and get rid of a condition which has such very serious possibilities if left to itself? In order to see what bearing my own statistics have upon this question, I have looked over the cases of hysterectomy for fibroids occurring in the last 100 abdominal operations which I have done for all conditions. I find that they number 19. This comprises both small and large tumors, and of these 19 cases 2 died. Both of these cases were large tumors which had existed for a great many years, and which presumably could have been successfully removed if taken earlier. The histories of these cases show some very interesting points.

CASE I. Mrs. A., fifty-two years old, married, two children, consulted me in July, 1898, for an abdominal tumor which began on the right side about twenty years ago. It grew slowly, but about six years previous to my seeing her had become so large as to occasion her a great deal of annoyance from its size and weight. She then placed herself under the care of an irregular practitioner, who promised her that he could cure her by such simple measures as massage, electricity and tampons. For six years she faithfully continued the treatment advised, all the time being buoyed up with the hope of relief which was always promised, yet all the time conscious that the tumor

¹ Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, March 28, 1900.

was slowly increasing. There had been slight hemorrhage, but it was not an important factor. There was some swelling of the feet and ankles. Her general health was fairly good and there was no especial trouble with micturition, defecation or digestion. She was not especially anemic. She was a small woman, and, by contrast, the size of the tumor constituted a great deformity. She measured 45 inches around the tumor at its largest circumference, distance from the sternum to the umbilicus $10\frac{1}{2}$ inches, and from the umbilicus to the pubes 13 inches. In view of the size of the tumor, which would render an operation hazardous, the fairly good condition of the patient, and the fact that if possible she wished to avoid an operation, it was concluded to postpone operative interference for the present. She was again seen in October of that year. There was a slight increase in the size of the tumor as shown by the measurements. Early in November she began to suffer from what seemed to be peritonitis. There was fever, increased pain and sensitiveness in the tumor, tympanites and inability to lie down for any length of time. The tumor sagged more and pulled upon the abdomen and the patient's condition was pitiable in the extreme. She could remain but a very short time in one position and it was hard for her to move without assistance. Her sleep was only in snatches, the longest period being half an hour. Two or three hours a night was all the rest she could get. There was a constant formation of gas in spite of large dejections. The abdominal walls became tense and shiny and she said she felt as if the skin were bursting. The veins in the lower abdomen stood out in cords as large as a pencil.

On November 15th Dr. Maurice Richardson saw her in consultation with me. In spite of the gravity of the situation, he felt that an operation held out her only chance, and it was therefore decided upon. The operation was done on November 17th. As her condition was so critical, and it was important to save all time possible, I asked Dr. Bennett, of New York, to superintend the anesthesia. Everything being ready for the operation, she was placed upon the table and anesthesia begun with nitrous oxide gas, for which ether was substituted as soon as unconsciousness occurred. Within three minutes after the beginning of the administration of the gas the operation was begun. On opening the abdomen there were evidences of acute peritonitis. The tumor was adherent extensively over its anterior surface, and there were small collections of turbid fluid at various points. The tumor had so filled up the pelvis that it was almost impossible to get any pedicle, so the capsule was split all around as low down as possible, and the tumor shelled out of its bed, and it and the uterus quickly removed, all bleeding points being clamped and tied as they appeared. Owing to the patient's enfeebled condition, the operation was hastened, and a large amount of shreddy fragments of the capsule and peritoneal surfaces was necessarily left adherent to the stump. As there was considerable oozing, and so much bruised tissue left, a Mikulicz gauze packing and drain were introduced and the incision closed except the lower two inches. The whole operation lasted fifty-five minutes, and the marvellous skill of the anesthetist was shown by the fact that less than two ounces of ether were used. The patient was in fair condition when put back to bed. At the afternoon visit her pulse was from 110 to 120. There

had been no vomiting, only slight nausea, and for the first time in years she was lying on her back without discomfort. The day following the operation an enema was given, with the result that enormous quantities of gas were passed. The patient complained of no pain, but was apprehensive and could not sleep. Quantities of serum oozed away from the abdominal wound. On the 19th, that is, two days after the operation, the drain was removed. A large amount of pink fluid without much odor was aspirated, and in the evening the abdomen was washed out and a glass tube inserted. The patient took nourishment freely, and the bowels moved at intervals. The temperature gradually rose, however. It reached 104° on the evening of the 19th. It was lower on the 20th, the patient's tongue was cleaner, and her general condition better. Following this, however, there was a gradual sinking of the patient. The discharge from the wound became very foul, the edges of the abdominal wound looked gangrenous, and in fact, it seemed as if there were no life in the abdominal wall. The appetite failed, the temperature gradually sank, while the pulse increased in rapidity, until the patient died on the morning of the 24th, just a week after the operation.

Dr. Whitney reported that the tumor weighed 32 pounds after being cut open and considerable fluid escaping. There was no evidence of any degeneration.

CASE II. Mrs. H., forty-two, no children, consulted me December, 1896. She first noticed five years before an abdominal tumor which had grown steadily, until now it was about the size of the pregnant uterus at term. The symptoms she complained of were irregularity of the menstruation, with more or less constant flowing, generally scanty. She had pain in the left side at night. For the last six months there had been a more rapid increase in the size of the growth, and greater weight. An operation for its removal was advised, and it was done on December 31st. The abdomen was opened, and the tumor, which was found to be free from adhesions, was removed in the usual way, leaving the cervix. On the right side the growth had pushed into the broad ligament, and had so dislocated the right ureter that it was cut when the broad ligament was tied off. As the upper portion was too short to be brought down and inserted into the bladder, an end-to-end suture of the ureter was made with fine silk. Fearing that the suture might not hold, and that there might be leakage of urine into the peritoneal cavity, a drain was employed. There was a good deal of shock following the operation. There was absolute suppression of urine for thirty-six hours. It then began to be secreted, and for the next two days there was a normal amount passed. Symptoms of peritonitis appeared, although apparently the suture of the ureter held, and the patient died from septic peritonitis on the fourth day.

These 2 cases whose histories I have given are the only fatal ones occurring in a series of 19, and it will be seen that they were both large tumors, presenting conditions which made the operations much more serious than if they had been smaller. Could these patients have been operated upon at an earlier stage there is very little doubt but that they would have recovered. The lesson that these cases has taught me is that there are distinct dangers in delay, and that a fibroid tumor which is giving rise

to symptoms should be removed, and that the mortality from such operations is practically *nil*.

The prominent feature and the element of danger in the 2 cases whose histories have been given was the size of the tumor. There are, however, as I have said before, other dangers which are no less to be feared. Thus in these 19 cases there were 2 where there was found malignant degeneration. I say malignant degeneration, though I believe pathologists are in doubt whether such cases are the occurrence of cancer alongside of a fibroid, independently, or an actual change of a fibroid into a cancer, with the probabilities in favor of the former. At least, Dr. Whitney says he never has seen a case where there seemed to be an actual change of one tissue into the other. Dr. Whitney's report of one is as follows: "The examination of the tumor of uterus removed June 11th showed a large fasciculated growth in the fundus, white and fibrous looking. The examination showed it to be a fibromyoma. The fundus of the uterus was enlarged, the cavity filled with a shaggy growth, and the walls extensively infiltrated with a soft, opaque new growth. Microscopic examination showed it to be made up of irregular masses of gland-like tissue in places filled quite solid with epithelial cells. The diagnosis is a fibromyoma combined with adenocarcinoma of the uterus."

The second case which showed a malignant change was a very interesting one. The tumor was about the size of a fetal head, and was of a multiple variety. One nodule had developed low down in the cervix, and it extended towards the left in the base of the broad ligament, so that its removal without cutting the ureter was almost impossible. A portion of it was therefore left. The greater part of the mass, according to Dr. Whitney's report, which I will not give in detail, was composed of nodules of varying size, which had undergone marked calcification, and at one part had become cystic, with rather gelatinous contents, and fragments of anemic necrotic tissue. In one small nodule projecting from the fundus there was a condition which, according to the microscopical examination, justified the diagnosis of a calcifying sarcoma, which Dr. Whitney did not regard as of a very malignant type. The patient returned home in a month, but there was a rapid growth of a malignant character in the course of a few weeks, and she died about four months after the operation.

It will be noticed that in the last case there was in addition to the other conditions a beginning anemic necrosis. This same change occurred also in 2 other cases, both large tumors, but both of which made good recoveries from the operation. One of them was distinctly septic before the operation, and it was undertaken only after a consultation and with grave doubts as to the outcome, but the recovery was absolutely uneventful.

To sum up these grave conditions incident to what are so often called benign and harmless tumors, we have 2 cases of death where the tumors were large, 2 cases of malignant degeneration, and 3 of anemic necrosis, 1 of the latter cases presenting malignancy as well. We thus have out of 19 cases 6 where life was threatened by the presence of these growths. With this array of possibilities before us it seems to me that when patients present themselves with tumors of moderate size, which are clearly causing symptoms which interfere with the patient's en-

joyment of life, that their removal should be urged. By this statement I do not mean that every fibroid tumor should be operated upon. Many give rise to absolutely no symptoms. They may either grow not at all, or so slowly that the menopause may be reached and the tumors atrophy, without in any way proving a source of disturbance. But when a tumor is causing hemorrhage, is causing pain and discomfort, is a source of embarrassment, as it well may be in a single woman, the operation may be prescribed, as not the only, but on the whole the best, course to pursue.

Modern methods of operating have lessened the weight of some objections; thus in young married women who do not contemplate with equanimity the loss of the uterus and an absolute end to all possibility of pregnancy, the hope that a myomectomy can be done may be held out. Increased experience shows that this may be done in the case of tumors of considerable size, and many a woman would be willing and glad to part with her tumor if she need not thereby lose uterus and ovaries.

I therefore find myself, as my experience in the history of these tumors, if left to themselves, enlarges, and the fear of a fatal issue in operating for small tumors lessens with improved technique, advising their removal at an early stage if symptoms are present. How strongly I urge the operation depends somewhat upon the circumstances under which the patient lives. If she is where I or some careful practitioner can watch her, and examine her from time to time, note the effect of any hemorrhage which may be present, observe the rate of growth of the tumor, and be prepared to operate or advise operation before the patient's general health has been undermined, I do not urge immediate operation so strongly. Should she desire an operation, however, I should accede willingly, as I believe a patient has a right to decide for herself in such a matter. In the case, however, of a patient who lives at a distance, who cannot be watched, and who cannot command skilled oversight or service, I should urge operation without delay.

HYSTERECTOMY FOR MYOMA IN AMERICA.¹

BY ERNEST W. CUSHING, M.D.,

Professor of Gynecology and Abdominal Surgery in Tufts University.

IN the development of the operation of hysterectomy America has had a large share, both by original inventions and by adopting and perfecting the work of Continental and British operators. Although the earlier surgeons worked in isolation, and in ignorance of the methods of each other and of European operators, yet during the last generation a constant succession of ambitious youths and of successful and mature surgeons has taken advantage of the unbounded courtesy of distinguished European operators, and especially those of Germany, to complete their education or to improve their practice, respectively, by observations in the great clinics of the Old World.

A complete review of the evolution of hysterectomy in America would be too voluminous for this occasion and the writer would refer to an article already published by himself on that subject.² It may suffice to

¹ Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, March, 23, 1900.

² Evolution in America of Abdominal Hysterectomy and the Total Extirpation of the Uterus. *Zeitschr. f. Geb. u. Gynäk.*, 1896; *Annals of Gynecology and Pediatrics*, June, 1895.

point out the principal contributions of Americans to the development of this branch of our art and we find that the country which first gave to the world ovariectomy for tumors (McDowell, 1809) gave it also :

The first successful hysterectomy (mistaken diagnosis), Burnham, 1853.

The first intentional hysterectomy, success, Kimball, 1853.

A very early if not original use of the position, with the elevated pelvis, and head to the light, Noeggerath, 1873.

The first application of galvanism to uterine myomata, Cutter, 1874.

The first application to the treatment of uterine myomata of Battey's operation of ablation of the appendages, Trenholme, 1876.

Valuable modifications of the intraperitoneal method of treatment of the stump, Marcy, 1881.

A series of improvements in the technique of the extraperitoneal method of treating the stump by which intraligamentous tumors and those deep in the pelvis can be removed, J. Price and his pupils, 1886.

Total abdominal extirpation of myomatous uterus by use of clamps (first resuscitation of the operation in America since those of Freund had been abandoned), Jones, 1888.

First separate ligation of the uterine arteries in their continuity, and total extirpation by this method, Stimson, January, 1889.

Method of total extirpation by use of a staff, Eastman, 1889.

Total abdominal extirpation, fastening stump of vagina to abdominal incision, for prolapse, Polk, 1889.

Methods for making the stump intra-abdominal, but extraperitoneal, Polk, 1888; Kelly, 1890; Byford, 1890; Baer, 1892.

Total abdominal extirpation of the uterus with suppurating appendages as a matter of election, Baldy, Krug, Polk, 1893.

Enucleation of the stump as well as the myoma by the use of a serrated gouge, without severing the uterine arteries, Eastman, 1894.

Total extirpation of the uterus in cases of extra-uterine pregnancy, where the tube which is not pregnant is diseased, Krug, 1894.

A collection of the results of the work of thirty-five American surgeons up to 1895, including operations for myoma, cancer and salpingitis, showed that during this transition period, when operators were experimenting and learning their art, and while the aseptic technique was being introduced into our hospitals, out of 1,188 cases there were 164 deaths, or a mortality of 13.8%. Since that time there has been an enormous improvement, so that at present abdominal hysterectomy is comparatively a safe operation. In the hands of good operators there are often series of 60 or 75 or more cases without a death, and in the hands of general practitioners the mortality is lower than would be expected.

The changes in methods of performing hysterectomy for myoma may be briefly summarized as :

(1) Entire abandonment of the extra-abdominal treatment of the stump by *serre-neud* or rubber ligature.

(2) The wide trial and substantial rejection of vaginal hysterectomy, as an operation of election in cases of myoma and salpingitis.

(3) The establishment of indications for the retention of the cervix uteri, as compared with total extirpation of the uterus.

(4) The adoption of a method substantially the same by most operators.

(5) The disuse of drainage whenever possible.

(6) The common employment of the operation by general practitioners, operating in the small hospitals which are springing up in all towns in the country of 3,000 or more inhabitants. Each of these hospitals has from four to six visiting physicians and surgeons, among whom there are sure to be several desirous of performing surgical operations, and ready to attempt the most difficult ones, with a zeal often in inverse ratio to experience and training.

This generalization of the operation at present works to its disadvantage, but as each of these new hospital acts as a training school for surgeons, by degrees good surgery is diffused throughout the country; the ablest men come to the front and by the American system of individual initiative, free competition and the free judgment of colleagues in each locality, the benefits of surgery, and very good surgery, are brought within reach of multitudes who otherwise would be unable to obtain it.

Before performing hysterectomy for myoma the most careful operators take great pains in cleansing not only the abdominal wall and the vagina but also the uterine cavity, since the danger of infection is now almost wholly from the cervical, respectively vaginal, canal. Personally the writer is confident that this precaution has been the chief feature in reducing the mortality of the operation in his hands from some 10% to practically nothing.

The abdomen being opened, the tumor is brought outside if possible; the round ligament on one side is tied and cut; then the ovarian artery on the same side is tied and clamped and cut between ligature and clamp. By making an incision through the peritoneum covering the uterus, passing from the insertion of one round ligament, just above the limit of the bladder, to the insertion of the other round ligament, the bladder can be separated from the tumor; a similar incision is then made through the peritoneum on the posterior surface of the tumor, which can then be brought outside of the abdomen even in difficult cases. The broad ligament being now open it is easy to find and feel, or even to see, the uterine artery on one side. This is tied securely, and clamped close to the uterus, and cut between ligature and clamp. The cervix uteri is now cut across, some traction being exerted and the knife being directed obliquely downward, so that the part of the stump remaining on the uterus is wedge shaped. It is well, though apparently not essential, to disinfect the cervical canal when this is cut across, by pushing into it a sound wrapped in cotton soaked with peroxide of hydrogen or sublimate solution. The stump is then seized with double tenacula, so that the flaps are brought together—not including the peritoneal surfaces in the grasp of the tenacula. The incision is then continued until the cervix is nearly severed, when, just as the last of the muscular tissue is cut, the other uterine artery is seen and clamped, when the round and broad ligaments are clamped and divided and the whole tumor is removed. It only remains to tie the second uterine artery, and the arteries of the round ligament and the ovarian artery, on the side last cut and to unite the flaps of the stump with a continuous catgut suture in the muscular tissue, with a second layer of continuous serous catgut suture uniting the peritoneal surfaces. The two layers of the broad ligaments are then brought together with a fine continuous catgut suture, burying the ends of the uterine arteries with their ligatures.

The toilet of the peritoneum is made and the abdomen closed without drainage.

If it is thought best to remove the whole of the uterus, the operation is quite similar, until the first uterine artery is tied, but instead of cutting across the cervix uteri the incision is carried down at the side until the vault of the vagina is reached, clamping the lateral vaginal arteries as they are cut. Then with scissors the cervix is liberated, keeping close to the uterine tissue and clamping the posterior vaginal artery. The end of the vaginal portion is seized with double tenacula and lifted up and freed from the tissues on the other side, clamping the vaginal arteries and the uterine when it is reached. After applying mass ligatures of catgut to the small vaginal arteries and ligating the uterine artery carefully, the muscular walls of the vagina are united with a continuous catgut suture and above this the peritoneum is united with a seroserous continuous suture, when the operation is finished as above stated. If owing to the enucleation of subperitoneal masses, or for any other reason, drainage is desired, it is easy to pass a rope of gauze from above downward into and through the vagina, closing the sides of the opening in the vagina with sutures which close the lateral vaginal vessels and approximate the muscular and peritoneal surfaces and drawing the peritoneum which covers the bladder down to the incision in the vagina. Gauze drainage is, however, much less used than was the custom three or four years ago, the rule being to avoid drainage whenever possible.

The method of cutting across the cervix (Kelly), or removing it wholly (Pryor), before securing the second uterine artery is of advantage in rendering the operation more rapid and also because in case there are difficulties on one side, such as an adherent sacrosalpinx, or a mass of subperitoneal myoma, it is more easy to enucleate and remove such an obstacle after the uterus is liberated on one side and the cervix divided, for then the whole tumor can be more readily lifted out of the pelvis and whatever remains adherent can more easily be felt and seen. The operation is more satisfactory to perform and to witness if the surgeon is really skilful and dexterous and has an exact knowledge of his anatomy. For those in whom these qualifications are not very evident, and for all beginners in hysterectomy, it is safer to tie the arteries of the round and broad ligaments and the uterines on each side before dividing the cervix or removing it.

It remains to consider the indications for total hysterectomy in cases of myoma, as compared with leaving a portion or the whole of the cervix uteri. In general it is better to leave the cervix:

(1) Because it makes the operation shorter and easier and gives less chance of hemorrhage during the operation and does not open so much cellular tissue for oozing and decomposition of blood after the operation.

(2) Because there is somewhat less chance of infection of the wound where only the small cervical canal is cut across and instantly closed by the double tenacula than when the whole vault of the vagina is opened.

(3) Because the vaginal portion of the cervix is a seat of sexual feeling and worth preserving on that account, and if the cervix is present the women do not feel so much mutilated as when it is gone.

(4) Because the lower parts of the broad ligaments

with the cervix form a better support to the pelvic contents than does the simple union of the vault of the vagina.

Total hysterectomy should be performed: (1) When the cervix is enlarged and diseased; (2) when the cervical canal is suppurating or septic; (3) when there is any suspicion of malignant disease, and (4) when vaginal drainage appears desirable.

IMMEDIATE REPAIR OF PERINEAL TEARS.¹

BY E. S. BOLAND, M.D., BOSTON.

EVEN the frequency of these injuries and the troublesome effects associated therewith, or entailed thereon, would not justify me in presenting this matter to this section had not our honored chairman requested it.

Frequency.—While such injuries are more common in primiparae, they occur very often also in those who have already borne children. No figures are available, but probably 80% of all primiparae receive some degree of tear, and among multiparae at least 20% will have the same injury. It would not be exact to say that the injury is overlooked, for it is more often not looked for at all, for its occurrence has sometimes been regarded as a reflection on the skill of the accoucheur—a groundless belief in the main, as will be admitted by those who have observed carefully the progress and termination of many cases of labor.

Causes.—No theory of prophylaxis or treatment would be satisfactory without some consideration of the causes of these injuries. Excluding the cases due to precipitate labor, narrow pubic arch, disproportionate size of the fetal head or trunk, or faulty adaptation of the head diameters, to the pelvic outlet, it may be said that vaginal and perineal tears are due to imperfect distensibility of the soft parts at the pelvic outlet. The more advanced the age of primiparae after twenty-five years the greater the liability to tears. Given a labor of normal duration and normal presentation, the vulvar orifice ought to stretch enough to permit the delivery and then resume its original size and shape.

Degree.—The degree of tear will vary from a mere nick in the mucous membrane of the fourchette down into the rectum and to a greater or less distance up into the rectovaginal septum, with all intermediate degrees of extent, together with, at times, radiating tears from the more commonly longitudinal one, the frequency of tears to the extreme extent mentioned above being, of course, quite rare; while those about half through the perineal body and running from one to three inches up the posterior vaginal wall, and down or back on the cutaneous surface to within a half inch of the sphincter ani are quite common and are the ones which will need our help oftenest.

While the average direction of the tear is, roughly speaking, parallel with the long axis of the vagina, a considerable variation of the situation and direction of the tears may be evident on exposing the vagina. There may be a central perforation of the perineum if the latter is lax and the labor very forcible and quick, and the vulvar ellipse be unstretched and untorn. The injury may be in two parallel lines leaving a central ridge of the perineal body, or a divergent tear may run up the inner face of one or both labia.

¹ Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, March 23, 1900.

The latter tears are usually quite shallow. Sometimes a tear involving the vestibule may prove troublesome from the hemorrhage set up. Some ordinary tears bleed quite freely, also, and it is evident that more consideration ought to be given to this matter of hemorrhage for its own sake. How often must it be said that hemorrhage paves the way, while the raw surfaces of the tear opens the door, for septic invasion? The patient, while not always complaining much at first, soon feels the soreness of the tear and the suffering is intensified by the urine and lochial discharges. If cicatrization takes place without union there is apt to be some loss of functional capacity of the vagina sooner or later, and operation for late repair will involve the elaborate plastic work of flap splitting, butterfly denudation, etc., which is discouraging to the family physician as well as terrifying to the patient.

Prevention.—If what was said above as to etiology is correct, a sure rule of prevention of these injuries might be as briefly summarized as a description of the snakes of Ireland. No doubt those happy practitioners who never have these injuries occur, and who treat these tears by denying their occurrence, would be indignant at such a statement, but the fact remains that the man who attends the most cases will see the most tears—if he looks for them—no matter how skilled or experienced he may be. No doubt some tears are prevented or minimized by retardation of too precipitate labor, anesthetic relaxation of the soft parts, etc. Possibly the same end is advanced by perineal support, position of the patient and lateral incision of the vulva. What has helped me most has been manual dilatation of the soft parts during the first stage of labor, under partial anesthesia from chloroform. The forceps cannot be held accountable for tears when properly used, and some go farther and say that they are a means of prevention. This is no doubt true in so far as they prevent the devitalizing effect on the soft parts of too prolonged labor. If the practitioner has but a limited responsibility in the production of perineal tears, he cannot evade the obligation to promptly repair such injuries. No doubt union will occur if suturing is done within twelve or eighteen hours of the injury, but no one acts on this assumption in caring for scalp wounds. Better always to go prepared to do the immediate operation.

Treatment.—Theoretically a parturient tear does not offer ideal conditions for surgery. Asepsis, dryness, pressure and rest cannot be wholly attained, but we must not abandon attempts at repair because we get some failures. If carefully carried out, the immediate operation of suturing ought to give 90% of successes. The pressure that tore the parts acts to some extent as an obtunder of pain from the needle punctures, and an anesthetic is not a necessity. Anesthesia also requires additional assistance, which often means delays and added expense, a consideration among our honest working people. If promptly and carefully done, the tears heal readily, and before the usual nine or ten days' confinement to bed are past, the stitches can be removed in the same order in which they were put in. The value of the prompt restoration of the perineal body does not depend wholly on the after results, but also on the influence it exerts to minimize the risk of septic infection in the puerperium.

To the man in family practice, this accident occur-

ing at night, the lack of skilled assistants and the need of simplifying the operation have sometimes led to poor surgery, which may not be much better than the antique method of tying the patient's knees together. Some, recognizing the fact of a tear, are content to put in one or two stitches on the cutaneous aspect of the perineum. Sometimes the results from this procedure are satisfactory, but there is a good chance of getting only what has been called a "skin perineum."

If we recall the fact that any tear is apt to go farther up the vagina than it shows on the cutaneous surface, the inadequacy of merely skin sutures is manifest; besides, these end stitches constitute a veritable dam across the gutter-shaped tear, above which blood clots and lochia distend and possibly infect, and certainly prevent union when union is most to be desired. If the tear is short at the vaginal end, the suture can be carried from the skin surface up to the end of the vaginal tear and parallel with the sides of the tear, but far enough out of sight to be in sound tissue. It gives a purse-string action that may be sufficient, but for a long vaginal tear it is not good. If these injuries were external wounds, no one would think of treating them in any way except by the ordinary interrupted suture at right angles to the wound and placed deep enough and close enough to evenly approximate the surfaces throughout. The trouble to some has been the difficulty of illuminating the vaginal part of the tear. The obstetric bag, of course, contains the needles, needle holder, suture material and scissors. If to this is added the head mirror of the laryngoscope with head band attached, you will be ready for the operation at any time and place—in the darkest room provided a kerosene lamp is at hand, and no home except the very wealthiest is without one. Aseptic catgut and kangaroo-tail tendon have the advantage of absorption, and if good are admirable, but silk is good enough, and it has this in its favor—its removal gives you a good chance to see your result. The ends of silkworm gut are too irritating. With the above outfit sterilized, the suturing is not difficult after a little experience. The patient can hold the lamp for you at her flank or on her abdomen if no kindly neighbor is at hand. After an antiseptic douche, which had better be interuterine, and the manual removal of all remaining clots, vernix caseosa, semidetached tags and marginal hair, the vaginal walls are separated and steadied by the fingers of the left hand; the head mirror will throw a cone of bright light into the vagina with midday distinctness, and beginning at the upper end of the tear the sutures are readily placed, each in turn being cut when tied before another is put in. Some patients will complain, but it is surprising how well the majority submit to it in preference to being put on a table with some outside assistant and all the detail of anesthesia. The satisfaction of delivery (which no one can imagine who has not experienced it) seems to reconcile her to the lesser suffering of the suturing. If the rectum is involved it often gives less trouble than might be supposed and only in extreme cases will the elaboration of rectally placed suture be needed. It seems best to catheterize the first twenty-four hours after suturing even if the patient can void the urine voluntarily. Unless specially needed, and, if so, carefully given, the post-partum douches may be omitted after suturing. If the parts sutured have been devitalized by

severe and prolonged pressure the chances are bad, but aside from this condition the results are surprisingly successful, even uniting in the face of what seems like septic infection sometimes. Any radiating tears of labia, vestibule or vaginal sides can be sutured with lighter material, as they are usually superficial and generally unite firmly before the main, deeper tears. Ligating of vessels first is not often needed. In the removal of the vaginal stitches the same light is needed, and ear forceps and pocket scissors all that are required. Begin above and work down and out.

It is cruel to add another instrument to the outfit which we must carry, but the head mirror is so useful for other purposes that this will offset the trouble and occasional expense of a broken one.

Medical Progress.

REPORT ON PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

(Continued from No. 7, p. 165.)

THE TREATMENT OF INJURIES OF THE SPINAL CORD.

BOLTON⁸¹ makes the following summary of his method of treatment:

(1) Extradural hemorrhage does not give rise to cord lesions or symptoms, and requires no treatment.
