THURSDAY, MAY 3, 1877

THE UNIVERSITIES BILL

VERY little light has been thrown on the future of Oxford and Cambridge by the discussions in the House of Commons last week and this week. Harassed as they are by the difficulties of the Eastern question, our legislators could not, perhaps, be expected to devote serious thought to the fortunes of higher education in England, but as Mr. Knatchbull-Hugessen said, the debate was "certainly more suited to the debating societies of Oxford and Cambridge than to the arena of the House of Commons." Lord F. Hervey, who opened it, had little weightier to remark than that Mr. Grant Duff was "no doubt a very learned and superior person," and Mr. Grant Duff's chief contribution was the venerable witticism that Lord F. Hervey ought to be carried round the country by himself and other advanced reformers, as "the shocking example" of the results of the present system. Mr. Trevelyan delighted the House and the country by the amusing patriotic statement that "It would not be possible to find in any European University forty mathematicians equal to the Wranglers in the Cambridge Mathematical Tripos, or twenty classical scholars to compare with those who stood first in the Classical Tripos at Cambridge or in the School of *Literæ Humaniores* at Oxford;" and with an equally cheerful indifference to the facts Mr. Lowe replied that the teaching of the Universities was "simply disgraceful." When we add that there was much dispute whether the glories of Lord Macaulay, who was not "a resident fellow of Trinity College, Cambridge," should be credited to that University, and that Sir William Harcourt was delighted to hear that an overworked judge like Sir Alexander Cockburn could find time, in spite of his work, to undertake the arduous office of chairman, which would require the "constant and daily attention of one having entire and absolute leisure," we sum up most of what was interesting and novel in the discussion before going into Committee.

On two questions, however, which are of speculative importance, much incidental light was thrown. The Bill gives large enabling powers to the Commissioners, and although, as "An Oxford Man" pointed out in NATURE (vol. xv., p. 391), it is very doubtful whether large reforms can be effected even on the initiative of a strong-willed and clear-headed Commission; it is perfectly certain that little or nothing can be done if the Commissioners are feeble and without origination. In their preparation of schemes for each of the forty colleges they are to be associated with three residents from the college itself, and it is only from the colleges that they can get money to effect any reforms. It is important therefore to understand what are the views of the Government with regard to the reforms which are practical or possible, because it is to advance these views that the Commissions have been selected. Afterwards, everything depends on the Commissioners themselves, on the spirit in which they have undertaken their task, and on the diligence, ability, and discretion with which they are likely to execute it.

The Opposition offered no formal objection to any of the names proposed by the Government, but they suggested the addition of three names to the Oxford and of two names to the Cambridge list. For Oxford they proposed Prof. Bartholomew Price, Prof. Huxley, and Prof. Max Müller, and for Cambridge Dr. Bateson, the master of St. John's College, and Dr. Hooker, the president of the Royal Society. The addition of these names would have greatly strengthened the Commissions, and those who are anxious to see the Universities question treated in a generous spirit and with a wide knowledge of the subject might have been reasonably hopeful of good results. To our mind it is a fatal objection to the Commissioners as they stand that they include no members who are not alumni of the Universities on which they are to sit. Prof. Huxley and Dr. Hooker would have been of the utmost service, because they would have approached University questions from the point of view of men whose lives have been spent outside the Universities. It is certainly important for the Commissioners to have a practical acquaintance with working details, but that would surely have been sufficiently guaranteed by the presence of nine University men on each Commission even though one outsider had been added to each. Prof. Huxley has sat on the Scotch Universities Commission, and has had the largest experience of teaching at unrestricted institutions like the School of Mines and South Kensington. Dr.

Hooker and he would have strengthened the hands of those who wish to see science represented in our higher education, and the addition of their names would certainly not have upset the balance of the Commission, as Prof. Price, Dr. Bateson, and Prof. Max Müller, would have adequately maintained the interests of the older studies. Surely, when we are setting about the reform of our universities, we want all available information about the systems of foreign countries, and Prof. Max Müller could have told the Commissioners many things they have not learnt from their own experience of Oxford and Cambridge. The refusal of the Government to add any names to the original list was an unfortunate sign of the spirit in which they have framed it, and of the attitude in which the Commissioners will face the problems before them. Ministers were successful, but their majorities were so small as to show that the sense of the few members who will not consent as partisans to vote on such questions was decidedly against them. They carried their point by 11, 34, 24, 26, 32 votes on the successive divisions. After their success nobody will care much what becomes of a bill which is meant to change as little as possible, when every crevice that could let in light from the outside world is carefully stopped against it.

The speech of the Secretary of War, who is Member for the University of Oxford, and the general tone of the debate, clearly confirm these anticipations. There will be a slight restriction of the "prize fellowships," the new Government name for the "idle fellowships" of Lord Salisbury. There will not be a great extension of the professoriate, provision even having been made for the amalgamation of several professorships into one. Some money—5 per cent. from some colleges, 10 per cent. from others, nothing perhaps from a third class—will be taken from the colleges for university purposes. There is a provision "for the extension, not for the suppression," of scholarships. Only the superfluities of the colleges are to go to the University, and Mr. Hardy has never had but one opinion on "what some people called the endowment of research." He did not state that opinion so frankly as Mr. Trevelyan, but there was little doubt from the tone of his remarks that it was substantially the same :—

"It was a mistake, therefore, to assume that we could create in men such qualities by merely endowing old men, and in his opinion it would be better to throw the funds of the Universities into the sea rather than to bestow them in the manner which had been proposed. The people whose prayers the House should listen to were the practical teachers of the University, who were bound to celibacy, and who asked them to make their career a better one, to give them a reasonable income, and to allow them to marry without being compelled to resign their positions. These gentlemen would have six months in the year, which they would be able to devote to the pursuit of science and literature. What they had to do was to find men for the places, and not places for the men. He begged them to consider well before they created a sort of hierarchy of sinecures and semi-sinecures which unless human nature was radically altered by this Bill would only lead to academical jobbery and intellectual stagnation."

No doubt the wholesale conversion of the fellowships of residents and, for that matter, of non-residents into professorships, created in a doctrinaire spirit, and apart from the gradual development of literature and science, would be recklessness and folly. Nobody in his senses wants such a thing. The real note of despair in the whole debate is that Oxford and Cambridge wish to be let alone, and Oxford and Cambridge men in the House are determined that they shall be let alone to consider every question as it comes up from the mere local point of view of Oxford and Cambridge. The jealous exclusion of outsiders is the surest proof of the intention of the framers of the bill and the clearest prophecy of its issues.

The Committee made no real alterations in the bill. There was a desperate attempt to maim it by striking out even the possibility of endowments for research. It was resisted and defeated by an overwhelming majority. Mr. Hardy said "the noble lord and the hon. gentleman seemed to be under the apprehension that if research were brought into the University education would be driven out. On the contrary, he held that no teaching could be successful that was not founded on the most minute research. There were, no doubt, many subjects of research which by their nature were not lucrative to those who prosecuted them but the prosecution of which was of great importance to education throughout the country, and especially to the University in which they were carried on. There was, however, no intention to carry research to the extravagant lengths which some speakers and writers feared would be the case, and which would utterly pervert the purposes of the University. So far from diminishing the educational power of the University, that which was proposed would give to education a more solid basis than it now possessed." Mr. Trevelyan accepted Mr. Hardy's statement as "in all respects satisfactory," and added a remark none the less valuable that it is almost a truism, "They could not have a University where education was proceeding without research proceeding at the same time." The Commissions will thus be left at liberty to use the funds they can detach from the Colleges for the endowment of research. But "Researchers," as Prof. Sylvester calls them, will not for many years to come, grow very fat on the good things of Oxford and Cambridge.

DEEP WELL-BORINGS IN LONDON

THE constantly increasing wants of our English metropolis were very amply provided for during all the earlier stages of its history by the stores of water contained in the extensive beds of gravel lying within the Thames Valley. These stores of water could be reached by means of shallow wells, and all the ancient and famous pumps of our city drew their supplies from this source.

But, as the population of the district increased, the value of this source of water-supply became greatly impaired from two causes; firstly, the excessive drain upon it, caused by the rapid multiplication of wells; and secondly, the pollution of its waters by the refuse-matter of a great city.

Hence it became necessary to seek for new sources of water-supply, and the success which had already attended the construction of Artesian wells in the Tertiary districts of Northern France, led to attempts being made to obtain supplies in a similar manner by putting down borings through the impervious London Clay into the water-bearing beds of the Lower London Tertiaries.

For a time the quantity of water thus obtained, as at Merton, Garrett, and many other points, seem to have induced the belief that an inexhaustible source of the all-essential element had been discovered; but the rapid multiplication of these Artesian wells soon revealed the fact that the new and valuable stores had their limit, and that this limit was being very rapidly approached in consequence of the excessive demands which were now being made upon the new source of supply. The deepening of the wells, by which means water was drawn from the Chalk, as well as from the Tertiary strata, promised, however, to do something towards staving off the evil day when London would no longer be able to depend on drafts being honoured by her great subterranean bank.

Such was the state of the question when Mr. Prestwich, now the Professor of Geology in the University of Oxford, undertook its complete investigation as an important geological problem. No one more competent for the task could possibly have been found, for during many years Mr. Prestwich's studies had been devoted to the Tertiary deposits of the London and Hampshire basins; and his great work—"A Geological Inquiry respecting the Water-bearing Strata of the country around London, with Reference especially to the Water-supply of the Metropolis," which was published in 1851—is a masterpiece of minute observation and close and accurate reasoning.

More than this, the geologist points to the work with pardonable pride, as affording convincing proof that his science has now acquired a character for exactness, analogous to that which is justly regarded as the crowning attribute of astronomy. After a most elaborate study of the nature and relations of the various strata which crop out all round the London Basin and of the disturbances to which they have been subjected since their deposition, Mr. Prestwich ventured on a bold *prediction*, namely, that the Chalk beneath London would be found to have a thickness of 650 feet, the Upper Greensand of 40 feet, and the Gault of 150 feet. (*Op. cit.* p. 142.)

At the time when this announcement was made no well in London had been sunk to a greater depth than 300 feet in the Chalk, but now we can appeal to no less than four deep borings in the metropolis, which afford the most convincing proof of the reliability of the data, and the accuracy of the reasoning by which Mr. Prestwich arrived at his interesting results. For the sake of distinctness, we place the estimated and determined results side by side in a tabular form:—

Mr. Prestwich's Estimate.		Boring at Kentish Town.	Boring at Crossness.	Boring at Loughton.	Boring at Meux's Brewery.
Chalk	650	645	646	650	653
Upper Greensand	40	13¼	12	40	28
Gault	150	130½	148	(?)	159

When it is remembered that the Chalk graduates downwards insensibly into the Upper Greensand, and that it is almost impossible to decide on their line of separation in the cores brought up by boring operations, it will be admitted on all hands that the agreement between the estimated and proved results is marvellously close.

One of the most important conclusions of Mr. Prestwich's work was that the strata below the Gault, the so-called "Lower Greensand," would in the future afford a most valuable underground source of water-supply to our overgrown city.

But in 1855 Mr. Godwin-Austen brought before the Geological Society of London his masterly essay "On the Possible Extension of the Coal-Measures beneath the South-Eastern Part of England," in which he announced the conclusion—based on a most elaborate study of the geological structure of the South of England and the adjoining portions of the Continent of Europe—that an old ridge of Palæozoic rocks underlies the line of the Thames Valley, and is only concealed from us by the Upper Cretaceous strata.

Mr. Godwin-Austen's announcement was as strikingly verified as was that of Mr. Prestwich; for, in the same year that it was made, a boring at Kentish Town which passed through the Gault, reached a curious series of red rocks which are now believed by geologists to be either a portion of the old Palæozoic ridge itself, or a set of littoral deposits formed upon its flanks. And in 1857 the deep boring at Harwich afforded still more unmistakable evidence of the existence of this old Palæozoic ridge in the fact that black slaty rocks were found immediately below the Gault clay.

Although the old ridge of Palæozoic rocks must thus limit the area of the available water-bearing "Lower Greensand" beneath the metropolitan district, yet Prof. Prestwich has constantly argued that very large and valuable supplies of water will yet in all probability be obtained from the latter source.

Hence it is that the endeavour to tap this great subterranean reservoir, which is now being carried out in such an enterprising spirit by the Messrs. Meux and Co., in the Tottenham Court Road, is attracting so much attention from geologists and engineers. The nodular beds at the base of the Gault were reached at a depth of 999 feet from the surface, and some sixty feet of rock below has since been penetrated. The splendid cores brought up by the diamond-borer are at once submitted to Mr. Robert Etheridge, the palæontologist of the Geological Survey, who is carefully studying every trace of fossils which they exhibit. At present there are very strong grounds for believing that the "Lower Greensand" has been reached, and we soon hope to be able to announce that the new source of water supply, so long ago pointed out by Prof. Prestwich, has at last been made available for the ever-increasing necessities of this great city.

J. W. JUDD

LATHAM'S ENGLISH DICTIONARY

A Dictionary of the English Language. Abridged by the Editor from that of Dr. Samuel Johnson, as Edited by Robert Gordon Latham, M.A., M.D., &c. (London: Longmans and Co., 1876.)

WE consider ourselves justified in reviewing an English dictionary in these pages for two reasons; first, because the method of its construction ought to be rigidly scientific, and second, because a large proportion of the words in any modern English dictionary must necessarily be scientific terms.

It is admitted by all competent to pronounce an opinion that there is ample room for a new dictionary of the

English language; that when Dr. Latham undertook the task for which his attainments so well fit him, he had an excellent opportunity for doing a splendid service to our tongue and making for himself a lasting name. The only dictionaries that make any pretence to exhaustivenesss, Webster's, Worcester's, and the Imperial, with all their merits, come far short of what an ideal national dictionary should be, and they cannot for one moment be compared with Littré's *magnum opus*. Webster's etymology is extremely unsatisfactory and misleading in its method, the vocabulary is a conglomeration on no principle, and the definitions are too frequently unmethodical. We consider Worcester in some respects more satisfactory, more scientific in its method than Webster. The Imperial is rather a small encyclopædia than a dictionary, minute description frequently giving place to definition, and the vocabulary being much fuller than that of any existing dictionary. This feature, however, seems rather to be the result of a desire to crowd in as many words as possible than of any well-considered scientific plan. The etymology of the Imperial might almost have been written a century ago. Thus Dr. Latham had a splendid field before him, and Littré has shown what one man is capable of doing in the way of dictionary-making. We need not for the hundredth time contrast his work with the endless pottering of the French Academy. Perhaps it scarcely needs to be proved that in the construction of a dictionary, as in most other great undertakings, failure will surely be the result unless one competent man has the supreme command.

The work before us is an abridgment of Dr. Latham's larger work in four quarto volumes. The abridgment has been made mainly by the omission of the illustrative quotations which form so large a feature in the larger work, and of certain disquisitions on extremely minute points which occur during the progress of the work. Many will be of opinion that the omission of the latter is distinctly beneficial; they are too frequently little else than laborious trifling. The omission of the quotations is, no doubt, a disadvantage; they bear the same relation to and throw the same light on the definition that specimens do in the case of geology and experiments in other sciences. A very few have been retained, and it would have been an advantage had there been many more, as there might easily have been had the various meanings under each word been run on instead of being paragraphed.

Dr. Latham calls his dictionary a new edition of Johnson; if it were only this it would be at once a confession that the work was an anachronism. To bring the heroic old compiler's work up to date would require quite as much labour as Johnson bestowed on the original; and as Dr. Latham's work has so much that is new in all departments, we must regard its title as mainly an act of courtesy to the memory of "the great lexicographer." As the abridgment contains all the vocabulary of the larger work, the two in this respect may be regarded as identical, and from its size and price, the larger work is evidently meant to be a practically complete English dictionary.

Dr. Latham's vocabulary is of course much more extensive than that of Johnson. He has read largely in modern works in all departments of literature and science, and thus been able to register many words that did not exist in Johnson's time, as well as many new meanings that have been given to old words. The consideration of vocabulary is probably the most serious that comes before any one who sets himself to the laborious task of compiling a dictionary. His duty is certainly to set down all words used by reputable writers. But is this all? How far back is an English dictionary-maker to go? to Spencer or to Chaucer? Mr. Freeman might possibly say to "Beowulf." Who are to be considered "reputable" writers? Should only "reputable" writers be taken into account? And should no word that has not been printed in a regular way be admitted? How far should slang terms and provincialisms, including Scotticisms (*pace* Prof. Blackie) be admitted? Again, what is to be considered literature? Must all science be excluded, and the vocabulary be confined to such words as occur in poetry, *belles lettres*, history, philosophy? These and many other questions must be settled at the very outset by the compiler of a dictionary making any pretence to completeness, and we are glad to see that, to a considerable extent, Dr. Latham has settled them on the liberal side. His aim has apparently been to make a work that would be useful to people of wide culture and general reading, and he has interpreted the English language to be the language used by the people of England in expressing their thoughts on the varied subjects that engage their attention.

We are at a loss to discover the principle, however, on which Dr. Latham has compiled his vocabulary. He has certainly inserted a large selection of scientific terms, but the selection appears to us to have been made in a capricious and arbitrary manner. He has, for example, given many of the technical names of the divisions and subdivisions of the animal and vegetable kingdoms, but it is not easy to see by what clue he has been guided. Why should Raptores and Natatores find a place while Scansores, Insessores, and all the other avian orders are omitted? Is it that the two former have been detected by Dr. Latham in some "literary" writer, while he has failed to come across the latter? Even Amphibia and Amphibian find no place, nor the adjective Avian. We find Infusoria and Cetacea, and Monotremata, but no Rodentia nor Carnivora, nor a host of other names even more likely than those capriciously registered to be inquired for by readers of works of popular zoology. It is a very nice question whether this class of words should be admitted at all into an English dictionary, but if it be decided affirmatively the only satisfactory scientific method is to admit all. A generic name (*e.g.*, Dionæa) in this respect is quite as important as that of the largest subdivision in zoology or botany.

The defects of the dictionary are equally apparent in other scientific departments. We find Oolitic and Triassic and Drift, the last in some detail, but not Laurentian nor Cambrian, nor such a common word as Pothole. Biogenesis, Abiogenesis, Heterogenesis, and Bacteria are conspicuous by their absence; as are also Eozoon, Atoll, Globigerina, Hipparion, and Amphioxus: Lepidosiren is given in some detail. To Basin no geological meaning is assigned. Palæozoic (with a bare reference of Cænozoic and Mezoic) is found, but not Azoic; Permian, but not Devonian, Silurian, or Purbeck; Labyrinthodont but not Pycnodont. We have Protoplasma but neither Protoplasm nor Protoplasmic. Photosphere we find, but not Chromosphere, nor Corona in its solar application, and neither Heliostat nor Siderostat. The dictionary contains various terms in electricity and magnetism, but not Magneto-Electric, Electro-Biology, Quantivalence, Anode, nor Cathode. Darwinian and Darwinism, long since used as current common terms, find no place here; and no one would guess from the definitions of Evolution and Development the immense significance which these terms have assumed in recent times.

We could give many instances of similar caprice in the admission of scientific terms, but our space does not admit of it. But it is not alone in this class of terms that the vocabulary appears to us to be defective; many words are wanting which, we venture to think, any man of common sense would look for in a modern English dictionary of the pretensions of that edited by Dr. Latham. Under Mule a reference is made to the spinning-jenny, but under neither Spinning nor Jenny is the use of the term explained. Readers of Arctic narratives will look in vain for an explanation of Ice-foot and Ice-master, and the reader will not be surprised at the omission of Snider, Whitworth, and Mitrailleuse. Can any sound reason be given for omitting such a word as Croquet? And where are we to look for an explanation of such national terms as Over and Bye, if not in the most recent of English dictionaries, which registers the "cricketal" signification of Stump? The work is evidently not meant for circulation in America, if we may judge from the absence of all Americanisms, even those which have become current coin in the English tongue, such as Bunkum, Caucus, Mocassin. Might not such words as Ecchymosis and Deoppilation have been spared (who is likely to look for them?) in favour of some or all of the terms referred to. Many words found in Tennyson, Morris, and Swinburne are marked as "obsolete," showing the danger of using the epithet at all.

The etymology seems to us unsatisfactory. To words whose origin is simple and obvious two or three lines are sometimes devoted; while of others whose etymology is certain enough, but which it would have taken some time and trouble to trace, no satisfactory information is given. What satisfaction is it to be told simply that Abandon comes from French *abandonner*, especially when the history of the word can be so beautifully traced? There is a like want of proportion in the definitions, which are in most cases extremely meagre, but in some cases capriciously and unnecessarily diffuse. In the arrangement of the various definitions under each word, moreover, we fail to discover, as a rule, any logical or historical method. In this as in some other respects Dr. Latham has stuck too closely to the old lines of dictionary construction, and missed the opportunity of compiling a work which might have cast all other similar works into the shade. We cannot say that it has dethroned either Webster or Worcester, unsatisfactory in many respects as these are; and there are two or three smaller and cheaper dictionaries, which we venture to think would be more useful to the general reader. The field is still unoccupied, for Dr. Latham's work can never, in our opinion, serve as the standard dictionary of our language. The work is handsome and well printed, and the "Historical Sketch of the English Language" is thoroughly satisfactory.

GUILLEMIN'S "WORLD OF COMETS"

The World of Comets. By Amédée Guillemin. Translated and Edited by James Glaisher, F.R.S. (London: Sampson Low and Co., 1877.)

MR. GLAISHER mentions that he was anxious that M. Guillemin's interesting work upon comets should appear in our language, from the fact of there not being so far any volume that occupied the ground covered by it, while, it may be added, that the recent important advances in this branch of the science renders a pretty complete summary of progress in late years a most desirable help and guide to the student, scattered as the reports of such progress almost necessarily are in the publications of scientific societies and in periodical scientific works at home and abroad.

The greater portion of the volume before us relates to those particular departments of the subject which may be expected to interest the general reader. The historical portion, especially in the earlier ages, when comets were regarded as omens, good or bad, to the time when Newton developed the laws by which their motions are governed, naturally commences the work: then follow chapters upon their orbits, the periodical comets from the short revolution of Encke's comet, to the revolutions of several thousands of years which have been assigned with a greater or less degree of probability to other of these bodies; more particular descriptions of several great comets in recent times, as the comets of 1744, 1811, 1843, 1858, 1861, and the great comet of Coggia in 1874, which made its appearance just prior to the publication of M. Guillemin's treatise. It is, however, in what we must term cometary physics that the volume is most complete, and in which its interest and probable usefulness will mainly consist. The theories of Olbers, Bessel, Faye, Roche, Tyndall, Tait, and others are noticed in a popular and readable style, and are fairly considered collectively, though differences of opinion must still prevail with regard to any inferences to be drawn from them. The researches of Dr. Huggins, Prof. Secchi, MM. Wolf and Rayet, in the spectral analysis of the light of comets, and particularly of Coggia's Comet of 1874, are described, and to these results, as collected by M. Guillemin, Mr. Glaisher has added an important article by Mr. Lockyer, which appeared while the great comet of 1874 was still visible, and in which are detailed the results of spectroscopic examination of the light of the comet with the aid of Mr. Newall's great refractor. The editor has also made some very desirable additions to M. Guillemin's chapter on "The Common Origin of Shooting Stars and Comets."

The work concludes with a list of elliptic comets and their elements and with a general catalogue of cometary orbits to 1876.

We have said that probably the chief interest and value of M. Guillemin's "World of Comets" will be found to consist in the extensive portion of his volume devoted to cometary physics, to the theories which have been advanced to explain their varied aspect, and the formation of the enormous trains by which some comets are accompanied. The comets of short period—a most interesting class—might well have been treated in somewhat greater detail, and in this division of the work we note several oversights. Thus it is stated that the researches of Dr. Axel Möller upon the motion of Faye's Comet, show that that body supports the theory of a resisting medium, first supposed to be indicated by Encke's investigations relating to the comet which bears his name; but as long since as the year 1865 Dr. Axel Möller had relinquished this idea, and from a rigorous discussion of the observations at the first three appearances, alluded to by M. Guillemin, had succeeded in representing the observations by the simple application of the planetary perturbations, without any hypothesis whatever, and his later researches have also negatived the existence of any trace of the effect of a resisting medium upon the motion of this comet. There is some ambiguity in the definition of the element π, or the longitude of the perihelion in the orbit of a comet; from the explanation given by M. Guillemin it might rather be inferred that the longitude is reduced to the ecliptic, which is not the case. The comet discovered by De Vico at Rome, February 20, 1846, is duplicated, appearing first on p. 140 with a revolution of fifty-five years, and again on p. 143 with a period of seventy-three years; the former period resulted from one of the earlier calculations. Pigott's comet of 1783 is named amongst the contents of a chapter p. 133, but there is no further reference to it. In the catalogue of orbits, there are several cases since the year 1866 where the inclination has been reckoned over 90°, as is frequently the case amongst the German computers, and with the unnecessary addition of the letter R in the column headed "direction of motion." To render these orbits consistent with the method hitherto in general use, and indeed adopted exclusively in the preceding part of the catalogue, the inclination given requires to be subtracted from 180°, and for the longitude of perihelion given in the fourth column, $2\,\Omega - \pi$, should be substituted.

These, however, are small defects which may easily be avoided in a future edition. As a whole, M. Guillemin's "World of Comets" must prove a welcome aid to the student on entering upon this branch of astronomy.

J. R. HIND

OUR BOOK SHELF

Fownes's Inorganic Chemistry. Edited by Henry Watts, B.A., F.R.S. Twelfth Edition. (London: Churchills.)

IN the present edition of this well-known manual the publishers have, wisely as we think, determined to divide it into two parts. In its old form the work had grown to be as unhandsome and cumbersome a volume as could be well imagined; like an overgrown yeast-cell it was obviously getting too big to hold together much longer, and many a student on his way to and from the lecture-room must have wondered, as he struggled to get the thick squat book into a comfortable carrying position, why the process of gemmation was so long delayed.

The present volume, which treats of physical and inorganic chemistry, contains a considerable amount of new matter, and may be regarded as an accurate representation of the present state of knowledge on these subjects. Among the more important additions we may mention an account of Mendeleeff's Laws of Periodicity, and a very good digest of what is known concerning the new metal gallium and its compounds; this element is associated with indium, with the probable atomic weight 68, as already indicated by M. Mendeleeff. The position of the cerite metals is also determined in accordance with the specific-heat estimations recently made by Hillebrand. On the other hand, it may be doubted if iodine tetrachloride has any real existence, and Michaelis has proved that the reaction $3PbSO_4 + 2POCl_3 = 3SO_2Cl_2 + Pb_3P_2O_8$ is not realised in practice. On the whole, however, the work fully maintains its reputation as a faithful exponent of the state of contemporary chemical knowledge. T.

The Microscopist: a Manual of Microscopy and Compendium of the Microscopic Sciences. Third edition. By J. H. Wythe, A.M., M.D. (London: Churchill, 1877.)

IT is now some twenty-five years since the first edition of this work appeared, and as the author himself remarks in his Preface, it is no small compliment to a work of this kind that for so many years it should hold a place among works of reference, although surrounded by larger and more pretentious volumes. For this third edition the book has been entirely rewritten, the advancement of microscopical science having naturally rendered considerable enlargements necessary. Still the work retains its principal qualities as before, viz., the precise and clear language, the absence of all unnecessary verbiage, and last but not least, the excellent arrangement of the contents. Thus after a brief reference to the history and importance of microscopy, we have able descriptions of the microscope itself and its accessories, followed by general remarks on its use and the more modern methods of microscopic investigation. Then, after a short chapter on the mounting and preserving of objects, we come to well-written and richly illustrated treatises on the application of the instrument in the different sciences, each science being spoken of in turn and in a separate chapter. For the beginner this arrangement is of special value, as it enables him quickly to form a general idea of the whole domain of microscopy. Mineralogy and Geology are followed by a chapter on Microscopic Chemistry; then the author treats of Microscopic Biology, devoting a chapter to Vegetable Histology and Botany, one to Zoology, the next to Animal Histology, and the last to Practical Medicine and Pathology.

The illustrations are original to a great extent; many also are taken from the works of Carpenter, Frey, Stricker, Billroth, and Rindfleisch. The larger plates, of which there are twenty-seven, are particularly well drawn, and add greatly to the general excellence of the work.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Hog-Wallows and Prairie Mounds

JUDGING from the descriptions of these deposits, they must be nearly, if not quite, identical with those which I described in a paper on "The Ancient Glaciers North and East of Llangollen," read at the British Association, 1865. These are a series of heaps of glacial drift covering more or less completely the habitat of Cheshire Cheese, *i.e.* the Vale Royal itself, and the slopes which extend from it to those Welsh Mountains that are so prominently seen from Chester. These mounds vary in size and shape according to their position. They are very well defined and numerous in the valley of the Alyn, between Wrexham and Mold, where they have the form of oblong hog-back mounds usually lying parallel to each other with their longer axes (if I may use the term) nearly at right angles to the general slope of the surface. They may be counted by hundreds, and in some parts are so near together as to form a series of connected undulations. They are largest and most abundant opposite the mouths of the lateral valleys opening into the main valley of the

Alyn. Their origin is well indicated in these positions, by the manner in which they lie opposite the mouths of the valleys at right angles to the course of the present streams.

The most remarkable of all these is a long ridge running parallel to the Great Western Railway near Gresford. It is marked and shaded on the ordnance geological map. Bailey Hill, Mold, is another. This is attributed to the Danes—described in the guide books as a Danish fortification. I have proved the glacial origin of these mounds by finding in them striated subangular boulders, that have travelled considerable distances; such, for example, as large blocks of the Llanarmon limestone, and rounded lumps of curly cannel, that must have crossed the ridge of the Hope Mountain, the height of which varies from 300 to 800 feet above the Leeswood and Tryddn valleys from which the coal must have been carried. On one occasion, during the construction of the Wrexham Mold and Connah's Quay Railway, I saw a large fire blazing in a navvy's shed, and upon examination found that the fuel was curly cannel they had found in making a cutting. They described this find as two pieces, each one "bigger than a man's head." I brought away an unburnt fragment of about 2 lbs. weight. It was a subangular corner, smoothed and faintly striated. The nearest cannel seam to this place—which is over the millstone grit—is about four miles, with the Hope Mountain intervening.

A curious example of the unexpected bearings of scientific investigations upon commercial interest was presented by these cannel boulders. Two or three years before I commenced the study of the ancient glaciation of this district, Mr. W. C. Hussey Jones had proved the value of this curly cannel as a source of paraffin, and what are called paraffin oils, &c. Great excitement resulted, and a great rush was made to "*the Flintshire eldorado.*" This curly cannel was sold at prices varying from twenty-five shillings to thirty shillings per ton at the pit's mouth, while the price of ordinary main coal was only six shillings. The owners of this cannel, or holders of leases or "tak notes," giving a licence to work it, made large sums of money (as much as 80,000*l*. was paid for the transfer of one lease), and consequently great search was made for new seams. Among the searchers were the farmers, landowners, and outside speculators, who commenced boring and sinking and forming companies for cannel mining in the region covered by these "hog wallows;" the evidence upon which their expectations were based being the discovery of pieces of cannel on or near the surface, turned up by the plough or otherwise. Many thousands of pounds were thus wasted. One very worthy man, that I knew very well—a hard-working Welsh farmer—spent the savings of a whole life-time in searching for cannel on his farm, where he had frequently turned up fragments in ploughing. His death speedily followed his ruin. There were many other similar cases. Had I commenced my investigations three years sooner I might have explained the strange and apparently incomprehensible anomaly of Leeswood cannel being found on the south side of the Chester and Mold Railway, and in the neighbourhood of Caergwrle, in spite of an intervening ridge of mountain.

One very curious and instructive feature of these mounds is their change of shape as we proceed from the hill slopes towards the great plain known as the Vale Royal, which was formerly a great estuary or fjord of the Dee. Instead of the long and rather steep hogback ridges we now find a general outspreading deposit dotted here and there rather sparsely with obtuse conical mounds, so obtuse and so much disturbed by agricultural operations that they can only be detected by careful observation.

My explanation of these differences is that the glacier which planed the millstone grit of the Hope Mountain by sweeping over and around it, originally spread out upon the waters of the estuary now forming the Vale Royal, and thus formed the outspread deposit; that it afterwards receded, and the icebergs that broke off and floated away from it were stranded here and there, thawed, deposited their contents, and thereby formed the mounds; while the oblong ridges mark the final step-by-step recession and oscillations of the dying glacier, which formed them partly as terminal moraines, and partly by ploughing up and thrusting before it, in the course of its advancing oscillations, the previously deposited glacial drift. I throw out these speculations suggestively, to be taken for what they are worth; they fit the facts well enough so far as I have been able to study them, but the main object of this letter is to direct attention to this and other corresponding deposits near at home that appear to me to be worthy of further investigation, especially by residents in the neighbourhood and the members of local field-clubs, &c. The Liverpool Naturalists' Field Club paid a visit to the district while I lived there, and I showed the geological members some of these deposits. W. MATTIEU WILLIAMS

Belmont, Twickenham, April 24

IT is apparent from Prof. Le Conte's description of the prairie mounds (NATURE, vol. xv. p. 530) that the drift mounds figured and mentioned by me (vol. xv. p. 379) have quite different origins. The prairie mound would seem to be somewhat similar and have the same origin as a tussocky bog or mountain. The formation of a tussocky bog has been described in "Valleys and their Relation to Fissures, &c.," p. 14. A tussocky mountain is similarly formed; very hot weather cracks the peaty upper soil forming deep fissures; while subsequent weathering changes the portions between the fissure into small hills. I lately saw on the coast of Wicklow a considerable area of Æolian drift of this hummocky nature; the hillocks being about four feet high. They were so regular as to have the appearance of being moulded from one model. These could not possibly have their origin in fissures; but they seemed to have a connection with bunches of bent, round which the wind collected heaps of sand. But again why should the bunches of this grass grow at regular intervals? In the same neighbourhood some of this Æolian drift is piled in long parallel ridges, about five or six feet high, and having quite an artificial look. These evidently are wind formed; but how it is hard to conjecture, as they run oblique to the prevailing and most effective winds. G. H. KINAHAN

Ovoca, April 24

Greenwich as a Meteorological Observatory

IN Mr. Buchan's objections to the hypothesis that the temperature of Greenwich is raised by the proximity of London one most important consideration has been omitted. Granted that the mean temperature of the summer months, June to September, is 0°·9 higher at Greenwich than at the eight other stations referred to, it does not follow that this alone is the cause of the higher average temperature at the former place. Greenwich occupies a position farther from the Atlantic and nearer the Continent than the majority of the selected stations, and we might therefore expect to find it subject not only to a higher temperature in summer, but also to a lower temperature in winter. If this be so, the excess which Mr. Buchan admits may be accounted for by the raising of the mean winter temperature from artificial causes; and this view of the case seem to be confirmed by observation. The station at Leyton, Essex, supplies the requisite data; for, although near London and rapidly increasing in population, it is, or rather was, in a country district when the observations were made. It is situated on the verge of Epping Forest, is separated from London by the Hackney Marshes, is rather more than 6¼ miles in a direct line from St. Paul's Cathedral, from which Greenwich is 4¾ miles distant, and is 7 miles nearly north of the last-mentioned place. The meteorological observations were undertaken with the express intention of comparing them with those at the Royal Observatory, with which object the instruments were mounted on a stand precisely similar to the Greenwich stand, and the exposure was unexceptionable. The comparison relates to the daily maximum and minimum temperatures for the three years ending November, 1863. The average was at Greenwich 50°·4, Leyton 49°·9. Allowing for elevation, the results are:—

				June to September	December to March	Maxima June to September	Minima June to September	Maxima December to March	Minima December to March
Greenwich...	51·0°	58·9°	43·0°	61·0°	41·9°	71·0°	51·1°	47·7°	36·1°
Leyton ...	50·2	58·3	42·1	61·3	40·8	72·0	50·7	46·9	34·8
Greenwich warmer than Leyton.	+0·8	+0·6	+0·9	−0·3	+1·1	−1·0	+0·4	+0·8	+1·3

These results prove that Greenwich is warmer than Leyton, which is farther removed from the influence of London, and that during the winter months the temperature is higher both by day and night, but chiefly by night, when the excess is 1°·3; also that in summer, while the nights at Greenwich are warmer than at Leyton, the days are cooler. The inference is that the artificial heat of London sensibly affects Greenwich, mostly by raising the temperature of the air in winter and at night, when it might be expected to do so with the greatest effect; and that the temperature at Greenwich by day in summer is depressed by the smoky atmosphere hindering the transmission of the sun's rays when they are most potent. H. S. EATON

Croydon, April 24

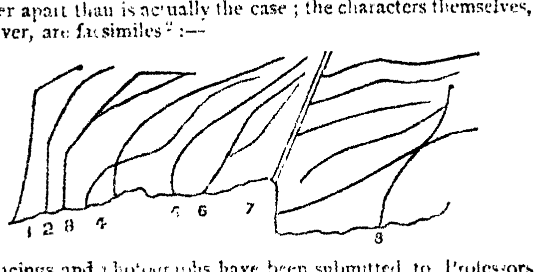
Ancient Characters at Cissbury

TWO years ago some marks were discovered at the entrances of galleries in one of the pits at Cissbury, which appeared to have been scratched on the chalk with a flint instrument. They were suspiciously like figures or masons' marks, but yet had all the tints of age, and resembled more or less early letters.[1] The little woodcuts  represent the forms with sufficient exactness. Other marks found shortly afterwards in a second pit were thought to be merely a trellis pattern. In attempting to cut them out of the rock, the chalk was broken into fragments, but fortunately rubbings had been previously taken.

The doubt as to the genuineness of the above marks was removed by the further discovery, in September, 1875, of a third set (again at the entrance of a gallery) in another pit at Cissbury Camp. They were arranged in two lines, the lower one presenting all the appearance of an inscription. A number of detached blocks, with distinctive marks upon them, were found in this pit amongst the rubble with which it was filled. One of these blocks, which was discovered about five feet below the surface, had four definite marks scratched upon it at even distances.

Up to the time that this third pit was opened no distinctive marks had been met with, except those above-mentioned, though there were many thousand accidental pick-marks on the walls and loose chalk.

I have now the satisfaction of mentioning that upon examining with more care the marks found in the second pit, the diagonal scratches of the trellis prove to be eight branching characters of a peculiar form. The vertical scores which cross them turn out to be later additions, cut with a finer tool than the serrated flint that has left its mark on the more superficial and broader lines of the characters beneath. In the following woodcut the vertical lines are not shown, and the rune-like forms are placed slightly further apart than is actually the case; the characters themselves, however, are facsimiles[2]:—



Tracings and photographs have been submitted to Professors Sayce and Rhys, and also to Dr. Haigh and other palæographists, who all consider the marks to be characters, though unable at present to give an opinion as to their date. But several on the detached blocks found near the surface, it is thought, may possibly be Anglo-Saxon.

Some of your correspondents may perhaps be able to say whether similar forms have been met with elsewhere. Can it be that the branching characters are examples of the symbols alluded to in the traditions of the Bards?

I may mention that Dr. Haigh thinks that the Celts had writing distinct from and earlier than the Oghams; and he has noticed on the stones of a sepulchral chamber at Keryaval, in Brittany, signs very like letters. J. PARK HARRISON

The Rocks of Charnwood Forest

IT has been a matter of regret to geologists that Mr. Plant has not published in some accessible form his stores of knowledge on Charnwood. We cannot tell how far our facts may be new to him, but we believe that we have been able to make considerable corrections in and additions to all contained in Jukes, Anstel, Coleman, or the Survey Memoir.

[1] *Journ. Anthropol. Inst.*, No. 18, p. 265.

[2] The last character, on the right of the inscription, has been corrected by lengthening the upper stroke. In the rubbing it was accidentally detached from the cross lines.

We are glad to find Mr. Plant supporting us on the intrusive character of the syenites. But the question can hardly be regarded as previously settled. Mr. Coleman leaned to the idea of their priority to the stratified rocks, Prof. Jukes to their being contemporaneous, and Prof. Ansted to their being metamorphic. When in NATURE (vol. xv. p. 97) Prof. Green suggested the first of these views no one adduced any proof to the contrary. Of all that Mr. Plant says we were well aware, but could not regard the evidence as conclusive. Our opinion is founded on the examination of actual contacts between syenite and sedimentary rock, a thing which so far as we know has not previously been described.

We are well acquainted with the very curious "altar stones" which are doubtless of volcanic origin, but these and the rocks of Bardon no more prove the Markfield syenite to be intrusive, than the ashes and breccias of the Borrowdale series prove the intrusive character of the Wastwater granite. Further, we cannot admit any connection between the Bardon "greenstones" and the Markfield syenite. T. G. BONNEY

St. John's College, Cambridge, April 28 E. HILL

Yellow Crocuses

SEVERAL years ago I observed that snowdrops which I had introduced into my garden were destroyed by poultry getting in among them at the hungry season when these are in blossom. I recollect placing a bantam cock in the garden, and observed that he pecked hastily at a few of the blossoms, and then left off. I then tore up pieces of writing-paper and spread them over the newly turned-up soil. These were hastily visited and as hastily dropped by a few of the poultry. Next I procured some Indian corn, and scattered it among the poultry for the first time. A few hens tried to swallow a grain here and there, but left the most of them. It required two or three days' experience to get them to feed on the Indian corn, and a very short time taught them to exclude snowdrop blossoms from their bill of fare. May not the case of the crocuses mentioned by Mr. Renshaw be explained as similar to that of schoolboys, who eagerly try a bright unknown berry and soon leave off when it is unpalatable? At least so I explained the fact of my snowdrops being more fiercely attacked on their first appearance in the garden than ever they have been since.

Our glen in a few weeks will be made beautiful by the blossoms of the bird-cherry, which grows plentifully on the margin of the streams and the waysides, attaining much larger dimensions than those given by Mr. Bentham in his "Handbook of British Flora," many of the trees being twenty feet high. The caterpillar of the pale spotted ermine moth feeds so eagerly on its leaves that I have, in some summers, seen the trees reduced to ugly skeletons by the middle or end of July. In autumn the beautiful red berries of the Guelder-rose adorn our thickets, but if "fruit has become beautiful so as to point it out to birds for the dissemination of the seed," we do not seem to have the birds which care for these berries, as only three weeks ago I pulled some fine clusters from a bush growing in a sheltered nook.

Tynron, Dumfriesshire, April 21 JAMES SHAW

INCLOSED is a letter that I had from my friend, Dr. Grierson, Dumfriesshire, a month ago, complaining of a pair of ducks that had gobbled up almost every one of his yellow crocuses, and only the yellow ones. I am further informed by Mr. John Young, Hunterian Museum, Glasgow, that the habit of the sparrows taking the yellow crocuses without touching the blue or striped has been long known to him. DAVID ROBERTSON

The Ship-Worm

Teredo navalis certainly is able to endure a long continuance of fresh water. At the town of Brisbane (Queensland), piles, &c., are sheathed with "Muntz metal" to prevent its attacks. The river is subject to long-continued freshes. I remember one which lasted at least ten days, and during that time ocean-going steamers could not ascend to the town, the flood was so powerful. Brisbane is situated far below the *extreme* salt-water flood, but whenever there is a fresh in the river, of even small amount, the water at that town is (according to my recollection) rather more fresh than salt at the end of each ebb tide.

I never saw *Teredo* there, but I took its existence for granted, from the fact that piles, &c., were protected with metal, and the caution given me by the builder of my boat against keeping her in the water when not in use. Brisbane is about twenty-five miles from the full influence of the Pacific, and, to the best of my recollection, the salt water is carried (on the flood) at least thirty miles up the river above the town, when there is no fresh coming down. So far does the salt water indeed extend, that at a time of severe drought (1865-66, I think) it was proposed to bring fresh water for the supply of the town from the principal affluent, the Bremmer, which joins the Brisbane about forty-two miles above the town, as it could not be obtained nearer on account of the high range of the salt flood. It was to have been brought in huge floating tanks towed by a steamer.

ARTHUR NICOLS

PROF. TYNDALL ON THE SPREAD OF DISEASE

PROF. TYNDALL occupied the chair on Saturday night at the concluding lecture of Dr. Corfield's course on the laws of health. The subject of the lecture was "Infectious Diseases." In proposing a vote of thanks, Prof. Tyndall paid a high compliment to the lecturer for the thoroughly sound instruction which he had so clearly conveyed. He had made it plain that contagion consisted, not of gas or vapour, but of definite particles sometimes floating in gas, in the air we breathed, or in the water we drank; and that, like organic seeds in the soil, they multiplied themselves indefinitely in suitable media, the great probability being that these disease-producing particles were living things. A close study of the subject, extending now over several years, enabled him to agree entirely with the lecturer in the parallelism which he had declared to exist between the phenomena of contagious disease and the phenomena of ordinary putrefaction. The case of flies, for example, to which the lecturer ascribed the power of communicating disease from one person to another, was exactly paralleled by phenomena in putrefaction. Chop up a beefsteak, steep it in water, raise the temperature a little above the temperature of the blood, pour off the water, and filter it; you get a perfectly clear liquid; but that liquid placed in a bottle and exposed to the air soon begins to get turbid, and that turbid liquid, under the microscope, is found to be swarming with living organisms. By suitably heating this perfectly clear beef tea, it can be sterilised, everything being killed which is capable of generating those little organisms which produce the turbidity; and by keeping it from coming in contact with the floating particles of the air, it might be preserved transparent for years. He had now some sterilised beef-tea of this sort, which had been preserved for eighteen months in a state of perfect transparency. But if a fly dipped its foot into an adjacent vessel containing some of the turbid fluid, and then into the transparent fluid, that contact would be sufficient to infect the sterilised infusion. In forty-eight hours the clear liquid would be swarming with these living organisms. The quantity of the turbid liquid which attaches itself to the finest needle-point suffices to infect any amount of the infusion just as the vaccine lymph taken up on the point of a surgeon's lancet spreads disease through the whole body. Here, also, as in the case of contagious disease, there was a period of incubation. In proof of what the lecturer had stated that the contagion of these communicable diseases was not gaseous or liquid, but solid particles, he would describe an experiment he had made only a few weeks since. Eighteen months ago he had a chamber prepared from which all floating particles of dust were removed, and in it he placed a number of vessels containing animal and vegetable refuse which soon fell into putrefaction, and also two or three vessels containing perfectly clear beef-tea and mutton broth, as transparent as water, in which the infective particles had been killed by heat. Although all these vessels had stood for eighteen months side by side there had been no communication of contagion from one to the other. The beef tea and mutton-broth remained as transparent as when put in, though the other vessels emitted a most noisome stench. But if a bubble were produced in one of the putrefying masses by blowing into it, and if on rising to the surface and bursting the spray of the bubble was allowed to fall into the transparent beef-tea or mutton-broth, in forty-eight hours it became as bad as its neighbours. It was not therefore sewer gas which did the mischief, but the particles which were carried and scattered by the sewer gas. Referring to another point on which the lecturer had insisted—viz., that there was no power of spontaneous generation of the germs or contagion of diseases, Prof. Tyndall said that, though at present great names were opposed to that view, he would venture to predict that ten years hence there would be very few great names opposed to the lecturer on that matter. With regard to the power of specific contagia to be generated in decomposing animal matter, he would say that for the last twenty-one years he had been in the habit of visiting the upper Alpine valleys, where, amongst the Swiss châlets, there was the most abominable decomposition going on from day to day, and exceedingly bad smells, but there these contagious diseases were entirely unknown. If, however, a person suffering from typhoid fever were transported there, the disease would spread like wildfire from this infected focus, and probably take possession of the entire population. It might be taken, therefore, that any of these special diseases required its special germ or seed for its production, just as you required a grape seed to produce a vine. He entirely agreed with all that the lecturer had stated as to these diseases "breeding true." He never found the virus of small-pox producing typhoid, or *vice versâ*. The subject was one of the most important which could engage the attention of the scientific physician—indeed, Prof. Tyndall doubted whether, in the whole range of medical art and science there was a subject of equal importance. But in dealing practically with this question of infectious disease, the scientific physician must not stand alone—he ought to be aided by the sympathy of an enlightened public. Here, in England, we did not like to be pressed into good behaviour by external influence; and if anything was to come in the way of really great sanitary improvement, it would be from the people themselves. Hence, in a people who were jealous of government interference, it was of primary importance that they should be properly instructed; and he did not exaggerate in the slightest degree in declaring that sound and healthy instruction had been imparted to them in the lecture which they had just heard.

SUSPECTED RELATIONS BETWEEN THE SUN AND THE EARTH

I.

WHEN the telescope first enabled us to scrutinise the solar surface, the spots thereby revealed formed a stumbling-block to some of the early observers, who were unwilling to attribute the smallest taint of imperfection to our luminary. And although the spots came speedily to be recognised as true solar appendages, yet until comparatively recent times they were looked upon as mere scientific curiosities, having no perceptible reference to ourselves, or indeed to anything else.

In the eyes of the last century astronomers the sun shone upon the earth and kept us in leading-strings, and this was an end of the whole matter. But we have now advanced one step beyond the position of those men, inasmuch as we have accumulated evidence tending to show that the physical state of the solar surface affects us in a variety of ways. With regard to some of these we are nearly certain, while with regard to others we are less so; in all we are profoundly interested, but we are not yet fully awake to a true measure of our responsibility or to the necessity of keeping a continuous watch upon the sun. It may perhaps be desirable here to review the somewhat heterogeneous mass of evidence from various quarters which leads us to believe in the existence of these peculiar relations.

Solar Spots, Magnetic Declination, and Auroral Displays.

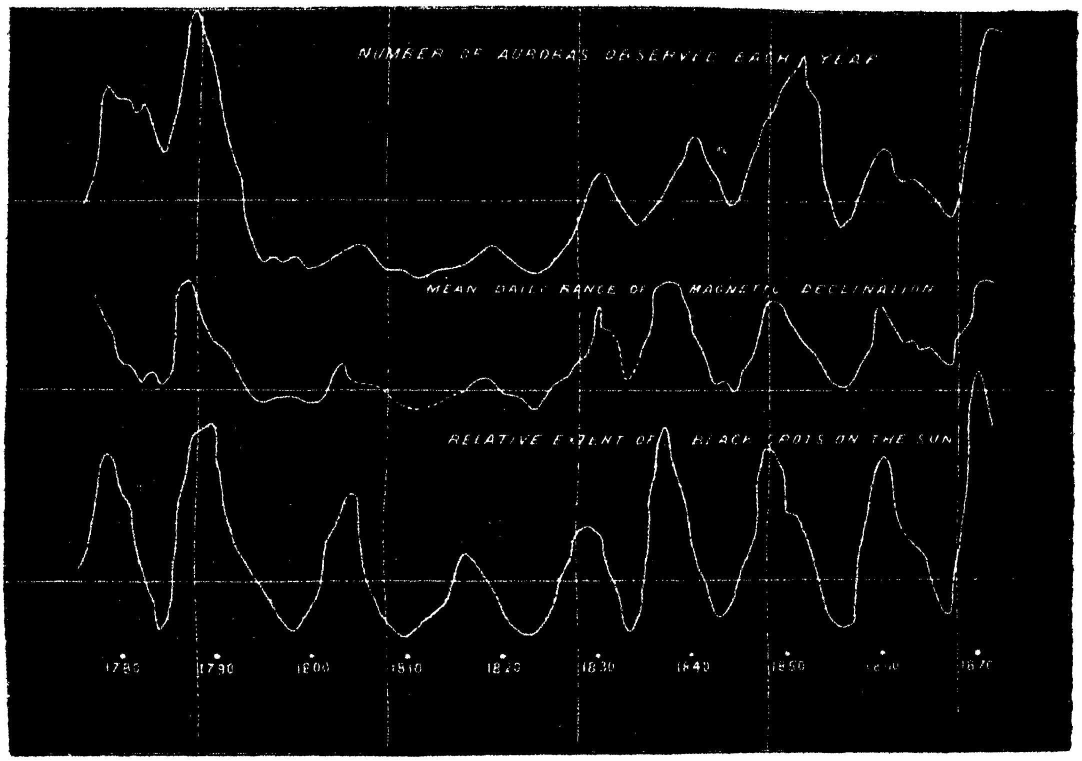


Diagram A

About fifty years ago a careful observer, Hofrath Schwabe, of Dessau, with true Teutonic persistence set himself to observe the sun's surface day after day, and as

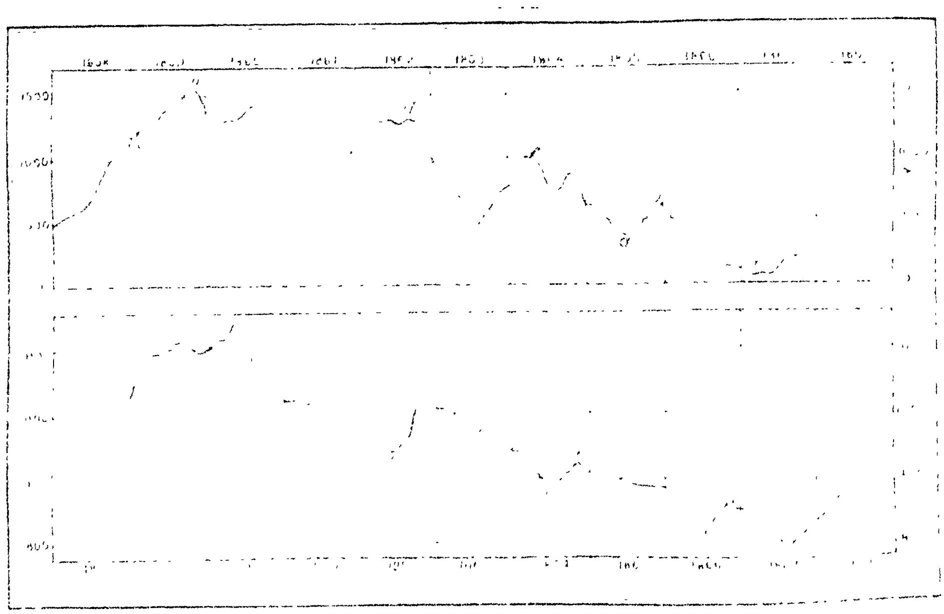

Diagram B.—The upper curve denotes sun-spot fluctuations, the lower curve magnetic fluctuations.

the discovery of a cycle in the frequency of spots. This

TABLE I.

Number of New Groups of Sun-spots observed each Year. The Observations from 1826 to 1863 were made by Hofrath Schwabe, the others were made at the Kew Observatory.

Year.	No. of new groups.	Year.	No. of new groups.	Year.	No. of new groups.
1826	118	1842	68	1858	188
1827	161	1843	34	1859	205
1828	225	1844	52	1860	210
1829	199	1845	114	1861	204
1830	190	1846	157	1862	160
1831	149	1847	257	1863	124
1832	84	1848	330	1864	113
1833	33	1849	238	1865	93
1834	51	1850	186	1866	45
1835	173	1851	151	1867	17
1836	272	1852	125	1868	115
1837	333	1153	91	1869	224
1838	282	1854	67	1870	403
1839	162	1855	38	1871	271
1840	152	1856	34	1872	186
1841	102	1857	98		

From which it appears that 1828, 1837, 1848, 1860, and 1870 were years of maximum, while 1833, 1843, 1856, and 1867 were years of minimum sun-spot frequency.

While Schwabe was observing the sun with praiseworthy regularity, Sir E. Sabine was likewise observing the magnetism of the earth. A freely suspended magnetic needle is usually thought to be very constant as to the direction in which it points, and this is no doubt quite true as far as large fluctuations are concerned. Nevertheless, between certain small limits it is always in motion—it has, for instance, a well understood oscillation depending upon the hour of the day, besides which it is also liable to irregular fluctuations that occur abruptly. Now Sabine perceived that these abrupt and spasmodical affections of the needle were most frequent in years when sun-spots were most frequent; and, furthermore, inasmuch as these fluctuations of the magnet are almost invariably accompanied with displays of the aurora borealis, he came to the conclusion that auroral displays occur most frequently in years of maximum sun spots. Our readers will no doubt remember the brilliant auroræ of 1870, which was likewise (see Table 1) a year of maximum sun-spot frequency.

What we have said refers to the spasmodical affections of the needle, but its diurnal oscillations are not less dependent on the state of the sun's surface.

Here also we have a maximum amount of fluctuation in years of maximum sun-spot frequency.

This near relation between sun-spots on the one hand, and magnetic oscillations and auroral displays on the other, is exhibited in Diagram A, which has been compiled by Prof. Loomis, the well-known American meteorologist.

Close and striking as is the relation between these three associated phenomena exhibited in the above diagram, the intimacy of this connection may be rendered even more obvious if we confine ourselves to such observations of the solar surface and of magnetic fluctuations as have been made with the greatest possible accuracy.

For this purpose Schwabe's eye-observations are not precise enough, and we must, as far as sun-spots are concerned, make use of some very accurate measurements of the solar spotted area made at Redhill by the late R. C. Carrington, along with the results deduced from the solar photographs taken at the Kew Observatory, under the superintendence of Mr. Warren De La Rue.

Again, as far as magnetic observations are concerned, let us employ the results derived from the self-recording magnetographs at the Kew Observatory.

Furthermore, in order to equalise oscillations of short period, let us plot a solar curve, each point of which represents the mean of nine months' sun-spot observations, and alongside of it a magnetic curve, each point of which similarly represents the mean of nine months' magnetic observations.

A comparison of this kind has been made by the writer of these remarks, the results of which were recently communicated by him to the Royal Society. These results are embodied in Diagram B, in which accurate sun-spot observations are compared with Kew declination ranges, that is to say, with the diurnal oscillations of a magnetic needle, freely suspended at the Kew Observatory.

A comparison of the two curves given above will show us that almost every prominent fluctuation of the sun-spot curve is represented in the magnetic curve, similar letters being employed to denote what appears to be corresponding fluctuations.

There is, however, a greater want of similarity for that part of the solar curve which is dotted, but this represents the results of eye-observations taken by Hofrath Schwabe, while the more accurate Kew photoheliograph was unfortunately out of action.

It will be perceived that the magnetic fluctuations invariably follow after or lag behind the corresponding solar fluctuations in point of time, the mean amount of this lagging being probably six months. We may therefore conclude from these comparisons that there is a very close and intimate relation between the physical condition of the sun's surface and the diurnal oscillations of the magnetic needle freely suspended at the Kew Observatory, and also that the former is probably the cause of which the latter is the effect, or at least that the magnetic change lags behind the corresponding solar phenomenon in point of time. BALFOUR STEWART

(*To be continued.*)

THE FRENCH TRANSIT MEDAL

WE recently announced that the Paris Academy of Sciences had presented an appropriate medal to those Frenchmen who were engaged in observing the recent transit of Venus, as well as to all the members of the Academy. By the kindness of the editor of *La*

Nature we are able to give an illustration of the principal face of this medal, the design being that of the artist M. Alphée Dubois. It will be seen that the artist has had recourse to mythology to represent under a graceful form the important astronomical phenomenon. Venus, in the simple costume of the goddesses, passes before the car of Apollo, the god of the sun, while Science observes the phenomenon on the earth and records the results. The legend is the composition of a member of the Academy of Inscriptions. On the obverse of the medal is the following inscription :—

INSTITUT DE FRANCE
ACADÉMIE DES SCIENCES
PASSAGE DE VÉNUS SUR LE SOLEIL
8-9 DECEMBER, 1874.

THE EFFECT OF INAUDIBLE VIBRATIONS UPON SENSITIVE FLAMES

DURING a recent visit to Birmingham my friend and host, Mr. Lawson Tait, showed me some interesting experiments with one of Mr. Galton's whistles, capable of yielding vibrations beyond the limit of hearing. This led to the suggestion of trying a sensitive flame with these whistles, and in fulfilment of my promise to select and send to Mr. Tait a burner sensitive to very high notes, I was yesterday led to make the following experiment, the result of which is, I believe, new, and I think sufficiently interesting to put on record. A sensitive flame was obtained just two feet high when undisturbed, but shrinking down to seven inches under the influence of the feeblest hiss or the clink of two coins. Adjusting the Galton whistle, which Mr. Tait lent me, so as to yield its lowest note, little effect was produced on the flame; a shrill dog-whistle produced a slight forking of the flame, but that was all. Raising the pitch of the Galton whistle, the flame became more and more agitated, until, when I had nearly reached the upper limit of audibility of my left ear, and had gone quite beyond the limit of my right ear, the flame was still more violently affected. Raising the pitch still higher, until I quite ceased to hear any sound, and until several friends could likewise detect no sound, even when close to the whistle, I was astonished to observe the profound effect produced upon the flame. At every inaudible puff of the whistle the flame fell fully sixteen inches, and burst forth into its characteristic roar, at the same time losing its luminosity, and when viewed in a moving mirror, presenting a multitude of ragged images, with torn sides and flickering tongues—indicating a state of rapid, complex, and vigorous vibration.

Nor was this effect sensibly diminished by a distance of some twenty feet from the flame. Placing the flame at one end of the large lecture theatre of this college, and blowing the whistle at the furthest point away, a distance at least of fifty feet and more than thirty feet above the flame, still the effect produced was very pronounced. There can hardly be a more striking experiment. A single silent and gentle puff of air sent from the lips through the whistle, nothing whatever to be heard, and yet fifty feet away an effect produced that might readily be seen by thousands of people.

The extreme smallness of the amount of motion actually concerned in producing this great change in the aspect of the flame is evident. For the inaudible vibrations, having at their origin but a small amplitude, gave rise to a spherical air-wave,[1] which at a radius of fifty feet—and with the vast enfeeblement due to this distance—knocked down a two-foot flame, though the surface acted upon had an area of less than a square inch—for it is only the root of the flame that picks up the wave motion. Of course everything depends upon the delicately-poised state into which the flame has previously to be brought. It then, like a resonant jar, enters into a state of vibration which appears to be synchronous with the note producing the effect. By this means it may be possible, with the aid of a mirror moving at a known speed, to determine the vibration number of these high notes, and thus with greater exactitude fix the upper limit of hearing.

The flame giving the effect here described was produced by coal gas contained in a holder under a pressure of ten inches of water, and issuing from a steatite jet having a circular orifice 0·04 inch in diameter.[1]

W. F. BARRETT

[1] I have no doubt a similar result would attend an experiment made in the open air, if the air were still enough to allow it to be made.

[1] The conditions necessary for obtaining the utmost sensitiveness of the flame are described in an article I published on the subject in the *Popular Science Review* for April, 1867.

SOUND-VIBRATIONS OF SOAP-FILM MEMBRANES

THE vibration-forms of membranes agitated by their fundamental and upper tones, have usually been studied by means of thin bladder or india-rubber stretched on a ring or frame (see Helmholtz "Sensations of Tone," chaps. iii. and v.; Pisko, "Die Neueren Apparate der Akustik," p. 75). While I was lately trying with Mr. R. Knight the capabilities of various membranes of taking impressions from vocal sounds for phonautographic purposes, the idea occurred of using soap-film. This was at once carried into effect by dipping the end of a lamp-chimney into some soap-solution, strengthened in the usual way with glycerine and a little gelatine. On singing near the open end of the chimney, the series of forms belonging to the various notes became plainly visible, those produced by the upper tones being as it were engine-turned in their complex symmetry, in a way to which the sand-lines on so coarse a material as caoutchouc can bear no comparison. To exhibit these forms at a popular lecture here last night, the light of an oxyhydrogen magic lantern was simply reflected off the vibrating film upon the screen in a disc of some three feet in diameter, so as to show its patterns on a large scale when set in movement by talking, singing, and playing a cornet in its neighbourhood. The effects were of singular clearness and beauty. To lecturers who may use this new and easy means of making the more complex sound-vibrations appreciable by the eye, I would mention that by slightly thinning the soap-solution, and adding a few drops of ammonia, they may obtain a film more free from interference-colours, so as to display the vibration-figures on an almost clear ground. But if this is done, the thicker mixture should be used afterwards, for the gorgeous scenic effect of the masses of prismatic colour whirled hither and thither by the musical vibrations.

EDWARD B. TYLOR

Wellington, Somerset, April 20

THE OTHEOSCOPE[2]

I COMMUNICATED to the Royal Society in November last, an account of some radiometers which I had made with the object of putting to experimental proof the "molecular pressure" theory of the repulsion resulting from radiation. Continuing these researches I have constructed other instruments, in which a movable fly is caused to rotate by the molecular pressure generated on fixed parts of the apparatus.

In the radiometer, the surface which produces the molecular disturbance is mounted on a fly, and is driven backwards by the excess of pressure between it and the sides of the containing vessel. Regarding the radiometer as a heat-engine, it is seen to be imperfect in many respects. The black or driving surface, corresponding to the heater of the engine, being also part of the moving fly, is restricted as to weight, material, and area of surface. It must be of the lightest possible construction, or

[2] On Repulsion Resulting from Radiation. Preliminary note on the Otheoscope, by William Crookes, F.R.S., &c. Read before the Royal Society, April 26, 1877.

friction will greatly interfere with its movement; it must not expose much surface, or it will be too heavy; and it must be a very bad conductor of heat, so as to retain the excess of pressure on one side. Again, the part corresponding to the cooler of the engine (the side of the glass bulb) admits of but little modification. It must almost necessarily be of glass, by no means the best material for the purpose; it is obliged to be of one particular shape; and it cannot be brought very near the driving surface.

A perfect instrument would be one in which the *heater* was stationary; it might then be of the most suitable material, of sufficient area of surface, and of the most efficient shape, irrespective of weight. The *cooler* should be the part which moves; it should be as close as possible to the heater, and of the best size, shape, and weight, for utilising the force impinging on it. By having the driving surface of large size and making it of a good conductor of heat, such as silver, gold, or copper, a very faint amount of incident radiation suffices to produce motion. The black surface acts as if a molecular[1] wind were blowing from it, principally in a direction normal to the surface. This wind blows away whatever easily movable body happens to be in front of it, irrespective of colour, shape, or material; and in its capability of deflection from one surface to another, its arrest by solid bodies, and its tangential action, it behaves in most respects like an actual wind.

Whilst the radiometer admits of but few modifications, such an instrument as the one here sketched out is capable of an almost endless variety of forms; and as it is essentially different in its construction and mode of action to the radiometer, I propose to identify it by a distinctive name, and call it the Otheoscope (ωθέω, I propel).

The glass bulb is an essential portion of the machinery of the radiometer, without which the fly would not move; but in the otheoscope the glass vessel simply acts as a preserver of the requisite amount of rarefaction. Carry a radiometer to a point in space where the atmospheric pressure is equal to, say, one millimetre of mercury, and remove the glass bulb; the fly will not move, however strong the incident radiation. But place the otheoscope in the same conditions, and it will move as well without the case as with it. In the preliminary note already referred to,[2] I described a piece of apparatus by which I was able to measure the thickness of the layer of molecular pressure generated when radiation impinged on a blackened surface at any degree of exhaustion. At the ordinary density of the atmosphere the existence of this molecular disturbance was detected several millimetres off, and its intensity increased largely as the generating surface and movable plate were brought closer together. It would be possible, therefore, to construct an otheoscope in which no rarefaction or containing vessel was necessary, but in which motion would take place in air at the normal density.[3] Such a heat-engine would probably work very well in sunlight.

Aided by the mechanical dexterity of my assistant, Mr. C. H. Gimingham, I have constructed several varieties of otheoscope. These I propose to exhibit at the *soirée* of the Royal Society on Wednesday next, as illustrations of the very beautiful manner in which, at this stage of my investigations, theory and experiment proceed hand in hand, alternately assisting each other, and enlarging our knowledge of those laws of molecular movement which constitute a key to the relations of force and matter.

The following is a list of the otheoscopes I have already made, together with some new experimental radiometers, which will be exhibited for the first time on Wednesday:—

1. *Otheoscope.*—A four-armed fly carrying four vanes of thin clear mica is mounted like a radiometer in an exhausted glass bulb. At one side of the bulb a plate of mica blacked on one side is fastened in a vertical plane in such a position that each clear vane in rotating shall pass the plate leaving a space between of about a millimetre. If a candle is brought near, and by means of a shade the light is allowed to fall only on the clear vanes, no motion is produced; but if the light shines on the black plate the fly instantly rotates as if a wind were issuing from this surface, and keeps on moving as long as the light is near.

2. *Otheoscope.*—A four-armed fly carries roasted mica vanes and is mounted in an exhausted glass bulb like a radiometer. Fixed to the side of the bulb are three plates of clear mica equidistant from each other in a vertical plane, but oblique to the axis. A candle brought near the fixed plates generates molecular pressure, which, falling obliquely on the fly, causes it to rotate.

3. *Otheoscope.*—A large horizontal disc, revolving by the molecular disturbance on the surface of inclined metallic vanes, which are blacked on both sides in order to absorb the maximum amount of radiation.

4. *Otheoscope.*—Inclined aluminium vanes driven by the molecular disturbance from the fixed black mica disc below, blowing (so to speak) through them.

5. *Otheoscope.*—A large horizontal coloured disc of roasted mica, driven by inclined aluminium vanes placed underneath it.

6. *Otheoscope.*—A bright aluminium disc cut in segments, and each segment turned at an angle, driven by a similar one below of lampblacked silver.

7. *Radiometer.*—A vertical radiometer, made with eight discs of mica blacked on one side, and the whole suspended on a horizontal axis which works in two glass cups. The motion of the radiometer is assisted on each side by driving vanes of aluminium blacked on one side.

8. *Radiometer.*—A vertical turbine radiometer, the oval vanes of roasted mica blacked on one side.

9. *Radiometer.*—A spiral radiometer of roasted mica blacked on the upper side.

10. *Radiometer* of large size, showing great sensitiveness.

11. *Radiometer.*—A two-disc radiometer, the fly carrying roasted mica discs blacked on one side; in front of each blacked surface is fixed a large disc of thin clear mica. The molecular disturbance set up on the black surface, and streaming from it, is reflected in the opposite direction by the clear plate of mica, causing the fly to move abnormally, *i.e.*, the black surface towards the light.

12. *Radiometer.*—A two-disc radiometer, the fly carrying roasted mica discs blacked on one side, similar to No. 11, but with a large clear disc on each side. The molecular disturbance, prevented from being reflected backwards by the second clear disc, is thus caused to expend itself in a vertical plane, the result being a total loss of sensitiveness.

13. *Radiometer.*—A two-disc, cup-shaped, aluminium radiometer, facing opposite ways; both sides bright. Exposed to a standard candle 3·5 inches off, the fly rotates continuously at the rate of one revolution in 3·37 seconds. A screen placed in front of the concave side so as to let the light shine only on the convex surface repels the latter, causing continuous rotation at the rate of one revolution in 7·5 seconds. When the convex side is screened off, so as to let the light shine only on the concave, continuous rotation is produced at the rate of one revolution in 6·95 seconds, the concave side being apparently attracted. These experiments show that the repulsive action of radiation on the convex side is about equal to the attractive

[1] *Molecular*, not *molar*. There is no wind in the sense of an actual transference of air from one place to another. This molecular movement may be compared to the movement of the gases when water is decomposed by an electric current. In the water connecting the two poles there is no apparent movement, although eight times as much matter is passing one way as the other.

[2] *Proc.* Royal Soc., November 16, 1876, p. 310.

[3] Since writing this I have constructed such an instrument. The movement takes place in the way I had anticipated.—W. C., April 20, 1877.

action of radiation on the concave side, and that the double speed with which the fly moves when no screen is interposed is the sum of the attractive and repulsive actions.

14. *Radiometer.*—A two-disc, cup-shaped, aluminium radiometer, lamp-blacked on the concave surfaces. In this instrument the usual action of light is reversed, rotation taking place, the bright convex side being repelled, and the black concave attracted. When the light shines only on the bright convex side, no movement is produced, but when it shines on the black concave side, this is attracted, producing rotation.

15.—*Radiometer.*—A cup-shaped radiometer similar to the above, but having the convex surfaces black and the concave bright. Light shining on this instrument causes it to rotate rapidly, the convex black being repelled. No movement is produced on letting the light shine on the bright concave surface, but good rotation is produced when only the black convex surface is illuminated.

16. *Radiometer.*—A multiple-disc, cup-shaped, turbine radiometer, bright on both sides, working by the action of warm water below and the cooling effect of the air above.

17. *Radiometer.*—A four-armed metallic radiometer with deep cups, bright on both sides.

18. *Radiometer.*—A four-armed radiometer, the vanes consisting of mica cups, bright on both sides.

19. *Radiometer.*—A four-armed radiometer having clear mica vanes. The direction of motion being determined by the angle formed by the mica vanes with the inner surface of the glass bulb.

DROUGHTS AND FAMINES IN SOUTHERN INDIA[1]

THE paper on this subject, noted below, a copy of which we have just received, will no doubt awaken much interest, not only on account of its scientific bearings but also from its bearings on so very practical a subject as the famines of India. It is most gratifying to see that the subject has been taken up by one who gives evidence on every page of rare capacity as a scientific statistician. There is throughout an absence of straining the facts before him beyond what they may legitimately bear, and a skill in combining them so as to eliminate, as far as possible, what is merely accidental from the results ultimately arrived at in their relation to the sun-spot period.

The data discussed in Dr. Hunter's paper are the amounts of the annual rainfall at Madras from 1813 to 1876, and the relative number of sun-spots from 1810 to 1876. The results of the inquiry are given in the following six propositions:—

1. That no uniform numerical relation can be detected between the relative number of the sun-spots and the actual amount of rainfall.

2. That although no uniform numerical relation can be detected between the relative number of sun-spots and the actual amount of rainfall, yet that the minimum period in the cycle of sun-spots is a period of regularly recurring and strongly marked drought in Southern India.

3. That, apart from any solar theory, an examination of the rain registers shows that a period of deficient rainfall recurs in cycles of eleven years at Madras; that this period consists of the eleventh and second series of years in the cycle; which two series also contain six out of the seven years of minimum sun-spots falling in this century up to 1878.

4. That after the period of minimum rainfall in the eleventh and second series of years in the cycle, the rainfall rises to a maximum in the fifth year; after which it again declines to its minimum period in the eleventh and second years.

5. That, apart from any solar theory, the statistical evidence shows that the cycle of rainfall at Madras has a marked coincidence with a corresponding cycle of sun-spots; that in this cycle of eleven years both the sun-spots and the rainfall reach their minimum in the group consisting of the eleventh, first, and second years; that both the rainfall and the sun-spots then increase till they both reach their maximum in the fifth year, after which they decline together till both again enter their minimum period in the eleventh, first, and second series of years.

6. That while the statistical evidence discloses a cycle of drought in Southern India, coincident in a marked manner with a corresponding cycle of sun-spots, it also tends to show that the average rainfall of the years of minimum rainfall in the said cycle approaches perilously near to the point of deficiency which causes famine. That the average is, however, above that point; and that, while we have reason to apprehend recurring droughts and frequent famines in these cyclic years of minimum rainfall, the evidence is insufficient to warrant the prediction of a regularly recurring famine.

It will be observed that these results are strongly confirmatory of the general conclusions arrived at by Meldrum and others, who have examined the question from data collected from a large area, and embracing an extended series of years, the only noteworthy point of difference being the larger rainfall of the first year of the cycle, as compared with the eleventh and second years which immediately precede and follow it. It is perhaps only to be looked for that such an anomaly should be met with in dealing with the rainfall of only one place, embracing a period of sixty-four years, seeing that the accidental occurrence of one or two cyclones, accompanied with unusually heavy local rainfall, would be sufficient to produce the anomaly in question. The anomaly would in all likelihood have disappeared if the area of observation had been wider or the time of observation longer. It is scarcely necessary to do more than point out the absolute necessity of establishing physical observatories in order to obtain the data for the investigation of the connection between the state of the sun's surface and the state of terrestrial convection currents, it being only through their cosmical relations that we may reasonably hope to solve many of the more difficult problems of meteorology, some of which lead to intensely practical issues.

[1] "The Cycle of Drought and Famine in Southern India," by W. W. Hunter, LL.D., Director-General of Statistics to the Government of India.

OUR ASTRONOMICAL COLUMN

MR. GILL'S EXPEDITION TO ASCENSION.—In an address to the Royal Astronomical Society on April 8, 1857, "On the means which will be available for correcting the measure of the sun's distance during the next twenty-five years," the Astronomer-Royal directed attention to a method of making observations for parallax, not applicable to the planet Venus, but applicable to Mars, namely, by "observing the displacement of Mars in right ascension when he is far east of the meridian, and far west of the meridian, as seen at a single observatory," and he particularised the advantage of this method, and expressed his opinion that it is "the best of all." The observations are not attended with the very great expense which is involved in the efficient observation of a transit of Venus, indeed if made at an established observatory need entail little or no cost; they may be conducted by a single observer or series of observers, in the latter case with a due regard to personal equation, and each observatory co-operating in the work, will furnish a result quite independent of the rest, so that the observer has the satisfaction of knowing that by the method recommended his own observations alone will give a value for the most important unit of measure in astronomy. The Astronomer-Royal confined his remarks to the observation of differences of right ascension, recommending as of the first consequence a firmly-mounted equatorial, and as advantageous though not absolutely necessary the chronographic method of transits first introduced by the American astronomers. The oppositions of Mars in 1860 and 1862 were referred to with regard to their relative advantages for such observations.

Mr. Gill has taken a further and an important step in the direction of utilising observations of Mars for the determination of the solar parallax. Encouraged by Lord Lindsay's liberal offer of the loan of the heliometer employed in the expedition to the Mauritius for the observation of the transit of Venus, Mr. Gill proposes to leave England this month for the island of Ascension, and to apply the heliometric method of measurement of distances instead of observing differences of right ascension, as suggested in the Astronomer-Royal's address, and as was stated in NATURE last week, the council of the Royal Astronomical Society have guaranteed 500*l.* for the expenses of Mr. Gill's expedition. Ascension has been fixed upon, not without a careful consideration of probable meteorological conditions about the time of the opposition of Mars in September, in which it is understood the records of the Meteorological Office have been of the greatest service, and in fact, have induced Mr. Gill to fix upon Ascension for the site of his temporary observatory in preference to St. Helena, the astronomical condition being about the same for the two islands, *i.e.*, their latitudes not differing much from the declination of the planet when nearest to the earth, so that it is observable at a considerable hour-angle on both sides of the meridian.

The *modus operandi* proposed by Mr. Gill, is as follows:—two stars, *a* and *b*, one preceding and the other following the planet, are selected for each night of observation, and their angle of position and distance relative to the planet are computed roughly for 4h. E. and 4h. W. hour-angle, and the right ascension and declination of the middle point between star and planet; so that the proper stars of comparison are readily found. The heliometer axis is directed to this middle point, the position-circle set to the position angle, and the segments set to the approximate distance. The observer finds in the field of view a star and the planet; by turning the handle by which the segments are moved in *distance*, the images of star and planet are made to move relatively to each other in the direction of a line joining the objects, while if the position-handle is turned, the images move in the direction of a line perpendicular thereto. Suppose that the star *a* is viewed through segment A, and the planet through segment B. According to Mr. Gill's usual practice the observation would proceed thus:—

I. Measure of position-angle.
II. Measure of distance, both limbs.
III. Reverse segments, and view star by segment B and planet by segment A.
IV. Measure position-angle.

This constitutes one measure.

V. Repeat this process with star *b*.
VI. Reverse position-circle and repeat the comparison with star *b*.
VII. Compare again with star *a*.

This constitutes a complete symmetrical set, which Mr. Gill has found can be secured on an average in 1h. 30m., sometimes in 1h. 10m., or if there be interference from cloud it may occupy 2h.

In the measure of a position-angle, by a movement of the handle for distance, the star may be made to move, relatively to the planet along the line of separation of the lenses, so that the star successively occupies positions 1, 2, 3 . . . 3, 2, 1, &c. This motion may be very slow and the position-circle being set so that the motion of the planet completes the bisection, the observer has only to go on moving the star slowly till the limb is seen to symmetrically bisect the star (the time of which is noted) precisely as Jupiter's limb bisects one of his satellites.

The measure of distance is conducted with equal care, but is not so readily explained without a diagram. Mr. Gill finds his method possesses very great delicacy. It sometimes happens that it is not possible to find a star sufficiently bright to compare with Mars in his full light. In such cases the brilliancy of the planet can be easily kept down by a wire-gauze screen, which, by an arrangement at the eye-end, can be laid over either segment of the object-glass and at any angle thereto.

In a letter to M. Leverrier, published in the *Bulletin International* of April 27, Mr. Gill states that the observations of Juno, which he made with Lord Lindsay at the Mauritius with the same heliometer, showed that the determination of the diurnal parallax by measuring with this instrument the distance of the planet from a star preceding and a star following is susceptible of an extreme precision, and he found the probable error in the determination of the planet's position for each complete observation of the morning or evening did not exceed ±0″·075. Lord Lindsay has stated that the value of the solar parallax, resulting from these observations of Juno (a single discordant one only being rejected) is 8″·82, which approaches near to Prof. Newcomb's value, 8″·85, adopted provisionally by the German astronomers, and to M. Leverrier's theoretical determination, 8″·86. This sufficiently indicates the utility of the method, and Mr. Gill intends to avail himself of the close oppositions of the minor planets Ariadne and Melpomene during his visit to Ascension to obtain values of the parallax by observation on the same principle.

COMET 1877 II. (WINNECKE, APRIL 5).—This comet may be expected to prove a fine telescopic object during the absence of moonlight in the circumpolar sky, with its stellar-looking nucleus and double or broad fan-shaped tail. The annexed positions for midnight at Berlin are from elements by Herr Plath, of Hamburg, and have been received from Prof. Winnecke:—

	R A	Declination.	Log. Distance from Earth.
	h. m. s.	° ′	
May 4	23 26 5	+65 59·2	9·99601
5	23 36 41	68 7·2	9·99640
6	23 49 22	70 11·6	9·99741
7	0 4 45	72 11·3	9·99902
8	0 23 31	74 4·5	0·00123
9	0 46 49	75 48·8	0·00400
10	1 15 34	77 21·5	0·00732
11	1 50 47	78 38·3	0·01116
12	2 32 59	79 35·1	0·01549
13	3 19 55	80 7·8	0·02028
14	4 8 57	+80 13·6	0·02548

The following orbit has been calculated by Mr. Hind from observations at Strasburg, on April 5 and 25, and at Berlin and Leipsic on April 14:—

Perihelion Passage, 1877, April 17·64687, G.M.T.

	° ′ ″	
Longitude of Perihelion	253 30 9	Mean Equinox, 1877·0
,, Ascending Node	316 33 53	
Inclination	58 54 22	
Distance in Perihelion	0·950250	

Heliocentric motion—retrograde.

These elements represent the observations during the interval very closely.

NOTES

M. FLAMMARION has been authorised by M. Leverrier to use one of the largest refractors of the Paris Observatory for the investigation of the motion of double-stars round a common centre of attraction. This liberality on the part of the chief of the Paris Observatory is highly creditable. M. Leverrier, indeed, is desirous of placing the immense means of investigation possessed by the observatory at the service of a number of independent workers not belonging to the staff of the establishment, but who have given solid proofs of their zeal and capacity for research in some particular science. His ambition is to create at the observatory a national astronomical institution where qualified scientific men may find ample means for following their own special studies.

SIR DAVID MONRO, late Speaker of the House of Representatives in New Zealand and an active promoter of science in that colony, died at Nelson, New Zealand, on February 15. He graduated in Medicine in the University of Edinburgh in 1834, where his great grandfather, grandfather, and father successively held the Chair of Anatomy. He devoted the leisure of an active political life to the pursuit of botany, and by his discoveries, which were published by Dr. Hooker in his "New Zealand

Flora," he added largely to our knowledge of the vegetation of New Zealand, on which he also wrote an instructive essay that is published in the first volume of the *Transactions* of the New Zealand Institute.

WE learn with the greatest pleasure that the Health Committee of the Police Board of Glasgow has agreed to carry out at eight stations in that city the system of continuous automatic observation of the constituents of the air, special attention being given to its impurities arising from manufactures and other causes which has been devised and worked out since March, 1876, by Mr. E. M. Dixon, in connection with Dr. Russell, Medical Officer of Health. The Committee has already expended fully 200*l.* in fitting up a laboratory and the observing stations with the instruments required, and are prepared to expend a sum of 300*l.* per annum in carrying out this very important practical investigation. The results, including meteorological observations made in connection with the scheme, will be published monthly, the first number appearing in June next.

GAY-LUSSAC, the great French physicist and chemist, was born in 1778, and his centenary will be celebrated by a festival and the erection of a statue either in Limoges or Paris.

A SERIES of lectures upon zoological subjects will be given in the Zoological Gardens, Regent's Park, on Thursdays at 5 P.M., after Whitsuntide. The first lecture will be delivered in the Lion House, and others in the lecture-room near the Reptile House. May 24: "The Lion House and its Inhabitants," P. L. Sclater, F.R.S; May 31: "Sea-urchins and Star-fishes," Prof. Huxley, F.R.S.; June 7: "Sloths and Ant-eaters," Prof. Flower, F.R.S.; June 14: "Whales and Porpoises," Prof. Flower, F.R.S.; June 21: "Man-like Apes," Prof. Garrod, F.R.S.; June 28: "Variation in Domestic Animals," W. B. Tegetmeier, F.Z.S.; July 5: "Hornbills and their Habits," Dr. Murie, F.Z.S.; July 12: "Birds of Prey," R. B. Sharpe, F.Z.S.; July 19: "Frogs and Toads," Prof. Mivart, F.R.S.; July 26: "The Ornithorhynchus," Prof. Garrod, F.R.S. These lectures will be free to Fellows of the Society and their friends, and to other visitors to the Gardens.

THE annual *conversazione* of the Royal Society was held at Burlington House on Wednesday week, and was numerously attended. There was a large collection of instruments brought together, among the principal of which were the following:—An Automatic Spectroscope, which can be used with 2, 4, or 6 prisms, solar eye-piece arrangement, and new split slit, whereby any lines in the spectrum can be measured; a Heliostat, with large crown-glass prisms, to be employed with the spectroscope; Governor for 18-inch reflector, which will keep time with a variation of rate of five seconds per minute, at pleasure; all designed and exhibited by Lieut.-Colonel Campbell, of Blythswood, and constructed by A. Hilger.—Prof. W. G. Adams exhibited an Apparatus for producing interference of light by means of thick plates, and Apparatus for the reflection and refraction of radiant heat and light, fitted to Clifton's optical bench, and constructed by Messrs. Elliott Brothers. The half-prism direct-vision spectroscope made for Greenwich, about which there has recently been a correspondence in NATURE, was also shown. Then there was a Hydroclinometer, an instrument for taking ranges, without any calculation, from coast batteries over 100 feet in height; a small hydroclinometer, a modified form of the above, for giving the inclination of slopes, &c., without any adjustment, and for larger guns; an electric position- and range-finder for coast batteries; a Field-Artillery range-finder; an Infantry range-finder; a patent self-adjusting optical square, which by a simple adjustment can immediately be corrected to the true right angle, without the aid of any other instrument; an electric chronograph, for the measurement of minute portions of time, velocities of shot, &c., by the *free* fall of a weight; these were exhibited by Capt. Watkin, R.A.—Lieut. G. S. Clarke and Prof. Herbert M'Leod showed an instrument called the Cycloscope, an apparatus for determining the speed of machinery by means of a tuning-fork or reed of known period; also for ascertaining the pitch of a tuning-fork by means of a cylinder rotating at a known speed. There were also Telephone and (patent) Thermo-electric Pile (in action), with specimens of Gray's telephone, exhibited by Messrs. C. and L. Wray; improved Holtz electrical machine with four plates and self-charging arrangement, in glass case, ready for use in any condition of the atmosphere, and Manometric apparatus, for showing effects of sound on a sensitive flame, exhibited by Mr. Ladd; teeth, bones, and ancient works of art lately found in caves in Derbyshire, exhibited by Mr. Boyd Dawkins, F.R.S.; specimens of cast and wrought iron treated by Prof. Barff's process for the prevention of corrosion, which consists in acting on iron at suitable temperatures with dry steam, exhibited by Prof. Barff; specimens of the core of well, from Meux's Brewery; the large induction-coil, with secondary wire of 280 miles, constructed for Mr. W. Spottiswoode by Mr. Apps (in operation), was shown in the meeting room, and Mr. Crookes's Otheoscope, of which we give an account this week.

ON Monday Prof. Boyd Dawkins commenced a series of eight Field Lectures on Geology at Owens College. Six of the lectures will be in connection with excursions to various places from Manchester.

MR. WILLIAM GOSSAGE, F.C.S., the inventor of several important processes in practical chemistry, died at Earlsleigh, Bowdon, Cheshire, on April 9, in his seventy-eighth year.

THE Council of the Royal Geographical Society have awarded the Royal medal to Capt. Sir George S. Nares, R.N., for having commanded the Arctic Expedition of 1875-6, and to Pundit Nain Singh, for having added a greater amount to our positive knowledge of the map of Asia than any individual of our time. In his first great journey he for the first time determined the position of Lhassa, the capital of Tibet, besides surveying the course of the great river Tsanpo, or Bramaputra, from near its source to near its entrance into the Himalayan region; in his last he traversed and surveyed the high Plateau of Tibet from its extreme north-west to Lhassa, a line of 1,200 or 1,400 miles of entirely new country. No reward was ever better earned than that bestowed by the Society on Nain Singh, who, indeed, deserves to be ranked among the first of explorers. While pursuing his arduous and dangerous work he was paid at the rate of 7*l.* per month, and now retires, satisfied we believe, on a pension of 50*l.* a year. Through his labours we have now for the first time a scientific basis on which to construct a map of Tibet. A gold watch, with an appropriate inscription, was at the same time awarded to Capt. Albert Markham, R.N., for having commanded the northern division of sledges in the Arctic Expedition of 1875-6, and for having planted the Union Jack in 83 deg. 20 min. 26 sec. N., a higher latitude than had ever been reached by any previous expedition.

IT is but a poor set-off to the horrors of war that it is a means of speading a real knowledge of geography; but that it does do so was shown in this country during the last Oriental war—the Crimean. As might have been expected, numerous war-maps have already appeared. The most satisfactory of these maps is a large one published by Mr. Stanford on the scale of fifty miles to an inch, including Turkey in Europe and her tributary states, together with such parts of neighbouring countries in Europe and Asia as are more immediately connected with the settlement of the Eastern Question. Any one wishing to follow the movements of the two armies could not obtain a better guide. All the physical and political features, including the railways up to date, are shown with great clearness. Mr. Stanford publishes two other war-maps, one on a smaller scale and at a cheaper price than the above, and Jankowsky's Russo-Turkish war-map, a picture or bird's-eye map of Turkey and the Black Sea. A very fine and moderate-priced map comes to us from Perthes, of Gotha. It is prepared by Dr. Petermann, and is evidently a compilation from several of the maps in Stieler's Atlas. It embraces all the country in Europe and Asia likely to be included in the theatre of war, so long at least as it is confined to the two combatants now in the field. This map, sold at a very moderate price, may be had in London from Mr. Stanford.

THE war just begun will in no way interfere, we believe, with the forthcoming Paris Exhibition. The works are progressing with such activity that everything but the Trocadero palace will be ready at an earlier date than was anticipated. The Trocadero building has been delayed by legislative difficulties, which, however, have been overcome, and that building will not be behind its time.

M. HENRY GIFFARD is constructing, near the Champ de Mars at Paris, a workshop for the preparation of sulphate of iron. The apparatus was tried for the first time last Friday, when the balloon *Eole* was inflated in an hour and a half, and was sent up with an aëronaut. The capacity of the balloon being 220 cubic metres, the rate of production is very satisfactory. It is expected that the sale of sulphate will cover almost all the expenses, so that numerous scientific ascents may be made in the ensuing summer. The monster captive balloon of 20,000 cubic meters will be inflated by the same process.

THE annual meeting of the Royal Institution was held on Tuesday. The Annual Report of the Committee of Visitors for the year 1876, testifying to the continued prosperity and efficient management of the Institution was read and adopted. The real and funded property now amounts to above 84,000*l*. entirely derived from the contributions and donations of the members. Seventy-two new members paid their admission fees in 1876.

THE forty-eighth anniversary of the Zoological Society was held on Monday. The number of fellows, fellows-elect, and annual subscribers at the close of the year 1876 amounted to 3,311, showing an addition to the strength of the society of seventy members during the year 1876. The number of honorary members at the same date was fourteen, of foreign members twenty-five, and of corresponding members 199. The total income of the society in 1876 was 34,955*l*., exceeding that of the year 1875 by 6,216*l*. The total expenditure of the society in 1876 was 31,635*l*. The total assets of the society on December 31, 1876, were calculated to be 15,516*l*., while the liabilities were reckoned at 4,430*l*. The total number of visitors to the society's gardens in 1876 had been 915,764, the corresponding number in 1873 (hitherto the most successful year in this respect) having been 713,048. The number of visitors in 1876 had therefore exceeded that of any other previous year since the opening of the gardens, by more than 200,000. The report stated that the total number of animals in the collection on December 31, 1876, had been 2,265.

IN the May part of Petermann's *Mittheilungen* Herr K. Zöppritz has a critical paper on Watson and Chippendall's Survey of the White Nile and Junker's Survey of the Sobat. Herr Zöppritz expresses some dissatisfaction with the observations of the former as being vague and careless and difficult to reconcile with data already obtained. A valuable paper by Dr. Dorst describes and discusses the movements of the ice between Greenland and Spitzbergen as observed by him in the steamer *Bienenkorb* in 1869. It is an important contribution to our knowledge of the currents of this region.

THE examination for the Sheepshanks Astronomical Exhibition, which is of the annual value of 50*l*. and tenable for three years, will be held on May 21 in Trinity College Lecture-room No. 4. All undergraduates of the University are eligible, but in the event of a candidate who is not a member of Trinity College being elected, he must become a member of Trinity. Candidates are required to send their names, and, if not members of Trinity, certificates of moral character and good conduct to one of the tutors of Trinity on or before May 19.

A DETAILED account of Father Cecchi's remarkable seismograph to which we recently referred will be found in the January number (1877) of *Elettricista*. The Cecchi seismograph has been adopted with good success at several of the larger Italian observatories and meteorological stations. In order to enable also smaller establishments to obtain a similar apparatus at much less cost, Prof. Cecchi has lately constructed a simpler one on the same principle, which meets all the requirements for seismical observations and gives nearly as many and as exact data as the larger instrument. A full description of this is now being published in the *Elettricista*, and the adoption of it for meteorological stations may be strongly recommended. The whole cost will not exceed 4*l*. or 5*l*.

M. SICARD, member of the Italian Anthropological Society, on making excavations on his property near Kischeneff, in Bessarabia, at a place called Moguil Liondia, discovered a very large tumulus of earth, with human skeletons, remains of iron objects, and an amulet of carved bone. One of the corpses appeared to have been interred with a horse, much in the same way as the tribes of the Tehuelches and Pehuelches still bury their fellow-men. Unfortunately the skulls were dispersed, but M. Sicard is going to continue his excavations, and will give a detailed account of his highly interesting discovery in the *Rivista di Antropologia e Etnologia*, published by Prof. Mantegazza.

AT the last meeting of the Ethnographical Section of the Russian Geographical Society, M. Poliakof, referring to the results of his last journey on the Obi, pointed out the remarkable similarity between the present state of civilisation of the Ostiaks and that of the prehistoric inhabitants of the reindeer period of France and Middle Europe. After a description of the features which the present flora and fauna of the banks of the Obi have in common with those of Europe at that period, M. Poliakof described the primitive mode of life of the Ostiaks. Their utensils and implements almost exactly resemble those of the stone period and the islands of the Pacific, being made exclusively of stone, of teeth and claws of bears, and of bone, and their clothes being either furs or woven from nettle filaments. M. Poliakof described at length their mode of life, their wretched homes, their customs, their family relations, and their religion, the latter being a mixture of the rudest fetishism with the strangest superstitions. This people are rapidly fading away before the advance of European civilisation.

DURING the diluvial epoch, the Danube entering into the Vienna Basin, formed an inland sea, and covered the Tertiary formations with deep layers of so-called loess, a mixture of loam, lime, sand, and foliaceous mica. The Imperial Academy of Sciences at Vienna has lately set in operation an extensive series of excavations with the view of uncovering the secrets hidden beneath this thick coating of alluvium, and has already been rewarded by interesting discoveries. The excavations in the neighbourhood of Zeiselberg have disclosed a widespread deposit of bones mingled with numerous evidences of the presence of mankind. These consist in quantities of charcoal, bones which have been worked, artificially prepared flints, &c. The bones among which these prehistoric remains were found, are those of the bear, horse, mammoth, ox, reindeer, rhinoceros, and wolf, all belonging to the diluvial fauna, and all apparently inhabiting the Vienna Basin at that distant epoch in the company of man, for a chance gathering of these remains through the agency of water is precluded by the local topography of the place.

NEWS from M. Prshevalsky, forwarded on March 23 by telegraph from Vernyi, appears in the official paper, the *Russian Invalid*. On February 11 he had reached Lake Lob-Nor, *viâ* the Valley of the Lower Tarim. The population of the Valley is very sparse. Its height above the sea is somewhat more than 2,000 feet. Its flora and fauna very poor. The topography is quite different from that represented on the maps. He was, at the time of telegraphing, in the mountains Altyn-Tagh, some distance south of Lake Lob-Nor. The valleys of the exterior spurs of these mountains reach about 12,000 feet above the sea. Here, as well as in the lower regions there are wild camels. In the neighbourhood of Lob-Nor he found the ruins of two old towns. He was to spend February and March at Lob-Nor, April on the Lower Tarim, and May and June on the Tian-Shan, returning to Kuldja at the beginning of July.

WE have received as a contribution to the Gauss Fund, 1*l*. from Mr. G. Griffith.

THE additions to the Zoological Society's Gardens during the past week include an Egyptian Gazelle (*Gazella dorcas*) from Egypt, presented by Her Majesty the Queen: an Indian Leopard (*Felis pardus*) from India, presented by Dr. Sidney Smith; a Crested Porcupine (*Hystrix cristata*) from Ceylon, presented by Capt. Smerdon, s.s. *Orion*; a White Pelican (*Pelecanus onocrotalus*) from Egypt, presented by Mr. A. C. Henderson; a King Parrakeet (*Aprosmictus scapulatus*) from New South Wales, presented by Miss Jones; a Suricate (*Suricata zenik*) from South Africa, presented by Mr. J. Forbes Dixon; an Indian Cobra (*Naia tripudians*) from Ceylon, presented by the Hon. W. D. Wright; a Beisa Antelope (*Oryx beisa*), two African Sheep (*Ovis aries*), eight Vulturine Guinea Fowls (*Numida vulturina*), from East Africa, a Toque Monkey (*Macacus pileatus*) from Ceylon, deposited; a Pigmy Marmoset (*Hapale pygmæus*), two Bay-headed Parrots (*Caica leucogastra*), a Rough Terrapin (*Clemmys punctularia*) from the Upper Amazons, purchased.

SCIENTIFIC SERIALS

The American Journal of Science and Arts, April, 1877.—On the sensation of colour, by C. S. Peirce.—Note on the binocular phenomenon observed by Prof. Nipher, by J. Le Conte.—Revision of the genus Belemnocrinus, by C. Wachsmuth and F. Springer.—Thorpe's and Bunsen's methods for the estimation of nitrogen in nitrates, by S. W. Johnston.—Westfield during the Champlain period, by J. S. Diller.—New embryonic forms of trilobites, by S. W. Ford.—The winds of the globe, or the laws of atmospheric circulation over the surface of the earth, by J. H. Coffin.—On some nitro-derivatives of diphenylamide, by P. T. Austen.—On mineral analysis; on some fluorides; and on molecular volumes, by F. W. Clarke.—On the identity of the so-called Peganite of Arkansas with the Variscite of Breithaupt and Callamite of Damour, by A. H. Chester.—On a fibrous variety of sepiolite from Utah, by the same.—On Dr. Peale's notes on the age of the Rocky Mountains in Colorado, by J. J. Stevenson.

Poggendorff's Annalen der Physik und Chemie, No. 2, 1877.—The spectra of chemical compounds, by M. Moser.—Researches on the volume-composition of solid bodies, by M. Schröder.—Current regulator for gas, by M. Teclu.—Contribution to Boltzmann's theory of elastic reaction, by M. Kohlrausch.—Further communications on the connection between the viscosity and the galvanic conductivity of various liquids, by M. Grotrian.—On the theory of resonators, by M. Grinwis.—On photography of the less refrangible parts of the solar spectrum, by M. Vogel.—Researches on the motions of radiating and irradiated bodies, by M. Zöllner.—New proof of the falsity of the emission theory of light, by E. Feussner.—On double excitation of the ebonite electrophorus, by M. Schlösser.

Beiblätter zu den Annalen.—Quantitative comparison between friction and galvanic electricity in respect of tension, by M. Nystrom.—On the deduction of a new electrodynamic fundamental law, by M. Clausius.—Thermoelectric researches, by M. Tidblom.

THE *Naturforscher* (March).—From this part we note the following papers:—On the functions of the larger brain (cerebrum), by Herr Goltz.—On the expansion of growing vegetable cells through the tension existing between the contents of the cells and the membrane forming them, by Hugo de Vries.—On the spectrum of the new star in Cygnus, by R. Copeland.—On the atomicity of phosphorus, by Ira Remsen.—On the high tides in the River Elbe, by K. R. Bornemann.—On the reproduction of eels, by M. C. Dareste.—On the formation of hail, by H. Fritz.—On the inhalation of air by the roots of plants, by MM. P. P. Dehérain and J. Vesque.—On electrolysis accompanied by the development of hydrogen at both electrodes, by Emil Elsaesser.—On the daily and yearly course of magnetic declination, by J. Hann.—On the behaviour of leaves in an atmosphere free from carbonic acid, by B. Corenwinder.—On the companions of the pole star, by A. de Boe and others.—On the spreading of drops of liquids, by Filippo Centolesi.—On the preparation of photographic plates in daylight, by Oswald Lohse.—On the origin of the flying power of bees, by Herr Dönhoff.—On the chlorophyll of Coniferæ germinating in the dark, by R. Sachsse.—On the behaviour of chlorophyll in the vine, by G. Briosi.—On the glycogen contained in muscles, by Th. Chandelon.

Journal de Physique, March.—On the dynamical theory of gases, by M. Violle.—On the effects of a jet of air sent into water, by M. de Romilly.—On the suspension and ebullition of water on a large-meshed tissue, by the same.—On the phenomenon of the black drop and its influence on observation of the transit of Venus, by M. André.—The persistence of impressions on the retina, various experiments with the projection-phenakisticope, by M. Gariel.—On Optography, by M. Kuhne.

Verga.—On some rare alterations of the first formation of the uterus and its attachments; on a cause not yet confirmed of distoma, by M. Sangalli.—On a new defence of the theory of Melloni on electrostatic induction, by M. Cantoni.—On the divisibility of comets into minute parts, and on a dark spot found in the Milky Way, by P. Secchi.

Revue des Sciences Naturelles, tome v. No. 4.—On the so-called cladodes of Ruscus, by M. Duval-Jouve.—Study of a chromogenic bacterium in the water of steeping of flax (*Bacterium rubescens*, Ray Lankester [?]), by Prof. Giard.—On the development of the Anguillula Aceti, Ehrb., by M. Hallez.—Economical Aquarium, by M. Sabatier.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 22.—"On Stratified Discharges v. Stratified and Unstratified Forms of the Jar-Discharge," by William Spottiswoode, M.A., F.R.S. It is well known that if a Leyden jar be discharged through a vacuum tube, the discharge generally takes the form of an unbroken column of light, extending from the point of the positive terminal to the hilt of the negative, *i.e.*, to the extreme negative end of the tube; and that it shows no trace of either negative glow or intervening dark space. On the other hand, I have found, by experiments with a large Leyden battery, that if a tube having one terminal connected with the negatively charged coating of the battery and the other held beyond striking distance from the positively charged coating, the discharge in the tube will show a separation of the positive from the negative part by a dark intervening space. Under suitable circumstances of exhaustion it will also show striæ, in the same manner as when the discharge is effected directly with a Holtz machine, having the conductors either closed or open beyond striking distance (see Roy. Soc. *Proceedings*, vol. xxiii. p. 460). Again, I have found, with the same battery, that if the tube be connected—otherwise as before—and held at a distance less than at first, but a little greater than striking distance, a stratified discharge much more brilliant and more like that produced by a coil will be exhibited. The latter form of discharge appears to the unassisted eye as an unbroken column of light, but with a negative glow and dark space. A revolving mirror, however, resolves the column into a regular array of striæ, having a rapid proper motion towards the positive terminal.

With a view to examining the transition from the stratified to the unstratified form as closely as possible, a Holtz machine was employed, with a battery of one or more jars. The outside of this battery and one terminal of the tube were connected with the earth; and the inside and the other terminal were alternately connected with the positive conductor of the machine, so that the battery was alternately charged and discharged through the tube. The amount of charge was regulated partly by the distance through which the conductors of the machine were separated, and partly by the number of revolutions of the machine during which the charging took place.

The first object proposed was to ascertain whether a jar could be charged with so small a quantity of electricity as of itself to give a stratified discharge in a tube.

A number of tubes tried with various amounts of battery charge, but with the same surface, showed that, as the charge was increased, the head of the positive column advanced towards the negative terminal, the dark space became narrower, and the glow contracted in dimensions; and when the head of the column drew very near to the negative terminal, the glow, instead of covering the whole surface of the terminal, formed a small drop at the point. On still further increasing the charge, the drop withdrew to the hilt of the terminal; and finally, when it had completely retreated into the hilt, the continuous or true jar-discharge took place.

With a view to testing experimentally how far the effects here described were due to quantity, and how far to tension, the size of the jar was altered, all other circumstances remaining the same. It was then found that the maximum charge compatible with stratification was greater with a large than with a small jar.

As a further experiment in this direction, a series of jars were arranged in cascade, and it was found that the greater the number of jars so arranged the smaller the charge necessary to ensure a true jar-discharge. A charge insufficient to destroy stratification with one jar was sufficient to destroy them when more than one was used in cascade. These results point to tension rather than to quantity as the determining cause of the character of the discharge.

The duration of the stratified discharges observed throughout these experiments was exceedingly short, indistinguishable, in fact, from that of the true jar-discharge. When viewed in a revolving mirror they showed no sign whatever of prolonged duration, and we may thence conclude that, so far as our present instrumental arrangements extend, there is no inferior limit to the duration of discharge necessary for the production of striæ.

A comparison of the results here obtained with those detailed in Part ii. of these researches, shows that the phenomena produced by suitable disposition of the Leyden battery coincide with those produced by the induction-coil. With the coil it was found that (1) for a given electromotive force the column of striæ was shorter the larger the battery surface or strength of current used; (2) that the proper motion, when directed as usual towards the positive terminal, was more rapid the greater the electromotive force employed. With the Leyden battery it was found that (1) in order to maintain the same length of column with an increased surface the charge must be increased in a larger proportion than the surface; and (2) it was noticed that the striæ which when the tension was low were distinct and well separated, became more blurred as the tension rose, until they sometimes were blended into an apparently unbroken column of light. The presence, however, of the negative glow still showed that the true jar-discharge had not yet been reached.

Geological Society, April 11.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—John Robert Campbell, James Carter, William Radcliffe Ellis, William Hamilton Merritt, William Morgans, and Edmund Albert Parsick, were elected fellows of the society. The following communications were read:—On sandworn stones from New Zealand, by John D. Enys, F.G.S. The author exhibited specimens of sandworn pebbles from near Wellington, in New Zealand, and described their mode of occurrence.—The Bone-caves of Cresswell Crags, third paper, by the Rev. J. Magens Mello, F.G.S. In this paper the author gave an account of the continued exploration of these caves, and of the completion of the examination of the Robin Hood Cave, noticed in his previous communications. Five deposits could be distinguished in the Robin Hood Cave, namely, when all present: 1. Stalagmite, 2 feet. 2. Breccia, with bones and flint implements, 1 foot 6 inches. 3. Cave-earth, with bones and implements, 1 foot 9 inches. 4. Mottled bed, with bones and implements, 2 feet. 5. Red sand, with bones and quartzite implements, 3 feet. The most important discoveries were made in the cave-earth, and chief among these was a fragment of bone, having on it a well-executed outline of the head and neck of a horse, the first recorded discovery of any such work of art in this country. As the result of the exploration of these caverns, the author said it is evident that during the Pleistocene period, Derbyshire and the adjoining counties were inhabited by a very numerous and diversified fauna, the vast forests and pastures which extended far to the east and south offering a congenial home to the mammoth, the woolly rhinoceros, the hippopotamus, the Irish elk, the reindeer, the bison, and the horse, whilst among them the hyæna, the glutton, the bear, the lion, the wolf, the fox, and the great sabre-toothed *Machairodus*, roamed in search of prey; and that with these and other animals man lived and waged a more or less precarious struggle, amidst the vicissitudes of a varying climate, sheltering himself in the numerous caves of the district, which were already the haunts of the hyæna and its companions.—On the mammal-fauna of the Caves of Creswell Crags, by Prof. W. Boyd Dawkins, F.R.S. In this paper the author gave an account of the remains found in the caves explored by the Rev. J. M. Mello. He stated that the recent explorations had proved that the Robin Hood Cave was inhabited by hyænas, not only during the deposition of the cave-earth and breccia, but also during that of the red-sand clay underlying it, which had also furnished traces of the existence of man. After noticing the conditions of the fossil bones found in the caves, the author proceeded to remark upon the general results of the explorations with regard to their Pleistocene fauna, and concluded that there is no evidence from these or other caves in this country to prove that their faunas are either pre- or inter-glacial, and that we have no proof of the existence of pre- or inter-glacial man in Britain.

Zoological Society, April 17.—Mr. Osbert Salvin, F.R.S., in the chair.—The secretary exhibited and made remarks on some young Anacondas which had been produced dead by the large female Anaconda purchased on February 15.—The secretary exhibited some photographs of the young gorilla, now living in the Berlin Aquarium, and made some remarks on what, it now seemed certain, was an example of this ape, which was formerly living in one of Wombwell's travelling menageries, and was after its death transferred to the late Mr. C. Waterton's collection.—A letter was read from Mr. W. A. Wilks, in which he gave an account of the success which had attended the endeavours of the Acclimatisation Society at Christchurch to introduce salmon into New Zealand from the United States.—A communication was read from Mr. W. A. Forbes, F.Z.S., containing a description of the peculiar organ known as the *Bursa Fabricii* in birds, and of its variations and modifications in the different genera of the class which he had had an opportunity of examining.—A communication was read from M. L. Taczanowski, in which he gave a list of the birds collected in North-Western Peru in 1876 by Messrs. Jelski and Holzmann. Amongst several new and interesting forms described was a new genus and species of Fringillidæ proposed to be called *Gnathospiza raimondii*.—A communication was read from the Rev R. Boog Watson, containing some notes on the Madeiran Mollusc identified by the Rev. R. T. Lowe as *Achatina folliculus*.—A communication was read from Mr. E. P. Ramsay containing the concluding portion of his list of birds met with in North-Eastern Queensland, chiefly at Rockingham Bay.—A communication was read from Dr. Otto Finsch, containing a preliminary account of the birds collected during his recent journey in the North-Eastern part of Turkestan.—A communication was read from Prof. Owen, containing the description of a new species of extinct kangaroo of the genus *Sthenurus*, which he proposed to call *Sth. minor*, together with some remarks on the relation of this genus to *Dorcopsis*.—Mr. Edgar A. Smith read a paper containing descriptions of new species of South-American *Helicidæ* in the British Museum.—The Marquis of Tweeddale, F.R.S., gave descriptions of four new species of birds from the Indian region. These he proposed to name as follows:—*Trichostoma leucoprocta*, *Chrysococcyx limborgi*, and *Pomatorhinus austeni* (from Tenasserim), and *Brachypteryx buxtoni* (from Sumatra).—Mr. Osbert Salvin exhibited and pointed out the character of a new genus and species of bird of the family Ampelidæ, from Costa Rica, and proposed to call it *Phainoptila melanoxantha*.

Meteorological Society, April 18.—Rev. T. A. Preston, M.A., in the chair.—W. Morris Beaufort and Arthur A. Pearson were elected fellows of the Society.—The following papers were read:—On the meteorology of Mozufferpore, Tirhoot, for 1876, by C. N. Pearson, F.M.S. This year partook of the abnormal character of its predecessor, but in a different degree, and with widely different results. The total fall of rain was 57·69 inches, of which no less than 43·34 inches were registered in August, September, and October.—On the Diéthéroscope, by Prof. J. Luvini, of Turin. This is a new instrument contrived by the author for observing the changes of atmospheric refraction optically.—Improved form of thermometer for observing earth temperature, by G. J. Symons, F.M.S. This apparatus consists of an iron pipe driven in the ground to the required depth, and a small but very strong thermometer, the bulb of which is so protected that no change of indication occurs when the thermometer is drawn out of the tube for reading. The pipe is closed at the bottom by welding, and the point hardened so as to penetrate the soil with ease. For depths of 3 feet and under the thermometer is inserted in a light rod, but for all greater depths it is mounted in a short weighted stick attached to a strong chain.—Note on the degree of accordance of Mr. Glaisher's and the Kew thermometer standards, by William Ellis, F.R.A.S. This paper gives an account of the comparison of eight thermometers at the Royal Observatory which had been previously compared with Mr. Glaisher's and the Kew standard thermometers, and the result shows that the two standards are practically identical.

Entomological Society, April 4.—Prof. Westwood, president, in the chair.—Messrs. G. Harding, C. A. Briggs, and J. T. Carrington were elected ordinary members, and Messrs. E. H. Birchall, T. D. Gibson-Carmichael, and V. Cluse were elected subscribers. The Secretary exhibited a collection of fine species of Lepidoptera from a place about twenty miles from Bangkok in Siam, forwarded to him by Mr. R. Garner, F.L.S., of Stoke-upon-Trent.—Mr. McLachlan exhibited a specimen of *Ophideres materna*, a brightly-coloured exotic species of *Noctuidæ*, given to him by Mr. R. H. Scott, of the Meteorological Office, with a note to the effect that it was taken at sea in lat. 25° 24′ S., long. 62° 10′ E. (the nearest land being the island of Mauritius, about 360 miles distant), by Capt. Raeburn, of the ship *Airlie*. The moth is a common Indian species, but is found also in Africa. A specimen was long ago received from Brazil, and Mr. Grote had recently noticed its occurrence in Florida. He also exhibited a cocoon and pupa of a species of *Cetoniidæ* (probably *Diplognathus silaceus*), from Cameroons, sent to Mr. Rutherford. The cocoon appeared to be formed of dark brown earth, but attached thickly to the exterior were oval, slightly flattened, deep black, hard bodies (each nearly five lines long by two broad), which he thought were probably the excrement of some rodent animal. Mr. Champion exhibited *Stenus kiesenwetteri* (hitherto only found in this country at Wimbledon), *Gymnusa brevicollis*, *Bembidium nigricorne*, and *Flocomerus lividus*, all from Chobham: also *Philonthus cicatricosus*, from Shoreham.—Mr. Howard Vaughan exhibited (on behalf of Mr. Bidwell) a specimen of *Notodonta trilophus*, taken about the year 1867 by a lamplighter at Ipswich, who had it alive with several specimens of *N. ziczac*. It was only the second (authentic) capture of the insect, the first having been found at Saint Osyth, Essex, by Mr. Douglas.—The President read a letter he had received from Mr. B. G. Cole respecting the subject of Season-Dimorphism in Lepidoptera. He observed that from a number of eggs laid by *Ephyra punctaria*, those that emerged in July were of the spotted variety, while those which remained in the pupa state till the following May, in all respects resembled the mother. Mr. Cole referred to some remarks by Dr. Knaggs, published in the Entomologists' *Monthly Magazine* (vol. iii. p. 238) as bearing on the same subject. He considered it probable that the insects that were produced by a slow process of development would produce the May form (which might be considered the type), whilst those whose development was hastened by the heat and light of summer would produce smaller and less perfect insects. Mr. McLachlan alluded incidentally to the Lepidoptera brought home by the Arctic Expedition from the far north (82° N.), and said that the larvæ of most of those species, must, of necessity, require more than one season to acquire their full growth; for the short and fitful summer was utterly inadequate for the full development in one season of most of the species, and furthermore, it was probable that the pupa state might habitually last several years.—The President read notes upon a strepsipterous insect, parasitic on an exotic species of Homoptera, (*Epora subtilis*, Wlk.), from Sarawak, accompanied by drawings illustrating the metamorphosis. He also read notes on the genus *Prosopistoma*, especially with regard to the species from Madagascar described by Latreille, of which he exhibited the types.—Mr. Cameron communicated a paper on East Indian *Tenthredinidæ*, and Mr. Butler a paper on the Lepidoptera of the Amazon Valley, collected by Dr. Trail in the years 1873-75.—Mr. Baly communicated descriptions of new species of *Halticidæ* and Mr. C. O. Waterhouse a monograph of the Australian species of the Coleopterous family *Lycidæ*.—Mr. F. Smith read descriptions of new species of the genera *Pseudomyrma* and *Tetraponera*, belonging to the family *Myrmicidæ*.

Institution of Civil Engineers, April 24.—Mr. George Robert Stephenson, president, in the chair.—The first paper read was on a deep boring for coal at Scarle, Lincolnshire, by Prof. Edward Hull, F.R.S. This boring was commenced about four years ago by a local company, to test the presence of coal in the neighbourhood of Lincoln—Mr. J. T. Boot, of Mansfield, being the engineer—and had been carried out by the Diamond Rock Boring Company. The total depth attained was 2,030 feet; but as this depth was insufficient for the object in view, it was desirable that the bore-hole should be carried further down. The following formations, with their approximate thicknesses, had been passed through:—

	Depths. Feet.	Thickness. Feet.
Alluvial Strata	1 to 10 ...	10
Lower Lias Clay and Limestone	10 ,, 75 ...	65
Rhætic Beds	75 ,, 141 ...	66
New Red Marl and Sandstone	141 ,, 1,500 ..	1,359
Permian Beds	1,500 ,, 1,900 ..	400
Carboniferous Strata .. .	1,900 ,, 2,030 ...	130

Although the carboniferous strata had been reached, the cores brought up were of so peculiar a character as to leave it uncertain to what portion of the carboniferous formation they belonged; and, as the question of the eastward extension of the Yorkshire coal-field was one on which a boring at this spot was calculated to throw much light, it was important, both in an economic and in a scientific point of view, that it should be continued until something definite had been determined.—The second paper read was on street tramways, by Mr. Robinson Souttar.

MATHEMATICS IN AMERICA

Elements of the Differential and Integral Calculus, by a new Method, founded on the True System of Sir Isaac Newton, without the Use of Infinitesimals or Limits. By C. P. Buckingham. (Chicago: S. C. Griggs and Co., 1875. 343 pp.)

Elements of the Infinitesimal Calculus, with Numerous Examples and Applications to Analysis and Geometry. By James G. Clark, A.M. (Ray Series. New York: Wilson, Hinkle, and Co., 1875. 441 pp.)

On a New Method of Obtaining the Differentials of Functions with Especial Reference to the Newtonian Conception of Rates or Velocities. By J. Minot Rice and W. Woolsey Johnson. (New York: D. van Nosbrand, 1875. 32 pp.)

AN American writer who had exceptional opportunities of contrasting the methods of mathematical teaching adopted in his own country with those which obtained at Cambridge twenty-five years ago, strongly condemns the Transatlantic system, and leads his readers to infer that the attainments of the ordinary graduate in this particular branch of study were only on a par with those of a fairly trained schoolboy here. It may be supposed, then, that not many of the students ventured upon the difficulties of the calculus. Indeed, he writes that "at Yale where the course used to be thought a very difficult and thorough one, the Differential was among the *optional* studies at the end of the third year." (Bristed: "Five Years at an English University," vol. ii, pp. 94, &c., 1852.)

We are not in a position to say that all this has been changed in the interim, but among many evidences of the increased interest taken in mathematical studies we may surely refer to the three works now before us. All three give evidence of careful study and honestly grapple with the difficulties which beset the learner at the very threshold of his inquiries. De Morgan long ago wrote that "it is matter of common observation that any one who commences the study, even with the best elementary works, finds himself in the dark as to the real meaning of the processes which he learns, until, at a certain stage of his progress, depending upon his capacity, some accidental combination of his own ideas throws light upon the subject." The authors of the third work under review refer to D'Alembert's precept, "Allez en avant, et la foi vous viendra."

Mr. Buckingham takes as his fundamental idea of the conditions under which quantity may exist to be that we must not consider it only as *capable* of being increased or diminished, but also as being actually in a *state of change*. "It must (so to speak) be *vitalised*, so that it shall be endowed with *tendencies* to change its value; and the rate and direction of these tendencies will be found to constitute the groundwork of the whole system. The differential calculus is the SCIENCE OF RATES, and its peculiar subject is QUANTITY IN A STATE OF CHANGE."

Conceding to Leibnitz the honour of being the first to construct a system of rules for the *analytical machinery* of the science, he will not allow that he ever got beyond the ancient conception of the conditions of quantity. The only original birthplace of the fundamental idea of quantity which forms the true germ of the calculus was in the mind of the immortal Newton."

An introduction of thirty-six pages discusses the method of Descartes, the infinitesimal method (the results of which are true, while the method is false—"true results *not* because its principles are true, nor because its errors are small, but because they are, whether great or small, exactly equal, and *exactly cancel and destroy each other*. . . . the system is but a mere artifice."), the method of limits (here our author discusses Lemma I., Book I. of the "Principia," considers Newton's defence of the Lemma, and the opinions of Comte, Lagrange, and Berkeley, and points out what he believes to be the fundamental errors of this method and of the infinitesimal method). What is called the true method of Newton is then treated of. Referring to Newton's letter to J. Collins (December 10, 1672), he says that the theory on which Newton formed *his* method of fluxions is contained in the second Lemma. The lemma is given in full and discussed. "It is to be remarked that the doctrine of *limits* is nowhere hinted at, but the results are direct, positive, and substantial." We cannot tarry longer over this matter, but in connection with this point refer to De Morgan's "On the Early History of Infinitesimals in England" (*Phil. Mag.* November 1852). Prof. Clifford, too, if our recollection of an oral communication be correct, puts this lemma prominently forward in his (? unpublished) "Foundations of the Differential Calculus and of Dynamics." In the work itself we have the calculi (differential and integral) applied to the subjects which usually find a place in similar treatises. There is an appendix of thirteen pages on geometrical fluxions. Many examples are worked out, but the merit of the work does not lie at all, we think, in this direction, but altogether in the numerous discussions which are to be found in almost every chapter.

Mr. Clark's work has been exceedingly well printed, the type is very clear, and the paper good. This treatise, too, is written with a view to remove "all grounds for that feeling of uncertainty which often possesses the student at the very outset, and from which he rarely finds it possible to extricate himself." Much space is given to an exposition of the Doctrine of Limits—the work being founded mainly on that by Duhamel. A large number of examples have been taken from English treatises (Hall, Walton, and Todhunter). Rather more ground is covered in this treatise than in the former; in neither, however, have we any discussion of maxima and minima of functions of more than two independent variables, nor of methods of changing the variables in multiple integrals. Here a few pages are devoted to definite integrals and to differentiation and integration under the sign $\int$. Seven chapters are devoted to the elementary parts of the theory of differential equations. The work, though it does not reach the level of the like works by Messrs. Todhunter and Williamson, is yet a compact and fair elementary treatise.

The third work on our list is a revised edition of a paper read before the American Academy of Arts and Sciences, January 14, 1873. It is the authors' intention to publish a text-book in accordance with the plan adopted in this pamphlet. The objects are, "first to present a new method of deriving the differentials of functions by means of their algebraic characteristics with the aid of a few elementary properties easily established, and secondly to show that the method of rates or fluxions may be advantageously used for the purposes of instruction, and the use of infinitesimals, limits, and series entirely avoided until the student is well grounded in the elements of the calculus."

The first seven articles under the head "the Newtonian Method of Fluxions," treat of the methods in general use at the present time, and contain extracts from Todhunter, Lacroix, Carnot, and Cournot, especially directing attention to the positive advantages of the Newtonian method, as set forth by the last-named writer. The next six articles are occupied with the "Proposed Method of treating the Differential Calculus."

The remaining half of the pamphlet is given to algebraic and transcendental functions. It would be very interesting to lay before our readers an account of the ingenious methods adopted by our authors, but it would take up too much space. Some idea of the original paper (and there are no great differences, we fancy, between the two publications) can be got from an account of it furnished by Mr. J. W. L. Glaisher, F.R.S., in vol. iv. (pp. 58-64) of the *Messenger of Mathematics* (1875).

Altogether, on a review of the three books before us, we anticipate that mathematical studies are destined to occupy a more prominent position in the American colleges and schools than they have in the past.[1]

R. TUCKER

[1] We are confirmed in our views on this subject by a perusal of Dr. Sylvester's characteristic address at the Johns Hopkins University on Commemoration Day, February 22, 1877.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Visibility of the Ultra-Violet Rays of the Spectrum

IT is well known how surprisingly rich in rays of high refrangibility the spectrum of the electric arc formed between carbon points is, above that of all other artificial flames; and also how far beyond the ordinarily discernible rays of the solar spectrum, formed by a glass prism, light may be traced by eyes carefully shielded, and raised to the highest susceptibility to perceive it. The name of "lavender-grey" rays has been given to them from a colour of that tint which they are considered to possess, but the term "ultra-violet," which is more commonly used, betrays perhaps a lingering doubt as to the sensible existence of another order of coloured rays in the spectrum distinct from the violet and superior to it in refrangibility, which has yet been detected by very close and careful observation. All doubts of this kind, which from want of sufficient acquaintance with that part of the spectrum I have myself been hitherto rather too prone to entertain, have lately been quite dispelled by frequent observations of the spectrum of the electric arc between carbon points thrown by a quartz prism on a white paper screen. The violet end of the spectrum terminates rather abruptly, or at least beams with bright colour that fades off very quickly; and in the dark space beyond it three more refrangible bright bands are visible with more or less distinctness. The middle one of the three is the brightest, and from its perfect freedom from colour, in which it contrasts most remarkably with the strongly-tinted light-belt near it, and its distant separation from the violet termination of the continuous spectrum, I at first hastily ascribed it to a "ghost," or faint image of the slit, indirectly refracted and reflected through the prism, and thrown with the spectrum on the screen. That it is not so, however, is shown by the action of these three lines on fluorescent substances, of all of which that I have tried they excite the fluorescence most strongly, especially that of fluorescin, eosin, rose of Magdala, and other solutions, all of which alike show these rays to be clearly defined and well-insulated spectral bands. In particular, the solutions of æsculin, paviin and amido-terephthalic acid are only excited by these "ultra-violet" lines, and not by any rays in the spectrum of lower refrangibilities, clearly showing that the vigorous fluorescence that they produce is not the effect of any ordinary light-beam of common refrangibility, irregularly transmitted by the prism, but that they are well-marked rays, probably of carbon, in the spectrum of the voltaic arc. The light of the middle band is bright enough to be easily reflected and examined separately from the rest of the spectrum on a white screen, where it is so nearly grey or colourless that it scarcely admits of being ranged in any colour scale, although the name "lavender-grey" perhaps expresses better than any other term the faintest possible tone of colour which, if it exhibits any at all, this almost purely neutral, or steel-grey band of rays may possibly be suspected to possess. It is a little more strongly absorbed by ordinary plate-glass than the neighbouring violet bands; but it remains visible in the spectrum of the arc formed by an ordinary flint glass prism, though much spread out and enfeebled by the dispersion, which greatly exceeds that of a quartz prism of the same refracting angle. It is perhaps for this reason that it is not perceptible in the spectrum of the arc as usually projected on a screen with a fluid-prism of bisulphide of carbon, but if the latter is replaced by benzine, which disperses the light less than flint glass, it forms a pretty conspicuous grey band in the spectrum. The other two lines or bands are so much fainter than the principal one, that in general they can only be found with the help of a fluorescent substance, and where so faintly visible it is not possible to speak positively as to their colour. The less refrangible is very near the violet termination of the spectrum, and when well seen it shares its violet tinge; the more refrangible one is nearly as far beyond the principal grey band as this band is beyond the margin of the violet, and as far as its weak light allows one to distinguish, it is of the same colour as the brightest band. In order to determine their positions, some measurements were made of metallic lines, and of the spectra of sodium, lithium, thallium, and strontium in the arc, with the result that the violet part of the continuous spectrum extends to the closely-neighbouring positions of the hydrogen line $H\delta$ (h), the potassium flame-spectrum line $K\beta$, and the last violet line in the arc spectrum of a salt of strontium. The first faint outlying ray occupies nearly the position of H_1 in the solar spectrum, and it is therefore in the true violet region of the spectrum, as its colour faintly indicates. The prominent grey line begins with its brightest edge about as much further beyond this, from the end of the violet field; and becoming weaker from there, it is about twice as broad as the distance between the two Fraunhofer lines H, its mean position in the spectrum being nearly as far from H as H is from h, reckoning the distances as they would be seen with the quartz prism and with solar light. The third faint line occurs about as far again from the violet as this band; and it lies at least as far beyond H as the distance between G and H in the solar spectrum. Yet it is visible there by glimpses, like the first faint member of the group, which it does not yet by any means surpass in the strength with which it produces fluorescence.

If any fresh proof was needed of the characteristic grey appearance of visible rays in this portion of the spectrum it was soon presented in one of the metallic spectra used to determine their positions. The spectrum of mercury exhibited a bright line (beautifully distinct when a fluid prism of benzine was used with a refracting angle of between 50° and 60°), much brighter than the principal grey carbon band, considerably more refrangible, and of the same tintless, and perfectly neutral grey appearance. Though not so distant from the violet as the most refrangible faint carbon line, it is yet according to the best measurements and identifications that were made, about as far beyond H_1 in a prismatic spectrum as H_1 is from G; and radiation of this high degree of refrangibility is evidently strongly luminous, when sufficiently intense, with homogeneous grey light characteristic of this region, and contrasting conspicuously in its appearance with the zone of violet colour, which often borders closely upon it in electric spectra.

The wave-lengths of the bands, and other positions in the spectrum, roughly obtained, by which it may be possible to identify some of them in photographic spectra, although open to some uncertainty from the inconstant length and strength of the arc of flame in the electric lamp, which confused and shifted some of the comparison lines, were as follows:—

Electric Arc with Carbon Poles.	Wave-lengths.
End of the violet field (*h*, $K\beta$, and last violet line in arc-spectrum of strontium, 4,080–4,100)	About 4,100.
First light-band; faint violet-grey (H_1, 3,968; H_2, 3,933)	About 4,000–3,950.
Second do., strong grey band	About from 3,900 to 3,800.
(Strong grey line of mercury	About 3,700).
Third do., faint, grey	Between 3,600 and 3,500 (?).

Other metallic arc-spectra probably present lines in this portion of the spectrum, of which it would be interesting to examine the apparent brightness and the colours. At present the most conspicuous that I have met with is the grey line of mercury, which is brighter and more refrangible than the grey band of the electric light between carbon points. Its very advanced position in the spectrum, and the absence, or negative appearance of colour in its pretty bright light, both taken together seem to indicate very clearly that the grey or "lavender-grey" division of the spectrum fully equals in extent, when seen prismatically, the violet, the indigo, the blue, or any of its other better known, and much more ordinarily visible companion regions, the seven Newtonian colour-spaces of the spectrum. A. S. HERSCHEL

College of Science, Newcastle-on-Tyne, April 26

Pele's Hair

I HAVE read with great interest Mr. Moseley's description of Pele's Hair in NATURE (vol. xv., p. 547), since it furnishes information which I was most anxious to obtain. It seemed to me extremely probable that the analogy between Pele's Hair and the artificial furnace products would not be confined to the long fibres, and I did my best to ascertain whether irregular glassy spherules occurred along with the natural products. I was unable to obtain specimens for examination, but paid a visit to my friend Mr. J. G. Sawkins, F.G.S., who had explored the crater and collected the hair, in order to ask him whether he had ever noticed the pear-shaped spherules. He told me that he had never seen anything but the glassy fibres. I must say that I felt very much inclined to believe that the specimens usually collected are the material which has been blown some distance by the wind, consisting of the fibres from which most of the spherules have been broken. Mr. Moseley's letter in NATURE, and another which he has kindly addressed to me, make me believe that the analogy between the artificial and natural products is more complete than I was able to ascertain before Mr. Moseley's observations were published. In conclusion I would say that these facts in no way invalidate my arguments in respect to meteorites. They merely show that in certain cases the glassy volcanic spray, like melted furnace-slag, can to some extent collect into more or less imperfect spherules, so far analogous to those in meteorites as to indicate how those remarkable bodies were formed, but these spherules are accompanied by many fibres, which I have never yet seen in meteorites. This difference appears manifestly to depend on the difference in the temperature of the space into which the glassy spray was thrown. If the temperature of the air in the crater of Kilauea were equal to that of the melting point of the lava, we should almost certainly find, as in meteorites, many spherules and no hairs. H. C. SORBY

The Critical Point of Carbonic Anhydride

As the writer is not aware that any attempts have hitherto been made by others to exhibit to a large class the phenomena attending the passage through the critical point of a liquid in the presence of its gas, he is of opinion that the following account of a method which he has found very successful may be of interest:—

Dr. Andrews's apparatus for the study of gases was employed in the experiments, and the image of the tube containing the carbonic anhydride was projected on a screen by means of the oxy-hydrogen lime-light and a solar microscope which magnified it about 120 diameters. Dr. Andrews's apparatus consists of a thermometer tube filled with carbonic anhydride and a second tube filled with dry air, which serves to measure the pressure applied. The lower ends of these tubes dip beneath the surfaces of mercury contained in test-tubes, which are suspended in strong copper cylinders communicating with each other, and filled with water, which presses on the mercury in the test-tubes. The pressure is applied by means of long steel screws which pass through the bottoms of the cylinders. For the filling and mounting of these tubes the University of Cambridge is indebted to the kindness of Dr. Andrews. The lantern was supported on three screws, which allowed it to be raised or lowered so as to bring any required portion of the thermometer tube into the field of view of the microscope. The best height for the lantern was found to be such that the top of the tube was rather less than half an inch above the axis of the microscope. When the oxygen was turned on, the radiation from the lime cylinder raised the temperature of the portion of the tube within the field of view above the critical point in little more than a minute, so that no other source of heat was required; but when the oxygen was turned off the tube cooled through several degrees.

The best method of performing the experiment is as follows:—The lantern having been properly adjusted, the gas should be lighted, the oxygen turned on, pressure applied until the surface of the mercury comes into the field of view and the microscope focussed so as to give a distinct image of this surface. The pressure should then be relieved and a blast of cold air from a bellows or gas bag directed against the tube. This will cool it considerably below the critical point. The pressure should then be increased, the cold blast being continued until the inverted image of the concave surface of the liquid reaches the middle of the field of view appearing as a broad dark line possessing considerable curvature, and, of course, concave downwards. The focussing screw should now be finally adjusted so as to give the best image of this surface, and the blast then stopped. Immediately after cutting off the blast the operator must obtain command over one of the screws and carefully increase the pressure as the temperature rises so as to keep the image of the liquid surface just above the centre of the picture on the screen. As the temperature and pressure increase the broad image of the surface becomes narrower and less concave until, as the temperature approaches the critical point, the line becomes very thin and faint and loses its curvature altogether; it then seems to explode into mist and vanish as the critical point is reached. Another half turn of the screw then produces the well-known clouds or flickerings, which are best seen on the screen somewhat below the middle of the field, and in a few more seconds all is steady. More pressure should then be applied until the mercury reaches the axis of the microscope, but no change of state will be manifested by the carbonic anhydride.

It is important that the image of the surface of the liquid should not be below the centre of the field of view on the screen, for if the liquid stand in the tube above the axis of the microscope, since the greatest heat is there concentrated, bubbles of gas are liable to be formed within the liquid and to damage the continuity of the surface. Perhaps the flickerings may be due to unequal temperatures at different parts of the tube, so that some are just above and others just below the critical point. The mode of propagation of a sound wave through a substance just at the critical point may be an interesting subject for inquiry.

After passing the critical point the blast of air should be directed against the tube for about a minute. This will, of course, cause the image of the mercury to descend upon the screen, but no change of state will appear to take place in the carbonic anhydride. The pressure should then be rapidly diminished by turning the screws, when a violent ebullition will be seen, showing that the whole of the contents of the tube had assumed the liquid state during the cooling, the gas having passed at the critical point into the liquid without breach of continuity, so that no indication of a change of state was apparent on the screen. On increasing the pressure and continuing the blast the liquid surface will again appear, and the experiment can be at once repeated. WM. GARNETT

Cavendish Laboratory, Cambridge

Floating Cast Iron

HAVING read the interesting letter on this subject which appeared in NATURE (vol. xv., p. 529), I send the following copy of notes of experiments which I made about three years ago.

Several pieces of pig iron were put into a ladle (holding about one ton of metal); these at *first sank*, and a rush of hot metal took place upwards; after a few seconds the pieces of pig iron appeared *floating, with very little of their bulk* above the surface of the molten metal. A piece of flattish metal of irregular shape floated with a small portion alone of its corners above the surface; it was close to side of ladle. Pieces of flat cast-iron bars, 20″ × 2′ × 1″, were carefully placed on surface (the latter being well skimmed); they floated without going below the surface. One of these pieces, which was put in *end on*, kept in this position for a few seconds, with its upper end above the surface; the other end then came up and floated on its flat side. In some cases a sharp crack was heard when the metals touched, and a white flame on one occasion burned like a gas jet from the side of one of the pieces.

The surface of the molten metal was in constant motion due to the currents within its mass, and showed the variegated texture or "break" peculiar to this condition of the metal. From notes of an experiment which I arranged for, but did not see carried out, I find that a cast-iron ball of about $2\frac{3}{4}''$ diameter, when lowered by a fine wire upon a well-skimmed surface of molten cast iron, *disappeared completely* at first, and then in a few seconds rose and floated with about half an inch diameter of surface exposed; it was then raised from the metal, when it showed a red glow on the lower part. It was again lowered, but now *did not sink*, but floated with about *twice* the surface exposed, as on the first experiment.

Different views are held as to the behaviour of cast iron when passing from the melten to the hot solid state, and finally to the cold (or ordinary temperature) state.

Some hold that the molten metal, on solidifying, expands like water passing into ice, and that it retains this expansion to such an extent that the cold solid is specifically *lighter* than the molten metal. Others hold that no such expansion takes place, and that finally the cold solid is specifically *heavier* than the molten metal. A third view is that the molten metal on solidifying *expands*, and that it then *contracts* during cooling, until it reaches ordinary temperature, when through the cooling it is specifically *heavier* than in the molten state.

From the fact that in foundry practice the linear contraction is taken at $\frac{1}{96}$th part, there can be little doubt that the finally cooled solid is specifically *heavier* than the molten metal; again, from the sharpness of form of iron castings and other circumstances, expansion appears to take place on solidification.

The above experiments, I think, favour this latter view, as the floating took place more readily with small than with large pieces, partly due to their relative bulks and surfaces.

A probable explanation, in part at least of these phenomena, I think, is that the cold metal, when at first put in, is specifically *heavier* than the molten metal, but owing to the great heat around it (over 2,000° F.) it is rapidly heated, and consequently *expanded*, and when sufficient volume has thus been obtained it floats. It is evident that small pieces, being more readily heated, may remain floating, whilst heavy pieces, whose volumes are larger in proportion to their surfaces, will take longer to heat, so as to induce the required change of volume, and may therefore at first sink, remaining below the surface till sufficiently expanded to rise and float. The experiment with the ball bears out this well, as, being a sphere, its surface was a minimum.

These experiments appear to corroborate very well those of your correspondent.

The following experiments which I lately made with lead may be of interest:—

An ingot of lead of 14 lbs. weight was placed on the surface of about 160 lbs. of molten lead; it at once melted. After allowing the metal to cool a little, an ingot was carefully placed on the surface, when it immediately sank, bubbles rising up to the surface; it was heard to strike the bottom of the ladle. Another ingot was tried; it also sank, and could be felt at the bottom (these ingots were cast from the lead in the pot). A small solid piece was cast of about $1\frac{1}{2}$ lb. weight, which also sank. Pieces of *sheet lead* were rolled up and placed on surface; these *floated*: the contained air and great surface in the latter would account for this.

These latter experiments with lead correspond very well with those of your correspondent with zinc. W. J. MILLAR

Glasgow

Yellow Crocuses

IN my garden the sparrows do not touch the crocuses. In a friend's, some miles off, they attack the yellow ones exclusively. I address you chiefly to report a fact related to me by the vicar of a neighbouring parish, whose garden is infested with mice. He tells me that for some time he thought he could not grow crocuses at all, as the mice destroyed the corms, discovering and digging down to them, even when there was no trace of the plants on the surface. At last he found that they did not attack the purple crocus, and on his planting the edge of a long border, with alternate clumps of yellow and purple crocuses, the mice almost entirely destroyed all the clumps of yellow, but left the purple untouched. Possibly the purple plant possesses some acrid or bitter taste, rendering it nauseous to animals—the corms to mice, the flowers to sparrows and other birds.

Newton-le-Willows, May 4 THOMAS COMBER

Hog-Wallows and Prairie Mounds

IF Mr. Williams is right, and the "hog-wallows" are simply American cousins of our "eshars" or "kames," is it not reasonable to credit that "atmospheric erosion" to which Prof. Le Conte attributes the formation of the former with a much more important influence upon the shapes of the latter than British geologists generally seem disposed to accord to it? It is very difficult to conceive that mounds of loose sand and gravel, whether in valleys or on plains, should have retained the impress of the glacier or the iceberg throughout the vast time that must have elapsed since these phenomena entirely disappeared. And if it be conceded that these mounds have been modified in any degree by subaerial denudation, it will be found difficult to limit the extent to which they are indebted to it for their present forms, or indeed to deny that it alone may have shaped them.

Newport, Fife, May 7 JAS. DURHAM

A "Golden Bough"

IN the gardens of New College, Oxford, there is a fine avenue of horse-chestnut trees, most of which have had some of their lower limbs lopped off, followed by the usual crop of abundant smaller shoots around the original bough. In one tree, however, with respect to one severed branch, these resultant shoots bear, year after year, not green, but pale yellow leaves, the summer through—

> "Primo avulso non deficit alter
> aureus, et simili frondescit virga metallo."

It would be interesting to know of other instances of such a veritable "golden bough," and whether any explanation can be given of chlorophyll so remarkably failing to develop its blue-green constituent under no obviously peculiar circumstances. It seems a strange anomaly to find an apparent case of host and saprophyte in one. HENRY T. WHARTON

SPONTANEOUS GENERATION

ON Friday evening last the Rev. W. H. Dallinger made an important communication to the members of the Royal Institution on "Recent Researches into the Origin and Development of Minute and Lowly Life-forms; with a Glance at the Bearing of these on the Origin of Bacteria." Biological Science to-day presents us with a magnificent generalisation; and that which lies within it and forms the fibre of its fabric, is the establishment of a continuity—an unbroken chain of unity—running from the base to the apex of the entire organic series. But does this imposing continuity find its terminus on the fringe and border of the organic series, and for ever pause there? or, can we see it pushing its way down and onward into the unorganised and the not-living, until all nature is an unbroken sequence and a continuous whole? That such a sublime continuity may be philosophically hypothecated is to be believed. But that data have been presented to us demonstrating how and by what path the inorganic passes to the vital, the living into the not-living, may be denied. The properties of living matter distinguish it absolutely from all other kinds of things, and the facts to-day in the hands of the biologist furnish us with no link between the living and the not-living. This is an inference which has been fiercely disputed.

But what are the nature of the proofs relied upon to establish the "spontaneous" or not living origin of living things? They were chiefly thermal experiments upon the lowest septic organisms, without an attempt to discover what was their life history, and whether they propagated by germs or not. It was argued that the adult organisms being killed at a given temperature much below the boiling point of water, if an infusion were boiled with every possible precaution, and whilst boiling hermetically sealed, and after a lapse of time on opening the vessel the organisms were found in a living state, they must have arisen *de novo*. That is, the not living would have produced the living; that this method is useful, and that it must be pursued in an exhaustive inquiry into the whole subject, must be freely admitted. But that it is the best, or at least the only, method of inquiry for the biologist we may gravely doubt.

Ten years ago Mr. Dallinger determined to endeavour to work out by actual microscopic observation the life history of some of the lowly life forms.

After four years spent in preparation he commenced his work in conjunction with Dr. Drysdale, the plan needing two observers. A characteristic feature of the work was that each set of observations should be made absolutely continuous, so that nothing should have to be inferred. An arrangement was made by which the little drop of septic fluid containing the objects under examination should be free from evaporation, and very high powers were employed. The largest adult objects included in the examination were the one-thousandth of an inch, the smallest adults were the four-thousandth. Six forms altogether were selected, and, by long, patient, and unbroken watching, their whole history was worked out. While reproduction by fission seemed at first to the observers to be the usual method, prolonged research made known that spores were produced. These were so small that a magnifying power of 5,000 diameters was needed to see them as they began to grow. The glairy fluid from which they developed seemed at first homogeneous, and it was only when growth set in that the spores became visible. All that could be learnt about the origin of the glairy fluid was that a monad, larger than usual, and with a granulated aspect towards the flagellate end, would seize on one in the ordinary condition. The two would swim about together till the larger absorbed the smaller, and the two were fused together. A motionless spheroidal glossy speck was then all that could be seen. This speck was found to be a sac, and after remaining still for from ten to thirty-six hours it burst, and the glairy homogeneous fluid flowed out. The young spores that came into view in this were watched through to the adult condition. Bearing on the subject of spontaneous generation, this fact was learnt, that while a temperature of 140° F. was sufficient to cause the death of adults, the spores were able to grow even after having been heated to 300° F. for ten minutes. Can it be philosophical, Mr. Dallinger asked, with the life history of bacteria still unknown, to assume it as a different method of propagation? Some experiments based on Prof. Tyndall's use of the electric beam to test optically pure air were made. The remains of infusions known to contain certain spores were diffused through glass tubes, in which were placed vessels with fluid. Monads always appeared in the fluids, but when after the air in the tubes had been allowed to purify itself by settlement, fresh fluids were introduced, no monads appeared. That there is no such thing as spontaneous generation of monads seems quite clear, and when bacteria are in like manner studied, there can be hardly a doubt the same law will be found to hold good with them.

GREAT GUNS

IT is natural that at the present time great interest should be taken in all efforts to improve, that is, to render more destructive, our implements of war. Even since the last war on the European field great advances have been made in this direction; and, as our readers know, one of the largest guns ever constructed is at present on its trial in this country. Some months ago experiments were made with what is known as the 81-ton gun, the invention of Mr. Robert Fraser; the gun was sent back to Woolwich for some alterations to be made, and on Friday the experiments were resumed at Shoeburyness on a larger scale. On the previous occasion the gun was loaded with 370 lbs. of powder, and threw a blind Palliser shell against the target. This target is of enormous strength, as strong and firmly founded as the ingenuity of engineers can make it. It is formed of four plates of the best rolled iron, each plate being 8 inches thick, and 5 inches of solid teak filled up each of the three intervals between the four plates. The 32 inches of iron and 15 inches of teak thus placed are solidly screwed together by bolts 3 inches in diameter, the whole forming, as far as scientific engineers and artillerists could construct it, an apparently impenetrable and immovable mass. To secure the target still more, iron plates were placed on the top and at the side, those at the side being strutted against the target with heavy timbers; and the supports at the rear of the target, to hold it up, as it were, against any blow, were of the like solid and substantial character.

The target stood at 120 yards' distance from the gun. On Friday the charge of powder was 425 lbs., and the weight of the blind Palliser shell 1,700 lbs. At the base of the latter was an expanding copper-ridge, known as the "Lyon" gas-check, which in the explosion would expand and fill the rifling, thus enabling the full energy of the exploded powder to be utilised.

After the gun was fired, by electricity, it was examined and found to have worked admirably; it had run back 55 feet on its tramway, which rises slightly, and had run down again to the firing-point. The shot was found not only to have penetrated three plates and the teak intervals to all four, as on the previous occasion, but to have bulged out the fourth plate some 15 inches from its normal position. The last plate was, moreover, broken across, the edges of the broken part gaping wide, and showing the head of the shot, which had thus penetrated further in distance than the 47 inches of iron and teak of the target. The powerful framework behind the target was greatly shaken. The shot itself had "set-up," *i.e.*, closed towards the head with the enormous energy, the rear-part, the gun-metal studs, and the copper gas-check, crumbling into pieces. The initial velocity of the shot, as registered by M. Le Boulenger's invention of wires with electric communication was 1,600 feet a second, and the striking velocity 1,585 feet. The mean pressure on the gun was found to be 20 tons, the interior remaining quite unaltered.

Herr Krupp, the well-known Prussian artillerist, has been devising a weapon even more formidable than that whose power of destruction was shown on Friday to be so immense. The Fraser gun is of wrought iron, but the new Krupp gun is of cast-steel, both being very nearly of the same weight, though the latter has the great advantage over the former of being a breech-loader. The length of the gun, including the breech-piece, is 29 feet 6 inches, the breech-piece itself being 6 feet 4 inches in length. The calibre of the gun is 15¾ inches. The weight of the projectile will be 750 kilogrammes, or 1,650 lbs., and the powder charge will be 396 lbs. The external diameter of the Krupp gun, independently of a narrow strengthening ring at the extreme rear, is 5 feet 10 inches, that of the Fraser gun being 6 feet. The core of the Krupp gun is a steel tube in two lengths, upon which four steel rings overlap, rising in steps from a point between the muzzle and the trunnions, and accumulating in the thickness towards its rear. These more massive rings are irrespective of the narrow strengthening ring over the powder chamber. The external diameter of the gun at the muzzle is 2 feet 3½ inches.

In common with the other large Krupp guns, the rifling of the new weapon is on the polygroove system, the elongated projectile being rotated by means of the gas-check. The velocity anticipated from the projectile fired from the Krupp 80-ton gun is 473 metres per second at the muzzle, or 1,552 feet, producing an energy of 27,543 foot tons, equal to 556 foot tons per inch of shot's circumference.

But this is not all. Should the demand arise, the great Prussian gun-maker has a design already prepared for a gun of 124 tons, to be made on the same plan as the one just described. The larger weapon would have a calibre slightly exceeding 18 inches, and would throw a steel shell weighing 1,000 kilogrammes, or a chilled iron shell of 1,030 kilogrammes. The weight of the projectile would therefore be practically a ton, and the charge of powder will be probably about 500 p

SUSPECTED RELATIONS BETWEEN THE SUN AND THE EARTH[1]

II.

IN my last article I endeavoured to show that as a matter of fact there is an intimate connection between the physical state of the sun's surface and the diurnal

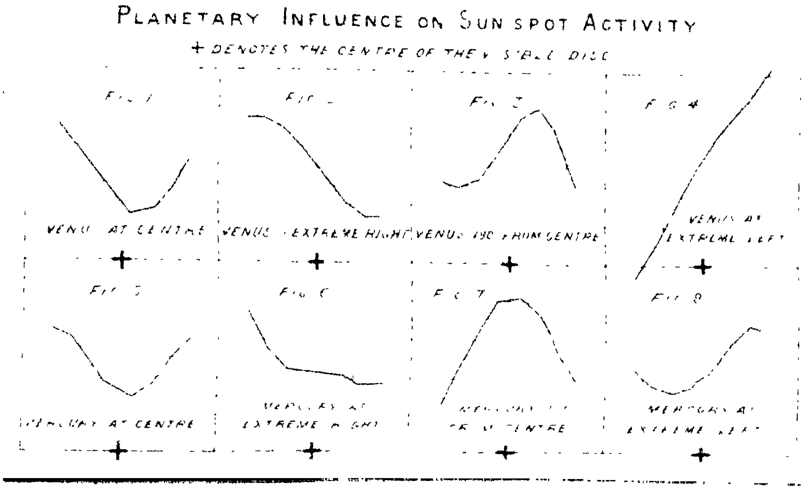

Diagram C.

range of the magnet freely suspended at the Kew Observatory. It was suggested that this relation might

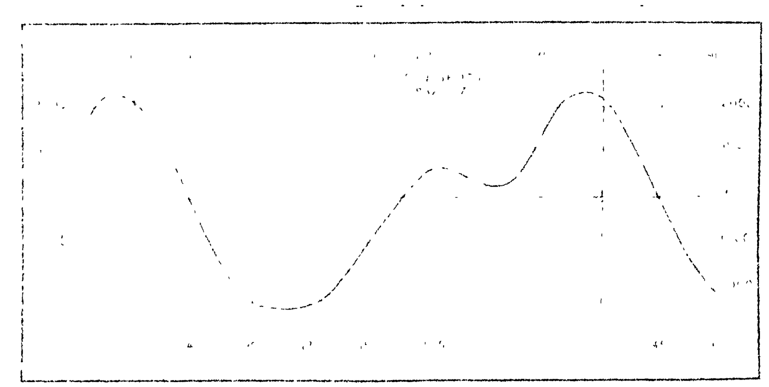

Diagram D.

be that of cause and effect, inasmuch as the variations of spotted area exhibited in Diagram B invari-

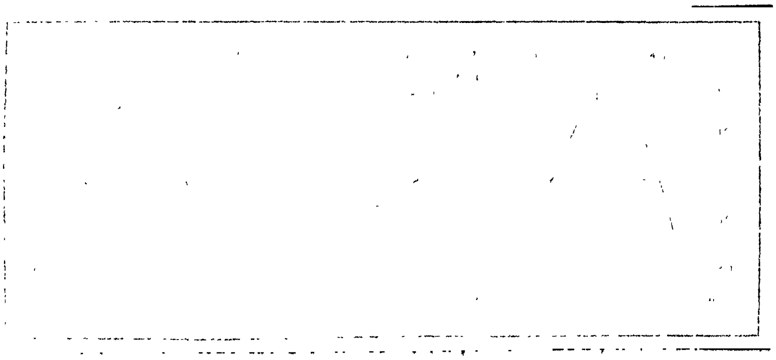

Diagram E.

ably precede the corresponding variations of magnetic range.

It cannot, however, with propriety be said that sun spots are the cause of magnetic oscillations, for it has been pointed out by Mr. J. A. Broun that even when there are no spots on the solar surface the magnet has yet a very considerable range in its daily oscillations. Then, on the other hand, the spectroscopic researches of Mr. J. N. Lockyer and others leave us little room for doubting that there may be vast solar activity without sun-spots, while, however, spots will probably make their appearance when the disturbance of the sun's surface is very great.

In fine, sun-spots will probably only afford us a rough means of estimating solar activity just as rainfall might give us a rough means of estimating the meteorological activity of a district of the earth. Is it not possible that sun-spots are in truth a species of celestial rainfall?

Be this as it may, it is evident that, inasmuch as sun-spots exhibit a recurring period, we are entitled to say there is a period of this kind in the meteorology of the sun. The interesting question then arises, What can be the possible cause of such a period? This question has been discussed by Mr. Warren De La Rue and those associated with him in his solar researches.

The theory propounded by these observers is that the planets are in some unknown way concerned in the production of spots. In their paper, which will be found in the *Proceedings* of the Royal Society for March, 1872, they make the following remark:—

"It might be said, 'How can a comparatively small body like one of the planets so far away from the sun cause such enormous disturbances of the sun's surface as we know sun-spots to be?' It ought, however, we think, to be borne in mind that in sun-spots we have, *as a matter of fact*, a set of phenomena curiously restricted to certain solar latitudes, within which, however, they vary according to some complicated periodical law, and presenting also periodical variations in their frequency of a strangely complicated nature. Now these phenomena must either be caused by something within the sun's surface, or by something without it. But if we cannot easily imagine bodies so distant as the planets to produce such large effects, we have equal difficulty in imagining anything beneath the sun's surface that could give rise to phenomena of such a complicated periodicity. Nevertheless, as we have remarked, sun-spots do exist, and obey complicated laws, whether they be caused by something within or something without the sun. Under these circumstances, it does not appear to us unphilosophical to see whether as a matter of fact the behaviour of sun-spots has any reference to planetary positions. There likewise appears to be this advantage in establishing a connection of any kind between the behaviour of sun-spots and the

[1] Continued from p. 11.

positions of some one prominent planet, that we at once expect a similar result in the case of another planet of nearly equal prominence, and are thus led to use our idea as a working hypothesis."

Proceeding upon this principle, these observers measured every sun-spot recorded by Mr. Carrington from the beginning of 1854 to the end of 1860, as well as every one photographed at the Kew Observatory from the beginning of 1862 to the beginning of 1867, and the results of all these measurements are recorded in Diagram C.

In this diagram each curved line is supposed to represent the behaviour, as regards size, of the various groups of spots as they pass across the disc of the sun by solar rotation from left to right. If, for instance, a spot were always to retain the same magnitude, its path would be represented by a horizontal line, but if it were to become smaller at the middle of its course than at either extremity, then we should have it represented as in the first figure. Now, from this diagram, we find that whenever either Venus or Mercury is between or nearly between our earth and the centre of the sun, the sun-spots behave as in the first figure; that is to say, as they are carried round by rotation nearer to the planet, they become less, and as they are carried away from the planet they become greater. Secondly, when Venus or Mercury is at the extreme right of the sun the spots diminish in size all the way across. Thirdly, when Venus or Mercury is on the other side of the sun, exactly opposite the earth, the spots have their maximum in the centre; and, finally, if Venus or Mercury be at the extreme left, the spots augment in size all the way across; in fine, they are always least in the immediate neighbourhood of Venus or Mercury, and greatest when that portion of the sun to which they are attached is carried by rotation to the position farthest from the influential planet.

If there be any truth in this evidence it would seem to follow as a corollary that when two influential planets are together on one side of the sun, their peculiar spot-producing action should be conspicuously great, and hence there should be a greater than usual amount of spots when such conjunctions take place.

On the other hand, when one influential planet is on one side of the sun and another on the other side, they might be supposed to counteract each other, and hence the spotted area would be conspicuously small. In a memoir which will be found in the *Transactions* of the Royal Society for 1870 the Kew observers have

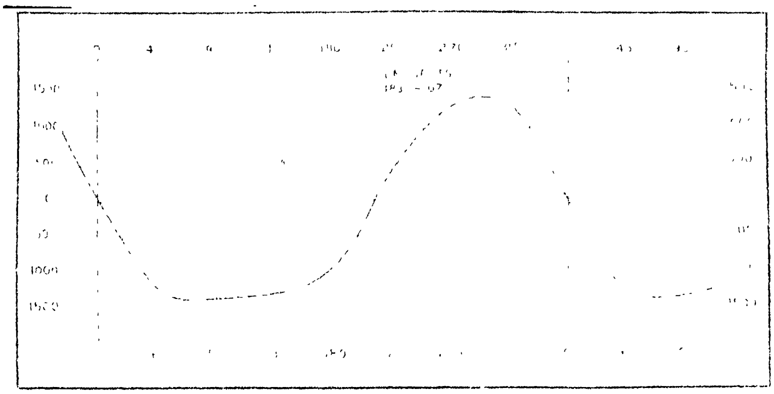

DIAGRAM F.

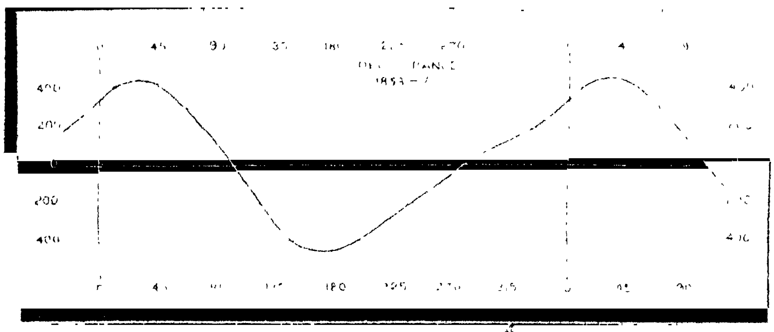

DIAGRAM G.

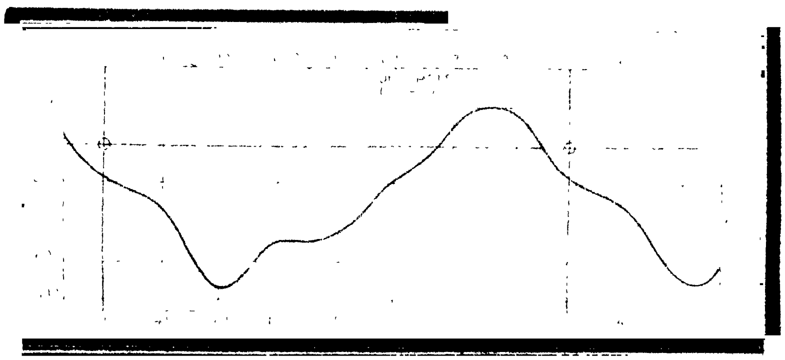

DIAGRAM H.

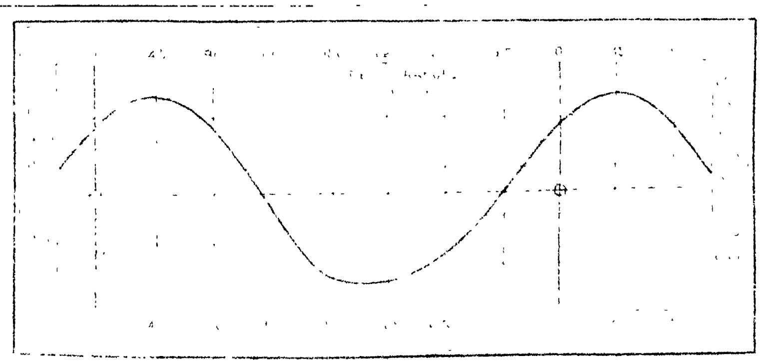

DIAGRAM I.

investigated this point also, and they appear to have found sun-spot inequalities depending on the relative positions of the various influential planets.

For instance, there is a greater than usual amount of sun-spots when Venus and Jupiter are together; there is the same a little before the time when either Venus and Mercury or Mercury and Jupiter are together, and finally, there is the same a little before the time when Mercury is nearest the sun.

These results of strictly solar observation are capable of being verified in quite a different manner. If the planets have an influence on the sun and if the state of the sun's surface affects terrestrial magnetism, it might be expected that we should have magnetic inequalities depending upon the positions of the planets.

By this it is not meant that the planets influence the magnetism of the earth directly, but rather through their effect upon the solar surface.

Again, it was shown in the last article that terrestrial magnetic effects at Kew lag behind corresponding states of the solar surface. This lagging behind ought therefore to be exhibited in any comparison which we make between sun-spot inequalities depending on the planets and magnetic inequalities at Kew depending on the same cause *if the latter inequalities are caused indirectly through the medium of the sun.*

A comparison of this kind has recently been made by the writer, using for this purpose those inequalities of short period that were most likely to be exhibited in the limited series of magnetic observations at his disposal for the purpose.

The results are embodied in the preceding diagrams. Diagram D represents the sun-spot, and diagram E the magnetic inequality due to the relative positions of Mercury and Venus (0° denoting conjunction). Diagram F represents the sun-spot, and diagram G the magnetic inequality due to the varying distance of Mercury from the sun (0° denoting perihelion). Diagram H represents the sun-spot, and diagram I the magnetic inequality due to the relative positions of Mercury and Jupiter (0° denoting conjunction). From all these it will be seen that there is a striking likeness in character between the planetary sun-spot inequalities, and the planetary magnetic inequalities derived from the records of the Kew Observatory—the latter, however, lagging behind the former in point of time, as might have been expected.

It is unquestionably a very strange and striking conclusion that the daily range of the magnet freely suspended in a vault of the Kew Observatory, should be sensibly greater about the times when Venus and Mercury, or Venus and Jupiter come together in position, and also about the times when Mercury is nearest the sun.

Perhaps it is not too much to say that the facts described in the last article go to show that the sun influences the earth, and possibly also the other planets in some unaccountable manner, while the facts of this article go to show that (shall we say in return) the most conspicuous planets of the system, and possibly also the earth, are not without an influence upon the state of the solar surface. I may be permitted, in conclusion, to transcribe a paragraph from a former essay on this subject (Owens College essays). "At first sight we are startled by the supposition that a planet like Venus, which comes nearer to the earth than it ever does to the sun, should in any way be accountable for such enormous manifestations of energy as those which occur over the sun's surface. But the wonder will disappear if we bear in mind that there may be two kinds of causes or antecedents. Thus we may say that the blacksmith is the cause of the blow with which his hammer strikes the anvil, and here the strength of the blow depends upon the strength of the smith. But we may likewise say that the man who pulls the trigger of a gun or cannon is the cause of the motion of the ball, and here there is no relation between the strength of the effect and that of its cause.

"Now, in whatever mysterious way Venus and Mercury affect the sun, we may be sure it is not after the fashion of the blacksmith—they do not deal him a violent blow producing all this enormous effect, but they rather pull the trigger, and immediately a very great change takes place." BALFOUR STEWART

(*To be continued.*)

THE NEW ZOOLOGICAL GARDENS AT CALCUTTA

THE propriety of establishing Zoological Gardens at Calcutta, has, as those who are acquainted with the proceedings of the Asiatic Society of Bengal are well aware, been before the public and the Indian Government for these last fifty years. It is, however, only within a very recent period that anything has been practically effected, and the first report on the progress made in the development of the new institution during the first year of its existence has only just reached us. Before alluding to its contents, a few words on the origin of the present scheme may be acceptable to those who take an interest in the subject.

Many previous plans for the institution of Zoological Gardens in Calcutta, including that proposed by Sir Joseph Fayrer in 1867, having come to nothing, Mr. L. Schwendler, of the Indian Telegraph Department, brought the subject again to the notice of the Council of the Asiatic Society in March, 1873. Mr. Schwendler proposed that the necessary capital should be raised by subscription, but that the Government of Bengal should grant the site and give a contribution towards the annual expenditure. This scheme, although taken up with interest by the Asiatic and Agricultural Societies and supported by the press, would have ended, like its predecessors, in failure, had not the energy of Mr. Schwendler led him to adopt a different course of action. Having a fine private collection of living animals of his own, Mr. Schwendler was able to prove to the Viceroy of India (then Lord Northbrook), who honoured him with a visit, how easy it was to maintain such an establishment in a climate so well adapted to animal and vegetable life as that of Calcutta. Instead of the large and expensive houses necessary in these inclement climes simple sheds suffice as a protection for the animals against the weather, and the luxuriant vegetation is ever springing up to contribute to their shelter and retirement. In fact, if only space is provided, and sufficient fencing is put up, animals can be kept almost in the same state as in their native wilds, and buildings may be dispensed with. So practical was Mr. Schwendler's illustration of how easily zoological gardens might be established in Calcutta by showing his own grounds fitted up for the purpose, that the Viceroy was convinced at once, and quickly brought the excellent Lieutenant-Governor of Bengal to a similar state of mind. Having taken up the matter, Sir Richard Temple set to work at it with his usual energy, and by a minute of September 24, 1875, granted a large site for the purpose on the road leading from Surat Bridge to the Governor's official residence at Belvedere. Shortly afterwards an honorary managing committee was appointed, with Lord Ullick Browne as president; Mr. Schwendler and Dr. King and Mr. Watson as members, and Mr. C. Buckland, private secretary to the Lieutenant-Governor, as honorary secretary. The objects of the new institution, besides the general instruction and recreation of the community, were specified to be to facilitate scientific observations on the habits of animals, to encourage their acclimatisation, and generally to promote the science of zoology. Upon the starting of the new institution, Mr. Schwendler immediately hastened to present to it his whole collection of living animals, and the Governor-General promised to remove the Barrackpore menagerie to the new site as soon as the necessary preparations were made. All the native princes, nobility, and gentry subscribed liberally towards the proposed gardens—for instance, the Maharajah of Burdwan gave 3,000*l*.; others followed this liberal example, and the greater part of the required capital of 30,000*l*. was quickly raised. Such rapid progress was made that occasion was taken of the Prince of Wales's presence in Calcutta on December 27, 1875, to inaugurate the new institution. His Royal Highness expressed his gratification at the results already achieved, praised Mr. Schwendler for the public spirit he had displayed, and accepted the patronship of the gardens.

The Royal Zoological Gardens of Calcutta thus inaugurated were opened to the public for the first time on May 6 of last year. From that date up to the close of the year more than 50,000 persons had visited them, without including members and donors, and soldiers with their wives and children who have a free entrance. The buildings are, of course, yet far from complete, but amongst those finished are, as we are informed, many deer-paddocks, which are already well tenanted; a large and several smaller aviaries, also well filled; a large bear-house in three compartments, and furnished with a large bath; two monkey-houses, and a very large pit fitted up for the residence of rhinoceroses. Within the gardens is also a large tank or lake, with two islands used for water-fowl, and a restaurant and keepers' dwellings have likewise been erected.

At the present time Mr. C. T. Buckland, C.S., is the president of the Association for the maintenance of the gardens, and Dr. J. Anderson and Mr. H. M. Tobin have the general superintendence and honorary care of them, the paid officials consisting of natives only. A European director was appointed in January, 1876, but the Government of Bengal were shortly afterwards stopped by the Supreme Government from contributing to the expenses of the gardens, and his services had consequently to be dispensed with.

s change of front in the Supreme Government, who had virtually pledged themselves to assist in the scheme, and who have not yet redeemed their promise to transfer the Barrackpore menagerie to the new gardens, is a subject of not unnatural complaint on the part of the committee, who are now striving hard to have matters replaced upon their former footing. As the Indian Government keep up botanical gardens in Calcutta, and pay a scientific officer a liberal salary to superintend them, they would surely be fully justified in treating the Zoological Gardens in the same way, especially until the new institution is fairly set a-going. Living animals, as we all know, are far more attractive to the general public than living plants, and there can be no question, we believe, that in Calcutta, as in London, zoological gardens are more popular than botanical. The public of Calcutta have come bravely down with a sum of 30,000*l*. to set the institution going, and will be greatly disappointed if the Government do not support them. A scientific director for the establishment is an absolute necessity, as it cannot be expected that Dr. Anderson and others who now manage it can continue their gratuitous services. Lord Northbrook is now earning his well-merited repose in this country, but looking to the countenance and favour that he has already shown to the Zoological Gardens at Calcutta, we cannot doubt that he will assist in the appeal that is, we understand, now being made to the authorities at home, to obtain permission from the Government of Bengal to continue the support which it gave at first. We may also fairly call upon Lord Salisbury, who has on many occasions shown his appreciation of scientific work, to devote a few minutes' attention to this subject. It is certain that no better step could be taken for the advancement of Zoological Science in India than the establishment of the Zoological Gardens of Calcutta on a firm footing. Like our Gardens in London they might easily be made a centre whence encouragement is diffused to zoological investigations of every kind. A well-selected director, appointed and paid by the Government, would at once place matters on a satisfactory foundation, and tend to bring together support to the Institution from every quarter, and we cannot doubt that the present obstruction will be removed by the Central Authority as soon as the real facts of the case are brough before them.

OUR ASTRONOMICAL COLUMN

Double-Star Measures at Cincinnati.—In Nos. 2 and 3 of the publications of the Cincinnati Observatory are two series of micrometrical measures of double-stars made with the 11-inch Merz refractor. The first series includes measures by Prof. O. M. Mitchell at the old Observatory, confined, with few exceptions, to the stars of the great Dorpat Catalogue, and made in the years 1846-48, a small number of which only had appeared in the *Sidereal Messenger*.—The second series comprises measures of objects situated for the most part beyond Struve's limit of south declination made in the years 1875-76, and will probably be found the most useful of the two, observations of these southern stars being as yet in small number. Mr. Ormond Stone, the present director at Cincinnati, remarks that "no systematic survey of the southern heavens similar to that made by Struve of the northern heavens has ever been undertaken," and a large proportion of Sir John Herschel's doubles have never been properly measured micrometrically. The Cincinnati object-glass having been refigured by Alvan Clark during the last winter, the director purposes devoting the instrument to supplementing the labours of other astronomers by measuring double-stars between 15° and 35° of south declination; no doubt in the course of this work new binary systems will be detected.

Amongst the stars in the second of the above series, is *h* 2036, the duplicity of which was first remarked by Sir John Herschel with the 20-feet reflector in sweep 307 (1830, Oct. 15), when the position was registered 53°·0, and the estimated distance was 2″. The last Cincinnati measures give for 1876·78, position 26°·4, distance 1″·64, and Capt. Jacob's intervening measures at Poona and Madras, confirm the retrograde motion in the angle; indeed, he first pointed out the probable binary character of the star, and also suggested another noticeable feature, viz., the apparent variability of *both* components (Mem. R.A.S., vol. xxviii. p. 41). A comparison of the whole of the estimates of magnitude to 1876, is certainly confirmatory of Capt. Jacob's suspicion. The stars have not been noted as differing more than half a magnitude, and generally have been considered of equal brightness, yet the estimations vary from 6·7 (Jacob 1857) to 9·0 (Ormond Stone, 1875). The object is well within reach in this country, and deserves watching. It may be remarked that the N.P.D. given in Sir John Herschel's fifth series of measures with the 20-feet reflector, is 1° too small. By an observation in the Washington zones, the position for the beginning of the present year is in R.A. 1h. 13m. 54·7s., N.P.D. 106° 26′ 15″.

Change of Colour in α Ursæ Majoris.—Herr Weber continues his observations upon the colour of this star, a periodical change in which from intense fiery-red to yellow was first suspected by Dr. Klein of Cologne about fifteen years since. According to Herr Weber the change is from fiery-red to white or slightly yellowish white. The following are recent observed epochs of red light:—1876: September 5, October 10, November 14, December 21. 1877: January 16, March 23, whence an average period of thirty-three days is indicated. The star was white or nearly white, 1876: October 28, December 30. 1877: February 8 and March 13. The star is said to remain red or reddish for a shorter time than it is seen white or yellowish white. See *Astron. Nach.*, Nos. 2,111 and 2,127.

α CENTAURI.—The measures of this star which have lately appeared in NATURE show that we are yet without any satisfactory orbit, and it is much to be desired that it may be closely watched during the next few years. Mr. Gill it is understood intends to establish a good epoch in the autumn with Lord Lindsay's heliometer at Ascension. It does not appear to be too late to secure measures which will possess the greatest interest in the actual near approach of the two fine stars forming this splendid binary.

THE PRESENT COMETS.—Elements of Winnecke's comet of April 5 calculated by Dr. Plath of Hamburg, upon the same extent of observation as those of Mr. Hind, published in this column last week, are almost identical therewith, and consequently negative the idea of ellipticity of orbit, notwithstanding the certain degree of resemblance with the comets 1827 II. and 1852 II., and near equality of intervals. On May 14 the comet approaches within 10° of the pole of the equator, near the 5½ m. star, B.A.C. 1211. It will be visible with telescopic aid some weeks longer.

We subjoin positions of the comet discovered in America by Mr. Lewis Swift on April 11, and by M. Borrelly at Marseilles three nights subsequently, also calculated by Dr. Plath.

For 12h. Berlin M.T.

M. Wolff, of the Observatory at Paris, observed the spectrum of Winnecke's comet on the morning of April 11, which he found analogous to the spectra of various comets he had observed since the year 1868, from the faintest to the brilliant comet of Coggia in the summer of 1874. All have exhibited the three bands, yellow, green, and blue, but M. Wolff remarks that the nature of this cometary matter is completely unknown. He did not succeed in obtaining the spectrum of the third comet of the present year, in which, like several other observers, he noticed a resolvable appearance.

BIOLOGICAL NOTES

ZOOLOGICAL CLASSIFICATION.—In a recent paper in *Pflüger's Archiv*, M. Hoppe-Seyler wonders at the readiness with which systematic zoology has ranked amphioxus with the vertebrates, from mere one-sided consideration of the presence of a *chorda dorsalis*, and the position of the nerve-cord above, and the alimentary canal below. A sound system groups species which are similar not merely in morphological respects, but in their whole organisation. Amphioxus has, beyond the chorda, nothing in common with vertebrates; it has no closed vascular system with red blood corpuscles, no liver which forms a gall, no proper brain, and it contains no gelatine-yielding tissue, which occurs in all vertebrates and also in the cephalopoda, but in no other invertebrata. In their entire highly-developed organism, the cephalopoda, stand nearest to the vertebrata; the amphioxus should have a place further down. M. Hoppe-Seyler further points out that comparing the composition of tissues from the lower organised animals upwards, we meet first with mucin yielding tissues, then with those yielding chondrin, then, in the cephalopoda tissues yielding glutin; the formation of actual bones does not occur in all vertebrata, and is likewise wanting in cephalopoda. Exactly the same order is seen in the stages of development of an embryo, *e.g.* of the hen in the egg, and it is difficult to think that the agreement is accidental.

LUMINOUS CAMPANULARIÆ.—The late Prof. Paolo Panceri recently made minute researches at Amalfi, near Naples, with a view to determine the exact seat of the light-giving organs in Campanulariadæ. The Gulf of Amalfi seems to be a favourite haunt of these minute animals, and Prof. Panceri found them abundantly on the algæ covering the rocks near the shore, particularly upon *Fucus ericoides*. The light of these polyps is intermittent, and only appears when the animals are touched or moved; fresh water, however, has the property of fixing it for a little time. It was principally with species of *Campanularia flexuosa* that Prof. Panceri made his interesting investigations, and the special question he wished to decide was whether it is the external cellular stratum (or ectoderm), or the internal one (endoderm) of which these animals are composed, which is the actual seat of the light. He found, by means of ingenious microscopical contrivances that the luminous movements of these polyps have their seat in the cells of the ectoderm, and not elsewhere, and that these cells alternately and successively show the light and again become dark, after being touched or placed into fresh water. Not only the bodies of the polyps, but also their slender stems and even the feet with which they adhere to the plants or rocks, contain these luminous cells. Prof. Panceri has published an account of his researches in the January part of the *Rivista Scientifico-industriale*.

RESPIRATION IN FROGS.—Mr. A. C. Horner has sent us an account of some interesting observations he has made on the spawning or deposition of ova in the frog (*Rana temporaria*). We are only able to give the conclusion of his paper:—I will now give a few facts connected with respiration which I have observed in these frogs. They can croak when they are immersed under water, but, as no air-bubbles escape, I was at first puzzled. I find, however, by holding my nose and shutting my mouth, that I can make a somewhat similar sound; but they seemed to croak louder when only the head and upper part of the body were under water than when their whole body was immersed, and as they distend their sides in the act of croaking, I thought it possible they might be able to draw in air by the rectum or the pores of their skin. When a frog out of water is touched suddenly, he shuts his eyes and distends his abdomen, and the same thing occurs when under water. Yet how is it that they can distend their abdomen without admitting more air? for they can distend it very fully, and I should think must require to expel all the air from the thoracic into the abdominal cavity. When a frog is under water, his sides sometimes pulsate rhythmically, just as when he is out of water, and about every ten seconds. Perhaps it is connected with the circulation of blood.

THE WOODPECKER.—In the April session of the German Ornithological Society Prof. Alton concluded the recital of his investigations on the habits of the woodpecker. The peculiar drumming sound often caused by it was shown on various grounds to be entirely disconnected with the search for insects as hitherto supposed, and was regarded as a call to the opposite sex. Dr. Brehm defended the woodpeckers against the charge of seriously injuring the trees, and considered the slight damages resulting from them as more than compensated by the colour and animation which they gave to the otherwise sober and quiet forests.

THE FLAMINGO.—At the same session Herr Gadow stated that by a study of the digestive organs of the flamingo he had found that it did not belong to the duck family as hitherto classified, but was to be placed among the storks, being very closely allied to the latter, although properly an intermediate link between the two families.

COPPER IN THE BLOOD.—The presence of copper in the blood of human beings and domestic animals has been placed beyond doubt by the investigations of various chemists, but has generally been regarded as an accidental circumstance due to the use of copper utensils in the preparation of food. M. S. Cloez, of Paris, recently examined the blood of a roebuck shot in the forest of Essarts, and found copper oxide present to the extent of 5½ milligrammes per kilogramme of blood. As this result would tend to show that copper is a normal constituent of the blood, the question which next awaits solution is that of the method of its entrance into the animal system.

THE RESPIRATION OF PLANTS.—We have already noticed the investigations undertaken by Prof. Borodin on the processes of respiration in plants. We find in the seventh volume of the *Memoirs* of the St. Petersburg Society of Naturalists the paper of Prof. Borodin in full, accompanied by a series of graphic representations, by means of curves, of his important measurements. We cannot attempt here to give a *résumé* either of the varied experiments made by the author or of the important questions arising from Prof. Borodin's inquiry, and discussed by him. As to the experiments themselves, we can only state that the reader will find in the paper a thorough discussion of their value and of the value of various methods used for the study of the subject. The main result is that in darkness the energy of respiration of a branch gradually decreases; a temporary action of light, however, increases it, this increase being mostly the result of the influence of the less refrangible rays (red, &c.), and it takes place only when the surrounding air can supply the plant with a sufficient amount of carbonic acid. The decrease of energy of respiration is caused by the decrease of the stock of starch in the plant, and the increase under the influence of light takes place because of the formation, under this influence, of a new stock of starch. Thus, other conditions remaining the same, the energy of respiration depends upon the existence in the branch of non-nitrogenous plastic substance; this is the material for respiration, the exhaled carbonic acid being the result of oxidation of a certain part of non-nitrogenous organic matter. While following the author in his discussion of this subject and of the opinions of Garreau, Pfluger, and Sachs, we further notice the importance of a fresh supply of oxygen in the atmosphere surrounding the plant as resulting from M. Borodin's experiments and the contributions they make to the most important and yet very obscure question as to the influence of temperature upon respiration. These important questions will be the subject of further studies, which the author proposes to continue for many years.

A TASMANIAN CARNIVOROUS PLANT.—Dr. B. Crowther, of Campbell Town, Tasmania, writing to *The Mercury* (Hobart Town), November 26, 1876, states that he was furnished with a plant which grows on rocky ground, whose crevices contain rich organic soil, different from the peaty soil Darwin's grew in. It is quite obvious, he states, on careful examination, that the plant lives to a great extent off the small flies and gnats it obtains. It is about six inches in height, and from its single vertical stem project from one to two dozen small foot-stalks, at irregular and variable distances. On the summit of each foot-stalk is a rounded disc, placed horizontally, about half an inch in circumference, fringed with tentacles of different sizes. In the centre is a hollow, with small fine filaments projecting vertically; on the ends of both the filaments and also tentacles are little reddish glands which secrete a sticky substance. The fly rests on the outer zone, is conveyed by the sticky tentacles to the centre, which at once closes upon the victim so tightly that a bulging may be seen corresponding to the fly inside. After it has been consumed, the trap again opens, showing the *débris* of the fly, which are doubtless washed away by the rain, so as to allow the trap to again set for another victim. The plant described by Dr. Crowther is evidently *Drosera peltata*, Smith, a well-known Australian species (in herbaria). It is not referred to by Mr. Darwin in his work on "Insectivorous Plants;" and any more exact information respecting its habits of life, and the mode in which it captures insects would be a very useful addition to our knowledge of these plants, especially if accompanied by drawings.

BOTANY OF NEW GUINEA.—The distinguished Italian naturalist and traveller, Dr. Beccari, has commenced the publication of a new illustrated work called "Malesia," for the purpose of bringing before the scientific world his numerous botanical discoveries in New Guinea and the Eastern Archipelago. The first number of "Malesia" has just been issued at Genoa, and is occupied with an article upon the palms of New Guinea and the adjacent islands. Fifty species of palms were collected by Dr. Beccari in these countries, many of which were previously unknown.

NOTES

MR. C. J. LAMBERT has presented to the Chemical Society 1,000*l.* and to the Royal Microscopical Society, 500*l.*, from a bequest of 25,000*l.* left by his late father, to be appropriated to benevolent and scientific purposes.

WE regret to learn that Prof. M'Crady who, on the death of Prof. Agassiz, succeeded to the Chair of Zoology in Harvard College, has found it necessary to tender his resignation to the authorities of the University. This step is all the more to be lamented as judging from the terms of the resignation, which we have read, it has been caused by a desire on the part of Prof. M'Crady to raise the standard of zoological education in the college to a higher level than was deemed advisable by the authorities. We hope that some means may be found of retaining Prof. M'Crady's services to the University. He is well known as an eminent original worker in an important department of zoological research.

WE regret to announce the death of a Russian geologist, Prof. N. P. Barbot-de-Marny. Having begun his scientific work in 1852, taking part in Hoffmann's exploration of the Ural, M. de Marny continued until 1876 his valuable work of the geological exploration of Russia. He explored the Kuma-Manych depression, the provinces of Archangel, Vologda, Volhynia, Podolia, and Kherson, and all the lines of railway radiating from Moscow, as well as those of Kief, Azov, Tsaritsin, Orenburg, and Caucasus. In 1874 he took an active part in the difficult exploration of the Aral-Caspian expedition and explored the Amu-Darya. The *Mines Journal* and the *Memoirs* of the Mineralogical and Geographical Societies, as well as those of the St. Petersburg Society of Naturalists, one of the presidents of of which he was for a long time, contain about 110 of his valuable papers, besides which he was the author of some important volumes. His "Formation Stage" was an important addition to our knowledge of the Tertiary of South-eastern Europe. He died at the age of forty-five, leaving a family, a library of books, many MSS., and—no money.

THE President of the Royal Academy is always very catholic in his invitations to the annual dinner, certainly one of the chief events of the London year. On Saturday last science was largely and well represented, and Dr. Hooker, in his reply to the toast of Science, happily performed what at first sight would seem a hard task under the circumstances. Dr. Hooker showed that the incongruity between art and science was only apparent; that art lends valuable aid to science, and that all true art must really be based on scientific principles; and that moreover the two have this in common, that success is unattainable in neither unless by close observation, enthusiasm, and the skilful exercise of the imagination. Some may be inclined to think that the new Grosvenor Gallery is more scientific in its method of selection than the much maligned Academy, but then the objects of the two are very different. At all events the man of science will be furnished with much food for thought and wonder in both. What seems to be generally regarded as the masterpiece in the Grosvenor, Mr. Burne Jones's "Six Days of Creation," may remind geologists of Hugh Miller's famous phantasy, written in the old "reconciliation" days. However this may be, its conception and execution are deserving of study from many points of view, including even the scientific.

THE great Museum of Applied Sciences in Moscow will be opened on June 11, the birthday of Peter the Great. The building is ready and the collections have been brought in. It has cost up to the present time half a million of roubles, occupies a space of 13,633 square yards, and is divided into three blocks. Besides spacious rooms for collections in applied science, it contains a large and well-ventilated auditory. Eleven scientific societies will hold their sittings in the Museum.

THE foundation of a permanent station for help to wrecked vessels on Novaya Zemlya is now in way of execution. We hope that the station will also be used for taking regular meteorological observations. An Eskimo family, which has already wintered for two years on the island, will remain there permanently, and be supplied by the Russian Government with all necessaries.

PROF. LEITH ADAMS has commenced a course of six lectures on the "Distribution of Animals as elucidating Past Changes of the Earth's Surface," in the Royal College of Science, Dublin.

A PRIZE of 10*l.*, which has been placed at the disposition of the Council by Col. A. A. Croll, is offered by the Society of Arts, with the Society's Silver Medal, for the best set of Blowpipe apparatus which shall be sold retail for one guinea. All apparatus for competition must be sent to the Society's house on or before August 1, 1877. Details will be found in the *Journal* of May 4.

THE Prince of Wales, in company with Mr. Cunliffe Owen, Col. Ellis, Lord Suffield, and M. Blowitz, visited the works of the Paris International Exhibition at the Champ de Mars and Trocadero, last Saturday. He was received by M. Krantz, Director of the Exhibition, the Minister of Trade, and some officials. The Prince of Wales was much pleased with the state of the works, which are progressing so rapidly that it is now possible to have a view of the buildings covering so large a space. He selected a space for the special exhibition of objects which he brought back with him from his tour in India.

IN the current number of *Mind*, Mr. G. H. Lewes gives briefly what seems to be one of the chief positions taken by him in his new volume "The Physical Basis of Mind." He finds that according to usage the word "consciousness" is equivalent to sentience or feeling; that it is also used in a special sense as signifying that we not only feel, but feel or are conscious that we feel. Now Mr. Lewes holds that every neural process implies sensibility, indeed *is* feeling or consciousness in the general sense of that term; accordingly consciousness, sentience—these neural processes may be said to have "various modes and degrees—such as perception, ideation, emotion, volition, which may be conscious, sub-conscious, or unconscious." In the last sentence the word "unconscious" describes a mode or degree of sentience which has not given rise to consciousness in the special sense, and Mr. Lewes contends that the word "unconscious" ought to be confined to this usage, that in strictness we should not speak of unconsciousness outside the sphere of sentience. He then proceeds to argue that to describe a neural process as a mere series of physical changes is to say that "organic processes suddenly cease to be organic and become purely physical by a slight change in their *relative* position in the consensus." The matter of fact of which Mr. Lewes has to persuade his readers is, that "the reflex mechanism necessarily involves sensibility," that a neural process is a feeling.

SIX years ago Dr. Maudsley contended against the popular opinion that insanity was on the increase in this country, the rapid increase of the registered insane being open to a less gloomy explanation. It is gratifying to find that Dr. Maudsley can in the current number of the *Journal of Mental Science* still maintain with every appearance of truth, that there is no evidence of an increased production of insanity in this country.

AT a recent meeting of the Chemical Section of the Society of Arts, Dr. B. H. Paul read a paper on "The Cinchona Alkaloids, their Sources, Production, and Use," in which he traced the history of the cinchonas from the early part of the seventeenth century to their successful cultivation in India and other countries. The chemistry of the cinchona barks is a point about which but little is popularly known. It would seem that a considerable amount of cinchonidine, one of the several alkaloids found in cinchona barks, is often mixed with the sulphate of quinine of commerce, sometimes, indeed, exceeding ten per cent., and though the medicinal efficacy of the quinine is not materially impaired by this mixing, a great difference is made in the intrinsic value, cinchonidine being worth not more than one-eighth as much as quinine. Considering the present high price of quinine, it is pleasant to be told by Dr. Paul that "the sulphate of cinchonidine has been proved to be very little inferior in efficacy—for certain kinds of maladies—to quinine," the price of this alkaloid being two or three shillings an ounce against sixteen shillings for quinine.

M. JABLOSKOW, a Russian electrician, has exhibited before the Physical Society of Paris a new process for producing electric light. The voltaic arc is quite suppressed and a current is sent merely through a plate of caolin, which ignites and fuses gradually, giving out a magnificent steady light. The transverse dimension which the current is able to warm and ignite varies according to the force of the battery. M. Jabloskow made a most interesting experiment. Cutting in two parts a plate of caolin which had been used for giving a light, he raised two separate lights with the same current. The light given by these two plates was found equal to the light which had been given a few minutes previously. The experiment was considered by all present to be a great success. Experiments on a large scale will be shortly tried at the large hall of the Magazin du Louvre. The generator of electricity was an induction machine of the Alliance type worked by two men.

AT the last meeting of the Russian Geographical Society M. Wojeikof reported upon his last journey in Japan. He started from Hakodadi and visited the Ainos of Jesso Island; he then went to Aomori, in the northern part of Nipon, and travelled to Jeddo, crossing Nipon Island three times from west to east. The northern part of the island is not populous, only the high valleys being settled. The climate of the western shores of Japan is far milder than is generally supposed, the tea-tree reaching here as far as 40° north latitude. The most important result of the journey is the measurement by barometer of the heights of about 600 places.

RUSSIAN newspapers announce that our countryman, Mr. Harvey, after having stayed for three days in St. Petersburg, continued his journey for the zoological exploration of the Pechora region. He is accompanied by a painter and a zoological collector.

THE last number of the *Isvestia* of the Russian Geographical Society announces that the south-western branch of the Society, established at Kief, is closed by Imperial Order for political reasons.

THE same periodical gives some information as to the journey made last summer by Capt. Pevtsov with a Cossack detachment which protected the caravan with corn, sent by Russian tradesmen from the Lake Zaisan, *viâ* Bulun-Tokhoi, to the Chinese town Gu-chen (Dzungaria, N. lat. 43° 50′, E. long. 90° 14′). The results of this journey are,—a survey of the route, 560 miles long, with maps of the towns, astronomical determinations of the positions of seven points, magnetical observations, barometrical measurements of heights, a complete geological exploration along the route, a collection of about 1,000 species of plants, and a zoological collection numbering 34 mammalia and 123 birds

THE Geological Survey of Finland, which was undertaken on the scheme of that of Sweden, but was interrupted in 1868, will be continued this year.

A TELEGRAM received by the St. Petersburg Academy of Sciences, announces that the mammoth found in the neighbourhood of Tomsk is very well preserved. A piece of its flesh with fat has been forwarded to the Academy, which, as we learn from a private source, proposes to send M. Poliakof for the exploration of the remains.

THE Russian Geographical Society has undertaken the publication of an historical sketch of geographical explorations in Northern Asia, with accounts of all expeditions, an index of works on Northern Asia, and a map showing the routes followed by all important exploring parties. The work will appear in 1879, that year being the tercentenary of the crossing of the Ural Mountains by Yermak, the conqueror of Siberia.

IN a recent communication to the Belgian Academy, M. van Monckhoven describes some improvements in the photographic reproduction of ultraviolet spectra of gases. He employs two large Geissler tubes placed parallel and communicating together by a capillary tube at right angles to them. The spectroscope consists of three 60° prisms of Iceland spar, cut so that the bisector plane of each of their dihedral angles is parallel to the optic axis of the crystal. With such prisms the ordinary and extraordinary spectra do not encroach on one another. The axis of the capillary tube is then made to coincide exactly with that of the collimator of the spectroscope, and the intensity of the light, which can be utilised during passage of the current from a Ruhmkorff coil, is found to be very much greater than if the tube were placed, as usual, perpendicularly to the axis of the apparatus. The author recommends using a plate of quartz in place of one of the large tubes of glass, so as to prevent too great absorption of rays of high refrangibility. To give an idea of the exactness with which even the most refrangible bright lines are reproduced, M. van Monckhoven presented three plates representing the solar spectrum, the bright lines of hydrogen combined with those of aluminium (of which the electrodes were formed), and the bright lines of a solar protuberance.

WE have received from Prof. E. S. Holden, of the United States Naval Observatory, a list compiled by him of the principal telescopes in the possession of public institutions and private individuals. The list, though imperfect, is a long one, and we regret that the pressure on our space prevents us from printing it. Those who would like to possess it will find it in the *Popular Science Monthly* for March. Among reflectors we notice that Lord Rosse's is still unsurpassed; it has an aperture of 6 ft. and a focal length of 55 ft. Mr. Ellery's, of Melbourne, has a 4 ft. aperture and a focal length of 32 ft.; that of the Paris Observatory an aperture of 1·20 metre and a focal length of 7 metres. Of refractors the two largest are now constructing; that for Yale College Observatory (by Clark and Sons) will have an aperture of 28 in., and the one for Vienna, constructed by Grubb, an aperture of 27 in. The refractor belonging to Mr. Newall, of Gateshead, has an aperture of 25 in. and a focal length of 29 ft.; the corresponding dimensions of the Pulkowa refractor are 14·93 in. and 270·6 in.; Lord Lindsay's, 15 in. and 15 ft.; that of Greenwich, 12·5 in. and 16·6 ft.; the largest in the Paris Observatory, 12 French in. and 5 metres; Rutherfurd's, of New York (a photographic refractor), an aperture of 10·5 French in.; Secchi, of Rome, 7·5 French in., and 14 French ft. Altogether Prof. Holden enumerates upwards of 140 telescopes that are at work on the heavens, and remarks, with some justice, that "it is a melancholy fact that the return from so many instruments is not so great as it should be, and it suggests the question as to whether future benefactors will not do better to provide astronomers to use the telescopes already constructed than observatories in which to put new ones."

TO those who take a practical interest in the ventilation of houses we would recommend a pamphlet by Mr. James Curtis, C.E., entitled "Fresh Air in the House, and How to Secure It" (Ward, Lock, and Tyler). Mr. Curtis has evidently studied the important subject of ventilation carefully, and his practical suggestions will be found useful to those anxious to secure a regular supply of fresh air in their houses.

IN the note on Mr. Shrubsole's discovery (vol. xv. p. 561), the word *chalk* should be *chert*.

THE additions to the Zoological Society's Gardens during the past week include two Green-winged Doves (*Chalcophaps indica*), a Hamilton's Terrapin (*Clemmys hamiltoni*) from India, presented by Mrs. M. A. Moore; three Water Ouzels (*Cinclus aquaticus*), European, presented by Mr. G. B. Davies Cooke; an Indian Python (*Python molurus*) from India, presented by Mr. C. A. F. Bowell; six River Lampreys (*Petromyzon fluviatilis*) from British Rivers, presented by Mr. A. H. Cocks, F.Z.S.; a Virginian Deer (*Cervus virginianus*) from North America, a Rock Cavy (*Cerodon rupestris*) from South America, deposited; two Raccoon-like Dogs (*Nyctereutes procyonides*), four Common Foxes (*Canis vulpes*) born in the Gardens.

UNIVERSITY INTELLIGENCE

OXFORD.—An examination will be held at St. John's College on Tuesday, June 12, and the two following days, to elect to two Foundation Scholarships for Classics, and to the Holmes Scholarship, which will be given for Natural Science. The subjects of examination in Natural Science will be Chemistry and Physics; there will be also a pass paper in Classics; there is no restriction of age. The scholarship is tenable for five years, and is of the value of 100*l.* per annum.

The Boden Professor of Sanskrit (Mr. Monier Williams) proposes to give two public lectures (open to all members of the university and their friends) in the large lecture room of the museum, on Wednesday, May 23, and Wednesday, May 30, at three P.M. The subject will be "The Sacred Places, Religious Creeds, and Superstitions of Southern India and Ceylon," and the lectures will be illustrated by diagrams and objects of interest (including a model of the Parsee Towers of Silence) brought from India.

CAMBRIDGE.—The "Rede" Lecture will be delivered in the Senate-house on Friday, May 25, at half-past two in the afternoon. The lecturer is Sir C. Wyville Thomson, and the subject of the lecture will be "On some of the Results of the Expedition of Her Majesty's ship *Challenger*."

LONDON.—At Tuesday's Convocation of the University of London a resolution was proposed thanking the Senate for their decision to admit women to degrees in medicine. To this an amendment was moved that it was undesirable to take this course before the House had considered the advisability of admitting women to degrees in all faculties. This was carried on a division by 142 to 120, and was afterwards adopted as a substantive motion by 144 to 116

EDINBURGH.—Lord Zetland has intimated that with the sum, amounting to between 4,000*l.* and 5,000*l.*, which he has received as compensation for the abolition of patronage in Orkney and Shetland, he intends to found several bursaries in connection with the Faculty of Arts in Edinburgh University. His lordship, in so disposing of the money, has in view the advancement of the educational interests of Orkney and Shetland, of either of which the intending bursars must be natives.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 12.—"On the Constant Vibration of Minute Bubbles." By Walter Noel Hartley, F.R.S.E., King's College, London.

Those who have given great attention to the study of fluid cavities in minerals, have occasionally met with vibrating particles which are apparently bubbles.

Mr. Hartley became acquainted with these at the close of last year, 1875, when Mr. P. J. Butler showed him a ruby containing a cavity partially filled with liquid carbonic acid, the bubble in which, when of small size, was in constant motion.

He also refers to a felstone containing portions of quartz with many cavities. The majority of these were water cavities, but others appeared to be empty; and in one of them Mr. Young had noticed a moving particle, supposed to be a bubble, which made its appearance only in a cold atmosphere. By dropping a little ether on the object, the evaporation cooled it sufficiently to condense a liquid in the cavity, and the moving particle was easily seen with a magnifying power of 400 diameters. By immersion in iced water, the temperature of which was 3°·5 C., the cavity had the appearance of being two-thirds filled with a liquid, the gas-bubble of course occupying the remaining space, and having a sort of trembling motion. The bubble decreased in size, and the motion became more and more rapid as the size became smaller, until it rushed up and down and across the space in which it was confined. The thought immediately occurred that this was not a gas-bubble, but a liquid in the spheroidal condition,—in all probability carbon dioxide in a perfectly dry condition, and perhaps mixed with some incondensable gas, so that its critical point was lowered.

He concludes:—I have proved that gas-bubbles in water as well as in carbonic acid, may be attracted by a source of heat giving an extremely slight rise of temperature. It is impossible to imagine a body which is not gaining or losing, or at the same time both gaining and losing heat; it is therefore impossible to imagine it entirely throughout at a uniform temperature. It is evident then that an easily movable particle which can be set in motion by exceedingly slight rises of temperature will make the transference of heat from one point to another plainly visible; I have shown that the minute bubbles in fluid-cavities are such particles; and I believe that the vibratory motions which I have described afford an ocular demonstration of the continual passage of heat through solid substances. These phenomena really make the molecular vibrations of matter plainly visible.

April 12.—"On Attraction and Repulsion of Bubbles by Heat," by Walter Noel Hartley, F.R.S.E., F.C.S., King's College, London.

The paper deals with the bubbles in fluid-cavities of crystals, and their behaviour when a source of heat is brought near them.

With regard to the attraction of bubbles by heat, the author has noticed this take place in some water-cavities when the bubbles were free to move, and no carbonic acid was present.

With regard to this second point, the repulsion of bubbles by heat, water being the only liquid. It occurs quite as frequently, if, indeed, not more so, in the specimens which the author has examined, than attraction; and it is seen to occur in cavities containing water and liquid carbonic acid.

In a paper which the author lately communicated to the Chemical Society, he has given details of experiments on certain bubbles in water-cavities, which prove that by rise of temperature the bubbles become denser than the water and sink.

Bubbles attracted by heat and those which are repelled have generally been found in separate and entirely different specimens, and it would appear most improbable that they should exist in the same piece of stone side by side.

My work, the author said, was discontinued for a long period of two months, but on being able to look over my specimens once more, I verified all my former observations, and became surprised by the following discovery:—A bubble which was repelled by a gentle heat was attracted after it had been heated more strongly, and then on cooling it was again repelled. It appeared to contain some liquid carbonic acid floating on water with the gas.

It may be considered an argument against the motions being due to any pyro-electric conditions of the minerals, that they have been noticed in crystals of fluor-spar, and that no matter in which direction sections of rock-crystal are cut, the movements are all equally well obtained.

Regarding the repulsion of gas-bubbles, two facts are striking, namely, the very slight rise of temperature (less than ¼° C.) on one side of the bubble capable of causing the movement, and the great tension existing within the bubble. The gaseous contents prevent attraction by resisting the repulsion of the liquid from the wall of the cavity. Warmth at one side of the bubble results in increased tension of the gas. This being partial, causes such internal molecular disturbance before it becomes uniformly distributed, that the bubble is rolled away from the source of heat. The bubble then takes up that position consistent with the least internal pressure. In this case it is the same bubble which moves from end to end of the cavity. When repulsion is followed on rise of temperature by attraction, the *modus operandi* is the following:—Repulsion due to the circumstances above mentioned occurs until such a temperature has been reached that, in spite of the presence of gas within the bubbles, the increased vapour-tension of water becomes a motive power by reason of evaporation and condensation, the motion of course being in the reverse direction.

April 19.—"On some Figures exhibiting the Motion of Vibrating Bodies, and on a New Method for Determining the Speed of Machines," by Herbert M'Leod, F.C.S., Professor of Experimental Science, and George Sydenham Clarke, Lieut. R.E., Instructor in Geometrical Drawing in the Royal Indian Engineering College, Cooper's Hill. [See Physical Society.]

Chemical Society, May 3.—Dr. Gladstone in the chair.—The treasurer announced that 1,000*l.* had been placed to the credit of the Society by the son of the late fellow, Mr. Lambert.—The following papers were read:—On some points in gas analysis, by J. W. Thomas. The author finds that nitric oxide is absorbed by caustic potash and pyrogallic acid, and recommends that a known volume of pure oxygen should be introduced after the absorption of carbonic acid and any decrease of volume noted as nitric oxide. He states that an excess of caustic potash should always be present in the alkaline pyrogallate, but that too much of the latter should not be used.—On the decomposition of nitric oxide by pyrogallate of potash, by Dr. Russell and W. Lapraik. The authors state the probable action of the above reagent is to convert nitric oxide into half its volume of nitrous oxide, but simultaneously another more obscure reaction takes place, so that 58 to 76 per cent. of the gas is absorbed instead of 50 per cent.—Contributions to the history of the naphthalene series. No. 1. Nitroso-β-naphthol, by Dr. Stenhouse and Mr. Groves. Nitroso-β-naphthol was obtained by the action of nitrosyl sulphate on β-naphthol and purified by conversion into a barium compound, &c.; it crystallises in brilliant hydrated yellow needles or anhydrous orange brown plates or prisms. It melts at 109°·5 C. By treatment with dilute nitric acid mononitro-β-naphthol is obtained. By acting on the barium compound of nitroso-β-naphthol with hydrogen sulphide a precipitate is formed which, by the action of potassium dichromate, is converted into β-naphthaquinone melting at 96° C.; this substance is interesting as being the first instance of two isomeric quinones derived from the same hydrocarbon.—On asbestos cardboard and its uses in the laboratory, by W. N. Hartley. This substance resembles thick greyish cardboard and is formed principally of asbestos fibres; it can be cut or moulded (by moistening with water) into any shape, and is extremely useful for crucible supports, muffles, &c.

Zoological Society, May 1.—Prof. Newton, F.R.S., vice-president in the chair.—Mr. Howard Saunders exhibited and made remarks on some nests and eggs of the Orphean Warbler (*Sylvia orpheus*) from the vicinity of Malaga, Spain. Amongst the eggs in each nest were one or two of larger size, supposed to be possibly the eggs of the Cuckoo. Mr. Howard Saunders also exhibited two skins of Dupont's Lark (*Certhilauda duponti*) from the same locality.—Prof. St. George Mivart read a paper on the axial skeleton of the Pelicanidæ, selecting *Pelicanus* as his type and standard of comparison. Prof. Mivart first compared it, as regards its axial skeleton, with *Struthio*, and the other *Struthionidæ*, and then compared the other *Steganopodes* with it and with one another.—A communication was read from Dr. M. Watson, Professor of Anatomy, Owens College, Manchester, on the anatomy of *Hyæna crocuta*, in which he described the very peculiar conformation of the female generative organs of that animal.—Mr. A. G. Butler read a paper wherein he gave the description of two small collections of Heterocerous Lepidoptera from New Zealand, recently brought to England by Dr. Hector and Mr. J. D. Enys.—A communication was read from Dr. O. Finsch giving an account of a small collection of birds from the Marquesas Islands. Amongst these were three examples of a new species of Kingfisher, proposed to be called *Halcyon godeffroyi*.—A communication from Mr. Frederick Smith contained descriptions of four new species of Ichneumonidæ in the collection of the British Museum. Amongst these was a new *Bracon*, remarkable for having its ovi-positor more than nine times the length of its body. This was proposed to be called *Bracon penetrator*, and had been received from Yokohama, Japan.—Prof. A. H. Garrod read some notes on the anatomy and systematic position of the genera *Thinocorus* and *Attagis*, which he considered should be referred to the Limicolæ in the neighbourhood of *Glareola* and *Cursorius*.

Geological Society, April 25.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Messrs. S. Bewsher, H. G. Bolam, Charles Thomas, and John M'Kenzie Knight were elected fellows of the Society.—On the upper limit of the essentially marine beds of the Carboniferous system, and the necessity for the establishment of a "Middle Carboniferous Group," by Prof. E. Hull, F.R.S. The author, in this paper, divided the whole of the Carboniferous rocks into successive stages from A to G inclusive, taking the Carboniferous beds of Lancashire as a type, and showed that these stages could be identified over the whole of the British Isles. It was only recently that their determination had been made in Ireland, so that until now the materials had not existed for a complete correlation of the series in the British Islands. The following is an abbreviated statement of the representative stages in descending order:

Essentially Freshwater or Estuarine, with one or two Marine Bands.

STAGE G.—*Upper Coal-measures* of Lancashire (2,000 feet) and other English coal-fields. Red Sandstones, &c., of Bothwell and Ayr, in Scotland. (Absent in Ireland.)

STAGE F.—*Middle Coal-measures* of Lancashire, &c., with principal coal-seams (3,000 feet). "Flat coal-series" of Scotland. Present in Ireland (Tyrone, Kilkenny).

Essentially Marine.

STAGE E.—"*Gannister Beds*" (Phillips), with marine shells and thin coals (2,000 feet), in Lancashire. "Pennystone series" of Coalbrook Dale, South Wales, &c. "Slaty black-band" series of Scotland. (Present in Ireland, Kilkenny, Dungannon, Lough Allen coal-fields.) Also in Belgium, Rhenish Provinces, and Silesia, with numerous marine shells.

STAGE D.—*Millstone Grit Series* of England and Wales, 3,500 feet in Lancashire; "Moorstone Rock" of Scotland; "Flagstone-series" of Carlow and Kilkenny; Millstone-grit of Fermanagh and Leitrim, with coals and marine shells.

STAGE C.—*Yoredale Beds*. 3,000 feet in Lancashire; Upper Limestones and "Lower Coal and Ironstone series" of Scotland; Shale series of Kilkenny and Carlow; Ironstone shales of Lough Allen, with marine shells.

STAGE B.—*Carboniferous Limestone*. Mountain Limestone of Derbyshire; "Scaur Limestone" in Yorkshire; "Lower Limestone" (Roman camp) of Scotland; Carboniferous Limestone of Ireland.

STAGE A.—*Lower Limestone Shale* of England. Calciferous Sandstone series ("Tuedian," Tate) of north of England and Scotland; Lower Carboniferous Sandstone, north of Ireland; Lower Carboniferous slate, with Coomhola grits, with marine shells, south of Ireland. (In Scotland, estuarine or lacustrine.)

Palæontological Results.—On making a census of the Molluscan and other fossils from the various stages above that of the Carboniferous limestone (stage B) as determined by the palæontologist of the Geological Survey, some interesting results were obtained, showing the prevalence of marine conditions up into stage E, and a general change in the character of the fauna in the succeeding stages. Including only the area of the British Islands, it was found that no fewer than thirty-seven genera, with seventy-four or seventy-five species, of decidedly marine forms, occur in the Gannister beds (stage E), of which all the genera and about forty species were known in the stage of the Carboniferous Limestone. The series includes *Phillipsia*, which has been found by Dr. F. Römer, in the representatives of stage E in Silesia. On the other hand, of the whole number of species in stage E (Gannister beds), only six are known in the overlying stages F and G, these being characterised by the prevalence of bivalves of supposed lacustrine or estuarine habitats, variously called *Unio* and *Anthracosia*. Of the few species of marine genera known in stage F (Middle Coal-measures), about five or six species are peculiar to itself, according to the determination of the late Mr. Salter. Such a remarkable difference in the fauna of the Upper and Middle Coal-measures, as compared with that of the Gannister beds, constituted, in the author's opinion, sufficient grounds for drawing a divisional line between these two divisions of the Carboniferous series. Of the several existing methods of classification adopted by different authors, none of them appeared sufficiently to recognise the palæontological distinctions and characteristics of the several formations. The large number of genera and species which are now known to range up from the Carboniferous Limestone into the Gannister beds, and no higher, indicated the proper horizon for a divisional line, in fact a palæontological break at the top of the Gannister beds. On the other hand, the mineral and palæontological differences between the Carboniferous Limestone and the overlying Yoredale series were sufficient to justify their separation into distinct divisions; while the Yoredale, Millstone-grit, and Gannister series are related by close mineral and palæontological resemblances. With a view, therefore, of bringing the classification of the Carboniferous series into harmony with the character of the representative faunas, and the physical features of the successive stages, the author suggests that stages C, D, and E, composed of essentially marine beds, should be united into a Middle Carboniferous group; while stages F and G would remain as at present, in the Upper Carboniferous, their fauna being essentially of fresh water. In the discussion which followed, Professors Ramsay, Boyd-Dawkins, Prestwich, and Hughes seemed to doubt the feasibility of permanently maintaining the lines of demarcation laid down in the paper.—On coal-pebbles and their derivation, by H. K. Jordan, F.G.S.

Physical Society, April 28.—Prof. G. C. Foster, president, in the chair.—Mr. W. Ackroyd described some methods of studying selective absorption in relation to the doctrine of aggregation. After referring to the absorption of iodine vapour and iodine violet solutions he showed that an analogy exists between these solutions and the aniline dyes, and a method was indicated by which the approximate size of the particles affecting light might be estimated.—Prof. H. McLeod exhibited several forms of apparatus which he has, in conjunction with Lieut. G. S. Clarke, R.E., arranged for determining the speed of machinery, &c., from observations made on the figures produced by combining their motion with that of a vibrating body; a description of them has already been communicated to the Royal Society. If a uniformly-moving point of light be reflected from a mirror attached to a tuning-fork vibrating in a plane at right-angles to the motion of the point, the reflected image will appear as an ordinary single wave, and a double figure of the form of a series of figures of eight, caused by the overlapping of two waves, will be formed if a series of points of light move uniformly with such a velocity that a point passes over two intervals during an odd number of vibrations of the fork. If equidistant perforations be made in a circle on a disc which is attached to a rotating axis and the number of vibrations of the fork be known, the form of figure reflected on to the screen will, theoretically, give the requisite data for determining the rate of rotation of the disc, and further, a slight increase or decrease in this rate causes the figure slowly to move in the same or opposite direction to the disc. If the fork make 3,600 vibrations and the disc 100 revolutions per minute, the circle must be divided into seventy-two equal intervals, but for such a number as 101 revolutions 71·287 intervals are needed. This fact would introduce some difficulty in preparing an apparatus for measuring the velocity of rotation so as to give the speed in whole numbers per minute, but it may be obviated by ruling convergent white lines on dark paper and so wrapping it round a cylinder that one line is parallel to the axis, an arrangement which gives every possible subdivision of a circle between any given intervals. The figures are then observed by examining these lines through a narrow slit in a light opaque screen attached to a tuning-fork or reed vibrating in a plane parallel to the axis of the cylinder. This observing apparatus is moved parallel to that axis until the figure remains stationary, when the number of rotations is read off on a graduated scale. Conversely, if the number of rotations of the cylinder is known, the period of the tuning-fork can be determined. Incidentally Prof. McLeod explained a simple method of causing a fork to vibrate, and the manner in which they have succeeded in maintaining the vibrations of a reed. It was found that variations in temperature influence the determinations, inasmuch as they cause the period of the fork or reed to vary. When the former is used it becomes necessary to deduct 0·011 per cent. of the result for each degree centigrade of rise above the temperature for which the fork is set, and 0·0277 per cent. when employing a reed.

Anthropological Institute, April 24.—Mr. John Evans, F.R.S., president, in the chair.—Dr. John Rae read a paper on the migrations of the Esquimaux. The chief subjects of Dr. Rae's remarks were two papers read before the Ethnological Society, twelve years ago, the one by himself, the other by Mr. Clements R. Markham. Dr. Rae considered that Mr. Markham's present view was in accordance with what he (Dr. Rae) advanced in 1865, viz., that the route of the Eskimo must have been along the coast of America, across the Strait (northward) to Banksland, and thence to the Parry Islands, &c., where so many traces of them remain. He gave some information regarding various peculiarities of the Eskimos, and exhibited a stone lamp, with a curiously-shaped piece of stone, used for adjusting the wick, which consists of a species of fibrous moss (sphagnum) brought with the lamp from Repulse Bay more than twenty years ago. The lamp when lit gave a clear bright flame, from each of the three bits of moss used, without any perceptible smoke. These form valuable articles of barter by the Eskimos in the neighbourhood of such localities, with the more distant natives, for they seem to be in almost universal use, from Behring Strait eastward to Hudson Bay.—Mr. Robert B. Holt then read a paper on earthworks in Ohio, and Prof. Busk, F.R.S., described some skulls from the same place.—The following gentlemen took part in the discussions:—Mr. Hyde Clarke, Mr. Allen, the president, and others.

Paris

Academy of Sciences, April 30.—M. Peligot in the chair.—The following papers were read:—On a phenomenon of insolation of the eye, which has not hitherto been explained, by M. Chevreul. A few days before St. Bartholomew's day the Prince de Navarre (afterwards Henri IV.) being with the Duc d'Alençon and the Duc de Guise, at the Louvre, playing dice, they twice saw blood spots on the dice, whereupon they separated, in alarm. M. Chevreul explains the phenomenon as an effect of contrast of colours in sunlight, and gives some experiments in illustration. Material black appears red in reflecting white light.—On carbuncular disease, by MM. Pasteur and Joubert. Are the effects due to the bacteridium or to a virus? The bacteridium may be multiplied indefinitely in artificial liquids, without losing its action on the system, so we cannot suppose it accompanied with a soluble substance (or virus) producing, jointly with it, the carbuncular effects.—Probable consequences of the mechanical theory of heat, by M. Favé. He seeks to explain the phenomena attributed by M. Boutigny to the "spheroidal state," by supposing that the calorific waves of the sidereal ether have a repulsive action on ponderable matter. Take the case of a little water poured into a red-hot capsule. The heated metal gives radiant heat, *i.e.*, impresses the ether with waves which are rapidly propagated. This motion upwards counterbalances that due to the weight of the water. The distance between liquid and metal depends on the *vis viva* developed by the ether. The motion of oscillation is combined with one of varying rotation due to the resultant of the repulsive forces not passing through the centre of gravity of the globule.—On a new deposit of liquid mercury, indicated in the upper valley of l'Herault by M. de Quatrefages, by M. Leymerie.—On a new Arctic expedition of M. Nordenskjöld, by M. de Saporta. He intends prolonging his exploration as far as Behring Straits. The expedition is to leave Sweden in the summer of 1878.—Electro-silicic light, by M. Planté. He calls attention to the bright light produced when one or other electrode of his secondary batteries is applied to a tube or plate of glass. The glass is decomposed, and the luminous effect is probably due to incandescence of the silicium.—On a process of solidification of sulphide of carbon, by M. Mercier. Treating oils with a little protochloride of sulphur, a transparent solid matter is got, with nearly the elasticity of caoutchouc. If a volatile liquid be added at the moment of mixture, as benzine, oil of petroleum, or sulphide of carbon, the solidification takes place all the same, and the volatile liquid is imprisoned as in a net-work, from which it can only escape slowly. The mixture may hold even 70 per cent. of sulphide of carbon.—On the treatment of phylloxerised vines with sulpho-carbonate of potash, by M. Fatio.—On the rooting out of phylloxerised vines, by M. Cornu.—On the comparative structure of the roots of American and indigenous vines, and on the lesions produced by the phylloxera, by M. Foëz.—On the regeneration of phylloxerised vine-stocks by the employment of sulpho-carbonate of potash, by M. Gueyraud.—M. Dumas presented the first document from a Commission charged by the Emperor of Brazil, to determine the geographical positions of the principal points of the empire. It treats of the position of Barra do Pirahy, relatively to Rio de Janeiro Observatory.—Observations of Comets II. (Winnecke) and III. (Swift, Borrelly), by M. Wolf.—On some observations of solar spots, by M. Denza. This confirms M. Janssen's observations.—On the surfaces whose principal radii of curvature are functions of each other, by M. Mannheim.—Investigation of the law which a central force must follow for the trajectory which it produces to be always a conic, by M. Darboux.—On the laws of Kepler; solution of a problem proposed by M. Bertrand, by M. Halphen.—Reply to a note of M. Kirchhoff on the theory of elastic plates, by M. Levy.—Singular solutions presented in the problem of curvilinear motion of a point under the action of a central force, by M. Boussinesq.—On substances capable of being produced at a temperature above that which causes their complete decomposition, by MM. Troost and Hautefeuille. Examples are: protoxide of silver, ozone, protochloride of platinum, sesquichloride, protochloride, and subfluoride of silicium.—Process of industrial preparation of pure salts of alumina, by M. Dacla.—On monochlorised acetones, by M. Etard.—Experiments proving that the septicity of putrefied blood is due to figured ferments, by M. Feltz.—On the fixation of tannin by vegetable tissues, by M. Müntz. The tissue of champignons, especially, may be "tanned" into a kind of vegetable leather.—On gaseous exchanges between plants and the atmosphere; reply to critical observations of M. Barthelemy, by M. Merget.—Researches on the absorption and emission of gases by roots, by MM. Deherain and Vesque.—On the spontaneous and regular movements of a submerged aquatic plant, *Ceratophyllum demersum*, by M. Rodier.—On the presence of mercury in the springs of Rocher (Puy-de-Dôme), by M. Garrigou.—On a case of hereditary hemiteria, by M. Martinet.—On increase of the production of springs, by M. Chefdebien.

SCIENCE AND WAR

RECENT wars have had particular interest for the man of science. If we go back some fifteen or twenty years and consider the different wars which have unfortunately occurred since that time, we shall find connected with each one of them certain features which undoubtedly mark progress in the art of killing and wounding. Some argue—and on very good grounds, no doubt—that the more sharp and terrible warfare is made the more speedily must it come to an end, and hence look with favour upon the means taken every day to render weapons more destructive and the soldier more cunning in his dangerous trade. We do not propose to discuss this argument, nor to enter at all into any comparison between the wars of our forefathers and those of to-day, but at a crisis like the present we need hardly apologise for bringing before our readers some points illustrating the marked influence of science upon modern warfare.

Starting from the close of the Crimean war, the first in which the electric telegraph was employed, we find ample examples of the assistance furnished to the soldier by scientific research. One instance taken from the war of 1858 is especially interesting. The Austrians held Venice at the time, it may be remembered, and to protect the harbour, torpedoes were laid down. The torpedoes were fired by electricity, and contained gun-cotton, this being the first instance on record of the employment of electric torpedoes and of the newly-invented nitro-compounds. Nor was this all. The torpedo-system devised at Venice by the Austrian engineers had yet another point of scientific interest. A camera obscura was built overlooking the harbour, and upon the white table of this instrument were reflected the waters of Venice. As the torpedoes were sunk one by one a sentinel in the camera noted the place of their disappearance with a pencil, giving each torpedo a consecutive number. A row-boat in the harbour described a circle around the sunken torpedo indicating the zone of its destructive power, and the sentinel again, with his pencil, made a corresponding ring upon the camera table. In the end, therefore, while the harbour itself was apparently free from all obstruction, a very effective means of torpedo defence was established, the key of which was only to be found in the camera obscura. The sentinel here had wires in connection with every torpedo, and was in a position to fire any one as soon as he observed—by means of the camera—the presence of a hostile vessel within the limits of any of the circles marked upon his white table.

In the American war of 1860, the electric torpedo, invented but two years before, played a most conspicuous *rôle*, and formed indeed with the use of big guns and monitor ironclads, one of the most important features of the struggle, at any rate from a scientific point of view. The war of 1866, when the Austrians suffered such a terrible defeat at the hands of the Prussians, will long be remembered as a combat between the old muzzle-loading rifle and the breech-loader, in which the latter was victorious. The Franco-German struggle of 1870 again, though marked by the employment of no special arm, if we except the mitrailleuse, was assisted by important applications of science; to wit, the reproduction, by means of photo-lithography of the French ordnance maps and plans, which were distributed in thousands throughout the German army, and the establishment in France of *la poste aérienne* to communicate with the besieged garrison of Paris. The regularity with which the mails left Paris *par ballon monté*, must still be fresh in the memories of our readers, the publication of correspondence from the French capital being maintained in our journals during the whole period of the investment. From September 23 to January 28, when Paris was practically cut off from the rest of the republic, no less than sixty-four balloons left the city with passengers, mails, and pigeons, and of these only three were lost, while five were captured. The return-post by "homing pigeons" was hardly so regular, but nevertheless half the number of despatches given in by correspondents at Tours and elsewhere, or in other words 100,000 messages, were by the unflagging energy of the postal authorities carried into the beleaguered capital. The despatches, most of them as brief as telegrams, were distinctly printed in broad sheets and photographed by the aid of a micro-camera; impressions upon thin transparent films were then taken and rolled in a quill attached to the tail of the winged messenger which was to bear them into Paris. Arrived at their destination, the tiny photographic films were enlarged again by the camera, and the despatches being once more legible, were distributed to the various addresses.

The present Russo-Turkish war cannot well be less interesting than those that have so recently preceded it, and we may especially point out two directions in which fresh examples of scientific warfare will probably manifest themselves—in connection, namely, with the cavalry pioneer and the Whitehead torpedo. Both of these will probably be seen in warfare for the first time, and before many days are past we may hear of their doings in action.

The cavalry pioneer must not be confounded with the Prussian Uhlan who played so conspicuous a part in the last war. The ubiquitous Uhlan, terrible as he was, did not work the injury which some of the Cossacks will have it in their power to inflict if accoutred as pioneers. These are selected from the smartest and most daring troopers, lightly armed and well mounted. In a belt round their waists they carry a few pounds of gun-cotton or dynamite, and with this highly destructive explosive they may work incalculable harm. A small charge of gun-cotton placed simply upon a rail and fired with a fuze suffices to blow several feet of the iron to a distance of many yards, thus rendering the railway unserviceable on the instant. A trooper may dismount, place a charge at the base of a telegraph pole, fire it, and be in his saddle again within sixty seconds. Wires may thus be cut and communication stopped in the heart of an enemy's country by fearless riders, who have but to draw rein for an instant to effect the mischief, while lines of railway in the neighbourhood are entirely at their mercy. Even light bridges and well-built stockades may be thrown down by the violent detonation of compressed gun-cotton, and forest roads considerably obstructed by trees thrown across, which are never so rapidly felled as when a small charge of this explosive is fired at their roots.

The influence of the Whitehead torpedo, of which we have heard so much of late, will likewise be felt for the first time during the present war. An implement so ingenious in its character that, as Lord Charles Beresford the other day happily remarked, it can do almost anything but talk, is in the possession of both belligerents, and will doubtless be heard of ere long on the Danube and in the Black Sea. These torpedoes are manufactured at Fiume on the Mediterranean, and, like Krupp guns, are to be purchased by any one who chooses to pay for them.

The British Government manufactures its own Whitehead torpedoes in this country, having paid several thousands of pounds for the privilege. The machinery inside this torpedo is still a secret, which is strictly maintained by our Government, but the principle of the invention is well known. It is a long cigar-shaped machine measuring a dozen feet and upwards. In the head is a charge of some violent explosive, such as gun-cotton, or dynamite, which explodes as soon as the torpedo strikes an obstacle. The motive power is compressed air, which is forced into the machine by powerful air-pumps, immediately before the torpedo is discharged into the sea, no less than 600 lbs. on the square inch being the pressure exerted. The Whitehead is shot from a tube, and moves through the water as straight as a dart, the compressed air working upon a screw in the tail of the machine. The delicate machinery permits the torpedo to swim at any depth below the surface that may be desirable, and it flies straight in the direction it is aimed, at a speed of something like twenty miles an hour. If it fails to strike the foe, then the intelligent apparatus at once rises to the surface, becoming innocuous as it does so, and may in this condition be captured without difficulty.

A torpedo of this sort striking the sides of an ironclad would almost infallibly send her to the bottom, and although it has been proved that a network or crinoline around the ship is capable of retarding the progress of a "fish" of this nature, and exploding the same harmlessly in its toils, it is obviously a very difficult matter thus to protect one's craft. Against heavy torpedoes, indeed, there seems no way of defence at all (the Whitehead generally carries a charge of 70 lb. or 80 lb., but moored torpedoes may contain a 500 lb. charge), and therefore Turkish vessels will have to give Russian ports a wide berth. All must remember how the magnificent fleet of the French was kept at bay by the torpedoes of the Germans in the North Sea in 1870, and the Black Sea ports are no doubt similarly protected. So demoralising is the dread of the torpedo with sailors apparently, that they will dare anything rather than venture into waters which conceal these cruel foes.

H. BADEN PRITCHARD

THE OWENS COLLEGE UNIVERSITY QUESTION

In his address on Tuesday last week, at the London University, the Chancellor noticed in dignified and sensible words the proposed application of Owens College to the Government for a Charter of Incorporation as a university, either by itself, or as the centre of a family of northern colleges. Nothing could well have been more unfortunate or ill-judged than the furious onslaught of Mr. Lowe, the member for the University, in the *Fortnightly Review*. The complaint of the Manchester people is that the London system, however suitable in itself, hampers the educational activity and usefulness of institutions capable of an independent existence, and it was scarcely decent for the member for that university to step forward in her interests as a mere partisan of the *status quo*. In fact there is no antagonism. Manchester has never denied that it is a good thing that there should be a university in London to examine all comers. She has said that she thinks it a bad thing for institutions with a sufficient permanent teaching staff, a large enough number of students and a solid establishment in the district to which they belong, to have to shape their work according to the ideas of any central university that must suit all comers. Mr. Lowe is the one member of Parliament who should have held his tongue on the matter till he was forced to speak, because a hasty utterance on his part could not but seem to compromise his University. Lord Granville took pains to remove the injurious impression of an unworthy jealousy in London which Mr. Lowe's article could scarcely fail to create. He tells us that London feels "absolutely no objections of a merely jealous character," and that London would have a "very friendly feeling to any university which, after due deliberation and with a sound regard to the real advantages of education, may hereafter be established." In that wise and sensible attitude it is open to the University to consider either of the two schemes suggested for the northern university. The first of them, which is that favoured by the college authorities, is that Manchester should be created a university much as Glasgow is. According to the views of the supporters of that scheme we should be prepared to multiply our universities as the Scotch have done, by chartering one in any large town where its students and its endowments, its history and its reputation offer equally solid guarantees of permanence. The other is that Manchester should be the capital—*primus inter pares*—of a new northern university on the original affiliation basis from which London has departed. The weakness of the affiliation principle is that it is scarcely in nature that it should not gradually relax, so that colleges should be affiliated on easier and easier conditions till it becomes useless to keep up the farce. But both schemes, the latter of which, indeed, is Dr. Carpenter's, are practicable—both worthy of careful consideration and discussion—and it is pleasant to see that the University of London, through her Chancellor, disavows any settled policy of obstruction.

Lord Granville reminded his hearers of what most people have forgotten—the history of the incorporation of the University. It was a subject of excited debate in this country and in Parliament, for ten years from its first inception. The project was started in 1825. Funds were then raised by subscriptions in 100*l.* shares, and the institution was in activity in 1828. In 1830 an application was made to the Crown for a charter, and the charter as prayed for had gone through nearly all the necessary preliminary stages, when its progress was stayed by the opposition of Oxford and Cambridge. In 1833 the application was renewed, and it was supported by an address to the throne from the City of London. It was opposed by Oxford and Cambridge, by the Royal College of Surgeons, by the teachers of medicine and surgery in the London hospitals, and by others. The matter was referred to the Privy Council, and argued before it in 1834. There was no question then of anything so futile as what has been once or twice suggested for Owens College, the title of university, without the privilege of degrees. The Privy Council found the subject surrounded by difficulties, and adjourned its consideration. Shortly after, Lord Melbourne's Ministry, which was friendly, retired from office, and Sir Robert Peel's, which took the view of the old universities, succeeded. An address to the Crown, however, was carried against the Ministry by 246 to 136, on the motion of Mr. W. Tooke, praying that a charter might be granted to the University of London, with no restriction but that they were not to confer degrees in divinity. The Privy Council was asked to report on the subject, but the report was delayed, and before they presented it Lord Melbourne returned to power. In August, 1835, the Chancellor of the Exchequer, Mr. Spring Rice, communicated to the Council of the existing University College that Government proposed to incorporate by charter as a university in London, a body of gentlemen eminent in learning and science, with the power of examining and granting degrees in arts, medicine, and laws to students of *certain colleges in London, therein named*, and of others existing throughout the country to be afterwards recognised, as well as of the schools of professional education. This university was to be supported by an annual grant. There were to be no religious tests. The existing body, which called itself the University of London, received a charter as a college and was named as one of the colleges entitled to submit students for examination. The two charters to the new university and the new college were issued on November 28, 1835. They have been several times modified. The list of affiliated colleges was always large, and as the Senate of the University had no control over the affiliated colleges it grew unwieldy, institutions of the feeblest character receiving affiliation. In 1863 a charter was granted empowering the Senate to admit persons not educated in affiliated colleges to examination, and this decision creates the University of London of to-day as distinguished from the institution of the same name founded in 1835. About half the students now come from affiliated Colleges and half from anywhere or nowhere. The examinations must be fixed in view of this fact. Examiners must take into account as a most vital matter the books on the subjects of their examination which are readily accessible to students, and they cannot shape their examinations in view of the practice in teaching of any one or more of the affiliated colleges. We hope that the proposed university of the north may have a shorter novitiate, and that she may be conducted in as elevated a spirit and with as resolute a desire to promote the interests of literature and science as the University of London has been. It would have been a painful spectacle if the youngest of our Universities, forgetful of her own early struggles, had spent her energies in an opposition which Oxford and Cambridge have thought unnecessary or unworthy of them. The speech of her Chancellor leads us to hope that the claims of the proposed new university will be considered calmly and on their merits.

NICHOLSON'S "LIFE-HISTORY OF THE EARTH"

The Ancient Life-History of the Earth; a Comprehensive Outline of the Principles and Leading Facts of Palæontological Science. By H. Alleyne Nicholson, M.D., D.Sc., M.A., Ph.D. (Gött.), F.R.S.E., F.L.S., Professor of Natural History in the University of St. Andrews. (Edinburgh and London: William Blackwood and Sons, 1877.)

THERE is no feature in which the ordinary geological manuals in common use in this country are more deficient than in the sketches which they give of the leading characteristics of the animal and vegetable life of the successive periods which they describe. The truth of this remark will be made strikingly apparent by a comparison of the works in question with some of the best German treatises on geology, such as those of von Hauer and Credner, and still more if we examine them side by side with that most excellent of text-books, Prof. Dana's "Manual of Geology."

Some writers on geology in this country would indeed appear to hold the opinion that, since the succession of geological formations was first determined in our own islands, an appeal to the facts of British stratigraphical geology must in every case be final in deciding all difficulties which may arise concerning the definition and limits of the different systems of stratified rocks in every part of the globe. Hence the controversies which have taken place in this country concerning the boundaries between the Cambrian and Silurian, the Devonian and Carboniferous, and the Permian and Trias have acquired an altogether factitious importance, and undue weight has been attached to the interpretation of some obscure section, the significance of a local unconformity, or the appearance—often a fallacious one—of a gradual transition between two sets of beds, while far more suggestive facts connected with the relations of the fossil contents of the two series of rocks are too often altogether lost sight of.

But it cannot be too strongly impressed upon the minds of English geologists that the district in which a system of strata is first detected may not necessarily be the one in which it is best adapted to serve as the type of that series; that as a matter of fact the best illustration of the features and relations of the Cambrian and Silurian is to be found, not in Wales, but in Bohemia; and of the Devonian, not in Devonshire, but in the Eifel. English students, too, need to be reminded that the classification of the stratified rocks is based not upon the occurrence of certain physical breaks, in the continuity of a series of beds, which are often, indeed, of very local character and small importance, but upon the great principle that each formation is characterised by a well-marked and distinctive fauna or flora. Concerning the fact, position, and significance of many of the physical breaks in the succession of formations, the ablest field-geologists, such as Sedgwick and Murchison, Jukes and Godwin-Austen, have frequently arrived at very opposite conclusions; and the importance which has been attached to these discussions on points of details has doubtless led many to entertain a notion of the instability of the foundations of the geological systems of classification which is very far from having any real foundation in fact. For it must not be forgotten that, however certain questions now pending concerning the nomenclature of the Welsh strata may eventually be decided—and these questions of nomenclature and priority are, after all, of very secondary importance—the grand fact first clearly determined by the discoveries of the illustrious Barrande in Bohemia, that there can be distinguished in the series of older Palæozoic strata three great divisions, each characterised by a well-defined fauna, is quite independent of these controverted points, and its value cannot be affected in any way by their decision either one way or the other.

It will be manifest from what we have said above that we regard the present work of Prof. Nicholson as dealing with a subject in connection with which the want of a competent text-book in this country has long been a serious evil; and of the general accuracy and reliability of the information supplied by this convenient little volume we can also speak in terms of high commendation.

Prof. Nicholson has wisely availed himself to the fullest extent of woodcut illustrations in aid of his descriptions of the fossil forms; and the 370 engravings, many of them containing illustrations of a number of different species, will be a great boon to the geological student. Some of these woodcuts now appear for the first time, but others have already done duty in the author's previous writings. We cannot unfortunately award anything like equal praise to all these illustrations, for while some of them are of exquisite truthfulness, detail, and finish, certain others are so coarsely executed and so wanting in character, that it is a marvel to us how so accomplished a naturalist as the author could have ever permitted them to disfigure his pages. There is one omission in connection with the illustrations, which will greatly detract, we fear, from the value which they would otherwise have for the student, namely, the absence of indications of the number of times which the scale of the drawings is magnified or reduced from that of the original objects. Every one engaged in teaching is aware what erroneous notions concerning fossil forms are often propagated by want of attention to this detail.

In his discussion of the characters distinguishing the flora and fauna of each of the great geological periods, Prof. Nicholson is usually very clear in his descriptions and happy in his choice of typical forms. The greatest danger which besets the writer of such a work as the present is that of overwhelming the student with masses of detail, unrelieved by those broader generalisations which may serve to aid his memory in grouping the facts about convenient centres. Had Prof. Nicholson in the present work prefaced each of his descriptions of the great geological periods with a succinct statement of its leading palæontological characteristics, and also furnished similar summaries for the greater epochs, we cannot but think that the work would have been far better adapted to the wants of the student, and at the same time its suitability for general readers would have been in no wise impaired.

The references to authorities at the end of the chapters will be found useful by all classes of readers, and the general remarks on the "Principles of Palæontology" with which the work opens will sufficiently prepare those who may be totally unacquainted even with the fundamental facts of geological science for a profitable perusal of the succeeding chapters. The work before us constitutes a popular exposition and summary of the facts of palæontology, suitably arranged for beginners; but as a text-book for the more advanced student of the science, it still leaves much to be desired. We search it in vain, for example, for information on many important questions, such as the classification of the multifarious forms grouped under the name of *Ammonites*, and we sometimes find obsolete names employed for certain genera and species. There are certain obvious errors and omissions which will doubtless be corrected and supplied in a subsequent edition of the work—such, for example, as the table of Cambrian strata on p. 79, and the absence of all notice of the remarkable Devonian fossil, *Calceola sandalina*.

As a compact and popularly written introduction to a very important department of science, Prof. Nicholson's new work may be safely recommended; and it is well worthy to take its place among that series of useful manuals for which we are already indebted to its industrious author.

OUR BOOK SHELF

Geological Survey of Canada. Report of Progress for 1874-75. Alfred R. C. Selwyn, F.R.S., F.G.S., Director. (Published by Authority of Parliament, 1876.)

ALTHOUGH Mr. Selwyn, like his predecessor, Sir William Logan, has the highest possible ideal of the importance of pure geological mapping, the necessity for the rapid exploration of a vast unsurveyed new land simultaneously with the development of rich coalfields, compels him to employ two very different systems of working. With a staff of only ten geologists, two-thirds of whose time is engrossed by topographical preliminaries, the usefulness of the survey as a whole must depend to a great extent on the judicious determination of the degree of importance attached to the details of its various parts. Accordingly, Mr. Selwyn has confined the detailed mapping to the settled eastern sea-board, carrying on at the same time reconnaissances in the central and western regions, where complete maps will not be demanded for some time to come.

During the past year Mr. Selwyn has been able, in addition to his administrative duties, to overtake some field-work, chiefly among the palæozoic rocks of New Brunswick and the coalfields of Cumberland and Sydney. The Report contains two geological maps of portions of the Cape Breton Coalfield, by Messrs. Robb and Fletcher, exhibiting all the completeness of the British coalfield maps.

Mr. R. W. Ells furnishes a map and report on the hematite ores of Carleton County, New Brunswick. The ore appears to occur in veins along the strike of highly-inclined Silurian rocks.

Mr. Henry G. Vennor has been surveying in the Laurentian region of Frontenac and Lanark Counties, and embodies the results of his labours in a map and report. It appears that apatite mining in this district has recently ceased to be a profitable industry. Mr. Vennor sees the cause of failure in the injudicious and costly manner in which the mining was carried on. Iron ore (magnetite) occurs at Eagle Lake in a bedded form, associated with hornblendic and dioritic rocks.

Mr. Robert Bell and Mr. Joseph Spencer describe the country between the head-waters of the Assineboine River and Lakes Manitoba and Winnepegosis. During a rapid survey of this little-known tract, they recorded the occurrence of Laurentian schists and rocks of Huronian, Devonion, and Cretaceous age. They also made many valuable observations on the superficial deposits, as well as on the physical geography of the region. An interesting point in their report is the frequency of old beaver-dams in places where there is now little or no water—an evidence of the former greater humidity of the climate.

In British Columbia Mr. James Richardson continued his explorations. He traversed metamorphic crystalline rocks (auriferous) extending over seven degrees of latitude and six of longitude. The complicated structure of the Nanaimo coalfield was further investigated, but the work is not yet complete.

Mr. J. Lionel Smith reports on the salt manufacture and trade of Ontario, and makes some interesting and useful comparisons between the various processes for the treatment of the brine in Canada and elsewhere.

Mr. J. Harrington closes the volume with notes on Canadian rocks and minerals.

R. L. JACK

The Schools of Forestry in Europe. A Plea for the Creation of a School of Forestry in Connection with the Arboretum at Edinburgh. By John Crombie Brown, LL.D., &c. (Edinburgh: Oliver and Boyd.)

THIS pamphlet is written in the form of a letter or address to the Lord Provost of Edinburgh and the promoters of the Arboretum at Inverleith, and is in short a strong argument in favour of the formation of a school of Forestry to be connected with the Arboretum. Dr. Brown shows that in France, Spain, Italy, Austria, Poland, Russia, Finland, Sweden, and in fact in almost every country except Great Britain, its Colonial dependencies and the United States of America, such schools exist under Government authority, and it is in these very countries that such schools would be of immense utility. The proposed curriculum of three years' study sketched out by Dr. Brown as likely to prove advantageous is, in the main, good, but we think that the French and German languages should be taken before the end of the third year. The notices of the arrangements and systems of studies in the various Continental forest schools are not without interest. Dr. Brown concludes his "plea" with a comparison of the English and Continental forests; the extent of the latter, together with the threatened lack of fuel by the extinction of forests as against our supplies of this necessary article from coal mines, being, no doubt, among the principal causes of the decrease of forest training in this country. The lack of special literature on the subject in the English language also compares badly with that of the Continent.

Unser Sonnenkörper nach seiner physikalischen, sprachlichen und mythologischen Seite hin betrachtet. By Dr. Schmidt. (Trübner, 1877.)

DR. SCHMIDT has more learning than method. In fact, he belongs to that school of paradoxers who are less common in Germany than in this country. He proposes to show that the sun is a cold inhabited body, heat being developed by the friction of its rays against the earth and other celestial bodies. Upon this physical theory he superimposes his mythological one. Words which have a slight resemblance in sound and meaning are gathered together from all parts of the world and assumed to be connected in spite of their belonging to different families of speech. Out of this hodgepodge are extracted such conclusions as that the sun-god was believed to illumine the dead in Hades or that the snake represented the return of Apollo to the light of day. But the philology of the writer may be easily appreciated when we find him speaking of "the Armeno-Caucasian family, to which belong not only Semites and Aryans, but also some Turanian tribes," and intimating that the roots of the Chinese language are allied to those of the "Armeno-Caucasian." As might have been expected, Dr. Schmidt is not always right in the words he quotes from the numerous languages, ancient and modern, which he has laid under contribution.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Passage of Plants Across the Atlantic—Haplomitrium Hookeri, Lyell

PROF. UNGER arrived at the conclusion that in Tertiary times there was a passage of plants from America to Europe. A plant found by myself last year in the Island of Dominica, West Indies, led me to think it probable that there had been an extension of at least one plant in the opposite direction. The plant to which I refer is one of the Hepaticæ, *Haplomitrium hookeri* of Lyell. It differs so much from other Hepaticæ that I was able approximately to identify it on the spot where I found it in considerable abundance. Should it prove to be specifically distinct, my remarks may still, to some extent, hold good. It was growing in a dark, moist, shady spot on the north side of a mountain at an elevation of about 4000 feet. *H. hookeri* is generally distributed over the North of Europe, but I cannot find that it has ever before been found out of Europe. Dr. Oliver kindly informs me that there are only European specimens in the herbarium at Kew. I have failed in obtaining information of its occurrence either in North or South America, or in the intermediate islands. Nees ab Esenbeck, in his "Synopsis Hepaticorum," whilst recording a large number of Hepaticæ from the West Indies, mentions *H. hookeri* only from Europe. Now it is by no means an inconspicuous plant, and it seems altogether unlikely to have been overlooked by such careful observers as Swartz and others who have studied the Hepaticæ of the West Indies. Hence I draw the following inferences, to which may be attached a greater or a less amount of probability. 1. That the biological centre for *H. hookeri* is Northern Europe. 2. That it has thence crossed the Atlantic in a rather narrow zone. 3. That it did not reach the Continent of America. This, of course, is subject to correction. It may have been found there. From the great extent of territory and variety of climate on the mainland, I think if it had ever reached America it would still be found there. 4. That it may have reached the West Indies and have died out from Cuba, Jamaica, and other islands, through the prevalence of dry seasons, before the lower Cryptogamic plants were studied by competent botanists. 5. That it has remained in Dominica because of the altogether peculiar moisture of the climate in that island. 6. That it has not hitherto been found in Dominica because, from some reason unknown to myself, botanists seem to have neglected this *true* pearl of the Antilles, matchless in the beauty of its natural scenery, and in the wealth of its Cryptogamic flora.

H. hookeri is noticed as peculiar in not recovering its freshness when moistened after having been dried. This I found to be the case. On being carefully moistened about eight months after it was collected and dried, it remained flaccid, whilst the rest of the mosses and Hepaticæ from Dominica, when similarly treated, looked as fresh as when they were gathered. But *H. hookeri* exhibited another peculiarity even more remarkable, for it alone of all the Muscineæ that I brought home, grew and produced fruit after so long a period of desiccation. The fruiting parts of a specimen which I sent to the herbarium at Kew were entirely developed in a moist case on the table at which I am now writing. It seems as if the plant, incapable of the imbibition or intussusception of moisture sufficient to restore the freshness of its foliage, nevertheless retained, in a very unusual degree, its capacity for such development as might secure the continuance of its species. Such a speciality no doubt favours the suggestion that *H. hookeri* may have crossed from the East, but I confess myself inclined to be suspicious when coincidences run too much on "all fours." I found many mosses in Madeira and several lichens in Jamaica, which I have been quite unable to distinguish from British species. These may be common cases of widely distributed forms. *H. hookeri* does not appear to be of this class. HENRY H. HIGGINS

Rainhill, May 2

Patenas in Ceylon

I REGRET that through an accident I was able only yesterday to read Mr. Heelis's reply to my letter on the subject of patenas in Ceylon. I have not a copy of my own letter by me and therefore cannot speak with certainty, but I believe that I only suggested that the cropping out of the thick band of quartzite amongst the gneiss was sufficient to explain the existence of many of the larger patenas in the Kandyan Province. The immense majority of the smaller and more isolated patenas I am fully aware cannnot be explained on my supposition, nor can they at present be explained on *any* reasonable supposition. I do not think, however, that even the most superficial observer can have any doubt as to the large patena mentioned in my letter between Pussellawa and Rambodde, covering several thousands of acres, being entirely due to the quartzite band that lies above it. In regard to the Dimbula patenas it is no doubt true that gneiss is almost always found underlying the soil, but this does not prove that the patena soil is derived from the gneiss. The depth of the rock below the surface is against this view, especially when taken in connection with the fact that I was never able to trace in the case of patenas as I did in scores of cases of jungle land, in railway and road cuttings throughout the Kandyan Province, the gradual changes from the hard rock upwards to the surface, which show that the soil has been produced by the disintegration of the gneiss *in situ*. The denuding forces at work among these mountains are so excessive (according to an estimate made by myself at Pussellawa the denudation was no less than ten inches in thirty years on land cleared for coffee) that strata probably of many thousands of feet in thickness have been carried away to the low country and the sea. It is not, it seems to me, at all an improbable supposition that in Dimbula and Ouvah a band of quartzite has during this denudation been disintegrated, and that its remnants are found now in isolated places resting on the gneiss. The limestone mentioned by Mr. Heelis as occurring in the Ouvah patena district proves, I think, a point in my favour, for the same kind of limestone is more plentiful in the neighbourhood of the quartzite band between Pussellawa and Rambodde than in any other district with which I am acquainted, there being no less than five entirely isolated spots near these villages where it occurs. This limestone is highly crystalline and of the same age as the gneiss, for I have found it at the upper fall at Rambodde passing almost imperceptibly both above and below into the gneiss. It is here about 450 feet above the upper surface of the quartzite band, where it crops out in the lower fall. Its stratified character may be readily seen at Pussellawa by the bands of mica-fragments that run through it in almost horizontal directions. I have never heard of this limestone covering any extensive area except at Matalé, where there must be some hundreds of acres of it. In other localities that I have visited it covers only an acre or more frequently only a fraction of an acre. The soil produced by its disintegration is, I believe, the richest in the island, as is shown by the fact that the limestone after being burnt is frequently used as a manure for coffee trees, and that the jungle growing below such rocks is generally of the richest description. I can scarcely therefore think that any considerable area of patena soil in Ouvah is formed by the disintegration of limestone, although it is quite consistent with what occurs at Rambodde that limestone should be extensively found in the neighbourhood of a large patena. As to the quality of the soil on the Ouvah patenas the test generally applied by planters is that of the power of the coffee tree to produce fruit. This is manifestly not a perfect test. Climate counts for a great deal, and the climate of Ouvah is recognised as the most favourable in Ceylon for the production of coffee, whilst that of Dimbula is acknowledged to be too humid for the perfect fruiting of the plant. I remember a pertinent remark made to me by a successful planter in regard to the relative values of soil and climate in the growing of coffee. "Give me the climate and I can make the soil." It is an exaggeration, but there is sufficient truth in it to illustrate well the point I am urging.

Finally in regard to abandoned clearings falling back not into "chena" and jungle but into patena land, I must confess I never met with an instance of it, and with Mr. Heelis' permission I would suggest that the Dimbula cricket ground is scarcely a case in point. It is probably the interest of the owner to keep it in grass and to prevent seeds accidentally carried to it from taking root. But supposing it were surrounded by forest and left to itself for twenty years, would it at the end of that period be still in grass, or would it have returned to "chena"? If it were genuine patena land, it would remain so, for plants accidentally imported into it would find no nourishment, but if it were impoverished jungle soil, I am inclined to the opinion that there would still be sufficient unextracted nourishment to enable at least the hardier species to grow in a stunted form until humus was deposited, when forest would succeed. Whilst differing from Mr. Heelis on the several points of his letter I cannot omit to thank him for the courtesy with which he has expressed his opinions.

Ouseburn, May 10

The Greenland Seal Fishery

ANOTHER year has passed and no steps have been taken to put some restriction upon the cruel and wasteful manner in which the seal fishery is prosecuted. Warning after warning has been given, and still nothing has been done. In 1868 Dr. Brown wrote (*Proc. Zool. Soc.*, p. 440): "Supposing the sealing prosecuted with the same vigour as at present, I have little hesitation in stating my opinion that, before thirty years shall have passed away the seal-fishery, as a source of commercial revenue, will have come to a close." This season the Dundee vessels have been turning their attention to the Newfoundland seals, for, says a paragraph in the *Daily News*, "Capt. Adams has for some years been of opinion that that ground [the Greenland seal-fishery] is practically used up, and hence his visit to Newfoundland." The small success of the Greenland sealers this season fully corroborates Capt. Adams's opinion, and forms a practical comment upon Dr. Brown's prediction!

From the same source (*Daily News*) I learn that "advices of a very gratifying character have been received from Newfoundland. The *Panther* has taken 20,000 seals, the *Neptune* 30,000, the *Arctic* 24,000, the *Aurora* 15,000, and high expectations have been formed regarding the success of the whole fleet. These four vessels have secured 89,000 seals; Capt. Gray says 20 per cent. may be added to the number of seals actually taken for those mortally wounded and lost, and that as these are breeding seals each old one will leave a young one to die of starvation. (See letter in *Land and Water*, May 9, 1874.) The result will be that these four vessels destroyed 213,000 seals! Similarly "gratifying" advices have been received from the other vessels of the fleet.

If the Royal Society for Prevention of Cruelty to Animals and the anti-vivisection advocates really wish to do service in the cause of humanity, let them reprint Capt. Gray's letter and distribute it broadcast, nor let them cease their efforts till a proper close time is obtained for these persecuted animals. Apart from all questions of humanity, common prudence would dictate that so rich a source of revenue, which, if properly cared for, may last an indefinite period, should be secured from the rapacity of those who will otherwise soon bring about its extinction. Now is the time for considering the steps which should be taken to bring the matter before the Governments concerned; if left till later in the year hasty legislation will probably, as in the last attempt, end in failure.

Norwich THOMAS SOUTHWELL

A New Lecture Experiment for Proving the Compound Nature of White Light

THE old method of showing the compound nature of light by the composition of artificial colours on the lecture-table, is to arrange the various colours in the proper proportion on a disc and to revolve this disc rapidly; but a pure white cannot be produced by this method since there is necessarily a partial absorption of rays on every part of the disc.

My method is to arrange seven lanterns, in the first place, so as to project their several circles of light side by side on a white screen, then to colour each circle by introducing slides of glass stained to imitate the seven colours of the spectrum (the proper intensity of colour being found by trial); we thus get seven circles on the screen coloured from red to violet and arranged side by side. Then by turning the several lanterns so that the projected circles shall exactly overlap each other we get one circle of white light, proving that the seven colours together make white light.

The same effect can be produced with five colours only if properly selected; and even two, the ordinary cobalt blue and deep orange, will nearly do. If these two last be made to partially overlap the effect is very striking. WM. TERRILL

Swansea, May 6

The Araucaria

IN your first number for March last you express your surprise that we should still be ignorant regarding some important phases of salmon life; but there is a question relating to facts much more within the sphere of our daily observation on which authorities differ as much. Does the common Araucaria (*A. imbricata*) require one year or two for the growth of a shoot on the main stem, estimating a shoot as the growth between two whorls of branches? Every gardener whom I have consulted on the subject in Scotland, from north to south, says positively that it requires two years, while the few of whom I have had any opportunity of inquiring in the south of England, decide equally positively in favour of one year. Prof. Balfour agrees with the former in as far as Scotland is concerned, while a gentleman residing on the border between the two countries, informs me that some of his have grown at the rate of a shoot in two years, others of a shoot annually, while a few show only a shoot for every year and a half since they were planted. It has been suggested to me that the difference, if it really exist, may be due to the more favourable climate of England; but araucarias may be seen growing as freely and as healthily in Ross-shire as in Kew Gardens. It would be satisfactory to have more general information on the subject from England and from the Continent of Europe, and still better to have it from the native countries of the tree.

There is another question equally important regarding it, namely, when the shoots are biennial, as they undoubtedly are in many cases, is there a timber ring in the stem for every year's growth, or one for every whorl of branches? On that point also the evidence is contradictory.

JAMES ELLIOT

The Hibernation of Swallows

IN connection with the Duke of Argyll's letter on this subject (NATURE, vol. xv. p. 527) there is an interesting communication in the *Ornithologisches Centralblatt* of May 1 from Herr J. Rohweder, under the head of "Ornithological Notes from Schleswig-Holstein." Herr Rohweder certifies to the competency and trustworthiness of the observer who communicated the facts to him. After the house-swallows (*Hirundo urbica*) in the autumn of 1870, from the beginning to the middle of September, had held their usual assemblies by hundreds on the sunny side of the roofs, stormy and rainy cold weather suddenly supervened. As suddenly did most of the swallows take their departure for the south. The few that remained behind flew about restlessly and anxiously, unable in the cold north wind to obtain sufficient insects to appease their hunger. Within a day after the others these also disappeared. Three days after, during which time no swallow was observed, Herr Rohweder's informant saw peeping out of the entrance of some nests under the projecting roof of the east side of his house, here a wing, there a tail or a few feathers. A ladder was obtained and the nests tapped, but no motion. On pulling at one of the overhanging wings a swallow was dragged out. It was alive, but seemed paralysed. After the swallow was held in the hand a while it fluttered about a short space and then fell to the earth. A second bird behaved in the same way, and a third showed few signs of life. A fourth appeared quite lifeless. In other nests six, and ten, and even fourteen swallows were found huddled together. Their condition was similar to those first found. The birds near the entrance of the nest appeared in a state of sound sleep, while those furthe in showed no signs of life. The former soon were able to fly, with difficulty, a larger or shorter round, only one flying to a considerable distance; the latter were thrown on a neighbouring heap of straw. On the following day, when the observer returned, no birds were found. The exact locality of these observations is not given. X.

Two Remarkable Meteors

WHILST walking on Sunday night with a friend, about 10.35 my attention was directed to a beautiful meteor, of a ruddy hue, not unlike Mars. It appeared a little to the south of Arcturus, and after passing along with a slow motion in an easterly direction, throwing out sparks meanwhile, disappeared near β Herculis. In size it seemed to be about four times as large as Jupiter, and continued visible for three or four seconds. About half a minute afterwards it was followed by another from the same quarter, which took almost exactly the same direction as the other. In colour and appearance it resembled the first, but was not quite so large. It remained visible about three seconds. The sky at the time was beautifully clear, and there was little or no wind.

Rottingdean, Brighton, May 14 W. H. S. J. HOPE

Yellow Crocuses

(Translation)

I have observed here that sparrows have shown a very considerable partiality for yellow crocuses during this spring. My neighbour and I vied with each other in our spring beds; he excelled in yellow crocuses and hyacinths, I in white and blue crocuses. One beautiful Sunday the whole of his crocuses were found bitten and torn by sparrows, and, what is noteworthy, also some yellow crocuses which had somehow wandered into my lot, while the blue and white remained almost untouched. Should this be regarded as an oversight, or was it a matter of taste?

So far the fact is incontestable, but it has not before been observed by me, though I am an old amateur. To be sure, for the last six years, I have always been, about the time of blooming, absent at the Reichstag, and perhaps, therefore, have forgotten early single observations. It may not be possible to obtain a positive explanation. The dryness of the spring, perhaps the colour-sense of the bird, or even a more or less delicate mixture of the plant-sap may account for it—quien sabe!

Hamburg, May 12 W. VON FREEDEN
Editor of the *Hansa*

Sound and Light

I SHOULD like to learn if the following phenomenon is well known and alluded to in scientific writings. While lying awake a few mornings ago, with my eyelids closed, I was startled by a railway whistle. At the same instant I perceived a blaze of light on a dark ground seemingly a few yards off. I made inquiry of my wife (who is of a much more nervous temperament than I) if she had ever observed such a coincidence, and was informed that in her case it is not a very unfrequent occurrence. I likewise reported the circumstance to some scientific friends, but they had neither read nor heard of noise being the occasioning cause of sensation of colour.

While the pen is in my hand I may mention, in reference to Mr. Renshaw's communication (p. 530), that sparrows are in the habit of demolishing the flowers of my yellow crocuses.

Bushy Hill, Cambuslang HENRY MUIRHEAD

Cloud Colours

A VEIN of thought is sometimes as a vein of the most fine gold, and observation is everything in meteorology as it is in geology, in which two difficult sciences we are much interested in this country, and of which your contributor is the unpretending student.

Now I first learned my lessons in weather science from the remarks of Admiral Fitzroy, the author of the Weather Book, which should be well known and read in this country. For years we have marked what an intimate correlation there is between the colour of the clouds and coming weather. Thus we have the cold dark blue and grey, and the reddish yellow masses of cloud as indicative of cold and snow, and we have the light bright grey with bright edges as accompanying or indicating hard frost. Then again we have the inky-coloured cloud, flying in shreds, as indicative of wind and rain, and also the mottled cloud of the same colour or thereabouts, as the sure indicative of rain. We have the sickly-looking green, the deep blue gloom, the muddy angry-looking red, and other such tints, as forecasts of storm, snow, rain, &c.; and frequently before a north-easter we have the grey bluish and whitish clouds setting from north-east, somewhat like the spread-out fingers of the hand. Our sunsets are often grand beyond my pen. The lavish wealth of crimson and gold is magnificent. It strikes us now to ask what relation chemistry and gases have with the cloud colours. I leave that to older minds than mine, beyond the banks of Newfoundland.

But we see, from all that has been said, the *vast* importance of noting the *colours* of the clouds. We depend much in this country on the colour of the clouds for weather prediction. Ice, however, at this time of year, by refrigerating the atmosphere, often interferes with calculation. H. C.

Hailer Grace, Newfoundland

THE PROGRESS OF EVOLUTION[1]

THE new journal mentioned below is edited jointly by Dr. Otto Caspari, of Heidelberg, Prof. Dr. Gustav Jäger, of Stuttgart, and Dr. Ernst Krause (Carus Sterne), of Berlin; and on the list of its contributors are the names of Charles Darwin, Ernst Haeckel, Friedrich von Hellwald, and many others whose scientific creed is Darwinism.

The editors in their introductory statement say that a new day has dawned for natural science, since our great countryman applied the natural laws which govern the whole universe to the phenomena of the development of life, and showed the fallacy of assigning that central position in nature to man himself which had been attributed to him for ages, as Copernicus did in the case of our planet three centuries ago. Man, who seemed to stand above nature hitherto has, without being drawn down from his eminent position, been incorporated with nature as one of her integral parts. The new monistic philosophy caused a wonderful reaction, and an animated reciprocal intercourse arose between the subjective and objective sciences. All the sciences which treat of man, from anthropology, ethnology, and the psychology of peoples, to the history of culture and states, national economy, the philosophy of law, history, and religion, and the sciences of morals and dietetics, proved to be natural sciences quite as much as mineralogy, biology, the practical education of man, and the cultivation of plants and animals.

The result of this general intercourse of the different sciences, has been a continued and encouraging confirmation of the monistic principle contained in the theories of descent and development; the literature, however, which was generated by the reaction, is dispersed and can be collected only from the various scientific journals. Thus, a general desire for collection and concentration has sprung up amongst all those who look upon the theory of development as a considerable progress of the human mind.

The new *Kosmos* will bring together what has hitherto been unconnected; will point out the gaps still existing, and thus lead to their being speedily filled; will reduce contrasts and contradictions to their true nature, and will oppose pernicious dogmatism. *Kosmos* will, with regard to the special domains of natural science, bear a certain critical and polemical stamp, its editors being aware that even science is best developed and strengthened in the fight for its existence, and that in the end the "fittest" theory will survive. All articles in the new serial are written in popular language, and are intended for a large circle of readers.

The first number contains a series of very interesting articles, of which we may mention—Philosophy and its Union with Natural Science, by Otto Caspari; On Inheritance, by Dr. Gustav Jäger; On Modern Anthropology, by the same; On the Chronicles of the History of Development, by Ernst Haeckel; The History of Creation and Chorology two Centuries ago, by Carus Sterne; On the Significance and Objects of Ethnography, by Friedrich von Hellwald; and an excellent review of Darwin's work on Cross and Self-Fertilisation, by Dr. Hermann Müller.

ENGINEERING EDUCATION IN JAPAN

THE technical education of engineers is a subject which has engaged public attention for a long time past and is one of great national importance. It is somewhat singular that this country, foremost as it has always been in matters of engineering enterprise, should be so behindhand in the systematic education of its engineers, there being no establishment in England devoted to that object which is recognised by the profession. Under the system that has been in vogue up to a comparatively recent period a youth intended for an engineer is taken from school at the age of sixteen being thereby deprived of the most valuable years of his education, and placed in some engineering manufactory, where he remains, perhaps, till he is twenty. In those four years his so-called "training" consists in going through the manual routine of the various workshops and "picking up" what knowledge he can by keeping his eyes open and living on good terms with the workmen. His last year is usually spent in the drawing-office, where, by a similar process of "picking up," he learns how to draw if not to design machinery or works of construction. At the end of that time his education is supposed to be complete, and he either remains as a draughtsman until something better is offered him, or he enters the office of another engineer for the purpose of improvement. All this time the far more important theoretical training is neglected altogether, no classes or examinations are held, no lectures or other instructions are given, and though some few energetic young men in some way make up this loss by private study they are a great exception, and the hours of manual work are usually so heavy (from 6 A.M. till 5 P.M.) as to render working in the evening both fatiguing and unprofitable.

The Continental system goes to the other extreme, teaching the theory and discarding the practice. This system is as bad as the other, for experience has shown that in engineering works a practical man without scientific training seldom makes such serious blunders as a scientific man without practical experience. It can only be by a judicious combination of the two systems, allowing science and practical experience to work hand in hand together in the education of an engineer that the best results can be looked for, and in these days of close competition, not only between man and man, but between country and country, it is of the utmost importance to a nation that its engineers should be instructed upon the best and soundest principles. The Indian Government recognised this when it established the Royal Indian Engineering College at Cooper's Hill for the systematic training of engineers for the Public Works Department of India; and it is remarkable that the profession of engineering should stand alone in England as having no recognised *Alma Mater* of its own. Many years ago an engineering college was established at Putney upon a good system, but it was badly managed, and after becoming a nuisance to the neighbourhood, was ultimately shut up; at the present time, with the exception of the technical classes at the Crystal Palace and at King's College, which, in a small way, are doing good work, there is no institution in this country devoted to the education of engineers.

While England is so far behindhand in this important question, a great work has been done by the Japanese Government in the establishment of an Imperial College of Engineering at Tokei, an institution which gives to its students a highly scientific training, combined with actual practical experience in engineering workshops which give employment at the present time to over three hundred workmen, but which are being largely increased and are turning out all classes of engineering work.

The system adopted is as follows:—The course of training extends over six years. The first two years are spent entirely at college; during the next two years, six months of each year are spent at college and six months in the practice of that particular branch which the student may select; the last two years are spent entirely in practical work. The system of instruction in the college is partly professorial and partly tutorial, consisting in the delivery of lectures and in assistance being given to the students in their work.

Candidates for admission must be Japanese subjects under the age of twenty, and must pass a preliminary examination, the best fifty being chosen as cadets, of which there are two classes. A student may elect to enter either as a Government cadet—in which case all his expenses are defrayed by Government, under whom he binds himself to serve for seven years at the expiration of his six years' training—or he may enter as a private cadet, paying his own expenses, in which case the obligation to serve subsequently under Government is dispensed with. In all other respects he is on the same footing as the Government cadet.

The whole system of training may be divided into three courses:—(1) General and Scientific, (2) Technical, and (3) Practical. The general and scientific course, which is taught during the first two years, includes (1) English language and composition, (2) geography, (3) elementary mathematics, (4) elementary mechanics, (5) elementary physics, (6) chemistry, and (7) mechanical drawing.

The Technical course consists of the following branches of engineering:—(1) Civil engineering, (2) mechanical engineering, (3) telegraphy, (4) architecture, (5) chemistry and metallurgy, and (6) mining. This course is taught during the third and fourth years of the curriculum. The practical course, in which the students are engaged during the last two years in the practice of the special branch each may have selected, consists of working in the laboratories of the college, and in the engineering works connected with it established at Akabane, where they serve a regular engineering apprenticeship. While this course is going on lectures on special subjects are given, and the students are required to prepare reports upon the work in which they have been engaged.

In the Technical course are included the higher mathematics and natural philosophy, engineering, civil and mechanical, geology, mineralogy, surveying, naval architecture, strength of materials, practice in the chemical, physical, metallurgical, and engineering laboratories, and in the drawing office and workshops.

The main building, which is a very handsome structure, consists of a central portion containing the large examination hall and library, drawing offices and class rooms, and on each side of this extends a wing containing other class rooms and lecture halls. This is the College proper, and surrounding it are separate buildings set apart for the dormitories, Professors' houses, museum and laboratories of which there are four devoted respectively to chemistry, physics, metallurgy, and engineering. The buildings have been very admirably arranged by the Principal of the College, Mr. Henry Dyer, C.E., and the architectural details have been carried out with great skill by Mr. C. A. de Boinville.

The staff of the College consists of a Principal and nine English Professors, assisted by Japanese teachers, and the Institution is under the jurisdiction of the Minister of Public Works.

A calendar of the College is published annually, which contains information relative to the admission of students, courses of study, and examination papers, as well as catalogues of the splendid collection of instruments in the laboratories, and of the books in the library, which seems to be exceptionally rich in almost every branch of general and scientific literature.

C. W. C.

SUSPECTED RELATIONS BETWEEN THE SUN AND EARTH[1]

III.

In the first of these articles I tried to show that the magnetism of the earth is affected by the state of the sun's surface. I shall now try to show that the meteorology of the earth is likewise affected by the same cause.

Mr. Baxendell, of Manchester, was, I think, the first to point out that the meteorological convection currents of the earth appear to vary according to the state of the sun's surface. More recently Mr. Meldrum, of the Mauritius Observatory, has brought this connection very forcibly before us by showing, from the results of his observations, that there are more cyclones in the Indian Ocean during years of maximum than during years of minimum sun-spots. This will be seen from the following table:—

TABLE II.

Comparison of the Yearly Number of Cyclones occurring in the Indian Ocean with the Yearly Number of Spots on the Sun.

Character as regards Sun-spots.	Years.	Total number Cyclones.	No. of Cyclones in max. and min. Periods.	Character as regards Sun-spots.	Year	Total number Cyclones.	No. of Cyclones in max. and min. Periods.
Max.	1847	5	23				
	1848	8			1862		
	1849	10			1863		
	1850	8			1864		
	1851	7		Min.	1865		
	1852	8			1866	8	
	1853	8			1867	6	
Min.	1854	4	13		1868	7	
	1855	5		Max.	1869	9	
	1856	4			1870	11	
	1857	4			1871	11	
	1858	9			1872	13	
Max.	1859	15	39		1873	12	
	1860	13					
	1861	11					

Prof. Poey has confirmed this conclusion of Mr. Meldrum by showing that there is a similar periodicity as regards the cyclones which make their appearance off the coast of Central America.

In the next place Dr. Arthur Schuster has found that the years of minimum sun-spots coincide very nearly with the good wine years in Germany. This will appear from the following table.

TABLE III.

Exhibiting the near Coincidence between the Years known as good Wine Years in Germany and the Years of minimum Sun-spots.

Dates of Minimum Sun-spots.	Years known in Germany as good Wine Years.
1784·8	1784
1798·5	(?)
1810·5	1811
1823·2	1822
1833·8	1834
1844·0	1846
1856·2	1857, 1858
1867·2	1868

Again, it has quite recently been remarked by Dr. Hunter, Director-General of Statistics to the Government of India, that the famines in Southern India have a period of recurrence which is nearly eleven years, being thus of the same duration as that of sun-spot frequency.

[1] Continued from p. 28.

Here we have evidence from various quarters of a connection of some sort between the state of the sun's surface and the meteorology of the earth, and it becomes a question of great interest what is the nature of this connection.

In the first of these articles a diagram was exhibited showing the close relation that exists between the state of the sun's surface and the range of oscillation of the magnet freely suspended at the Kew Observatory. If instead of taking the daily magnetic ranges we take the daily temperature ranges, that is to say, the differences between the maximum and minimum thermometers, we find an apparent reference to the state of the sun in these also, inasmuch as these ranges appear to be greater at times

DIAGRAM K.—The Upper Curve denotes Temperature Range, the Lower Curve Declination Range.

of maximum than at times of minimum sun-spot frequency. Nevertheless the correspondence is not nearly so well marked as in the case of the magnetic declination, and there is no doubt much local irregularity. But here the following question of much interest and importance crops up. Do these fluctuations of the daily temperature range at the Kew Observatory coincide in point of time with the corresponding solar fluctuations? or do the former lag behind the latter, as is the case with the magnet? The practical bearing of this question is easily seen, for if temperature oscillations and other meteorological fluctuations are simultaneous with the corresponding solar changes, we can hardly expect that a study of the sun's surface will ever enable us to forecast meteorological occurrences; but if on the other hand the solar changes precede the meteorological ones, we may hope, when the nature of the connection between them is fully understood, to make use of solar observations in order to predict the greater meteorological occurrences. Now it appears to the writer that there are certain well-marked fluctuations of temperature range at the Kew Observatory which coincide very closely with corresponding magnetic fluctuations, and which therefore lag behind the solar fluctuations nearly six months (see Article I.); but this interesting and important question can only be determined by further investigations.

DIAGRAM L.

I may here remark that meteorologists are beginning to suspect a somewhat intimate connection between the magnetism and the meteorology of the earth. Mr. Baxendell was, I think, the first to point out that there is a diurnal inequality in the direction and velocity of the wind apparently connected with the daily changes of magnetic declination. On this subject the writer has recently received a letter from Mr. J. A. Broun, the well-known meteorologist and magnetician, who says, "My present opinion is that meteorological phenomena are due to solar actions; that the heating action is not the only one; but that the action which produces variations in the earth's magnetic force affects the conditions of the atmospheric gases, introducing forces which we cannot in the present state of our knowledge appreciate, though the facts appear to me to prove their existence."

It will be seen, by Diagram K, that there is a very marked likeness between the annual variation of the temperature range and the annual variation of the declination range at the Kew Observatory.

There yet remains a question which is nearly allied to the present inquiry. If the sun affects the earth in a variety of ways, and if the planets affect the sun, why should not the moon affect the earth? Now it is known to affect terrestrial magnetism, producing a well-marked variation of a tidal nature, that is to say with two maxima and minima in each lunar day, and there are also indications of a variation with only one maximum and minimum.

Again, Mr. Park Harrison was the first to point out that terrestrial temperature is influenced by the relative position of the sun and moon.

The writer of this article has found in the daily temperature range at the Kew Observatory an unmistakable reference to the phase of the moon.

In summer when the full moon is low in the heavens, we have a less decided reference, which seems to imply a maximum of daily temperature range about new moon and also about full moon. But in winter, when the full moon is high, we have a very decided reference showing a maximum of daily temperature range about new moon, and a minimum about full moon.

Again, in the magnetic ranges at Kew the same features occur, namely, in summer a maximum range at new and at full moon, and in winter a maximum at new and a minimum at full moon.

The winter lunar variations of the temperature and declination ranges at Kew are exhibited in the Diagrams L and M, from which it will be seen that there is a very decided likeness between the two.

These last diagrams are especially interesting because they exhibit an influence which appears to be similar *in form* to that which the planets may be supposed to produce upon the surface of the sun. This, however, is a question which can only be decided by further investigation.

If we now bring together the results of these three papers we may compare the three problems, solar research, terrestrial magnetism, and meteorology, to three corners of a triangle that are bound together. Of their three relations we are, it may be said, perfectly certain of the connection between solar research and terrestrial magnetism. The connection between solar research and meteorology

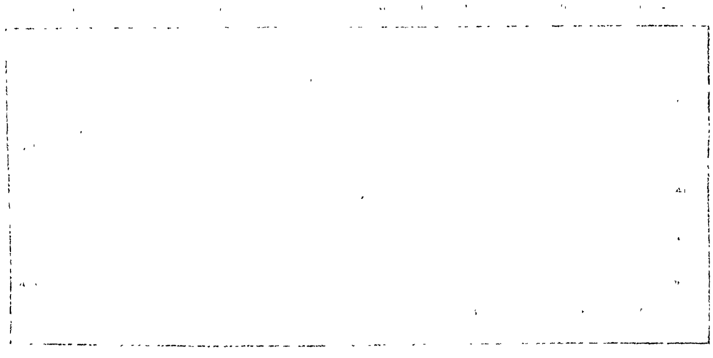

DIAGRAM M.

is perhaps not so well defined, but our evidence is here supplemented by independent traces of a connection between magnetism and meteorology. Thus the three things hang together, and scientific prudence points to the desirability of their being studied together as a whole, a consideration which will not, I trust, be overlooked in the contemplated reorganisation of British meteorology.

I would desire now to conclude by asking, in all honesty, Have we not here a plea for the establishment of some institution that will keep a daily watch upon that luminary which is thus seen to affect us in such a variety of ways?

BALFOUR STEWART

THE SOUTH AFRICAN MUSEUM

OUR notice of the condition of the South African Museum, and the various sums allotted to research by the Government of the Colony, has called forth some criticisms on the part of the Cape-town *Standard and Mail* of April 7. "What NATURE and other scientific organs in Europe mean by 'research,'" it states, "is not what the responsible advisers of the Cape mean by their favouring grants. It would not be saying too much, nor putting it too strongly, to assert that there is no scientific research carried on in connection with any botanical gardens in South Africa. In regard to our museums there is some genuine work being done; at all events in the South African and Albany museums original observations are being recorded. As to our libraries which absorb 2,000*l.* per annum of the public money, the less said, perhaps, the better. The South African Library, as far as standard works in such branches of science as anatomy, chemistry, mineralogy, natural philosophy, &c., are concerned, is simply deficient, and unaccountably so, considering the demands of these departments and the standing of some of the directors. The only sums voted for purely original scientific work are those for 'Geological Researches,' for the publication of Dr. Bleek's Bushman Researches, and for the Meteorological Commission. With the exception of the first of these, which amounts to 1,500*l.*, research in the sense NATURE must mean, is fostered by only some four or five hundred pounds." The writer then goes on to describe the consequences of Dr. Bleek's death; the linguistic and ethnological researches he was carrying on have been stopped, and instead of appointing a qualified scholar to fill his place, the Government allowed his office and salary "to be absorbed into the general and ignoble management of the South African Library, which is only a representative of Mudie, being conducted in the charitable idea of providing, at three pounds sterling per annum, the current literature of the day to subscribers who for the same reading would have to pay in a circulating library about four times the amount. . . . 'Novels are the solace of my life,' was the plea (of Mr. Goodliffe) from the chair in favour of continuing a national institution subsidised by the Government of the Colony, and therefore supported from the revenue of the country, as a receptacle for the custodianship of the popular writings of the period. The scientific work of South Africa has been done by amateurs holding no professed natural history appointments." The Gill College Herbarium now receives a subsidy of 100*l.* a year, but "Prof. Macowan worked at the botany of the Colony for thirteen years before he received any grant to enable him to prosecute the study, or to cover the expenses of preserving a large herbarium." The Colonial Herbarium in Capetown "has a collection of types of the very highest value to Cape botany—those arranged and classified by Dr. Harvey. It has the collections of Dr. Pappe, the late Colonial botanist, consisting of thousands of species, which were bought by a former Government for some 200*l.* Other collections more or less valuable are also in the Herbarium." But "the greater part of these interesting and valuable plants has been destroyed by rain leaking through the roof of the library buildings into the room where they are kept, and by the ravages of moths, &c. In a short time the herbarium will be simply nothing but a mass of uninteresting fragments. We understand that some time back the Parliament voted a small sum to be expended in putting the herbarium into order. How far anything could possibly have been done by those in charge may be learned from the fact that Dr. Rehman, the Austrian botanist, found whole fasiculi destroyed."

SPONGY IRON FILTERS

IN a paper presented by Prof. Frankland, F.R.S., and read before the Royal Society, Mr. Gustav Bischof describes numerous experiments made with spongy iron filters and with charcoal filters. He states that chemical analysis is incapable of discriminating between living or dead, fresh or putrescent organic matters. The microscope reveals their nature more fully; but it is nevertheless frequently a matter of great difficulty to decide as to the existence or non-existence of *Bacteria* of putrefaction, or their germs, in water.

We must refer our readers to the paper for a full account of the experiments and the conditions under which they were performed. Mr. Bischof states that they show that *Bacteria* present in drinking water are *not* killed in passing through charcoal and are killed in passing through spongy iron.

He adds: "I believe that the action of spongy iron on organic matters largely consists in a reduction of ferric hydrate by organic impurities in water. We know that even such organic matters as straw or branches are capable of reducing ferric to ferrous hydrate. We know that even such indestructible organic matter as linen and cotton fibres are gradually destroyed by rust stains. This action is slow when experimenting upon ordinary ferric hydrate, but it may, *in statu nascendi*, be very energetic, the more so if we consider the nature of the organic matter in water. Ferric hydrate is always formed in the upper part of a layer of spongy iron, when water is passed through that material. The ferrous hydrate resulting from the reduction by organic matter may be re-oxidised by oxygen dissolved in the water, and thus the two reactions repeat themselves. This would explain why the action of spongy iron continues so long.

"It is, however, quite certain that there is also a reducing action taking place when ordinary water is passed through spongy iron. This is clearly indicated by the reduction of nitrates.

"Our knowledge of those low organisms, which are believed to be the cause of certain epidemics, is as yet too limited to allow of direct experiments upon them. It is not improbable that, like the *Bacteria* of putrefaction, they are rendered harmless when water containing them passes through spongy iron; but until we possess the means of isolating these organisms, this question can only be definitively settled by practical experience."

CENTROIDS AND THEIR APPLICATION TO SOME MECHANICAL PROBLEMS[1]

THE principal object of the following paper is to suggest the use of a more general form than is commonly employed in the statement of some of the more important theorems of elementary mechanics. Such a generalisation, if in itself satisfactory, has two-fold advantages; it both facilitates the direct solution of problems otherwise apparently complex, and it enables a common method to be employed in an infinite variety of cases, each of which otherwise has to be treated in its own special way. The methods to be described are purely geometric, and admit in all cases of graphic solutions. In the study of mechanism and in all applications of mechanics to engineering work this is a matter of considerable importance, for graphic methods have such enormous advantages in these cases that they must supplant all others when they give equally good results.

By the centroid of any body *A* relatively to another *B* is meant *the locus of the instantaneous centres of A in its motion relatively to B.*[2] The expression includes two things, which must be distinguished from each other;—(i.) the locus as part of the moving body *A*, (ii.) the locus as part of the body *B* relatively to which *A*'s motion is observed, and which may for convenience be regarded as fixed. These loci may be entirely different as to form, but in all their properties they are absolutely similar and reciprocal. It would therefore be wrong to give them different names, they can be distinguished, when necessary, as the centroid *of a body*, and the centroid *for the motion of a body* respectively. The centroid of *A* is therefore the locus *upon A* of its inst. centres relatively to *B*; the centroid for the motion of *A* is the locus *upon B* of the same centres.

The following are the most important characteristics of these curves. As the bodies to which they belong move the centroids roll upon each other, and every point in each becomes in turn the inst. centre. Their rolling, therefore, represents continuously the whole motion of the bodies (considered as changes of position merely), quite irrespective of their form; in other words it defines the path of motion of all points in the bodies. The two centroids have always one point in common—their point of contact—this point being the instantaneous centre. This point may be included in both bodies, and has no motion relatively to either. Any motion which it has must therefore be common to both, so that it may be entirely neglected in investigating their relative motions. In problems affecting the motion of either body relatively to a third this is often of much use.

For the sake of definiteness it has been presupposed in the foregoing paragraphs that the motions referred to were conplane, or, more generally, took place about some fixed point. When the motion is conplane this point is at infinity, and the centroids are plane curves, sections of the cylindric ruled surfaces formed by the successive positions of the instantaneous axes. When the distance of the point is finite, the centroids are, of course, spheric curves, the instantaneous axes forming cones of which the point mentioned is the vertex. These theorems were given by Poinsot in his "Théorie Nouvelle de la Rotation des Corps." It may be interesting just to mention also the case of general motion in space, where (as Belanger seems first to have pointed out), the solids of instantaneous axes, or *axoids*, as Reuleaux calls them—are general ruled surfaces twisting on each other. Each generator of the surface is a "screw," and on each in turn a twist occurs. The surfaces are in general non-developable.

For the sake of brevity, only conplane motions will be considered in this paper. This class of motions includes nine-tenths of those occurring in mechanism. Two or three special cases of frequent occurrence may first be mentioned. If the relative motion of two bodies be a simple rotation, the centroids are a pair of coincident points, one of which must still be considered to roll on the other. The instantaneous centre here becomes a permanent centre. It is convenient, however, to treat the point not only as a permanent centre, but as a special (limiting) case of the centroid. If all points in a body move in parallel straight lines, the centroid for the motion of the body is a point at infinity, and the centroid of the body is also a point at infinity coincident with the former. If the path of the body were infinitely long, the two points would roll round each other. If, on the other hand, a body move parallel to itself, every point in the centroid for its motion (and therefore all points in its own centroid) must be at infinity. The two centroids must again be coincident, so that the motion is represented by the line at infinity rolling on itself.[1]

Proceeding now to notice the bearing of the theory of centroids upon some of the theorems of elementary mechanics, these may be taken in order of simplicity, commencing with those which involve only the notion of change of position. If, then, the line joining any moving point with the point of contact of its centroids be called its instantaneous radius, we can state the general theorem thus: *The direction of motion of every point in a body is normal to its instantaneous radius.* While this obviously includes the simpler special cases already examined, its form allows of direct application to the most general cases, and especially to all cases in mechanism. Two corollaries out of many which are deducible from it may be mentioned as of some special interest: (i.) The inst. radii of a point moving in a straight line are parallel; and (ii.) the inst. radii of a point moving in a circle must pass through one point. In either case the centroids may be quite general curves, as is easily seen. These corollaries have important practical applications in me-

[1] Abstract of a paper read before Section A of the British Association at Glasgow, by Prof. Alex. B. W. Kennedy, C.E., of University College, London.

[2] The word *centroid* was suggested to the author by his colleague, Prof. W. K. Clifford.

[1] Some physical conception of this case can easily be obtained by rolling one hyperbola upon another. The change in the appearance of the rolling as the point of contact recedes along either branch is very striking.

chanism, especially in "parallel motions," both real and approximate.

The familiar theorem that *the relative velocities of points in any body vary as their instantaneous radii* needs merely to be mentioned. It is to be regretted that it is not more generally used, for while it does not increase the difficulty of comprehending simple cases, it is of enormous advantage in simplifying such (apparently) complex ones as not unfrequently occur in mechanism.

The expression for static equilibrium is also tolerably familiar :—*the sum of the moments of all the forces acting upon a body about its inst. centre must* = 0. For practical purposes, however, it is generally more convenient to state the proposition :—*the resultant of all the forces acting upon a body must pass through the point of contact of its centroids.* The application of this proposition to all the simpler cases is self-evident, and at the same time it reduces complex cases to their smallest possible dimensions, rendering most very easy, and in many cases greatly aiding the comprehension of the alterations in conditions of equilibrium corresponding to consecutive alterations in the positions of mechanisms as their links move. It may just be noted that as the two forces of a couple have for their resultant a force (infinitely small) acting along the line at infinity, the proposition gives at once that where the inst. centre of a body is at infinity it is in equilibrio under any number of couples of any magnitude. In the case of a body moving parallel to itself, therefore (see *ante*) all couples may be neglected so far as its static equilibrium is concerned, whatever their magnitude or sense.

The following are, in conclusion, a few of the kinetic propositions the solution of which is greatly aided by the use of centroids :—

(I.) If a force[1] constant in direction and position act upon a body, then (i.) if it cut the centroid for the motion of the body in one or more points motion will take place until the first of these becomes the point of contact, and will then cease ; (ii.) if it pass entirely without this centroid, there will be continuous motion. As corollaries to (i) may be mentioned (*a*), if the centroid for the motion of a body be a curve of the 2nd, 3rd . . . *n*th order, the body has a maximum of 2, 3 . . . *n* positions of equilibrium under some one or more forces constant in direction and position. Also (*b*), if a body have not more than a single position of equilibrium under any such force, the centroid for its motion must be a straight line.

(II.) If the position of a force relatively to the body upon which it acts remain constant, then (i.) if it cut the centroid of the body in one or more points, motion will take place until one of these becomes the point of contact, (ii.) if it lie entirely without the centroid of the body, there will be continuous motion. This gives corollaries as to positions of equilibrium similar to those just stated.

(III.) If a force constant in direction act always at the same point of a body, motion will continue until the instantaneous radius of the point becomes parallel to the direction of the force. There is here no case of continual motion ; the theorems as to number, &c., of positions of equilibrium are similar to those given above.

English writers have used these curves very little. Among modern continental writers who have employed them may be mentioned Dwelshauvers-Dery (Liége) who uses them in his "Cinématique" for questions relating to relative velocities ; Schell (Carlsruhe) in his "Theorie der Bewegung u. d. Kräfte ; Reuleaux ("Theoretische Kinematik," and elsewhere), who gave them the name (*Polbahnen*), by which they are known in Germany, and who has used them ably and extensively for kinematic problems ; and lastly Pröll, who has made use of them in his recent "Versuch einer graphischen Dynamik." The writer has not, however, found them anywhere unreservedly adopted, and has, therefore, made this attempt to show how easily centroidal methods adapt themselves to the general treatment of mechanical problems, especially those connected with mechanism, and at the same time how well suited they appear to be for educational purposes.

[1] Or here, and in the following propositions, the resultant of any number of forces.

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF 1882, MAY 17.—Hallaschka, in his "Elementa Eclipsium," describes this eclipse as broadly total, whereas, it will be, in reality, total, though the zone of totality will not be a broad one. An error in the moon's semidiameter led to the statement in Hallaschka's work. The following elements of this eclipse, calculated upon the same system that has been applied in the examination of other solar eclipses in this column, will probably be near the truth :—

Conjunction in R.A., May 16, at 19h. 41m. 11·7s. G.M.T.

		°	′	″
R.A.	...	53	56	35·4
Moon's hourly motion in R.A.	...		36	14·5
Sun's „ „ „	...		2	28·7
Moon's declination	...	19	38	46·4 N.
Sun's „	...	19	19	38·8 N.
Moon's hourly motion in decl.	...		4	56·0 N.
Sun's „ „ „	...		0	33·8 N.
Moon's horizontal parallax ...	...		58	15·1
Sun's „ „ ...	...			8·8
Moon's true semi-diameter ...	...		15	52·4
Sun's „ „ ...	...		15	48·8

The central and total eclipse begins at 17h. 53·8m. in longitude 3° 11′ W., and latitude 10° 40′ N. ; it occurs with the sun on the meridian in 63° 44′ E., and 38° 35′ N., and ends at 21h. 18·8m. in 138° 51′ E., and 25° 25′ N. The following are points upon the central line in that portion of its track where observations are most likely to be made :—

Long.	Lat.	Sun's Zenith dist.	Long.	Lat.	Sun's Zenith dist.

The central line therefore commences in the west of Africa, and traversing that continent in the direction of Upper Egypt, it passes over the Nile below Thebes, thence over the extremity of the peninsula of Sinai, near Ras Muhammed, and almost directly over Hillah, the site of the ruins of Babylon, to Teheran. The position of this capital according to Gen. Stebitzky (*Astron. Nach.*, No. 2,113) is in longitude 3h. 25m. 41·7s. E. of Greenwich, and latitude 35° 41′ 7″, this point referring to the station of the Indo-European telegraph ; so that the central line of shadow according to our elements passes sixteen miles to the south of it. Calculating directly for this longitude we have the following results :—

	h.	m.	s.	
Totality begins May 16 at	22	36	29	local M.T.
„ ends „	22	38	13	local M.T.
Duration		1	44	

The sun at an altitude of 67°. So that the greatest duration of totality in this eclipse about 12° east of Teheran is about 1m. 46s.

The central line subsequently traverses China, passing off at or close to Shanghai, at which place a total eclipse of short duration may be observed.

The next total solar eclipse on July 29, 1878, which crosses the United States is pretty fully noticed in the various Ephemerides, though in due time the American astronomers will no doubt provide a chart showing on a larger scale the breadth and position of the zone of totality over their country. Then follows the total eclipse of January 11, 1880, in which the track of the central line lies almost wholly upon the Pacific, the total phase being visible for a brief duration only near the coast of California, above San Francisco. The total eclipse of May, 1882, of which the elements are here given is the next in order of date.

THE COMETS OF 1402.—It is singular, considering the attention which the Chinese paid to the observation of comets, their annals containing reference to several hundreds of these bodies, should not have recorded the appearance of the two evidently great comets of 1402. In particular is this the case with the first comet, which, according to the descriptions in the European chronicles collected by Pingré, was first seen early in February, and increasing daily in brilliancy, would appear, if we may rely upon the historians, to have presented a wonderful aspect shortly before Easter. On Palm Sunday, and two following days, we are told "its increase was prodigious;" "le dimanche, sa queue fut longue de vingt-cinq brasses; le lundi, de cinquante et même de cent; de plus de deux cents le mardi." It then ceased to be visible at night, but during the eight following days it was seen near the sun, which it preceded; its tail had then shortened to "une ou deux brasses," but its brilliancy was such that the light of the sun did not prevent its being seen at noon-day. It continued visible till the middle of April.

Some years since the late Mr. John Williams, Assistant-Secretary of the Royal Astronomical Society, and author of the valuable work upon Chinese cometary astronomy, at the request of the writer, made a strict search for mention of a comet or comets in 1402 in several Chinese authorities in his possession, but without any success; nor is there any reference to a comet in this year in M. Biot's translations. Failing thus to obtain any data for calculation beyond the vague indications of the comet's positions given in the "Cometographie," the writer endeavoured to utilise them to form some idea of the orbit, and found that with perihelion passage assumed on March 21, in longitude 208°, ascending node 117°, inclination 55°, least distance 0·38, and direct motion, the principal circumstances of the comet's appearance, so far at least as regards track across the heavens, might be represented; but its extraordinary brightness is not easily accounted for. The comet is mentioned in Kaempfer's History of Japan, which renders it the more curious that the Chinese annals should have no account of it. Struyck thought it was a return of the comet of 1661, but in his day that body was thought to be identical with Apian's comet of 1532, an idea which was negatived by Mechain's subsequent calculations and by the non-discovery of the comet about the year 1790, notwithstanding Maskelyne's efforts to insure observations if it returned at that time.

METEOROLOGICAL NOTES

VARIATIONS IN THE RELATION OF THE BAROMETRIC GRADIENT TO THE FORCE OF THE WIND.—In a very suggestive paper recently communicated to the Meteorological Society of London, Mr. Clement Ley shows that the mean velocity of the wind corresponding to each barometric gradient is much higher in summer than in winter, and that this is the case at all stations examined, with all winds, with all lengths of radius of isobaric curvature, and with all values of actual barometric pressure. The diurnal and seasonal variation in the relation of the gradient to the force of the wind is unquestionably one of the fundamental questions of meteorological research, and we hope Mr. Ley will soon again return to its discussion, with ampler data for a more satisfactory handling of the subject than he has yet had before him. That the mean diurnal oscillations of the barometer cannot be neglected in the inquiry is very evident. Thus, while in June at 8 A.M. the barometer at Kew is 0·015 inch above the daily average, on the coast at Falmouth it is only 0·001 inch; but while at 3 P.M. it is 0·015 inch below the average at Kew, it is still 0·001 inch above the average at Falmouth. Crossing to the Continent and contrasting Helder on the coast with Namur inland, it is seen that in June at 8 A.M. the barometer at Helder is 0·004 inch under the average, while at Namur it is 0·008 inch above it, but at 3 P.M. it is at Helder 0·007 inch above, whereas at Namur it is 0·011 inch below the average. An interesting part of the paper is that descriptive of the mean diurnal variations in the velocity of the wind, in which, among other interesting features, it is pointed out that at the coast stations, the mean horary curve in summer approximates in type to the winter curve at the inland stations, the diurnal maximum being about 2 P.M. In connection with this it is interesting to note that while at Valentia and Falmouth the anemometric maximum occurs in summer about 2 P.M., the barometric minimum does not occur till from three to four hours later. The point might be even still more strikingly put by a reference to the observations made at Pola, near the head of the Adriatic Sea, where during June, July, and August, 1876, the anemometric maximum occurred from 10 A.M. to noon, and the barometric maximum from 11 A.M. to 1 P.M. The two maxima are thus all but contemporaneous, a result directly opposed to the view generally entertained that in such cases the barometric maxima are contemporaneous with the anemometric minima. London presents very considerable facilities for the working out of this question in its two well-equipped observatories at Greenwich and Kew, and in the number of meteorological stations situated within a radius of fifty miles, in connection with the Meteorological Office, Mr. Glaisher, and the London Meteorological Society. Observations made at these stations at 9 A.M., 3, and 9 P.M., would render possible the drawing of the isobarics over the south-east of England, with an approach to correctness sufficient to give the barometric gradients for Greenwich and Kew as may meet the requirements of the problem. Isobarics drawn from the Daily Telegraphic Reports alone, while sufficient in a first tentative inquiry, are, owing to the great distances between the stations, necessarily very hypothetical, and therefore much too rough for any satisfactory investigation of this important subject.

CLIMATE OF PEKIN.—A memoir on this subject, read by H. Fritsche before the Imperial Academy of Sciences of St. Petersburg on August 17, 1876, has just been published in the *Repertorium für Meteorologie*. The memoir is an able and exhaustive discussion of the elaborate meteorological observations made at Pekin from the beginning of 1841, and published by the Russian Government under the superintendence successively of Kuppfer, Kaemtz, and Wild. H. Fritsche has thus been able to give in a very complete form the hourly and general monthly averages for temperature, pressure, and humidity, and very satisfactory, though necessarily less complete, averages of wind, cloud, rain, snow, hail, and thunderstorms. The mean temperature and pressure of each day of the year has been worked out in detail, and several of the more important extremes are also tabulated. This well-discussed material has a peculiar meteorological value, arising from the position of Pekin with reference to the continent of Asia, since it results from that position that Pekin may be regarded as situated during the winter months in an extensive anti-cyclone, the prevailing winds being from the continent seawards, and from at least April to July, in an extensive cyclone when the prevailing winds blow from the sea in upon the continent. Hence its dry winter climate, the mean monthly rainfall amounting only to 0·14 inch, and its wet summer climate, the average rainfall in July being nearly 20·00 inches. Hence also snow falls only on eleven days during the year. Thunderstorms occur on twenty-seven days, from the end of April to the beginning of October, reaching the maximum in June, July, and August, when a thunderstorm occurs on an average about every fifth day. The same season marks the period of hail, which is, however, of rare occurrence, being only once in two years. Of special interest are the hourly averages in their relation to the winds and weather of this part of Asia. Thus, while the climate of Pekin loses much of its continental character during the summer months, the hourly barometric curves lose their strictly continental character, the morning minimum, for instance, falling close to, or even slightly below, the mean of the day, thus tending to be assimilated to the curves of the sea-side climates about the latitude of Pekin.

WHY THE BAROMETER DOES NOT ALWAYS INDICATE REAL VERTICAL PRESSURE.—Mr. Robert Tennent writes from Edinburgh to point out why the barometer does not always indicate real vertical pressure. He points out that as the upper currents of the atmosphere when in motion are more mobile than the lower, and less retarded by friction than the lowest, there are frequent movements or "liftings" from the lower to the upper layers, and this affects the barometric column, "the normal upward diminution of pressure which takes place when the atmosphere is at rest being greatly altered when its upper portion is in rapid motion." Mr. Tennent says "the practical conclusion from this is obvious. On weather charts the constant rise and fall of the barometer which is there reported, is to a large extent simply due to the passage of air over a resisting surface; over a surface devoid of friction these mechanical effects would be entirely removed, its rise and fall would be greatly reduced, and might be considered as being solely dependent on the effects of heat and vapour. The gradients and isobars which are dependent upon it would also be similarly affected. The barometer does not indicate the real weight of the atmosphere, it only exhibits the amount of its elasticity from which its real weight can only be deduced when the dynamical element of motion does not enter into one of its currents." . . . "As a general rule, in the British Isles equatorial winds are accompanied by these rapid upper movements, while Polar winds move with a greater uniformity in the velocity of their various layers, and sometimes even those on the surface move more rapidly when copiously supplied from a vertical source. There is hence a remarkable difference in their *mode of inflow*. Equatorial winds as they increase in force are hence accompanied by 'lifting' and a fall of the barometer. Polar winds are not attended by 'lifting,' and if their supply is copious and partly from a vertical source, their increase in force is accompanied by a rise of the barometer. The range of the thermometer is equally great both above and below its mean. But with the barometer the extent of its range above the mean is not more than one-half of that which takes place when it is below it. When it is below the mean, equatorial winds generally prevail which are accompanied by 'lifting' and extensive range. Above the mean, Polar winds prevail which are not attended by 'lifting' or such extensive fluctuations. Hence, as a general rule, equatorial winds exhibit fictitious or dynamical pressure, while Polar winds possess more nearly real or statical pressure, being unaccompanied by the mechanical oscillations due to the passage of air over a resisting surface."

THUNDERSTORMS AT ANTIBES ON MARCH 26, 1877.—Col. Gazan has given a brief account, in the *Bulletin International* for April 18, of three thunderstorms which occurred at Antibes, in the south-east of France, on March 26, possessing certain characteristics well deserving of attention. About 7 A.M. a flash of lightning occurred followed by a clap of thunder, and at 7.10 A.M. a fall of hail without rain, lasting ten minutes. The hailstones were for the most part regularly round, quite opaque, and not bigger than common peas, the largest not much exceeding half an inch in diameter. Clear patches of blue sky in the east and south-west formed a striking contrast to a nimbus cloud in the west, which was connected with the upper clouds. The clouds were absolutely motionless, the air so calm that not a leaf was stirring, and the fall of hail exactly perpendicular. At 11.10 A.M. the sky was entirely overcast, and under the same conditions as before a fresh fall of hail took place, mingled with heavy rain, the hailstones being more equal in size and generally smaller. About 2.30 P.M. a pretty smart shower of rain fell, which, immediately after a flash of lightning followed by thunder, increased in violence, and was accompanied with hail. The largest of the hailstones did not much exceed the largest of those of the two falls preceding. During the whole time there was not a breath of wind until just before the end of the last thunderstorm, when a light westerly breeze sprang up. Col. Gazan infers from the quiescent state of the air, as shown by the absence of motion in the clouds, the perfect calm at the earth's surface, and the regular distribution of the hailstones over the ground, that the three thunderstorms were formed immediately over the place and that the phenomena were unattended with any gyratory movement whatever—conclusions which, if correct, have important bearings on the theory of thunderstorms, and therefore are well deserving of the most careful examination on the part of observers of the phenomena of atmospheric electricity.

METEOROLOGY IN ITALY.—The *Rivista Scientifico Industriale* publishes a "project for the constitution of an Italian Meteorological Society" from the pen of Prof. D. Ragona, director of the Modena Observatory, in which the writer points out the importance of meteorology, and adds that this science owes much to Italy, as it was in that country that the most valuable meteorological instruments, viz., the barometer, thermometer, and rain-gauge, were invented. More than 100 meteorological stations are already in existence, some of which are renowned for exactness of the determinations and delicacy of the researches they have made. They have also the advantage of great variety in their elevations, more than sixty of them being situated between 200 and 2,500 metres above sea level. Several influential persons have already consented to become members of the new society, and amongst them are the Minister for Agriculture, Industry, and Commerce, and Prof. G. V. Schiaparelli, of Milan. We wish the project every success.

METEOROLOGY IN FRANCE.—The prefects of three different departments have published a circular notifying to the mayors of the several communes under their authority the required conditions for receiving daily the weather-warnings issued by the observatory. It is the first time that official action has been taken for the propagation of the system inaugurated by M. Leverrier. The progress made under his direction is very remarkable, and meteorology is becoming very popular in every part of France. The system is to continue on the voluntary principle.

SUNDAY WEATHER WARNINGS.—The weather telegrams sent every Sunday by the British Meteorological Board have been discontinued, as it is only during winter that the taking of observations has been authorised. The head of the Meteorological Office has written to M. Leverrier notifying the fact, and expressing a hope that the Sunday service will be resumed next September. This decision has given rise to some sarcastic paragraphs in the French leading journals, which doubt whether storms will be found strict Sabbatarians even in summer.

GEOLOGICAL NOTES

GEOLOGICAL MAP OF BELGIUM.—Considerable discussion has lately taken place in Belgium regarding a detailed geological map of that kingdom which it has been proposed to construct. The Academy of Sciences, the Geological Society of Belgium, and the Association of Engineers have all formed committees of inquiry as to the best methods of preparing the map. It may interest geological readers to know the scheme which after prolonged discussion has been agreed upon by the Geological Society of Belgium. The organisation of the staff is proposed to include a geological committee charged with the actual survey, and consisting wholly of geologists; a cartographical committee composed of cartographers and geodesists, to take charge of the engraving and publication of the map in chromolithography; a director, as president of both committees, to be appointed by the King, on the recommendation of the geological committee. Each committee is to be independent of the other, and to have the utmost liberty within its own proper sphere of action. The Government, on the recommendation of the Royal Academy of Belgium, names the first five members of the geological committee, and the additions to this number are made by the Government on the recommendation of the committee itself. The geological committee may nominate for appointment by the Government as associate members, the assistants which it will require for the execution of the work, and it will regulate their remuneration subject to ministerial approbation. This committee will settle the legend of the map, as well as all details which can be regulated in advance; it will determine by whom and under what conditions the geological work is to be carried on, and it will decide upon the memoirs or other works connected with the geology of the country, which are to be published as accompaniments of the map. Each published sheet of the map will bear the name of its author. The geological committee will communicate through the director with the cartographical committee before the final printing off of the sheets of the map. The cartographical committee will comprise five members, including the director-president, all appointed by the Government. The Director will convoke the committees as often as he considers necessary and at least once in three months. It will be his duty to superintend the execution of the work determined by the committees, and to give an account of its progress at every quarterly meeting. He will also present annually to Government a report upon the whole work connected with the map and upon the employment of the funds placed at his disposal. These regulations embody the views of the majority of the Geological Society of Belgium, but from the keen and prolonged debate on the subject (well reported in the *Bulletin*), it is clear that some members of the Society shrewdly foresee the difficulties which are sure to arise if these regulations are finally adopted by the Government. The whole scheme is too cumbrous. Unless the president happens to be a man of singular powers, it will be a matter of herculean labour to get a harmonious and complete result out of the independent work of two committees, who need not be summoned above once a quarter, and who are not compelled to have any direct communication with each other until just before the final issue of each sheet of the map. The actual survey will be made, in part at least, by paid assistants. Their work will be subjected to the criticism of the geological committee, the majority of which may change from time to time, thus affording no guarantee of uniformity of system. The maps, after coming out of the ordeal of this committee, will pass under that of the cartographers, who, it seems, are to have full power to bring out the maps in any style or shape they choose, and who may possibly be quite unacquainted with geological requirements. We can anticipate the astonishment with which some fine day one of the assistants may peruse a published copy of his own "feuille." Perhaps his name engraved at the bottom of the sheet may be the only indication he will recognise of his association in a work with which his connection ceased when he handed his field-maps over to the geological committee. It is to be hoped that the Government will reduce this somewhat complicated machinery. A responsible director, with, if need be, a small council of geologists, palæontologists, and map-makers with whom he might from time to time consult, would be sufficient to organise a staff of field-surveyors and to carry out in fullest detail and in complete harmony a geological survey of the country.

Ice-Work in Labrador.—Mr. H. Y. Hind, who has already published much valuable information regarding the glacial phenomena of British North America, has recently visited part of the north-eastern coast of Labrador, and has prepared some notes of the chief geological results of the journey. His contributions to our knowledge of the glaciation of that part of the world are of special interest, and will no doubt be welcomed by those geologists who still maintain the potency of icebergs and floating-ice over glaciers and ice-cap. He describes the "pan-ice" of the Labrador coast—that is, the frozen sea-water of the bays and shallow seas along the coast, and shows that though in winter it has no lateral motion but merely rises and falls with the tides, in spring and summer it breaks up into pieces or "pans" from a few square yards to many acres in extent. These "pans" pressed by the south-east Arctic current against the coast, and accommodating themselves to all its sinuosities, are pushed over the low islands and promontories with irresistible force, grinding and polishing the hard rocks, rasping the sides of steeper cliffs, and driving before them every boulder and pebble which may be lying on the surface, as well as any blocks which they may be able to detach from the solid rocks. The same kind of action takes place in the shallow seas, the bottom of which, down to a depth of twelve or fifteen feet, is smoothed and planed by the drifting ice. While the prevalent drift is from the north-west out of Davis Strait, a change of wind sometimes brings the endless chain of loose ice back again. The rocks are again abraded and the loose blocks are driven to and fro until they acquire the true boulder-form. In the sheltered depressions of the sea-floor accumulations of *débris* must be taking place like some varieties of boulder-clay. Mr. Hind remarks that this form of ice-work goes on over hundreds of miles of coast. He assumes that it has been the means of smoothing and polishing the rocks of Labrador up to a height of many hundred feet above the sea during the gradual elevation of the land. At the same time he states that though he believes the deep fjords to have been excavated by glaciers, he has found after the most careful search only one example of glacial striæ. An obvious objection will occur to many readers; it may be that the smoothing and polishing of the hills of Labrador has not been done by pan-ice but by solid sheets of land-ice which moved over the country, no doubt grooving and striating it from end to end. All that pan-ice has effected may have been merely the rubbing down of the exposed parts of this general glaciated surface, and the consequent removal of the striæ. The sea-bottom off the Labrador coast freezes in sixty and seventy feet of water, forming what is called "anchor-ice." Seals taken in seal-nets from depths of ten or fifteen fathoms are often found frozen solid when brought to the surface, where, however, they thaw in a few hours. The Labrador climate, as is well known, owes much of its severity to the constant supply of ice drifted past it from the north. Mr. Hind examined thousands of icebergs near at hand last summer, and in only one or two instances did he detect upon them any foreign material. He concludes that true icebergs have little opportunity of transporting rock and *débris*, though he admits that where they ground they may be deepening the water by their incessant rolling and grinding, as the swell of the sea sways them to and fro. He speaks of a loose fringe of such stranded bergs on banks at a distance of ten or fifteen miles from the outermost islands, extending for hundreds of miles along the coast of north-eastern Labrador. These banks intercept the icebergs and prevent them approaching nearer to the land, so that it is only the broken fragments of the smaller "foundered" bergs which enter the fjords and channels.

Human Remains in a Raised Beach.—During the recent long excursion of the geology class of the University of Edinburgh, an interesting find was made in the raised beach to the west of Pittenweem, on the coast of Fife. The storms of last winter have cut away some new slices of the coast, and laid bare fresh sections of the low raised beach which fringes the more sheltered parts of that coast-line. Portions of the skull, arm, and shoulder-bones of a full-grown skeleton were observed protruding from an upper argillaceous layer of the undisturbed gravel of this raised beach. In examining them, one of the phalanges of a child was likewise obtained. Some additional bones were picked up on the beach, but the greater part of the skeleton had no doubt been removed by the waves. From the position of the bones seen *in situ*, it was inferred by the students that the body had originally been cast ashore by the sea with one arm extended beyond the head, and that in this posture it had been covered up with mud and gravel. The stratum, containing the remains, lay about 4½ feet above the present high water-mark, and was covered with earthy sand.

NOTES

WE regret to see what we must characterise as an unwarranted attack made upon Sir Wyville Thomson in the current number of the *Annals and Magazine of Natural History*, as to the disposal of the specimens obtained by the *Challenger* Expedition. Dr. Martin Duncan appears to have taken for granted that an extract of a private letter which some indiscreet friend of Mr. Alexander Agassiz published in *Silliman's Journal*, and which then found its way into the English journals, is "official." He would have done well to have ascertained whether this was really the case before allowing himself to comment on Sir Wyville Thomson's proceedings in such severe terms. So far as we are aware, out of the many naturalists actually engaged to work out the results of the *Challenger* Expedition, only *three* are not Englishmen, two being Americans, and one German. These three gentlemen are of the very highest repute in their respective branches, and Sir Wyville Thomson has, in our opinion, done well for science to secure their services.

A LARGE and influential deputation of members of both Houses of Parliament, headed by the Duke of Richmond and Gordon, President of the Scottish Meteorological Society, waited on the Chancellor of the Exchequer on Tuesday to advocate that society's claims to State assistance. Sir Stafford Northcote said that the Treasury was prepared to grant 1,000*l*. for services rendered to Government during the past twenty years, and as regards the future he promised to consider the matter.

MR. J. RUSSELL REEVES, F.R.S., after whom that magnificent bird Reeves' pheasant was named, died on the 1st instant at Wimbledon, aged 73. As a young man in the H.E.I.C.'s service in China, Mr. Reeves contributed not a little to our knowledge of the flora and fauna of that country, several new plants and animals having been sent home or described by him. His love for natural history continued to the time of his death, and for some time he kept up a good aviary at his house at Wimbledon.

THE Rhind lectures, delivered in Edinburgh by Dr. Arthur Mitchell, on the condition and antiquity of the cave-man of Western Europe, in other words the early, or earliest European of whom we have any knowledge, were brought to a close on Friday last. Dr. Mitchell showed that the cave-man's weapons of the chase and war were made of bone or horn, and highly finished, while his implements of stone were extremely rude, and calculated chiefly to serve as tools in the making of his bone implements, thus placing him in the bone rather than in the stone age of civilisation. From an elaborate examination of the objects which the cave-man has left, displaying an art-faculty, and from the study of the crania of the cave-people themselves, he showed that they must have possessed a high capacity for culture in all directions, and must have been as complete in their whole manhood as living Europeans. From an exhaustive examination of the cave-fauna, and of the actual fauna of Western Europe, Dr. Mitchell gave reasons, which certainly call for grave consideration on the part of archæologists, for believing that the antiquity of the cave-man of Western Europe is to be measured by a few thousands, and not by tens or hundreds of thousands of years.

THE Anthropological Institute will hold a Conference at 4, St. Martin's Place, Trafalgar Square, on May 22, on the Present State of the Question of the Antiquity of Man, when the following papers will be read:—Prof. Boyd Dawkins, F.R.S.—"On the Evidence Afforded by the Caves of Great Britain;" Prof. McKenny Hughes—"On the Evidence Afforded by the Gravels and Brick Earth;" Mr. R. H. Tiddeman.—"On the Hyæna Bed in the Victoria Cave." Communications have also been solicited from foreign anthropologists.

THE Paris Acclimatisation Society distributed its medals last Saturday at the Vaudeville. One of them was awarded to Mr. Alfred Mosenthal, Consul of the late Transvaal Republic, for his admirable work on the acclimatisation of the ostrich. Successful experiments on his system have been made on a large scale in Algiers.

MR. ETHERIDGE writes to the *Times* with reference to his examination of the red and green shales found below the depth of 1,073 feet in the boring at Meux's Brewery, and of which Prof. Judd spoke in a recent article in NATURE on Deep Well-borings in London. He states that the evidence now shows them to be of palæozoic age, and of the continental type of Devonian rocks containing the molluscan fauna of that period.

AT the April session of the German Geological Society Herr Speyer exhibited a number of fine palæontological specimens belonging to the Permian formation, obtained at a depth of 242 metres from borings in the vicinity of Memel. The twenty-five species found embraced eleven molluscs, five entomostracæ, two bryozoa, &c. Although nearly all of them are represented in the Lower Permian of Thuringia, Hesse, and Wetterau, but one-third of the number are found in the corresponding English formations. The above-mentioned borings yielded in the midst of the Permian formation occasional specimens of dolomite, with crinoidal stems and imperfect remains of brachypods, belonging properly to the Devonian.

THE monument to Liebig to which we have previously referred, was unveiled at Darmstadt, his birthplace, on the 12th inst., the seventy-fourth anniversary of his birth.

THE Annual Meeting of the Cumberland Literary and Scientific Association was held at Keswick on the first three days of the present month. This association, as we have previously intimated, is formed of a large number of local Cumberland societies, and both its first and its recent meetings have been highly successful. The idea of thus associating the various local societies of a county is admirable, and we would strongly recommend its universal adoption. The president at the last meeting was the Bishop of Carlisle, who gave a really interesting and fairly liberal address on the "Analogies and Contrasts between Human and Divine Science," the greater part of which consisted of an account of some recent advances in physical science. Several other papers were read, nearly all of them scientific, and more or less on subjects connected with the district. The new president is Mr. Isaac Fletcher, M.P., F.R.S., and the next meeting will be held at Cockermouth in May, 1878.

COMMANDER PERRIER read a paper at the last meeting of the Geographical Society of Paris, on the determination of the longitude of Algiers by telegraphy. The exact longitude is 2′ 50″·21 east from Paris, the probable error being only 0″·01. The time required for the transmission of the electricity from Paris to Marseilles was found to be only $\frac{7}{100}$ of a second; the distance between these two cities being 863 kilometres, it shows that the velocity of the electricity was not less than 46,000 kilometres per second. Similar experiments tried on the submarine cable between Algiers and Marseilles proved that the time required to travel was $\frac{23}{100}$ of a second; for a distance of 926 kilometres this shows a velocity of only 4,000 kilometres. But the battery used for signalling in the aërial line was composed of 100 elements, and only ten elements were used in the sub-Mediterranean cable. The triangulation of Algeria is an accomplished fact, and the calculations will be finished two or three months hence. When the operations shall have been completed it will be possible to know the exact length of an arc of meridian passing through the Paris Observatory, and extending from Shetland to Laghouat. The amplitude will be exactly 30°. An arc of parallel will be measured, also extending from Nemours on the Marocco frontier to Bona, in the vicinity of Tunis. The mean latitude will be 36° and amplitude 10°.

THE following courses of instruction for science teachers will probably be organised this summer at South Kensington :—1. Chemistry (Elementary), from July 4 to July 26, by Mr. W. Valentin, F.C.S.; 2. Sound, from June 19 to July 11; 3. Light, from July 12 to August 3, both by Prof. Guthrie, F.R.S.; 4. Steam, from July 4 to July 26, by Prof. Goodeve, M.A., and Prof. Shelley; 5. Biology, from June 13 to July 5, by Prof. Huxley, Sec. R.S. Details may be obtained by application to the Science and Art Department.

THE award of the Public Schools' Prize Medals of the Geographical Society for the present year has been as follows :—Physical Geography—Gold medal, Walter New, Dulwich College; Bronze medal, Arthur Smyth Flower, Winchester College. Political Geography—Gold medal, William John Newton, Liverpool College; Bronze medal, John Wilkie, Liverpool College.

ARTIFICIAL flowers called *barometers* are being now exhibited in a number of Parisian opticians' shops. They are coloured with a material composed of chloride of cobalt. When exposed to sun and dry air the leaves become deep blue; when the air is saturated with moisture they become pinky. All the intermediate shades are easily observed.

A REPORT from Dr. v. Bary on his recent excursion into the Tuareg region of the Western Sahara was read at the last meeting of the Berlin Geographical Society. His researches yield but few grounds in support of the theory that the Sahara was formerly the bed of a sea. He is inclined more to the belief that North Africa has long been free from a covering of water, as no traces of Tertiary formations were found, and the sand-downs cannot be regarded as proofs of the former existence of a sea. The traveller found the valley of Mihero not only remarkable for the number of crocodiles existing in its pools, but also on account of the rich growth of trees in striking contrast to the surrounding deserts. A mass of luxuriant climbing plants prevents the passage of beasts of burden.

FINNISH papers report that vast masses of smoke are issuing from a mountain adjoining the river Tana, and that the snow in the vicinity has been melted away. The region has hitherto been free from evidences of volcanic activity. The theory has often been advanced that the gradual elevation of the shores of the Gulf of Bothnia is due to volcanic forces, and it is possible that these are finally seeking a vent.

THE royal tigress in the Berlin Zoological Gardens, lately brought forth a litter of two, which she utterly refused to take care of. They were accordingly placed amidst the family of a Newfoundland dog, who welcomed the new-comers warmly and bestows upon them all necessary maternal attentions.

AN extensive movement of subsidence has taken place at Marano Marchesato, in the territory of Cosenza (Calabria). Vast chasms have opened, a great number of houses have been destroyed, and many others threaten ruin. The movement extends to the north, passing the hills of S. Fili e Bucita as well as to the river that divides Marano from Rende, the waters of which are partly escaping through large fissures in its bed. At the observatory of Cosenza there have been noticed for some time a barometrical depression of 10 mm., an extraordinarily low state of temperature with variable winds, fresh snow on the mountains, and a very abundant rainfall. The magnetic instruments, too, show an extraordinary agitation.

THE town of Iquique, in Peru, was visited by a destructive earthquake on May 10. The damage done is not so great as was at first anticipated, and it is stated that no lives have been lost. Early on the following day, between 2 and 3 A.M., a shock of earthquake is reported to have occurred at Comrie and the surrounding district of Perthshire; the shock, as usual, came apparently from south-west, proceeding to north-east, and was accompanied with a noise resembling that of distant thunder or the discharge of cannon. On May 2 several shocks of an earthquake were experienced in the neighbourhood of Löfta, in Sweden, causing some degree of damage.

IN the April session of the Berlin Anthropological Society, Baron v. Schleinitz, commander of the late German exploring expedition, gave an extended account of his anthropological studies among the inhabitants of New Guinea and the islands of the Melanesian Archipelago, which possess an interesting character on account of the isolated character of the region. The natives belong almost exclusively to the pure Papuan race. Three sharply-distinguished types were noticed. The first, prevalent in the northern part of New Guinea, is characterised by a thin, ill-shaped, hairy body, smooth face, thick lips, woolly hair, prognathous features, thin calves, &c. A second, occupying the islands of New Hanover and New Ireland, is slightly modified. The colour is a light brown, scarcely darker than that of South Europeans; the body is better proportioned and more fully rounded; clothing is not worn by the men and rarely by the women. A comparatively strict observance of morality, the rights of property, and family relations was, however, observed. A third race, found on the western coast of New Guinea, evidently possesses a slight mixture of Malaysian blood. They are russet brown and dolichocephalous, with intelligent and handsome features, and well proportioned form. Many of the tribes inhabit villages built on piles and well secured against attack. Polygamy is prevalent in certain regions, and a legalised system of marriage appears to be general.

WE have received from Prof. Henrici the sum of 1*l*. 10*s*. towards the Gauss Monument Fund.

THE additions to the Zoological Society's Gardens during the past week include a Hoolock Gibbon (*Hylobates hoolock*) from Assam, presented by Mr. John Scrymgeour; two Mauge's Dasyures (*Dasyurus maugæi*) from Australia, presented by Capt. J. C. Harris; an Antarctic Skua (*Stercorarius antarcticus*) from the Antarctic Seas, a Ceylon Hawk Eagle (*Spizaëtus ceylonensis*) from Ceylon, presented by Capt. W. Vincent Legge; two White eared Conures (*Conurus leucotis*) from South America, presented by the Lady Greville; three Touracous (*Corythaix persa*) from West Africa, presented by Mr. J. G. Tayler and Capt. R. H. Crewe; a Saddle-billed Stork (*Xenorhynchus senegalensis*), a Black Sternothere (*Sternothærus niger*) from West Africa, five Kappler's Armadillos (*Tatusia kappleri*) from South America, purchased; a Wild Boar (*Sus scrofa*), born in the Gardens.

UNIVERSITY INTELLIGENCE

OXFORD.—The Master and Fellows of Balliol College give notice that they are willing to receive as members of the College without further examination, selected candidates for the Indian Civil Service, not exceeding in number ten, and to assist in their education. Any candidate who wishes to avail himself of this proposal is requested to communicate with the Master of Balliol.

CAMBRIDGE.—The Adams Prize awarded biennially for the best essay on some subjects of Pure Mathematics, Astronomy, or other branch of Natural Philosophy, the competition being open to all persons who have at any time been admitted to a degree in the University of Cambridge, has been adjudged to Edward John Routh, M.A., F.R.S., St. Peter's College. The subject of the essay is "The Criterion of Dynamical Stability." The value of the prize is about 250*l*.

A Warden of Cavendish College in the place of the Rev. T. J. Lawrence, resigned, will be elected on Tuesday, June 5. The College is intended for students somewhat younger than ordinary undergraduates, and the teaching and discipline correspond with those of the higher forms in a public school. The salary is 500*l*., or a capitation fee of 5*l*. when the number of students exceeds 100. Candidates are requested to communicate with the Rev. Prebendary Brereton, Little Massingham, Rougham, Norfolk.

GLASGOW.—The Town Council has given a subscription of 5,000*l*. to the funds of the University of that city.

BRISTOL.—It will be seen from our advertising columns that a Principal is wanted for University College. For so young an institution the salary offered is very fair, and we hope that a thoroughly good man will be obtained for the post, one who, if not a man of science himself, at least regards it as of equal importance with literature.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 12.—"On certain Molecular Changes which occur in Iron and Steel during the separate acts of Heating and Cooling," by Prof. Norris, M.D., Queen's College, Birmingham.

An exhaustive study of the various conditions has led to the elucidation of the nature of hardening, softening, tempering, annealing, &c., and has further shown that numerical values may be assigned to these states.

The research has further established the existence in steel and in iron containing *free* carbon of a contraction or shortening which is excited by heat, and which proceeds simultaneously with the dynamical expansion, and masks its true amount. This is divisible into *high* and *low* temperature contraction.

The presence of a cooling expansion or crystallisation, which comes in during the dynamical contraction, and masks its true amount.

These effects, due to crystallisation and decrystallisation, are the causes of the so-called kicks, or temporary contractions and expansions which occur during the heating and cooling of the steel.

That the low-temperature contraction and cooling expansion are due to decrystallisation and crystallisation which occur during the acts of heating and cooling, while the kicks themselves are simply the thermal effects associated with these changes, and are proportionate to their extent.

That protracted annealing, that is, *extremely slow cooling*, brings about molecular separation of the carbon and iron; and steel in such a state contracts greatly when high temperatures are reached, producing the *contraction returns* seen at the end of the heating, and which are due to the condensation produced by the recombination of the carbon and iron. Steels in this state are less susceptible to cooling expansion (crystallisation), and therefore to low temperature contraction on subsequent heating.

April 26.—"Researches on Emeralds and Beryls.—Part II. On some of the Processes Employed in the Analysis of Emeralds and Beryls," by Greville Williams, F.R.S.

"On the Nature and Origin of the Beds of Chert in the Upper Carboniferous Limestones of Ireland," by Prof. Edward Hull, M.A., F.R.S., Director of the Geological Survey of Ireland. With "Chemical Notes," by E. T. Hardman, F.C.S., of the Geological Survey of Ireland.

From a review of the whole circumstances, it appeared that the origin of the chert-beds was to be attributed to the replacement of the original limestone or calcareous "ooze," due to organic agency by silica, and that the rock is truly a pseudomorph, a view held by several observers.

The manner in which this replacement had been brought about was then touched upon. It was shown that there was reason for believing that at the close of the period during which the carboniferous limestone was formed over the area of Central Ireland, the sea-bed was elevated so as to be covered by the waters of a shallow sea exposed to the sun's rays, and of a warmer temperature than when at a greater depth. The waters appear to have been charged with a more than usual supply of silica in solution, derived (as Mr. Hardman suggests) from the surrounding lands, formed, for the most part, of highly siliceous materials. As silica is less soluble than carbonate of lime, chemical replacement would naturally take place, the carbonate of lime being dissolved out and its place taken by the silica. The warm condition of the sea-water, its exposure to sunlight, the porous character of the coralline, crinoidal and other forms, and the soft and "oozy" condition of the foraminiferal mud would give easy access to the sea-waters, and the process of silicification would take place analogous to that described by Dr. Martin Duncan, F.R.S., as having occurred in the West Indies.

Linnean Society, April 19.—G. Bentham, F.R.S., vice-president, in the chair.—M. Cassimir De Candolle read an important paper on the geographical distribution of the Meliaceæ. His general conclusions with regard to the Melia family may thus be summarised: (*a*) The number and the mutual affinities of the various genera of Meliaceæ decrease from the Asiatic region towards Africa and America on one side and towards East Polynesia on the other; (*b*) Between the Meliaceæ of America and Africa there exists analogy, whilst Polynesian species belong to Indian type; (*c*) New Caledonia contains within itself a remarkable number of distinct species, the type of which, however, is Indian; (*d*) in Australia three Indian genera are found, along with three genera exclusively belonging to Australia; (*e*) No species of Meliaceæ have hitherto been collected in the most eastern islands of Polynesia; if subsequent observations reveal such it will be interesting to know whether they pertain to Indian or American type.—Another contribution on the geographical distribution of the Indian fresh-water fishes (Part II. The Siluridæ), read by Dr. Francis Day, curiously enough in some ways points to a similar conclusion to that derived from the plants above-mentioned. Dr. Day showed that of the twenty-six genera of Siluroidæ represented in the Indian Empire, ten are found in the Malay Archipelago, two more reach Cochin China or China, whilst *Clarias* only is common to India and Africa, and moreover it likewise is found in the Malay Archipelago. He infers that the said freshwater fish of India are more closely related to a Malayan than to an African fish fauna.—Mr. R. Irwin Lynch, of Kew Gardens, brought before the notice of the Society some observations on the disarticulation of the branches of *Castilloa elastica*, the caoutchouc tree of Central America. He has noticed that the lateral branches are detached from the ascending stem of the plant in a regular manner from below upwards in the same way as leaves, and this happens always at the point of insertion. In certain Euphorbiaceous genera which have leaf-like branches, these fall as does a leaf, and they bear in their axils a bud from which alone the permanent branches are produced. They are themselves subtended by a leaf reduced to a scale.—Capt. Chimmo followed by two communications, one concerning the mode of obtaining and the structure of the so-called *Euplectella* of the Philippines, the other a description of a supposed new Rhizopod.

Anthropological Institute, May 8.—John Evans, F.R.S., president, in the chair.—Special thanks were voted for the present to the Library of a complete set of the volumes relating to the voyage of the *Novara*, published and presented by the Austrian Government.—On an exhibition, by Mr. R. Biddulph Martin, of objects from a large refuse heap in the neighbourhood of Smyrna, Mr. Hyde Clarke, Col. Lane Fox, and the president offered remarks.—Mr. A. L. Lewis communicated a description of the remains of a stone circle at Colderham, Kent, illustrating his remarks by a well-prepared plan.—Dr. John Rae read a paper on the skulls of the Esquimaux, attributing the fact that two distinct types of skull exist among these peoples to an admixture of blood. An interesting discussion followed, in which Dr. Beddoe, Col. Lane Fox, and others took part.—Dr. Beddoe, F.R.S., communicated a paper on the Aborigines of Queensland, whom he described, on the authority of Mr. Christison, who had had many years' knowledge of them, and employed them very largely in sheep-farming, to be, in many respects, not so black as they have been painted.

Royal Microscopical Society, May 2.—H. C. Sorby, F.R.S., president, in the chair. A number of donations to the society were announced, including a sum of 500*l*. presented by Mr. C. Lambert, from a bequest of 25,000*l*. left by that gentleman's late father, to be appropriated to benevolent and scientific purp

—The first of a series of lectures founded in honour of the late Prof. J. Quekett was delivered by Sir John Lubbock, Bart., M.P., "On Some Points in the Anatomy of Ants." Commencing by reference to the occasion, and appropriately giving a short history of the life and labours of Prof. J. Quekett, the lecturer proceeded to describe in a minute and interesting manner the general structure and microscopic anatomy of these insects, pointing out the differences found to exist between individuals of different species, and also between the various classes of the same species. Attention was specially drawn to the structure of the antennæ, and to certain organs presumed to be those of hearing, also to the structure of the mouth, with its extensive muscles and mouth-sac. At the conclusion of the lecture, the "Quekett Medal" of the society, struck for the occasion, was presented to Sir John Lubbock by the president, amidst great applause from the fellows.

Victoria (Philosophical) Institute, May 7.—Dr. C. Brooke, F.R.S., in the chair.—A paper on the indestructibility of matter by Prof. Challis, F.R.S., was read.

ROME

R. Accademia dei Lincei, March 4.—The Roman Tuscia and the Tolfa, by M. Ponzi.—On graphical statics, by M. Battaglini.—On some cavern-myriapods of France and of Spain, by M. Fonzago.—Studies on some anouran amphibians of Piedmont, by M. Lessona.—On a new function of the liver and the effect of ligature of the vena porta, by M. Tommaso-Crudeli.—On the Meibomian glands, by the same.—On the chemical constitution of the cyanamides, by MM. Fileti and Schiff.—On the tenacity of copper, steel, brass, and aluminium, at various temperatures, by M. Pisati and others.—On the dilatation, capillarity, and viscosity of fused sulphur, by M. Pisati.—On organisation of the meteorological services of forecast for agriculture; on publication of meteorological observations; and on history of the atmosphere, April to September, 1876, by M. Tarry.—On the small proof plane, by M. Volpicelli.—Ephemerides and graphic representation of the height of the water surface of the Tiber, measured daily in 1876, by M. Belocchi.—On titanite and apatite of the plain of Spedallacio, near Sarsalba, and on mancinite, by M. Uzielli.—Indian corn and pellagra, by M. Selmi.

PARIS

Academy of Sciences, May 7.—M. Peligot in the chair.—The following papers were read:—Two general laws of geometric curves, by M. Chasles.—Studies of Mr. Sylvester on the algebraic theory of forms, by M. Hermite.—Note *à propos* of M. Favé's communications on the theory of heat, by M. Resal. He opposes M. Favé's views.—On determination of the difference of longitude between Paris and Berlin, by M. Mouchez. The first series of astronomical observations are on the eve of completion.—Researches on the law of Avogadro and Ampère, by M. Wurtz. Oxalate of potassium loses its water when heated in dry air under a certain pressure, but does not lose it, if heated under the same pressure, in chloral vapour or in a mixture of air and water vapour. We may infer that hydrated chloral vapour does not act like dry air, but like a mixture of anhydrous chloral and water vapour.—Chemical researches on the green matter of leaves, by M. Fremy (third paper). He thinks it proved that the colouring matter of leaves is a mixture of phylloxanthine and phyllocyanate of potash. During life chlorophyll acts by decomposing CO_2. When the leaves die and fall the colouring matter is destroyed and gives up to the ground the salt of potash it contained. Change of colour of chlorophyll; its passage to blue and to red or orange, by M. Trecul.—On meteorological predictions sent from the United States, by M. Faye. Some think the success of these owing to the *rôle* of the Gulf Stream, which they suppose to be the grand route taken by storms in traversing the ocean. M. Faye shows this to be a mistake; the path of storms depending on currents in the higher regions of the atmosphere.—On the identity of anthrax in all the species of domestic animals, by M. Bouley. Contagion is its most essential character.—M. Bernard made some remarks in presenting his *Leçons sur le diabete et la glycogénèse animale*.—Reports on the geodetic and topographic works executed in Algeria, by M. Roudaire. This relates to his measurement of the meridian of Biskra, and survey of the region of the Chotts.—Practical reduced form of the development of Taylor, by M. Rouyaux.—Integration of linear differential equations of any co-efficients, with or without second member, by M. André.—Solar spots observed at Madrid in April, 1877, by M. Ventosa. Another confirmation of what M. Janssen observed.—On M. Janssen's communication on the sudden formation of a very important sun-spot, by M. Gazan. He thinks the spot was not formed suddenly; all spots are preceded by violent agitation of the luminous matter. He passes some other strictures.—Researches on accidental double refraction, by M. Maré. The double refraction produced by hardening is identical with that produced by a regular heating of the contour of the plate.—On the interior resistance of thermo-electric elements, by M. Rolland. The experiments were made with Clamond's pile. The curve of resistances oscillates continually; its course, at first rather irregular, becomes nearly normal only after about twenty minutes; it is then fixed at a height which it retains during about ten minutes. When the pile cools the curve again oscillates irregularly.—On acid acetates, by M. Lescœur.—On some derivatives of acetylacetic ether, by M. Demarçay.—On nitrosalicylic acid, by M. Phipson.—Action of toxical and antiseptic vapours on the fermentation of fruits, by MM. Lechartier and Bellamy. The action of vapour of phenic acid, cyanide of potassium, and camphor destroys or diminishes considerably the vitality of fruit cells.—On the same subject, by M. Gayon. He tried chloroform, ether, and sulphide of carbon with similar results. Sulphide of carbon and camphor (in the two series of experiments) acted less powerfully than the other substances; they allowed a little fermentation.—On two new niobates, by Mr. Lawrence Smith. These, found in North Carolina, he names *Hatchettolite* and *Rogersite*.—Researches on the mode of formation of Cyclopia, by M. Dureste.—Note on the peristaltic movement of the intestine, by M. Guerin. The matters in the intestine are not moved along by an action *a tergo*, resulting from simple circular contraction of the muscular membrane, but by a double propulsive and suctional action, realised through contraction of the circular and longitudinal planes of the intestine.—On a whale, properly so called, caught in the Bay of Tarentum, by M. Capellini.—On the mines of New South Wales, by M. Simon.

SCIENCE AND WAR

II.

At no other time has there been so much want of unanimity among the Great Powers of Europe on the subject of Ordnance. There are to be found at the present moment cannon of a dozen different descriptions in the gun parks of European nations, differing from each other not only in respect to their construction, but in the metal of which they are made. So far as small arms are concerned, we know there is but one opinion; some nations prefer one breech-loader to another, but all agree in the employment of breech-loaders. In the case of cannon, however, it is different. Germany relies upon breech-loading ordnance, while Great Britain has forsaken the system and gone back to muzzle-loaders; Austria makes her guns of bronze, Germany of steel, Russia favours steel and brass, America cast iron, while England has cannon of steel encompassed with iron, and France weapons of iron girt with steel.

The balance of favour is beyond question with the breech-loader at the present moment. All the new artillery of the Russians and the Turks is of this kind, while the field-guns both of the Germans and Austrians are upon the same system. France has done nothing lately for the regeneration of its ordnance, and there remains but Great Britain and Italy to represent muzzle-loading artillery. But Italy, although she has adopted the British system for very heavy guns, is by no means a confirmed believer in it, and will doubtless hesitate before following our example very far, beset, as she is, with neighbours armed with breech-loaders.

Of all the Powers, it is, curiously enough, steady-going Austria, which has taken the boldest and most independent course in the matter of artillery. It was but at the end of 1875 that the Austrian War Office decided to adopt the Uchatius cannon for field artillery, and yet at this moment every artillery regiment of the vast Austro-Hungarian army is armed with the new weapon. Within eighteen months no less than 2,000 of these cannon have been cast and finished, and now the Vienna arsenal is engaged in the manufacture of heavy guns of the same character. Never was a more energetic step taken. A new cannon of some sort was held to be absolutely necessary to uphold the prestige of the army, and a Commission having been intrusted with the selection of an arm, pronounced without delay in favour of the scheme brought forward by Gen. von Uchatius. In October, 1874, the first round was fired from an Uchatius gun, and a twelvemonth afterwards the sweeping reform which was to introduce an entirely new artillery throughout the Austrian service was decided upon. Government sanctioned an expenditure of 1,800,000*l.* to be spent in two years, and Gen. von Uchatius was directed to give all the assistance in his power towards the fulfilment of the design.

The Uchatius gun is made of so-called steel-bronze. Chilled bronze would be a better name, since Uchatius casts his metal in a chilled, or metal mould, in the same manner, pretty well, as Sir William Palliser produces his famous chilled projectiles. Bronze, as everybody knows, has been a favourite metal with gun-founders from the earliest days, and in the East, especially, magnificent castings of this nature have been produced. About 90 per cent. of copper and 10 of tin is the mixture commonly employed in making ordinary bronze, but 8 per cent. of tin is the proportion preferred by Uchatius. The difficulty in casting bronze, as those who have any experience know full well, is that of securing homogeneity, soft particles of tin becoming isolated in the mass, and giving rise to the defect known as "tin-pitting." Whether we have lost the secret of bronze-casting, or whether in former times they were more skilful at the work, certain it is that founders of the present day are unable to secure so uniform an alloy as formerly. This was very apparent when some eight or ten years ago our own Government adopted, for a brief time, bronze artillery. The addition of a small percentage of phosphorus did not mend matters, and the highest authorities on the subject were at a loss to suggest an effective remedy. Our bronze guns, too, had another defect which could not be overcome. After firing the bore became affected, and the weapon, as it was termed, "drooped at the muzzle." These were the two defects indeed that led mainly to the abandonment of the bronze gun in this country, and they are, too, the difficulties which Gen. von Uchatius appears to have overcome. He has got rid of "tin-pitting" and his guns do not "droop at the muzzle."

Uchatius found that by subjecting the alloy in a liquid form to considerable pressure, he was enabled to secure a perfectly homogeneous mass, a result which was also furnished, he discovered when he had gone a step farther, if the molten metal was rapidly cooled. Steel-bronze is apparently made much in the same way as the toughened glass, of which we have heard so much lately. After being cast in a mould, the alloy is thrust into a reservoir of oil, heated to a high temperature, so that the metal suddenly cools, but only down to a certain point. Then the casting is withdrawn and allowed to get cold more gradually. A regular and crystalline structure is in this way produced, which has none of the defects of ordinary bronze. It is a moot point whether phosphorus enters into the composition at all. Chemists tell us they can find no trace of it, but this is no absolute proof that a small percentage of the element was not originally contained in the alloy, being burnt out after it had done its work of harmonising the two metals. The inventor is rather reticent on the point, but in any case, it is very certain that he produces a uniform and homogeneous alloy of a hard crystalline nature.

One other expedient Uchatius has recourse to in making his cannon. When he has cast his gun and chilled it, he proceeds to dilate the bore. Wedges of steel, shaped in the form of cones are forced into the tube of the gun one after another, until the calibre of the weapon has been increased by something like seven or eight per cent. This expansion or dilation of the tube has not only the effect of hardening or steeling the core, but also of rendering the gun more elastic and capable of resisting more effectually the strain put upon it at the moment of firing. The gun, after this process, is in a state of elastic tension, and it is said that there is a pressure from without, inwards, equal to that which was exerted to dilate the gun in the first instance; and that this is actually the case can scarcely be doubted, since it is a fact that a section of the gun before being quite severed, will tear itself loose with considerable violence, and will be found on separation to have partially returned to its former calibre.

So far as practical trials have been conducted with the weapon, the Austrian Government have every reason to be satisfied with the Uchatius gun, which compares favourably with the Krupp steel cannon in the matter of accuracy and durability; while as regards its cost, it is far cheaper than any other rifled ordnance. A steel field-piece costs upwards of 100*l.*, even when not protected with rings, while the iron-steel weapon manufactured in this country, costs about 70*l.* sterling; the steel bronze cannon of Gen. von Uchatius, on the other hand, are made for 35*l.* apiece.

In construction, the Austrian gun is so similar to that of Herr Krupp, of Essen, that the latter claimed compensation for an infringement of his patent when the manufacture of the Uchatius gun was first commenced. The Essen works, our readers may know, supply not only Germany with steel breech-loaders, but have provided the present belligerents with all their modern artillery. Russia has still many brass cannon on hand, and Turkey a goodly number of Armstrongs, but both powers mainly depend upon their steel Krupps. These stood the German army in such good stead during the last war that their reputation is firmly established. They are of crucible steel, and the breech, instead of being upon a hinge, or in the form of a block, moves round in a D-shaped socket, the escape of gas being further prevented by rings of phosphor-copper.

The manner in which the ordnance of this country is constructed is sufficiently familiar to our readers. A tube of steel is encompassed by jackets of wrought-iron, and in this way the toughness of the latter is combined with the hardness of the former. All our guns, as we have said, load at the muzzle, while those of Russia, Germany, Austro-Hungary, and Turkey, are breech-loaders. Italy, in the case of the 100-ton guns with which she intends to arm her two stupendous turret-vessels, the *Duilio* and *Dandolo*, has adopted our method of construction, except that she employs smooth, instead of studded, projectiles. With the employment of a gas-check at the base of the shot to prevent windage and so secure the full force of the exploding charge, the use of studs in a shot appears to be unnecessary, a sufficient spin being imparted to the projectile by the soft metal of the gas-check before-named, which causes the shot to rotate after the manner of a Snider bullet. So satisfactory, indeed, were the Italian trials of these projectiles last year that it is by no means improbable that we, too, may give up the use of studded shot.

As to the comparative value of breech-loaders and muzzle-loaders, we shall not offer an opinion. No doubt a muzzle-loader is the stronger weapon, because its breech is solid, but our cousins, the Germans, urge very justly that since their guns do not burst, they are quite strong enough. Advocates of the muzzle-loading system argue again that their weapon is more simple in construction and for this reason is to be preferred; but on the other hand the sponging and loading of a gun is more easy to effect, if it opens at the breech. Indeed, in the case of very heavy guns located in a casemate or on board ship, the Germans reproach us with the assertion that we must needs have recourse to all sorts of complicated and awkward machinery in loading, while in their case a simple pulley or crane is all that is necessary. Either, say they, we must expose our gunners through the open port when loading, or, as in the case of the *Thunderer*, rely blindly on hydraulic apparatus to work the guns for us. So stands the question; perhaps the present war will bring us a solution of it.

H. BADEN PRITCHARD

THE FORESTS OF PEGU

Preliminary Report on the Forest and other Vegetation of Pegu. By Sulpice Kurz, Curator of the Herbarium, and Librarian, Royal Botanical Gardens, Calcutta. (Calcutta: C. B. Lewis, 1875.)

INDIAN forest reports have of late years become as plentiful as the proverbial blackberries. The frequent appearance of them is a consequence that might be expected when we consider the wide range of country which comes under the supervision of the Forest Department of India. So far as bulk or quantity of printed matter is concerned, no one can say that these forests are not fairly represented in the Government papers which appear in the course of a year, but the quality of these reports is another question. They too often contain merely the dry details of work carried on during the year, and are interesting only to those immediately connected with the special department from which the reports emanate. Occasionally, however, a report is issued which in reality is something more, containing much valuable information on subjects connected with forest conservancy, and amongst such Mr. Kurz's may be classified. It is, in fact, rather a description of the vegetation of Pegu, to which are added appendices occupying quite two-thirds of the whole bulk of the volume. Taking the actual report itself, which, as indicated in the title, is of a preliminary character, the matter in which will be worked out in Mr. Kurz's forthcoming book, we find it divided into two parts, first, the "General Report," and second, the "Special Report." The general report is again divided into two sections—(A) A general aspect of the country, its geological and climatological features, in connection with the flora. (B) A botanical description of Pegu, with special reference to its forests. After a very brief topographical sketch of Pegu, Mr. Kurz considers the geological aspect of the country from a botanical point of view, which, unlike that of the true geologist, is not to consider the age of the rocks, &c., but simply their extent and quality, from which inferences may be drawn of the vegetation found growing upon each formation. The geology of Pegu is described as being very simple and uniform, the hills being composed solely of sandstone, skirted at their base by a strip of diluvium, "interrupted by a deeper or shallower alluvium wherever choungs come down from the hills, and succeeded by the vast alluvial plains, through which the Irrawaddy and Sittang flow." The laterite formation is described as being of the highest importance in the various floras of India. The term laterite, as generally used by foresters in Burmah, comprises several heterogeneous rocks and soils, all characterised by a more or less ferruginous appearance, but really connected in no other way than that they are all permeated by hyperoxide of iron. "No other formation," Mr. Kurz writes, "except metamorphic and volcanic ones, can boast of such a variety of species, in spite of its apparent sterility, as laterite. It is this rock that affects vegetation so much that the great difference between the floras of Malacca, Borneo, Sumatra, &c., on the one hand, and that of Java on the other side, is produced. It is also this formation which allows so many Australian genera, like *Melaleuca*, *Bæckea*, *Tristania*, *Leucapogon*, &c., to spread so far to the north-west, some of which, like *Tristania*, spread as far north as the Ava frontier. If all laterite plants were to be erased from a list of the plants of Pegu proper the flora would be rendered very uninteresting indeed."

The seasons of Pegu seem to be similar to those of Lower Bengal; the cold season, however, is shorter, and the hot, dry, as well as the rainy seasons, are earlier by a month than in Calcutta. The dry season ranges from about December to April, the cold part of which terminates usually, and sometimes, abruptly about the end of February; during this period the thermometer rarely rises above 88° in the shade, sinking as low as 57° and sometimes to 55° and 54° before sunrise. Heavy dews prevail and fogs are plentiful in the early hours of the day, the after parts of which are clear and bright. During this season rain is almost unknown. The hot part of the dry season comprises the months of March and April, during which time, chiefly in the former month, an occasional heavy thunderstorm moderates the intense heat. In the early part of May the regular monsoon rains, which cease during November, set in. The thermometer, during the hot season, rises rapidly to 95° and 100° in the shade. The nights, however, are cool and refreshing. In the hottest province of the country, at the height of the season, the thermometer never registered above 74° before sunrise. Great heat and dryness prevails in the open country, and on the ridges, "while in the narrow valleys of the eastern slopes of Yomah, and in the Martaban hills, where evergreen forests skirt the streams, dew often falls so heavily, that one becomes quite wet when marching in the early mornings through the herbage along their bank. But after an ascent of 100 or 200 feet, we meet with the same dryness again in the deciduous forests, as in the open lands. It is here that we can almost every morning observe a white sheet of vapour in the depths of the valleys, resting on the forests, which enables us to appreciate clearly the *rôle* which evergreen forests play in the attraction of the currents of vapour."

The foregoing abstracts will serve to show the nature of Mr. Kurz's report, a good deal of which is interesting. It might, however, have been considerably condensed without losing any of its value, indeed its value would have been much enhanced.

Whatever advantages or disadvantages Burmah may present to travellers generally, to a botanist the advantage must be very great in having specimens ready gathered, and only requiring to be picked up, for we are told that owing to the extreme violence of the gales which prevail at the end of April and the beginning of May, the amount of old trees, branches, &c., thrown down is often astounding, offering an easy and fruitful harvest of specimens of woody plants, otherwise quite out of reach on account of their height. At other seasons apes and squirrels are most useful agents for procuring flowers and fruits of lofty trees. Another advantage is that in the cold season there is an absence of mosquitoes. Space will not allow us to do more than mention the appendices which we have before referred to. In the introduction to the first, which is a list of Burmese trees arranged in their natural orders, with brief remarks as to the quality and appearance of the wood, &c., we are treated to some remarks on the value or otherwise, of native names of plants. Mr. Kurz says, "there are still very respectable botanists and practical men who look upon native names for plants, as something absolutely reliable, some even believe that native names are preferable to scientific ones, because the former are permanent, and are not altered from one day to another, as is the case in science." Our own experience is that while a native name, is often a great help to the accurate determination of the genus or species, it is, on the other hand, often a delusion and a snare, for it frequently occurs that the same name is applied indiscriminately to plants even of distinct natural orders. This, perhaps, is not so much the case with Indian plants as with plants from other countries. Mr. Kurz points out the difficulty that must always present itself in India, where the same plant is known in different localities by different names, whereas the scientific name would be identical all the world over, or if not actually identical, certainly traceable. This lengthy report concludes with some extracts from the author's journal of his tours. It is illustrated with a sketch map of Pegu, and two plates of a new genus *Mayodendron*, named in honour of Lord Mayo, and one of the appendices contains a botanical description of this plant.

INFLUENCE OF CLIMATE ON PULMONARY CONSUMPTION

Influence of Climate in the Prevention and Treatment of Pulmonary Consumption. Lettsomian Lectures for 1876. By Charles Theodore Williams, M.A., M.D., Oxon. (London: Smith, Elder, and Co., 1877.)

THE fact that consumption is the great destroyer of men and women in the prime of life, nearly one-eighth of all the deaths which occur being due to it, is more than sufficient to warrant any amount of minute and patient inquiry which might result in the prevention and more successful treatment of this terrible disease. Dr. Williams treats the subject in its climatic relations, and gives what is, in many directions, an elaborate and able discussion of a large amount of fresh data adduced with reference to the therapeutic action of British, Mediterranean, African, Indian, Australian, sea-voyage, and other climates, differing widely from each other as regards temperature, humidity, elevation, and exposure to sudden changes of weather. In concluding the inquiry he draws some valuable conclusions as to those patients who ought to winter abroad, and those on the other hand who may remain at home, those who are most likely to be benefited by sea-voyages, and those most benefited by dry climates, and how far the temperature and elevation is to be taken into account. The question of moist climates, whether hot or cold, is also examined with the view of ascertaining whether such climates are desirable at all for consumptive patients. The results would have been rendered even more valuable if the author had availed himself more freely of the labours of others who have written on the same subject.

But it is the remarkable conclusion arrived at regarding the winter climates of the south of England which arrests attention. This conclusion is that Torquay, Bournemouth, Ventnor, and the whole of the western end of the English Channel possess climates less beneficial to consumptive patients than are the climates of Hastings, St. Leonards, and the eastern end of the Channel; and it is thence inferred "that it is the stronger influence of the Atlantic warm current and its accompanying winds on the shores of Devonshire and Cornwall, which though it raises their winter temperature many degrees, clothing their hillsides with verdure and causing what would otherwise be waste places to bloom with rare exotics, deprives them of the stimulating and bracing influence which is possessed by the less beautiful shores of Sussex with its breezy downs and colder winter climate."

It may be doubted if the facts warrant this very broad conclusion. It has been shown by Buchan and Mitchell in their discussion of the weather and mortality of London, published in *Jour. Scot. Meteorol. Society*, vol. iv., p. 205, that the three periods of the year most fatal to consumptive patients are November and the first half of December, when the temperature is rapidly falling and is at the same time low; in January when the temperature falls to its annual minimum; but chiefly from March to about the middle of June, when the air is driest. Now these results, which are based on the enormous population of London and the long period of thirty years, would have led to the expectation that the winter and spring climate of Torquay was certainly not less beneficial to consumptive patients than that of St. Leonards.

It seems not improbable, from an examination of the whole facts, that the discrepancy may be accounted for by the comparatively small number of patients whose cases have been discussed by Dr. Williams, viz., 243, of whom 100 were under medical treatment at Torquay, 58 at Ventnor, 57 at Hastings, and 20 at Bournemouth, and to an important point missed in the discussion, viz., the very different types of weather which have prevailed in the different years and the varying mortality from consumption attending on these types of weather. It is indispensable in such a discussion that tabular statements be prepared, showing the number of patients under medical treatment for consumption at each place during each month of each year, and the results of the treatment as respects each patient, in order that the results may be compared with the meteorology of the place and year to which they refer. Till this be done we cannot be said to be in a position to make any comparative statement of the therapeutic effects on consumptive patients of the climates of the different sanatoriums of the south of England; it being evident, for instance, that the relatively high position of Hastings as a sanatorium for consumption may be wholly due to a chance excess of patients sent there during exceptionally mild seasons, and the relatively low position of Bournemouth to the mere accident of one or two consumptive patients more than the average being there in a particular season when the weather happened to be peculiarly severe.

OUR BOOK SHELF

Annals of the Astronomical Observatory of Harvard College. Vol. xiii.

WE must congratulate the authorities of Harvard College on the publication of the Annals of the Observatory. The volume is the result of a large portion of the work of the institution during the time that it has been without a director, since the death of Prof. Winlock in June 1875. An account is given of the several funds available for purpose of publication, and then follow the biographical notes of W. C. Bond, G. P. Bond, and J. Winlock, the several directors since the foundation in 1815. We then come to the details of the instruments in use and plans of the observatory and grounds. The work done from the year 1855 appears to have been chiefly the measurement of binary stars, transit observations, investigation of lunar phenomena, drawings of nebula, photographs of the sun, and spectroscopic observations, the latter consisting largely of the examination and drawing of the chromosphere. In Part II. we find some thirty-four exquisitely-finished plates depicting the results of the foregoing observations, published at the expense of the Bache fund. These were made by or under the direction of the late Prof. Winlock. It seems a pity that the authorities do not publish from time to time a selection of these papers on special subjects. Part II. would be widely bought by astronomers if its contents were given separately, and the plates, which are, perhaps, the finest accessible, were practically not buried in an odd volume of a lengthy series of "annals."

Cultivated Plants; their Propagation and Improvement. By F. W. Burbidge. (Edinburgh and London: William Blackwood and Sons.)

THAT Mr. Burbidge possesses the pen of a ready writer no one can deny when it is borne in mind that in a very short time he has produced several books on horticultural or gardening subjects. His "Domestic Floriculture," published by the same firm as the present volume, was, up to that period, the best of his productions; for though it was not of a scientific character, it was of a nature calculated to elevate window gardening from the mere habit of simply allowing a few ordinary plants to struggle for an existence through adverse circumstances to a system in which all might take an interest.

The present volume is one of a different character from any of those which have preceded it. Mr. Burbidge, in fact, says in his Preface that the primary intention of the book was as a popular handbook on plant propagation and improvement, with a hope also that it might "serve young gardeners as a stepping-stone to works of a higher scientific character, and more especially to those of Charles Darwin." Nevertheless, the chapters or sections devoted to "Hybridising and Cross-breeding," "Natural Fertilisation and Cross-breeding," and "Artificial Fertilisation and Cross-breeding," will be useful as bringing together from various and widely scattered sources, what has been done in these cognate branches of scientific research. In these sections we think Mr. Burbidge has done his work well, the references to the quotations being fully given not only to English but also to French and German works.

The great bulk of the volume is devoted to a "General review of some of the most popular groups of cultivated plants, with notes on their propagation and natural affinities." In this the arrangement of the orders is somewhat novel, for instead of being classified in a scientific manner they are placed alphabetically. The habits and peculiarities of the principal plants in each order are briefly described as well as their economic uses, together with notes on the most general method of propagation.

The book will no doubt meet with a wide circulation; the chapters on propagation, grafting, and budding, being of a practical character, will be useful to other readers besides those of a purely scientific turn. As a further illustration of this we may point to the chapter on Seed-saving, in which we are reminded of the excellence of the produce of the Continental seed farms, especially those of Erfurt, which are noted for their Primulas, Stocks, Balsams, Asters, &c.; we are also told that the seed of such common plants as Cineraria and Calceolaria is, when of a "good strain," worth from 10*l.* to 15*l.* per ounce, and Primula seeds even more. The book has a good index, always a special point of value in one intended for reference.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The "Hibernation" of Birds

I TRUST your correspondent "X" will not object to my pointing out that the "hibernation" story which he retails in NATURE (vol. xvi., p. 43) has in common with dozens, not to say scores, of others, the defect of being delivered at second-hand, without even the slightly confirmatory evidence which the name of the observer of the marvel and of the place where it occurred would supply. As such it may surely be dismissed to the limbo of (I will say) legends. That which has been furnished by the Duke of Argyll (vol. xv., p. 528) rests on a better base, and is almost the first I have met with for which a respectable man vouches. Far be it from me to deny the possibility of a miracle being wrought in Persia, but I confess that without impugning Sir John McNeill's veracity, I simply refuse to believe the story except I regard as miraculous the incident he relates. Now there is a common supposition that miracles are only performed with some worthy end in view, and, moreover, that unless a miracle is recognised as such by the witnesses thereto its effect is nullified. This supposition may, however, be wrong, for it is hard to conceive what may have been the end of this miracle, and its supernatural quality is clearly not acknowledged by the distinguished persons present. One would find greater satisfaction, perhaps, if the Duke of Argyll had expressed his belief in it, but he contents himself with saying that he had "frequently heard" his brother-in-law relate the circumstance. The identity of this phrase with that said to have been used by another great man on another occasion is very striking, and since the story, though old, is short, perhaps you will let me tell it. I have heard that King George IV., some years before his death, was strongly possessed with the notion that he had been present at the battle of Waterloo. Once as he was recounting his personal adventures on that eventful day, he perceived some uncourtly sign of incredulity shown by one of his audience. Turning to the late Duke of Wellington, who was of the company, he appealed to him—"Isn't that true, Arthur?" The adroit reply was—"I have *frequently heard* your Majesty say so."

May 19 THE REVIEWER OF PALMÉN'S WORK

Barlow's and Laslett's Determination of the Elasticity and Strength of Timber

ON comparing the results of Mr. Barlow's determination of the modulus of elasticity of Teak timber, given in his "Strength of Materials," p. 82, sixth edition, with the results of different Dutch investigators on Djati timber of Java, I was struck by the great difference between those results, those of Mr. Barlow being very much higher than the others, though Teak of British India and Javanese Djati are merely different names for the same species, *Tectona grandis*, L., of the family Verbenaceæ. My own experiments, which will, I hope, be afterwards published in my inaugural dissertation, show also the complete identity between Teak and Djati. This led me to detect a serious error in Mr. Barlow's calculations. He measures the deflection produced by a certain weight of a batten 7 feet by 2 inches square, supported at both ends on two props, the bearing distance being 6 feet, as is stated on p. 67 in the general description of his arrangements. The value of E is found in this case by the formula—

$$E = \frac{l^3 w}{16 a d^3 \delta}$$

in which l is the bearing distance; in the case of Mr. Barlow, equal to 6 feet. Now all Mr. Barlow's E's are calculated by introducing $l = 7$ feet instead of $l = 6$ feet, as should be; the consequence is that all those values are too great. So for Teak timber the value of E is found to be $= 603,600$ lbs., while the true value is $E = 380,023$ lbs. on the square inch. Also in the formula for the strength—

$$S = \frac{l w}{4 a d^2}$$

l is the bearing distance, Mr. Barlow calculates $S = 2,462$, taking $l = 7$ feet, the real value being $S = 2,110\cdot5$ for $l = 6$ feet.

Mr. Thomas Laslett, in his "Timber and Timber-trees" (London: Macmillan and Co., 1875), following the arrangements of Mr. Barlow, commits the same error. On p. 42 he tells us that in all his experiments pieces were taken $2'' \times 2'' \times 84'' = 336$ cubic inches, and that each piece was placed upon supports exactly 6 feet apart. But for l is taken, instead of the bearing distance 6 feet, the whole length 7 feet. So all the numbers for the moduli of elasticity of the different woods calculated by Mr. Laslett are too great in the proportion $7^3 : 6^3$, and the numbers for the strength in the proportion $7 : 6$.

The reduced values for E from Mr. Laslett, namely, $E = 362,870$ and $E = 305,876$, and that from Mr. Barlow, $E = 380,023$, agree tolerably well with the mean results of Dutch investigators, $E = 404,210$, and much better than does the uncorrected value, $E = 555,180$. Other determinations of the E of Teak timber are not known to me.

The results of Mr. Barlow were already published in the year 1817. Since that time several editions of this valuable work have appeared; in the year 1867 the sixth edition, revised by his two sons. General Morin gives in his "Résistance des Matérieux" all the results of Mr. Barlow on timber, reduced to metric weights and measures. Also MM. Chevandier and Wertheim, in their "Mémoire sur les Propriétés Mecaniques du Bois." It is scarcely to be believed that none of these eminent men, nor any one else, have remarked this error in the calculation of Mr. Barlow's often used numbers. S. FIGEE

Haarlem, Holland

Basking Shark

I THINK it but just to Prof. Bocage to ask you to publish the inclosed letter, which only reached me on the first of this month, owing to its having been sent to a wrong address. I regret that I overlooked Signor Capello's memoir on *Selache maxima*, which was so plainly indicated in the *Zoological Record* for 1869. I had, indeed, the "Catalogo dos peixes de Portugal que existem no Museu de Lisboa, por F. de Brito Capello," which was published in No. vi. of the Lisbon *Journal of Science*; but No. vii., which the author (whose kindnesses to me when at Lisbon, in 1868, I cannot forget) sent to me, I never got, and hence one cause of my oversight. E. PERCEVAL WRIGHT

Trinity College, Dublin

Lisbonne, le 14 février, 1877

MONSIEUR ET HONORÉ CONFRÈRE,—Dans l'article que vous avez publié dans la NATURE sur le "Basking Shark," vous avez, comme le Professeur Paul Gervais et d'autres, attribué à M. Steenstrup la découverte des appareils tamisants ou fanons branchiaux du squale pèlerin ou *Squalus maximus*. Si vous vous donnez la peine de consulter No. vii. du *Journal des Sciences Math., Phys. et Nat. de Lisbonne*, vous y trouverez, à p. 236, la description de cet appareil; vous trouverez également ces appareils figurés sur la planche qui accompagne cet article et qui contient aussi la figure du poisson. La description et la figure des appareils branchiaux ou des fanons branchiaux du *Sq. maximus* (et des espèces congénères) ont été donc publiés par M. Capello, aide-naturaliste au Muséum de Lisbonne, en août de 1869; c'est-à-dire 4 ans avant la publication de l'article de M. Steenstrup. Si vous consultez le *Record of Zoological Literature* pour 1869 (vol. vi.), vous y trouverez, p. 139:—

"*Selache maxima.*—A *detailed* description and figure of an example from the coast of Portugal is given by M. Capello under the name of *Cetorhinus blainvillii*, *Jour. Ac. Sc. Lisbon*, No. vii., p. 233."

Je vous envoie par la poste le No. vii. du *Jour. des Sc. de Lisbonne.*

J. N. BARBOSA BOCAGE

Gold in Carboniferous Conglomerate

MANY of your readers are aware that the fact of the occurrence of gold in Lower Carboniferous conglomerate as in New South Wales is not at all new. The Gay's River Gold Field of Nova Scotia, where the gold occurs in Lower Carboniferous conglomerate resting on the edges of Cambrian slates having small veins of auriferous quartz, was first pointed out by Prof. Hartt and elaborated by myself in a paper communicated to the Nova Scotian Institute of Natural Science in 1866. In Dawson's "Accadian Geology," of 1868, the same fact is referred to; also in Seluria, Prof. R. Jones received specimens of the conglomerate from me in Paris, 1867, to satisfy Sir R. J. Murchison of the fact. In the collection of ores and concrete minerals sent by H. S. Poole, Esq., Government Inspector of Mines to the Centennial Exhibition, in my charge, was a very instructive specimen of slate with a little of the conglomerate attached, having a beautiful display of gold. This was much admired. The conglomerate of Gay's River is overlaid by limestone with Lower Carboniferous fauna and gypsums. The conglomerate is worked still with good results.

D. HONEYMAN

Provincial Museum, Halifax, Nova Scotia

Japanese Mirrors

A SHORT time ago a friend showed me a curious effect, which I had previously heard of, but had never seen. The ladies of Japan use, in making their toilet, a small round mirror about $\frac{1}{16}$ to $\frac{1}{4}$ inch in thickness, made of a kind of speculum metal, brightly polished and coated with mercury. At the back there are usually various devices, Japanese or Chinese written characters, badges, &c., standing in strong relief, and brightly polished like the front surface. Now if the direct rays of the sun are allowed to fall upon the front of the mirror and are then reflected on to a screen, in a great many cases, though not in all, the figures at the back will appear to shine through the substance of the mirror as bright lines upon a moderately bright ground.

I have since tried several mirrors as sold in the shops, and in most cases the appearance described has been observed with more or less distinctness.

I have been unable to find a satisfactory explanation of this fact, but on considering the mode of manufacture I was led to suppose that the pressure to which the mirror was subjected during polishing, and which is greatest on the parts in relief, was concerned in the production of the figures. On putting this to the test by rubbing the back of the mirror with a blunt pointed instrument, and permitting the rays of the sun to be reflected from the front surface, a bright line appeared in the image corresponding to the position of the part rubbed. This experiment is quite easy to repeat, a scratch with a knife or with any other hard body is sufficient. It would seem as if the pressure upon the back during polishing caused some change in the reflecting surface corresponding to the raised parts whereby the amount of light reflected was greater; or supposing that of the light which falls upon the surface, a part is absorbed and the rest reflected, those parts corresponding to the raised portions on the back are altered by the pressure in such a way that less is absorbed, and therefore a bright image appears. This, of course, is not an explanation of the phenomenon, but I put it forward as perhaps indicating the direction in which a true explanation may be looked for.

The following account of the manufacture of the Japanese mirrors is taken from a paper by Dr. Geerts, read before the Asiatic Society of Japan, and appearing in their *Transactions* for 1875-76, p. 39:—

"For preparing the mould, which consists of two halves, put together with their concave surfaces, the workman first powders a kind of rough plastic clay, and mixes this with levigated powder of a blackish "tuff-stone" and a little charcoal powder and water, till the paste is plastic and suitable for being moulded. It is then roughly formed by the aid of a wooden frame into square or round cakes; the surface of the latter is covered with a levigated half-liquid mixture of powdered "*chamotte*" (old crucibles which have served for melting bronze or copper) and water. Thus well prepared, the blackish paste in the frame receives the concave designs by the aid of woodcuts, cut in relief. The two halves of the mould are put together in the frame and dried. Several of these flat moulds are then placed in a melting box made of clay and "chamotte." This box has on the top an opening, into which the liquid bronze is poured, after it has been melted in small fire-proof clay crucibles. The liquid metal naturally fills all openings inside the box, and consequently also the cavities of the moulds. For mirrors of first quality the following metal mixture is used in one of the largest mirror foundries in Kiôto:—

Lead	5 parts.
Tin	15 ,,
Copper	80 ,,
	100

For mirrors of inferior quality is taken—

Lead	10 parts.
Natural sulphide of lead and antimony	10 ,,
Copper	80 ,,
	100

* * * * * *

"After being cooled the melting-box and moulds are crushed and the mirrors taken away. These are then cut, scoured, and filed until the mirror is roughly finished. They are then first polished with a polishing powder called *to-no-ki*, which consists of the levigated powder of a soft kind of whetstone (*to-ishi*) found in Yamato and many other places. Secondly, the mirrors are polished with a piece of charcoal and water, the charcoal of the wood, *ho-no-ki* (*Magnolia hypoleuca*) being preferred as the best for this purpose. When the surface of the mirror is well polished it is covered with a layer of mercury amalgam, consisting of quicksilver, tin, and a little lead. The amalgam is rubbed vigorously with a piece of soft leather, which manipulation must be continued for a long time until the excess of mercury is expelled and the mirror has got a fine, bright, reflecting surface."

R. W. ATKINSON

University of Tokio, Japan

THE DECENNIAL PERIOD OF MAGNETIC VARIATIONS, AND OF SUN-SPOT FREQUENCY

A CENTURY and half ago Graham discovered that the north end of a magnetic needle moved from morning till afternoon towards the west, returning thereafter to its most easterly position in the morning again. Van Swinden, who, half a century later, studied this phenomenon during several years, occupied himself greatly with the deviations from the diurnal law. One of these, the occurrence of the greatest westerly position before noon or after 4 P.M., he found to happen most frequently in 1776, the number of times increasing from 1772, and diminishing from the year of maximum till 1780. He then asked the question whether there was not a period of *eight years*. Van Swinden's results were greatly affected by imperfections of his instrument, and we can only consider that the excess of irregular days in 1776 was probably chiefly due to real causes.

Though several series of magnetic observations were made during the eighteenth century, and two series early in this (those of Beaufoy and Arago), yet, as far as I can discover, Kaemtz seems (in 1836) to have been the first to remark that the mean value of the diurnal oscillation of the magnetic needle was not constant, but varied from year to year: this conclusion he founded on Cassini's observations, which gave the mean oscillation 9′·71 in 1784, and 15′·10 in 1787. The illustrious Gauss drew more distinct attention to the fact, for, in studying the observations made at Göttingen in the years 1834 to 1837, he pointed out that the mean diurnal oscillation for each month in the second year was greater than that for the corresponding month of the first year; and that a similar increase was to be found in the third year compared with the second. This increase Gauss did not think could go on long, and he predicted that by continuing the observations for several years, an oscillation in the mean value would present itself. It is not a little curious that in discussing the Göttingen observations for the next three years, Dr. Goldschmidt should have failed to remark that the maximum was attained in 1837, and that thereafter the mean diurnal oscillation was diminishing. This was reserved for Dr. Lamont, the distinguished astronomer of Munich, who, in the end of 1845, by adding the mean oscillations obtained from his own observations in 1842-1845, to those already found for the preceding years at Göttingen, was able to state that the minimum was then attained, but that a longer series of observations was required, in order to determine the law of the oscillation.

It was only in the end of 1851, when the maximum oscillation (which occurred in 1848-49) was decidedly past, and the mean oscillation had again begun to diminish in value, that Dr. Lamont published his conclusion that the diurnal oscillation of magnetic declination (as well as of magnetic force) obeyed a law whose mean duration was nearly 10⅓ years. For the determination of this mean he employed the epoch of maximum oscillations shown by Cassini's observations in 1787 (already noticed by Kaemtz), and he assumed that there were six periods from that date till 1849.

Schwabe had previously, from his persevering observations of the number of spots on the sun's surface, arrived at the conclusion that these obeyed a decennial law, so that the number was a maximum in 1828, 1837, and 1848, while it was a minimum in 1833 and 1843. The agreement of the epochs, 1843 and 1848, with those of minimum and maximum magnetic disturbance deduced by Sir E. Sabine from the observations made in the colonial observatories, was at once remarked by him, as well as that of Lamont's epochs with those of Schwabe.

This coincidence was also immediately afterwards, and quite independently, brought to public notice by Dr. Wolf, of Bern (now of Zurich), and M. Gautier, of Geneva. It is, however, with the important labours of the former of these philosophers that we are most concerned. Dr. Wolf began at once a systematic search for observations of sun-spots, and examined hundreds of volumes printed and in manuscript, dating from the first discovery of the existence of spots on the sun's surface. All the observations thus accumulated he has endeavoured to connect and to reduce to a common unit; and from the numbers thus obtained he has concluded that the sun-spot period, as well as that of the magnetic variations, occupies on the average 11⅑ years.

One great cause of the difference between the results of the Munich and Zurich astronomers is to be found in the interval 1787 to 1818. According to the former, three periods *ought* to have occurred in this interval; according to the latter, only one maximum happened, *in fact*, between the two of 1787 and 1818. Dr. Wolf has concluded, from the magnetic observations of Gilpin (1786–1806), that a minimum of the diurnal oscillation of the magnetic needle occurred in 1796, and a maximum in 1803, and these epochs he has supported by the observations of the numbers of sun-spots, as well as of those of the aurora borealis, a phenomenon known to be associated with magnetic disturbance, and to have the same epochs of frequency. On the other hand, Dr. Lamont has maintained that Gilpin's observations are without value, as his needle was supported on a steel pivot, and sometimes did not move freely; he has also objected to the observations of sun-spot frequency made during the time in question, that they were made rarely, without any common system, and by few observers, some having at times seen no spots when others saw many.

If we could assume with the astronomer of Munich that Gilpin's observations and those of sun-spot and auroral frequency made at the same time are worthless, all our knowledge of the epochs of magnetic oscillations since 1818, and of sun-spot frequency since 1826, would induce us to conclude that there were really three periods during the thirty-one years 1787–1818. If, however, any value can be given to the observations during that interval, it is not allowable to assume that the durations of the periods have always been the same, the more especially that we know the period has varied in length from eight to twelve years within the last half century. That some value is due to observations of three different phenomena has been allowed by most writers, and Dr. Wolf's period of 11⅑ years has, in consequence, been accepted by many of the most eminent men of science who have had occasion to allude to the subject.

Having had to study this question in connection with the results of observations made during twenty-three years at Trevandrum, I have examined with care the magnetic observations of the last and the present century, determined the exact times for which the yearly mean diurnal oscillation of the magnetic needle was a maximum or minimum, and have arrived at the following conclusions:—[1]

1st. That there are not sufficient grounds for rejecting the observations of Gilpin, which appear to be in general trustworthy as regards the change of mean position of the needle from year to year, and of the diurnal range from winter to summer.

2nd. That these observations should, according to the mean law, show a maximum near 1797, and another should have occurred near 1807. I have found that they do indicate a maximum in the former year; and though another maximum appears in 1803, that there are grounds for believing the maximum may really have occurred after 1806, when Gilpin's series terminated.

It has to be stated, however, that the maximum shown by Gilpin's observations in 1797 is very small; that the whole interval between the preceding and following minimum is not six years; and that no such short period and small maximum have been observed during the last half century. Since, however, the shortness of the period and the smallness of the maximum are both confirmed by the observations known to us of the frequency of sun-spots and of the aurora borealis, I can only conclude, in conformity with the facts, that both these were real phenomena, which may yet be repeated and aid in the determination of the cause of the decennial period. The mean duration of the period at which I arrive is therefore almost exactly that which Dr. Lamont had previously obtained, or 10·45 years.

For this result the facts have been taken as they present themselves; since it would be difficult to conclude that the observers of all the three phenomena could have erred in the same way during nearly twenty years. In addition to this, after a careful study of Dr. Wolf's sun-spot numbers, I find it impossible to accept his period of 11⅑ years. How ill the facts satisfy this result may be shown by two comparisons in which the epochs accepted by the Zurich astronomer are employed.

Thus a maximum of the magnetic oscillation occurred in 1787 by the observations of Cassini and Gilpin; this epoch has been confirmed nearly by Dr. Wolf's sun-spot numbers, and by Prof. Loomis for the auroral frequency. We have then the last observed maximum 1870·9, about which there can be no doubt. In the interval between these two maxima there were, according to Dr. Wolf, only seven periods, consequently we have—

$$\frac{1870{\cdot}9-1787{\cdot}3}{7} = \frac{83{\cdot}6}{7} = 11{\cdot}94 \text{ years,}$$

a period which differs as much from his mean period as that does from Dr. Lamont's. If on the other hand we take one of Dr. Wolf's sun-spot epochs about eighty years

[1] See "On the Decennial Period," &c., *Trans. Roy. Soc. Edin.*, xxvii., pp. 563-594.

before 1787, and employ the number of periods he has himself given for the interval, we find—

$$\frac{1787 \cdot 3 - 1705 \cdot 5}{8} = \frac{81 \cdot 8}{8} = 10 \cdot 23 \text{ years.}$$

If, then, we commence with the epoch of 1787 and compare it with any epoch of maximum since, we shall always find for the mean duration at the least 11·9 years according to Dr. Wolf; and if we compare it with any of the epochs given by him upwards of eighty years before, we shall never find a greater mean than 10·75 years, and this result includes an interval of 172 years before 1787, with all the uncertainty of the earlier epochs. This great difference of more than one year in the mean duration, as derived from eighty-four years after 1787, and eighty-two to 172 years before, disappears to a great extent if we admit three periods between 1787 and 1818.

It has been already remarked that the duration of a period is not constant, but varies within certain limits. The question naturally presents itself—Does this variation follow any law, or is it accidental, increasing one year and diminishing the next? The number of periods for which we have the epochs of maxima and minima of the diurnal oscillation of the magnetic needle accurately determined, is not sufficient for any very sure reply. At the same time the results I have obtained indicate a period of nearly forty-two years for the repetition of the variations in question; and if this conclusion is confirmed by next maximum, that should occur in the year 1879. It may also be pointed out that according to the law of forty-two years a maximum should have occurred in 1818 − 42 = 1776. Now this year, according to Dr. Wolf, was a year of minimum. The variation of his sun-spot numbers for that period, it appears to me, is not sufficient to give his conclusion much weight; while, on the other hand, Van Swinden's result, which it is extremely probable was a consequence of the decennial law, gives 1776 for the year of maximum; and that it was so is further supported by the magnetic observations of Cotte, at Montmorency. The exceptional period about 1797 shows, however, that any definite conclusion from observations during the last sixty years may be impossible, since causes of variation exist with which we are insufficiently acquainted as yet.

When we compare the mean range of the diurnal oscillation of the needle for the year in which it is a maximum with that for the year of minimum at any station, we find that the ratio of the two is very nearly constant for places so widely separated as Toronto, Dublin, Trevandrum, and Hobarton. I have also found that the *law* of the diurnal movement is the same in the year for which the range is least, and in that for which it is greatest. This shows that it is the same cause which is acting, the variation being one of intensity only. Since few or no sun-spots are visible in the years of minimum range, we perceive that the sun-spots happen only when the intensity of the force producing the magnetic variations exceeds a given value. It also appears that considerable variations in the amount of magnetic disturbance may exist near the equator when there are few or no sun-spots; and, on the other hand, that the spotted surface of the sun may be a maximum, and no corresponding increase of the magnetic oscillations be visible. The latter are, however, exceptional cases, since increases of sun-spots and of magnetic movements occur frequently near the same time; the increase of the one, however, bears no constant proportion to that of the other.

It has been already stated that the ratio of the diurnal oscillation of the needle in the year of maximum to that in the year of minimum is very nearly constant for places very widely separated from each other; there are, however, slight variations in the ratio shown at some places; thus, although it is nearly the same at Toronto, Dublin, Trevandrum, and Hobarton (1·55), it is slightly greater for Munich and Lisbon (1·71). This is probably due to the action of disturbances which are known to obey local laws. I have also found for Trevandrum, nearly on the magnetic equator, that the disturbances, or the deviations of the magnetic needle from the mean position, do not show exactly the same epochs of maximum and minimum in the decennial period when different hours are considered. Thus, though the cause is cosmic, the actions appear to be influenced, though but slightly, by circumstances of locality.

When we seek for the cause of the decennial period, we are met at first by the three phenomena which obey this law: the magnetic variations, the sun-spots, and the aurora borealis. The connection between the first and third is so marked, that if a magnetic disturbance commences during the day in a high latitude, it is quite certain that the aurora will be seen as soon as the disappearance of sunlight permits. This is a fact I have verified during several years' observations in the south of Scotland. Both these phenomena are results of electrical motions. It did not seem improbable then that the solar spots might be connected with disturbances of electrical equilibrium, and that these might be due to the different electrical states of the sun and of the planets.

We do not know, however, of any planet with a period of ten and a half years, nor of any combination of planetary positions which would produce such a period. My own researches have failed in connecting the variations of the sun's spotted surface with the time of revolution of any planet by a law which holds for different decennial periods. This fact, however, does not disprove a planetary action. We are unacquainted with the nature of the medium through which the electrical actions producing the magnetic variations are conveyed. Physicists seek to reduce the phenomena of nature to the fewest possible factors: many then have been induced to believe that electrical and magnetical actions are conveyed by the same ethereal medium which we believe transmits heat and light. The facts do not appear to be easily explained by such a hypothesis; thus I have found that certain electrical actions of the sun producing marked diminutions of the earth's magnetic force happen exactly at successive intervals of twenty-six days; when one point or meridian of the sun returns to the same position relatively to the earth; this action, similar to that of a beam of light reflected from a revolving mirror, which illuminates a particular point only at the same part of its revolution, has no resemblance to that of light and heat, which are propagated equally in all directions.

If, then, we can suppose that the electrical medium is disposed unsymmetrically around the sun, that the disposition and extension varies, it is obvious that the supposed planetary actions would also vary, and might be quite different for different parts of their orbits, in different decennial periods. This suggestion may explain why I have not been able to find a law remaining the same in the different periods; and it is not opposed to the conclusions of Messrs. De la Rue, Stewart, and Loewy, who have found very remarkable relations between certain positions of the planets and the amount of the sun's spotted surface during a single decennial period

Any hypothesis which seeks to explain the mode of production of the sun-spots (by cyclones or otherwise) must also explain why the causes become insufficient for their production every ten and a half years. M. Faye, the distinguished French astronomer, considers that the prime cause of sun-spots is to be found in the excess of heat radiated; so that the spots are the symptoms of a dying sun; that we have in fact here a phenomenon like the flickering of an expiring lamp which may have a periodical character. Such a hypothesis will scarcely satisfy the demands of science, but we must evidently wait for more facts before any satisfactory theory can be proposed.

JOHN ALLAN BROUN

HOW TO DRAW A STRAIGHT LINE[1]

THE great geometrician Euclid, before demonstrating to us the various propositions contained in his "Elements of Geometry," requires that we should be able to effect certain processes. These *Postulates*, as the requirements are termed, may roughly be said to demand that we should be able to describe straight lines and circles. And so great is the veneration that is paid to this master-geometrician, that there are many who would refuse the designation of "geometrical" to a demonstration which requires any other construction than can be effected by straight lines and circles. Hence many problems—such as, for example, the trisection of an angle—which can readily be effected by employing other simple means, are said to have no geometrical solution, since they cannot be solved by straight lines and circles only.

It becomes then interesting to inquire how we can effect these preliminary requirements, how we can describe these circles and these straight lines, with as much accuracy as the physical circumstances of the problems will admit of.

As regards the circle we encounter no difficulty. Taking Euclid's definition, and assuming, as of course we must, that our surface on which we wish to describe the circle is a plane, we see that we have only to make our tracing-point preserve a distance from the given centre of the circle constant and equal to the required radius. This can readily be effected by taking a flat piece of any form, such as the piece of carboard I have here, and passing a pivot which is fixed to the given surface at the given centre through a hole in the piece, and a tracer or pencil through another hole in it whose distance from the first is equal to the given radius; we shall then, by moving the pencil, be able, even with this rude apparatus, to describe a circle with considerable accuracy and ease; and when we come to employ very small holes and pivots, or even larger ones turned with all that marvellous truth which the lathe affords, we shall get a result unequalled perhaps among mechanical apparatus for the smoothness and accuracy of its movement. The apparatus I have just described is of course nothing but a simple form of a pair of compasses, and it is usual to say that the third Postulate postulates the compasses.

But the straight line, how are we going to describe that? Euclid defines it as "lying evenly between its extreme points." This does not help us much. Our text-books say that the first and second Postulates postulate a ruler. But surely that is begging the question. If we are to draw a straight line with a ruler, the ruler must itself have a straight edge; and how are we going to make the edge straight? We come back to our starting-point.

Now I wish you clearly to understand the difference between the method I just now employed for describing a circle, and the ruler method of describing a straight line. If I applied the ruler method to the description of a circle I should take a circular lamina, such as a penny, and trace my circle by passing the pencil round the edge, and I should have the same difficulty that I had with the straight-edge, for I should first have to make the lamina itself circular. But the other method I employed involves no begging the question. I do not first assume that I have a circle and then use it to trace one, but simply require that the distance between two points shall be invariable. I am of course aware that we do employ circles in our simple compass, the pivot and the hole in the moving piece which it fits are such; but they are used not because they are the curves we want to describe (they are not so, but are of a different size), as is the case with the straight-edge, but because, through the impossibility of constructing pivots or holes of no finite dimensions, we are forced to adopt the best substitute we can for making one point in the moving piece remain at the same spot. If we employ a very small pivot and hole, though they be not truly circular, the error in the description of a circle of moderate dimensions will be practically infinitesimal, not perhaps varying beyond the width of the thinnest line which the tracer can be made to describe; and even when we employ large pivots and holes we shall get results as accurate, because those pivots and holes may be made by the employment of very small ones in the machine which makes them.

It appears, then, that although we have an easy and accurate method of describing a circle, we have at first sight no corresponding means of describing a straight line; and there would seem to be a substantial difficulty in producing what mathematicians call the simplest curve, so that the question how to get over that difficulty becomes one of a decided theoretical interest.

Nor is the interest theoretical only, for the question is one of direct importance to the practical mechanician. In a large number of machines and scientific apparatus it is requisite that some point or points should move accurately in a straight line with as little friction as possible. If the ruler principle is adopted, and the point is kept in its path by guides, we have, besides the initial difficulty of making the guides truly straight, the wear and tear produced by the friction of the sliding surfaces, and the deformation produced by changes of temperature and varying strains. It becomes therefore of real consequence to obtain, if possible, some method which shall not involve these objectionable features, but possess the accuracy and ease of movement which characterises our circle-producing apparatus.

Turning to that apparatus we notice that all that is requisite to draw with accuracy a circle of any given radius is to have the distance between the pivot and the tracer properly determined, and if I pivot a second "piece" to the fixed surface at a second point having a tracer as the first piece has, by properly determining the distance between the second tracer and pivot I can describe a second circle whose radius bears any proportion I please to that of the first circle. Now, removing the tracers, let me pivot a third piece to these two *radial* pieces, as I may call them, at the points where the tracers were, and let me fix a tracer at any point on this third or *traversing* piece. You will at once see that if the radial pieces were big enough the tracer would describe circles or portions of circles on *them*, though they are in motion, with the same ease and accuracy as in the case of the simple circle drawing apparatus; the tracer will not however describe a circle on the *fixed* surface but a complicated curve.

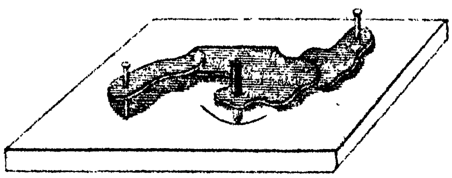
This curve will, however, be described with all the ease and accuracy of movement with which the circles were described, and if I wish to reproduce in a second apparatus the curves which I produce with this, I have only to get the distances between the pivots and tracers accurately the same in both cases, and the curves will also be accurately the same. I could of course go on adding fresh pieces *ad libitum*, and I should get points on the structure produced, describing in general very complicated curves, but with the same results as to accuracy and smoothness, *the reproduction of any particular curve depending solely on the correct determination of a certain definite number of distances.*

These systems, built up of pieces pointed or pivoted together, and turning about pivots attached to a fixed base, so that the various points on the pieces all describe definite curves, I shall term "link-motions," the pieces being termed "links." As, however, it sometimes facilitates the consideration of the properties of these structures to regard them apart from the base to which they

[1] Lecture at South Kensington in connection with the Loan Collection of Scientific Apparatus, by A. B. Kempe, B.A.

are pivoted, the word "linkage" is employed to denote any combination of pieces pivoted together. When such a combination is pivoted in any way to a fixed base, the motion of points on it not being necessarily confined to fixed paths, the link structure is called a "linkwork:" a "linkwork" in which the motion of every point is in some definite path being, as before stated, termed a "link-motion." I shall only add to these expressions two more: the point of a link-motion which describes any curve is called a "graph," the curve being called a "gram."

Fig. 1.



The consideration of the various properties of these "linkages" has occupied much attention of late years among mathematicians, and is a subject of much complexity and difficulty. With the purely mathematical side of the question I do not, however, propose to deal to-day, as we shall have quite enough to do if we confine our attention to the practical results which mathematicians have obtained, and which I believe only mathematicians could have obtained. That these results are valuable cannot, I think, be doubted, though it may well be that their great beauty has led some to attribute to them an importance which they do not really possess; and it may be that fifty years ago they would have had a value which, through the great improvements that modern mechanicians have effected in the production of true planes, rulers and other exact mechanical structures, cannot now be ascribed to them. But linkages have not at present, I think, been sufficiently put before the mechanician to enable us to say what value should really be set upon them.

The practical results obtained by the use of linkages are but few in number, and are closely connected with the problem of "straight-line motion," having in fact been discovered during the investigation of that problem, and I shall be naturally led to consider them if I make "straight-line motion" the backbone of my lecture. Before, however, plunging into the midst of these linkages it will be useful to know how we can practically construct such models as we require; and here is one of the great advantages of our subject—we can get our

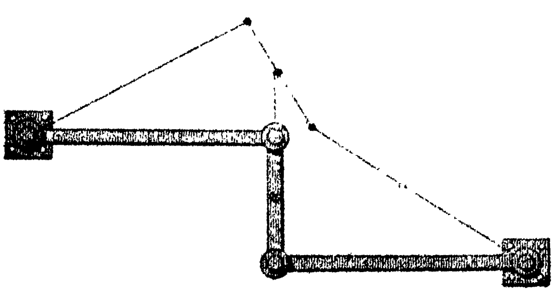


Fig. 2.

results visibly before us so very easily. Pins for fixed pivots, cards for links, string or cotton for the other pivots, and a dining-room table, or a drawing board if the former be thought objectionable, for a fixed base, are all we require. If something more artistic be preferred, the plan adopted in the models exhibited by me in the Loan Collection can be employed. The models were constructed by my brother, Mr. H. R. Kempe, in the following way. The bases are thin deal boards painted black; the links are neatly shaped out of thick cardboard (it is hard work making them, you have to sharpen your knife about every ten minutes, as the cardboard turns the edge very rapidly); the pivots are little rivets made of catgut, the

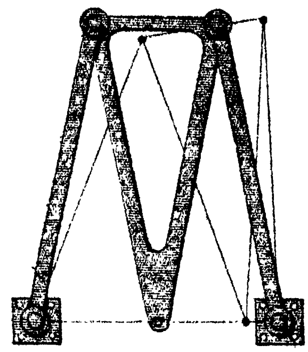

Fig. 3.

heads being formed by pressing the face of a heated steel chisel on the ends of the gut after it is passed through the holes in the links; this gives a very firm and smoothly working joint. More durable links may be made of tin-plate; the pivot-holes must in this case be punched, and the eyelets used by bootmakers for laced boots employed as pivots; you can get the proper tools at a trifling expense at any large tool shop.

Now, as I have said, the curves described by the various points on these link-motions are in general very complex. But they are not necessarily so. By properly choosing the distances at our disposal we can make them very simple. But can we go to the fullest extent of simplicity and get a point on one of them moving accurately in a straight line? That is what we are going to investigate.

To solve the problem with our single link is clearly impossible: all the points on it describe circles. We must therefore go to the next simple case—our three-link motion. In this case you will see that we have at our disposal the distance between the fixed pivots, the distances between the pivots on the radial links, the distance between the pivots on the traversing link, and the distances of the tracer from those pivots; in all six different

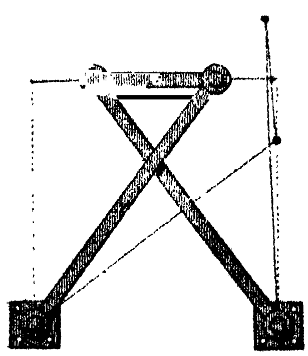

Fig. 4.

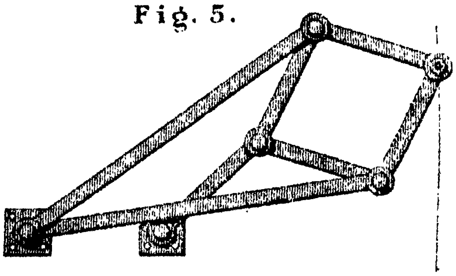
distances. Can we choose those distances so that our tracing-point shall move in a straight line?

The first person who investigated this was that great man James Watt. "Watt's Parallel Motion," invented in 1784, is well known to every engineer, and is employed in nearly every beam-engine. The apparatus reduced to its simplest form is shown in Fig. 2.

The radial bars are of equal length—I employ the word "length" for brevity, to denote the distance between the pivots, the links, of course, may be of any length or shape,—and the distance between the pivots or the traversing link is such that when the radial bars are parallel the line joining those pivots is perpendicular to the radial bars. The tracing-point is situate half-way between the pivots on the traversing piece. The curve described by the tracer is, if the apparatus does not deviate much from its mean position, approximately a straight line. The reason of this is that the circles described by the extremities of the radial bars have their concavities turned in opposite directions, and the tracer being half-way between, describes a curve which is concave neither one way nor the other, and is therefore a straight line. The curve is not, however, accurately straight, for if I allow the tracer to describe the whole path it is capable of describing, it will, when it gets some distance from its mean position, deviate considerably from the straight line, and will be found to describe a figure 8, the portions at the crossing being nearly straight. We know that they are not quite straight, because it is impossible to have such a curve partly straight and partly curved.

For many purposes the straight line described by Watt's apparatus is sufficiently accurate, but if we require an exact one it will, of course, not do, and we must try again. Now it is capable of proof that it is impossible to solve the problem with three moving links; closer approximations to the truth than that given by Watt can be obtained, but still not actual truth.

Fig. 5.



I have here some examples of these closer approximations. The first of these, shown in Fig. 3, is due to Richard Roberts of Manchester.

The radial bars are of equal length, the distance between the fixed pivots is twice that of the pivots on the traversing piece, and the tracer is situate on the traversing piece, at a distance from the pivots on it equal to the lengths of the radial bars. The tracer in consequence coincides with the straight line joining the fixed pivots at those pivots and half-way between them. It does not, however, coincide at any other point, but deviates very slightly between the fixed pivots. The path described by the tracer when it passes the pivots, altogether deviates from the straight line.

The other apparatus was invented by Prof. Tchebicheff of St. Petersburg. It is shown in Fig. 4. The radial bars are equal in length, being each in my little model five inches long. The distance between the fixed pivots must then be four inches, and the distance between the pivots or the traversing bar two inches. The tracer is taken half-way between these last. If now we draw a straight line—I had forgotten that we cannot do that yet, well, if we draw a straight line, popularly so called—through the tracer in its mean position as shown in the figure, parallel to that forming the fixed pivots, it will be found that the tracer will coincide with that line at the points where verticals through the fixed pivots cut it as well as at the mean position, but, as in the case of Roberts's parallel motion, it coincides nowhere else, though its deviation is very small as long as it remains between the verticals.

We have failed then with three links, and we must go on to the next case, a five-link motion—for you will observe that we must have an odd number of links if we want an apparatus describing definite curves. Can we solve the problem with five? Well, we can, but this was not the first accurate parallel motion discovered, and we must give the first inventor his due (although he did not find the simplest way), and proceed in strict chronological order.

In 1864, eighty years after Watt's discovery, the problem was first solved by M. Peaucellier, an officer of Engineers in the French army. His discovery was not at first estimated at its true value, fell almost into oblivion, and was rediscovered by a Russian student named Lipkin, who got a substantial reward from the Russian Government for his supposed originality. However, M. Peaucellier's merit has at last been recognised, and he has been awarded the great mechanical prize of the Institute of France, the "Prix Montyon."

M. Peaucellier's apparatus is shown in Fig. 5. It has, as you see, seven pieces or links. There are first of all two long links of equal length. These are both pivoted at the same fixed point; their other extremities are pivoted to opposite angles of a rhombus composed of four equal shorter links. The portion of the apparatus I have thus far described, considered apart from the fixed base, is a linkage termed a "Peaucellier cell." We then take an *extra* link, and pivot it to a fixed point whose distance from the first fixed point, that to which the cell is pivoted, is the same as the length of the extra link; the other end of the extra link is then pivoted to one of the free angles of the rhombus; the other free angle of the rhombus has a pencil at its pivot. That pencil will accurately describe a straight line.

I must now indulge in a little simple geometry. It is absolutely necessary that I should do so in order that you may understand the principle of our apparatus.

(*To be continued.*)

FOSSIL FLORAS AND GLACIAL PERIODS

A RECENT notice in NATURE (vol. xiv. p. 336) of certain inferences of Prof. Heer in connection with the Arctic fossil plants obtained by the Swedish Expeditions of 1870 and 1872, suggests some thoughts on the relations of fossil plants to climate, which, though I have discussed them elsewhere, deserve to have attention again directed to them. In my Bakerian Lecture before the Royal Society in 1870, and in my "Report on the Pre-carboniferous Flora of Canada," published by the Canadian Survey in 1871, I deduced from the generalisations of Prof. James Hall as to the growth of the American Continent from the north-east, in connection with the distribution of the fossil plants of the Upper Silurian, Erian, and Carboniferous systems, the conclusion that these assemblages of plants entered North America from the north-east, and propagated themselves southward and westward. Prof. Asa Gray had, as early as 1867, stated similar conclusions with reference to the modern floras of America and Eastern Asia, and has more recently extended them to the Tertiary floras on the evidence of Heer and Lesquereux.[1]

The further conclusion that all the old floras appeared suddenly and abruptly in the temperate regions, and with a great number of species, I have illustrated in the Report above referred to, as far as regards the Palæozoic plants, and have referred to the evidence of it in the case of the Cretaceous and Tertiary floras in my address to the American Association in 1875.

With regard to the succession of these floras, it is true that it has been the fashion with certain European palæontologists to regard our rich Devonian or Erian flora

[1] Address to the American Association, 1872.

of America as of Carboniferous age, simply because it contains forms not found as yet in rocks so old in Europe. But this notion is at variance with stratigraphy and animal fossils, and quite as wide of the mark as the often-repeated dictum of some of the same authorities that the Cretaceous flora of Vancouver Island and the Eocene flora of the North-western plains are equivalents of the European Miocene. In point of fact, we have in America distinct floras of Erian and Carboniferous age with an intermediate sub-flora of Lower Carboniferous date,[1] and succeeding them the Triassic and Jurassic flora, that of the Cretaceous, that of the Eocene, and that of the Miocene; and there is good reason to believe that all of these invaded the Continent from the northward and lingered longest in the south. There may no doubt have been counter migrations from the south, but these seem to have left less trace in the geological record. The special Lower Carboniferous or "Culm" flora, and that of the Eocene in Europe, may be of this character.

If we compare these facts with those known from other sources as to the alternation of cold and warm climates in the northern hemisphere, it would seem that they harmonise most closely on the hypothesis advocated by Sir Charles Lyell, that these changes of climate have depended mainly on the distribution of land and water and of the ocean currents.

Assuming a condition in which much tropical land existed, along with islands in the Arctic and sub-Arctic regions, surrounded with deep water over which warm currents were distributed, a rich flora might extend as far northward as the supply of light would permit. Further, if such condition of equatorial protuberance were coincident with a less obliquity of the ecliptic, there might be less difficulty with regard to a continuous supply of light than under present circumstances. Succeeding elevation of northern and temperate land and depression of that nearer the equator, would destroy the more southern flora and cause that of the north to advance over the newly-elevated continental plateaus. This would more especially be the case if, as we may infer from the possible connection of equatorial subsidence with the retardation of the earth's rotation, the depression of the northern land was very slow and gradual, and that of the equatorial land more sudden and paroxysmal.

Invasions of plants from the north would thus result from continental elevation in the temperate regions, and these invasions would go on contemporaneously with the introduction of less equable and cooler climatal conditions. These might not, however, advance so far as to cause extreme glacial phenomena, except in those, perhaps rare, circumstances, when Arctic land was elevated while the greater part of the tropical and temperate areas remained under shallow seas with little heating and radiating surface and invaded by much northern ice. Further, when we take into consideration the growth of the continents in later geological times, it is evident that such periods of exceptional cold would be more likely to occur in these later times, and that they might be less intense in earlier geological periods, and might attain their maximum in the last glacial period. They would also be irregular as to the intervals between them, and might through long periods be absent altogether. We have proof of the efficacy of such causes in the contrast between the climates of Labrador and England at the present day, and also in that sameness of the climate of those regions in the Post-pliocene period, of which I long ago pointed out the evidence in my "Acadian Geology." Such moderate views as to glacial periods may also serve to render more explicable the facts as to the absence of evidence of glacial action in Arctic Tertiary formations as observed by Nordenskjöld.

It will of course be understood that my conception of glacial periods is not that of continental ice-caps; but rather such conditions as would cover great breadths of shallow sea in the northern hemisphere with a permanent and continuous ice-pack, accompanied of course with "bordage" and "anchor ice" and with glaciers descending to the sea from high lands; the whole resembling that now occupying large areas of the Arctic seas, and occurring in winter in the Gulf and River St. Lawrence. To such agencies I have been accustomed for the last twenty years to refer our Canadian boulder clay and glaciated rocks. Further, to this extent we have evidence, locally at least, of ice-action in temperate latitudes (in non-fossiliferous conglomerates with boulders) as far back as the Huronian age, while the evidence of alternate submergence and emergence of the northern land extends down to that of the Post-pliocene, whose greatness geologists are only beginning to realise.

It is a corollary from these views that there can have been no change within geological time in the position of the earth's axis of rotation. The distribution of sediment by the polar currents, and the lines of plication and upheaval of the crust, as well as the distribution of successive floras, prove that the poles have remained since the Laurentian period where they now are. I need here merely refer to the fact, well known to all American geologists, that the earthy matter of the thick Appalachian sediments lies parallel to the line of the modern Arctic currents, which seem in all geological time to have been potent agents in carrying the *débris* of the disintegrated Arctic rocks to the south, and filling up the voids caused by equatorial subsidence. Further, the great organic limestones, which represent the contemporaneous food-bearing warm currents from the equator, lie on the plateaus and in the bays of the old Eozoic and Palæozoic land.

We need not, however, in consistency with such views, refuse to attach any importance which they may seem to require to astronomical cycles affecting the eccentricity of the earth's orbit and the precession of the equinoxes, or to the possible diminution or inequality of solar energy, or to the secular cooling and contraction of the earth or the retardation of its rotation. But geologists and palæontologists, in speculating on past conditions of the earth, should endeavour in the first instance to gauge the value of the causes indicated by their own sciences; and where climate is in question no evidence can be more important than that of continental elevation and depression, in connection with the appearance and diffusion of those assemblages of land plants which furnish so sure testimony as to climatal influences.

I should perhaps apologise for throwing out these suggestions with so little of illustration or proof. For much of this I may refer to my published memoirs;[1] and I have now before me a mass of additional evidence, collected in all the great regions from Newfoundland to British Columbia by several recent observers, which I have not at the moment time or opportunity to throw into a connected form. My present object is to invite the attention of the many young and active geologists now working at these subjects to lines of investigation from which they may be deterred by some of the theoretical views now current.

A NEW STIMULANT—PITURY

Baron von Mueller writes to the *Australian Medical Journal* on the origin of the Pitury, a stimulant said to be of marvellous power, and known to be in use by the Aborigines of Central Australia. After years of efforts to get a specimen of the plant, he had obtained leaves, but neither flowers nor fruits. He can almost with certainty, after due microscopic examination, pronounce those of the Pitury as derived from his *Duboisia Hopwoodii*, described in 1861 (*Fragm. Phytogr. Austr.* II., 138). This bush extends from the Darling River and Barcoo to West Australia, through desert scrubs, but is of exceedingly sparse occurrence anywhere. In fixing the origin of the Pitury, a wide field for further inquiry is opened up, inasmuch as a second species of *Duboisia* (*D. myoporoides, R. Br.*) extends in forest land from near Sydney to near Cape York, and is traced also to New Caledonia, and lately by him also to New Guinea. In all probability this *D. myoporoides* shares the properties of *D. Hopwoodii*, as he finds that both have the same burning acrid taste. Baron Mueller adds: "Though the first known species is so near to us, we never suspected any such extraordinary properties in it as are now established for the later discovered species. Moreover, the numerous species of the allied genus *Anthocercis*, extending over the greater part of the Australian continent and to Tasmania, should now also be tasted, and further the many likewise cognate *Schwenkeas* of South America, should be drawn into the same cyclus of research, nothing whatever of the properties of any of these plants being known. The natives of Central Australia chew the leaves of *Duboisia Hopwoodii*, just as the Peruvians and Chilians masticate the leaves of the Coca (*Erythroxylon Coca*), to invigorate themselves during their long foot journeys through the deserts. I am not certain whether the Aborigines of all districts in which the Pitury grows are really aware of its stimulating power. Those living near the Barcoo travel many days' journeys to obtain this, to them, precious foliage, which is carried always about by them broken into small fragments and tied up in little bags. It is not improbable that a new and perhaps important medicinal plant is thus gained. The blacks use the *Duboisia* to excite their courage in warfare, a large dose infuriates them."

THE ANTIQUITY OF MAN

ON Tuesday evening last a conference was held at the rooms of the Anthropological Institute on the Present State of the Question of the Antiquity of Man. The chair was taken by the president, Mr. John Evans, F.R.S. There were also present Lord Talbot de Malahide, Prof. Huxley, Prof. Prestwich, Prof. Rolleston, Prof. Busk, Prof. Boyd Dawkins, Prof. McK. Hughes, Rev. Prof. Sayce, Mr. J. Heywood, Col. Lane Fox, Mr. A. W. Marks, Capt. Douglas Galton, Rev. E. W. Edgell, and many other gentlemen.

The President in opening the conference alluded to the altered position of the question since it was first brought before the British public in 1859 and pointed out the extreme caution which was necessary in dealing with the subject as it lay within the domain of the archæologist, the anthropologist, and the geologist, neither of whom alone was sufficient by himself to offer a very strong opinion on the subject. Great care was also necessary with regard to the facts of the discoveries themselves, as the objects discovered were liable to get mixed with other objects below them, and this was important in the case of cave deposits in which there might be interments of a later date than the human skeletons deposited in the caves. The question was now very much within the province of the geologist, whose business it was to determine the antiquity of the deposits in which the discoveries may have been made. After alluding to several recent discoveries in France, Spain, and Switzerland, the President remarked that each successive discovery or presumed discovery must be received in a cautious but candid spirit, and looking to the many sources of doubt and error which attached to isolated discoveries, their watchword must for the present be "caution, caution, caution."

The debate was opened by Prof. Boyd Dawkins by an inquiry into the value of the evidence offered by the bone-caves of Great Britain. The antiquity of man is not to be measured by the system of chronology used by the historian, but by the physical and biological changes familiar to the geologist. Beyond historical record time past cannot be estimated in terms of years, because of our ignorance of the length of the intervals, and of the time necessary to produce the changes which mark the hour on the geological dial. The caves of Cresswell Crags, recently brought before the Geological Society, were taken as types, showing the strange association of human implements and remains of animals. Bones and teeth of species now found only in the south, such as the spotted hyæna and lion, were lying side by side with those of northern habit, such as the reindeer, while some are extinct, such as the mammoth and woolly rhinoceros, and others, such as the stag, horse, and bison, still live in the temperate regions. This mixed fauna is universal in British bone-caves, and in those of France and Germany, and it cannot be accounted for by the supposition of Messrs. James Geikie and Croll that the southern animals inhabited Britain in a warm period inter-glacial, while the northern were here at another time after, with an interval between them of from 5,000 to 12,000 years; not only because they are closely associated together in the same strata, but because we have full proof that northern and southern species coexisted at the same time on the same place, in the fact that the reindeer formed an important portion of the prey of the hyæna. It may, however, be accounted for by the overlapping of faunas according to the ever-varying summer heat and winter cold over what was then a vast continent, extending from Northern Africa as far as the 100-fathom line off the coast of Scotland and Scandinavia. The palæolithic man of the caves belongs to the northern group of the pleistocene animals, and his remains are therefore of late pleistocene age. This northern group invaded Europe as the glacial cold came on, was pushed down as far south as the Mediterranean, the Alps, and Pyrenees, as the ice-sheet advanced southwards, and on its retreat passed again northwards. It therefore follows that they are both pre- and post-glacial in Britain. Some caves have been inhabited by man in post-glacial times, as, for example, that of Pont Newydd, near St. Asaph, but it does not follow that all palæolithic caves are post-glacial. The Victoria Cave offers no evidence as to the antiquity of man, because fibula found in association with the pleistocene mammalia, and supposed to be human, is most probably ursine. Further the relation of the deposit in which it was found to the glacial strata of the district is a matter of dispute.

The facts brought forward by Mr. James Geikie, that all palæolithic remains are of earlier date than post-glacial times may be interpreted otherwise. The "something like perpetual summer" which he considers necessary for the presence of the southern animals in the mixed fauna of the caves and of which there is no trace in post-glacial times, is inconsistent with the abundance of reindeer invariably associated with the palæolithic remains of the caves. The barren areas in Great Britain, in which no pleistocene species are found, may be reasonably accounted for by the fact that they were covered with ice, *while* the species were living in more glaciated regions in the south, than by the view that they were equally distributed over the whole area, and afterwards removed by ice for the glaciated regions. The glacial phenomena are no guide to age in non-glaciated districts. In fine, the evidence of the caves is decisive that these palæolithic inhabitants are of late pleistocene age, post-glacial, and possibly pre-glacial, and glacial.

Prof. Hughes, after a few remarks on some foreign cases in which man had been referred to periods more remote than was generally included under the term glacial, commenced by explaining that in using the word glacial he meant the period in which conditions prevailed in the area in question such as must have caused glacier ice, or in adjoining areas which, by supplying berg or coast ice or influencing the climate, must have affected the area in question. He then proceeded to criticise the cases adduced from the neighbourhood of Brandon and Thetford. By an appeal to sections he showed that the beds in which the flint implements had been found were remains of valley deposits resting on older deposits which he referred to the middle glacial.

He explained the various divisions of the middle glacial beds and correlated them with deposits of the same age in Hertfordshire, pointing out that there were several horizons at which loams occurred. He then showed that the beds in which the flint implements had been found rested upon various members of the middle glacial series and occurred in troughs and hollows scooped out of the middle glacial beds. In the case of the

Beeches Pit, opposite Culford, he said that the implements were found in a deposit which seemed to be the end of a terrace of valley gravel which, further down as it was followed towards Icklingham, became more clearly marked, consisting of gravel and brick-earth with pupa, pisidium, and mammalian remains.

The only deposits at all like boulder clay which either in the Beeches Pit or at Botany Bay overlaid these implement-bearing loams, he considered to be the wash either from boulder clay or directly from the chalk as the case might be.

Mr. R. H. Tiddeman then read "Some Observations on the Hyæna Bed at the Victoria Cave, and its Bearing on the Antiquity of Man." After some remarks on the disputed fibula formerly determined to be human, which had been found at a great depth in the cave deposits in the hyæna bed, the author went on to call attention to two bones, one certainly of goat, and another a rib of a small ruminant probably belonging to the same species, on both of which are cuts or hacks which appear to be the result of human workmanship. These were also found in the same bed at the depths respectively of 25 and 15 feet. In considering the age of these it was remarked that the condition of a bone is not necessarily a test of age, and in many instances might be a most fallacious guide. It was admitted that the goat has not been usually considered as introduced into Britain before Neolithic times, but it certainly had appeared in the Victoria Cave in association with the remains of hyæna, *Elephas antiquus*, *Rhinoceros leptorhinus*, and *Hippopotamus*. In the caverns in the neighbourhood of Dinant-sur-Meuse, in Belgium, M. E. Dupont records the goat as occurring in the lower beds in the same association. It seems, therefore, not improbable that it should have occurred in Britain at the same time.

If these are human workmanship, as appears probable, this cave holds only in common with other caves, the works of man so accompanied, and the actual finding of man or his works in the cave is a secondary question compared to the correlation of the beds with certain great and widespread physical changes.

The hyæna bed contains amongst others besides hyæna, the following—*Elephas antiquus*, *Rhinoceros leptorhinus*, and *Hippopotamus*. These were chosen as a well-marked fauna, about which no doubt was entertained that they were contemporary. They occur in non-gravels in France and Switzerland and in the south and east of England, and in each of these countries are associated with man's bones or handiwork. The geologists who have worked chiefly at the drifts of the south of England maintain, and rightly, that these remains are then post-glacial; but to infer that they are so in the north of England may lead to error. Their remains appear to have been removed from the open country there by glaciation, although from their existence in the Victoria Cave and another near Skipton they must at one time have been as abundant in the valleys as they are in the south. The author considered that this later glaciation was on the wane during its maximum at about the parallel of Derbyshire, and it appeared probable from authorities quoted that it had not extended over the southern end of the Pennine Chain. The glacial drifts further south and of earlier age than the animals referred to appeared to be the relics of an earlier glaciation than that of the north country, and extended further south. The author believed that the acceptance of two great and well-marked periods of glaciation differing in their extent would reconcile many of the differences which now exist amongst geologists as to the age of man and the drifts of this and other countries.

An interesting discussion followed, of which we hope to be able to give some account next week.

OUR ASTRONOMICAL COLUMN

THE REVOLVING DOUBLE STARS.—Dr. Doberck, of Col. Cooper's Observatory, Markree, has published elements of ξ Bootis, calculated from measures extending over ninety-five years, which interval appears to be about two-thirds of a complete revolution. In this second computation for the same star he has followed a suggestion made in this column (NATURE, vol. xiv. p. 475), with regard to the probable interpretation of Sir William Herschel's measures in 1792 and 1795, and his results prove the necessity for the alteration proposed.

We are now indebted to Dr. Doberck for orbits of thirteen of the revolving double stars, calculated in every case in the most complete manner possible from the available data, and which have been communicated from time to time to the Royal Irish Academy. They form collectively a very valuable contribution to this department of astronomy. Col. Cooper may be congratulated on such work emanating from his observatory, and Dr. Doberck likewise on the success which has attended his efforts. We subjoin the periods and eccentricities for Dr. Doberck's stars, omitting only ζ Aquarii, which from the great length of period is open to more uncertainty than the others :—

	Period. Years.	Eccentricity.
γ Coronæ Borealis	95·5	0·350
ξ Scorpii	95·9	0·077
ω Leonis	110·8	0·536
ξ Bootis	127·4	0·708
τ Ophiuchi	185·2	0·582
η Cassiopeæ	222·4	0·576
λ Ophiuchi	241·0	0·493
44 Bootis	261·1	0·710
μ^2 Bootis	290·1	0·617
36 Andromedæ	349·1	0·654
γ Leonis	402·6	0·739
σ Coronæ Borealis	843·2	0·750

The number of binary stars of which the orbits have been determined by various calculators with a greater or less degree of precision, now amounts to twenty-five. The shortest period of revolution hitherto detected belongs to 42 Comæ Berenices, which, according to M. Dubiago, of Pulkowa, in a communication from M. Otto Struve to the St. Petersburg Academy in May 1875, amounts to only 25·71 years. The star was single in 1845 and 1870–71; in 1829 and 1854–55 the distance of the components slightly exceeded six-tenths of a second, which is the greatest separation. The inclination of the orbit to the tangent-plane of the heavens is 90°, or so nearly so that the measures appear to be represented upon this assumption within their possible errors; thus the apparent orbit is a right line, with the direction 11° – 191°. Notwithstanding the difficulty of the case, M. Dubiago has been able to assign the other elements of the orbit with a fair degree of probability as follows :—peri-astron passage 1859·92, angle between the peri-astron and the node, 99° 11′, eccentricity 0·480, semi-axis major 0″·657. The distance of the components at the present time will therefore be 0″·50, with the smaller star on an angle of 11°.

From the elements of ξ Bootis by Dr. Doberck, to which reference is made above, the following appear to be the angles and distances, up to about the epoch of the approaching periastron passage, 1898·04 :—

1882·0	Pos.	271·7	Dist.	3″·81		1896·0	Pos.	191°·5	Dist.	1″·57
86·0	,,	259·7	,,	3·29		97·0	,,	174·0	,,	1·36
90·0	,,	242·8	,,	2·71		98·0	,,	150·8	,,	1·21
92·0	,,	231·1	,,	2·38		1899·0	,,	123·5	,,	1·17
94·0	,,	215·3	,,	2·00		1900·0	,,	98·2	,,	1·30

PHYSICAL OBSERVATIONS OF MARS.—Mr. Marth has communicated to the Royal Astronomical Society an elaborate paper intended to facilitate physical observations of the planet Mars during the favourable opposition of the present year, when it is much to be desired that observations tending to improve our knowledge of the planet may be undertaken by those who are provided with adequate instruments. Mr. Marth has calculated the areographical longitude and latitude of the centre of the disc for the times of about ninety sketches of Mars, by Dawes, von Franzenau, Harkness, Kaiser, Lassell, Lockyer, Rosse, and Secchi, and with the aid of a table applicable to the interval June 9—December 14, with very little trouble the observer will be enabled to refer to the particular drawing which applies the most nearly to the time of any proposed observation, and will thereby be assisted in fixing upon the details of the surface to which it may be desirable to direct his attention. The table contains the angle of position of the axis of Mars, no doubt from Bessel's elements, or rather those deduced by Oudemanns from the observations of the Königsberg astronomer, the areographical western longitude and the latitude of the centre of the disc, the apparent diameter, the amount and position of the greatest defect of illumination, and the areocentric angle between the earth and sun, all quantities for Greenwich alternate noon. Vol. xxxii. of the "Memoirs of the Royal Astronomical Society," contains the sketches of Lassell, Lockyer, and Rosse, and this volume alone would be of considerable assistance to the intending observer, as will appear from Mr. Marth's second table.

CHEMICAL NOTES

CRYSTALLISATION UNDER GALVANIC CURRENTS.—A recent number of the *Journal* of the Russian Chemical and Physical Society (vol. ix., fasc. 2) contains an interesting report, by M. Shidlovsky, on observations he has made as to the microscopical crystallisation of various metals under the influence of a galvanic current. Placing on the object-glass of the microscope two fine metallic plates, the edges of which are about a quarter millim. distant, immersing them in a drop of water and passing a current through, M. Shidlovsky watched the growth of small ramified threads of crystals of metal transported from the cathode to the anode plate. The growth of these tree-like agglomerations goes on very speedily; their branches spread out to the anode plate, vibrate on reaching it, and collapse, whilst another ramified tree grows from the cathode spreading out to the anode; this goes on until the space between the plates is filled with a spongy metallic mass. Each of the metals experimented on (lead, silver, zinc, tin, copper, and iron) gives its own characteristic ramifications, and if the two plates be of different metals the tree has ramifications characteristic of the metal of which the anode plate is made. Gold and platinum do not exhibit any appearance of crystalline trees, nor does the crystallisation appear when the anode is gold or platinum. Iron submitted to a continuous current does not show a transport of crystals, but the phenomenon appears immediately when the currents are originated by a Ruhmkorff's coil or by a Holtz's machine. Iron-powder suspended in water undergoes a rapid motion under the influence of a strong inductive current, forming threads which spread out from the cathode to the anode plate.

ISODIBUTYLENE.—The same volume contains the second part of the important paper by Prof. A. Butlérof on the polymerisation of hydrocarbures from the ethylene series:—On isodibutylene.

ON THE THERMIC FORMATION OF OZONE.—M. Berthelot has recently investigated this question by subjecting pure and dry oxygen to the influence of the silent discharge, whilst passing the gas into a flask containing 500 c.c. solution of titered arsenious acid. At the end of thirty minutes, six to nine litres of oxygen had passed through the flask, the temperature being raised one-third of a degree; then by passing the oxygen current without the action of the discharge for an equal time, the thermal data were rendered complete. The arsenious acid solution was then treated with potassium permanganate, and redetermined with a solution of oxalic acid. By this means the quantity of arsenious acid oxidised, and consequently ozone absorbed, was determined. The amount of oxygen absorbed was found to be 30·3 and 51·9 milligrams, corresponding to 90·9 and 155·7 m.m. ozone, the heat set free being 118·2 and 223 calories respectively. Hence for one molecule the heat is equal to + 68·8 calories. Subtracting from this the heat formed in the oxidation of a molecule of arsenious acid + 39·2 calories (Favre and Thomsen), we have + 29·6 calories for the heat set free in the condensation of one molecule ozone into oxygen, and consequently − 29·6 in the reverse process. Ozone therefore is a body in which heat is absorbed in its formation, its activity in combination being probably due to this heat being set free. This is worthy of note when it is remembered that it is condensed oxygen, condensation generally setting free heat.

CHLOROPHYLL IN CONIFERÆ.—Coniferæ are remarkable amongst other plants for developing their chlorophyll even in places which seem perfectly dark. In the Reports of the *Naturforschende Gesellschaft* of Leipzig, Herr R. Sachsse publishes the results of some investigations he made in order to ascertain whether the chlorophyll formed under these circumstances is quite identical with ordinary chlorophyll. He extracted the chlorophyll from young Coniferæ, which had germinated in the dark, by boiling them in alcohol. He obtained a solution which showed the ordinary chlorophyll spectrum; all bands were in the right position and showed the correct grades of intensity. When the solution was concentrated the absorption at the end of the spectrum was continuous, when more diluted the absorption was resolved into the well-known three bands. The only peculiarity in this spectrum, when compared with that of chlorophyll of ordinary origin, was the somewhat lesser intensity of band V. According to Kraus's idea this would prove a predominance of cyanophyll over xanthophyll. The solution of Coniferæ chlorophyll very readily turns to modified chlorophyll.

CHEMISTRY OF THE GRAPE.—In several treatises lately presented to the Royal Academy of Physical and Mathematical Sciences of Naples, Prof. G. Licopoli gives an account of some recent micro-chemical researches upon oranges, lemons, and grapes. The latter are of special interest, as Prof. Licopoli tried to determine the time and place at which, in the grape, the different chemical substances which are contained in it (such as tartaric acid, chlorophyll, albuminoid matter, sugar, colouring matter, &c.) first begin to form. The conclusions which the author draws from his labours are the following: Tartaric acid and chlorophyll first show themselves in the tissue of the pistils in course of formation. Oxalate of lime next shows its presence in the sub-epidermic tissue in the form of raphides, in the endocarpic epidermis in the shape of conglomerated crystals (dumb-bells?), and in the kernels in raphides. The albuminoid matter first appears spread over the whole of the fruit, but predominates in the mesocarp. Colouring matter results from the metamorphosis of chlorophyll, its appearance and diffusion showing the growth of the fruit, and the progress the chlorophyll has made at the time of its formation. The growth of this colouring matter begins in the peripherical tissues, and continues towards the central ones. Sugar is found in the pericarp wherever there is tartaric acid present. Resinous matter or wax appears first on the surface of the epicarpic epidermis. Tannic acid is principally formed in the seed, and particularly in the hard and friable part of the episperma; the fibro-vascular fascicles of the pericarp, however, also contain this acid.

NOTES

WE regret to hear that the state of health of M. Leverrier, the distinguished director of the Paris Observatory, is causing great anxiety to his friends. He has been entirely prostrated by his enormous labours, which have been almost unceasing for the last twenty years.

M. BELGRAND read, at the last sitting of the Council of the Paris Observatory, a report on the necessity of extending telegraph warnings to Algeria, and taking advantage of the documents collected by the Algerine Meteorological Service. The necessary steps will be taken by M. Leverrier, and observations extending from Marocco to Tunis, and from the Mediterranean coasts to Laghouat and Biskra will be sent to and from Paris to every Meteorological Office in connection with the meteorological system. At the same sitting M. Leverrier announced that he had taken steps to utilise the weather telegrams sent from America by the *New York Herald.*

THERE is no ground whatever, we are informed, for the rumour that M. Krantz will resign his office of Director of the International Exhibition, or that the Exhibition will be postponed. The works are progressing favourably, and will not be interrupted. The British Commission have secured a large plot of ground close to the Champ de Mars for their private use. This ground measures more than 5,000 square yards.

THE Emperor of Brazil, who is now in Paris, has been assiduously attending the meetings of various scientific societies. On Friday he was present at the meeting of the Zoological Society. Several communications were read on fishes, insects, and worms from Brazil. He was also present at the last sitting of the Geographical Society of Paris. A paper was read on the Pampas by an American gentleman, whose flattery of the Emperor was so high that his Majesty left the room to show his disapproval. The lecturer stated that the Argentine Republic was building a strong wall to protect the Pampas against incursions from uncontrollable Indians, and that in doing so not less than 20,000 square miles of excellent grazing ground will be reclaimed.

THE Congrès Scientifique of France is holding its present session at Versailles on the occasion of a floral meeting, as we intimated two months ago. The principal attraction is a series of excursions held in the vicinity of Versailles.

THE Russian Council of State has granted a yearly sum of 2,000 roubles to the West Siberian Branch of the Russian Geographical Society at Omsk.

RUSSIAN newspapers announce that Prof. Ahlquist had reached, on April 10, Koudinsk, 530 miles north of Tobolsk. His companion, M. Bergroth, remained at Tobolsk.

SCIENCE in Italy has suffered a heavy loss through the death of Prof. Dr. C. L. Rovida, formerly first physician at the Ospedale Maggiore of Milan, and for the last three years Professor of Special Pathology and Clinical Medicine at the University of Turin. Next to Prof. Moleschott in rank, if not in fame, he was one of the few Italians who follow a rigidly scientific method of investigation and instruction.

THE fourth number of the *Bulletin* of the Geographical Society of Egypt contains an interesting account of a journey to Harar with a plan of that place, published by two Arabian officials; one of whom, Fayous Effendi, accompanied the Italian expedition to Zeilah.

MOUNT VESUVIUS shows signs of fresh activity. The crater is continually sending forth clouds of smoke which at night assume a fiery aspect from the deep-lying glowing lava masses.

CAPT. R. GESSI, the Italian explorer of Albert Nyanza under Col. Gordon, is now preparing at Cairo to undertake, on his own account, a new expedition in company with a naturalist and a photographer. He intends to push forward to the Equatorial Lakes, studying, on his route, all the principal facts of meteorology, anthropology, and natural history, taking sketches and photographs of men, animals, plants, and interesting geological features.

A CORRESPONDENT writes to us that the medal "of the first class" of the Paris Acclimatisation Society was presented, not to Mr. Alfred Mosenthal, but to Messrs. Julius de Mosenthal and J. E. Harting, the joint authors of the work recently published by Messrs. Trübner and Co., on "Ostriches and Ostrich Farming," and reviewed by us in vol. xv. p. 176. This work was published some time *after* the experiments, to which we referred last week, were made at Algiers. These experiments will be found to be fully detailed in the work in question.

A LETTER received at Rome from the commander of the *Scilla* states that the Italian expedition for the exploration of Central Africa were occupied at Zeilah on April 27 with the final preparations for their then imminent departure to Shoa.

IN the last two numbers of the *Bolletino della Società Geografica Italiana* Prof. Gio. Beltrame publishes an interesting paper on the language of the Akkás—an African tribe of which two individuals were brought over to Italy some years ago. This first attempt at giving an idea of the Akká language and its grammar will prove a valuable contribution to the study of comparative African linguistics

AN immense quantity of locusts have shown themselves in the Algerian provinces, and are travelling from the south towards the Mediterranean. The number of these insects was so prodigious that the trains from Blidah to Algiers were almost stopped in the beginning of May.

MR. JOHN F. DOLLEY writes to the *Times* under date Uitenhage, Cape of Good Hope, South Africa, March 19:—"In this part of South Africa we have just witnessed a magnificent sight, such as a person can hardly expect to see more than once in a lifetime, if even then. It was on the beautiful clear starlight evening of the 16th of March, at about eight o'clock, when suddenly every one was startled with a bright lightning, like a flash, and on looking for the cause discovered a large meteor coming out of the eastern horizon, and which travelled slowly across the firmament, in an oblique direction to the westward, when it burst, sending forth streams of fire, as if from a hundred rockets, and then was heard a low rumbling noise as of thunder in the distance. The meteor appeared to be nearly, if not quite, as large as the full moon, but not round, more of an oblong shape, and while travelling through the air it very much resembled a large turpentine ball. It gave forth a bright bluish light which lit up the whole sky, and you could distinguish everything around you for miles as plainly as in the daytime.

A party of Hottentots who were coming in from 'Hankey,' a station belonging to the London Missionary Society, state that the driver of the waggon was struck down in the road, and that they all felt a glow of heat as the fireball passed them. The illumination lasted for nearly a minute, and the light was such that it dazzled the eyes of all who saw it."

A TELEGRAM from New York on the 16th states that forest fires are making great ravages in North-eastern New York, Long Island, Massachusetts, New Hampshire, Maine, Pennsylvania, Canada, and New Brunswick. A large part of the White Mountains is in flames. The summer hotels are in danger, and railways are interrupted. A great number of mills and dwellings have been destroyed, and hundreds of persons have been rendered destitute.

STEAM at ordinary pressure sent into saline solutions on which it has no chemical action, gives a rise of temperature that seems at first sight paradoxical, the temperature produced being always higher than that of the steam. M. Müller, of the Berlin Chemical Society, has been studying the phenomenon. Chloride of sodium is one of the best salts to use. A solution of it sufficiently concentrated to have a boiling point of 127° may be raised to 125° simply by sending steam into it at 100°. Here, then, the steam produces a rise of 25° above its own temperature. The more concentrated the solution the higher is the rise. M. Müller points out, in explanation, that saline solutions at 100° absorb the steam at the same temperature, and the result is a rise analogous to that produced when a gas, like ammonia, is dissolved in water. These experiments throw new light on the controverted question, what is the temperature of the steam which escapes from a concentrated and boiling solution? Is it 100° or a temperature near that of boiling of the solution? The new results seem to be against the latter, and common, view.

INTELLIGENCE has been received from Quebec stating that ships which have recently arrived at that port have encountered unusually large fields of ice and remarkably high icebergs in the Atlantic. The *Una*, from Leith, passed through eighty-five miles of heavy ice.

AT the meeting of the Royal Society of Edinburgh on Monday night, reports were read from four lighthouse keepers on the west coast of Scotland, detailing their experiences of earthquake shocks on March 11 and April 23. The keeper of the Pladda lighthouse says the tower by his dwelling-house shook very much; the Lismore keeper reported that everything in his lighthouse shook at an alarming rate and awoke all the inmates. Mr. Stevenson, C.E., said these observations were valuable because of their trustworthiness.

THE engineers of the French Northern Railway have been making experiments with the vacuum brake, which has been found to work satisfactorily owing to its simplicity of construction. MM. Sartiaux and Lartique have devised some ingenious arrangements for bringing it into action automatically if any mistake has been made respecting the crossings. Should distressed passengers want to call for help they can also put the continuous break into operation instead of ringing a bell as is customary.

THE Superintendent's Report on the Botanic Garden and Public Plantations for 1875-76 has recently been officially published in Jamaica. It deals almost entirely with plants of economic value, foremost of which is the coffee, the ordinary kind (*Coffea arabica*), apparently giving way to its formidable rival *Coffea liberica*, which was introduced to Jamaica in 1874, and is now thriving, especially in some districts. In one situation, at a height of about 1,000 feet above the sea, a plant that had only been planted out a little over a year has already fruited. This seems to indicate that in the course of a few years the new coffee may be widely cultivated in Jamaica from plants raised from seeds ripened in the island. Amongst other important plants treated of in the report which have received special attention, may be mentioned cocoa, sugar canes, pine apples, cinchonas, jalap, &c.; of this last we learn that nearly two acres are under cultivation, producing during the year under review a crop of 1,700, and it was estimated at the time the report was written that an additional 3,000 would be obtainable in the course of a few months, all of which would find its way to England.

DR. LAUDER LINDSAY of Perth has for years been forming a collection of lichens, which, although frequently broken up and distributed, still forms the nucleus of a good type collection. The collection consists of—1. Herbarium, the main object of which is to illustrate the Variations of the Commoner Species: and so to encourage (1) the establishment of Typical, Comprehensive, or Aggregate Species; (2) the abolition of Named Trivial Variations; and the (3) consequent Reduction of Names, and Simplification of Synonymy and Classification. 2. Museum of Illustrations of the Economic Properties and Applications of Lichens. 3. Library of Lichenological Works, Foreign and British. 4. Drawings (original) of Microscopical Structure, several thousands unpublished. 5. Correspondence with Lichenologists. 6. Unpublished Manuscripts—of (1) Outlines of Lichenology:" (2) "Lichenographia Britannica:" and of other works or papers illustrative of Lichens in various aspects. The collection has been offered—with all the cabinets and fittings in which it is contained—as a donation to the Royal Botanic Gardens of Edinburgh, on the simple conditions—(1) That a small room is provided for its accommodation in connection either with the Herbarium, or Museum of Economic Botany; and (2) That it is kept in proper order either by the Curators of said Herbarium or Museum, or by any of the numerous students of the Edinburgh School of Botany. But it is understood that no such donations can be accepted by the said school, by reason of the very inadequate accommodation provided by Government for the more essential requirements equally of students and teachers. As has been repeatedly pointed out—officially and otherwise—there is at present urgent need—(1) of a new commodious class or lecture room; (2) of a new commodious museum; (3) of botanical laboratories; and (4) of extra special rooms for such herbarian or other purposes as the reception and maintenance of such donations as that now referred to.

A NEW burner for obtaining high temperatures in laboratories has recently been described by M. Godefroy. It consists of four metallic cylinders one within another; the first and the third are pierced with lateral holes at their base. The intervals between the cylinders communicate, one set with two vertical pipes uniting in a horizontal pipe below, the other set with another similar system. A piece of metallic net at the lower part regulates the entrance of air.

AT Tabor, in Bohemia, 423 metres above the sea, in a house out from the town, M. Farsky made observations of the amount of carbonic acid in the air from October 10, 1874, to the end of August, 1875. The average obtained was 3·43 volumes in 10,000 volumes of air; a number smaller than that of Saussure and Boussingault (4·15), and higher than those got by Schulze in Rostock and Fittbogen in Dahme. The most numerous variations are in November, December, February, March, and April, the least in October. M. Farsky says that the more variable the weather, and the sharper the transition from one weather to another, the greater are the variations in proportion of carbonic acid in the air. The strong north-west and south-west winds reduce the amount of carbonic acid, while the cold north and north-east winds, which are always thought the heralds of clear weather, cause an increase in the carbonic acid. Further, the carbonic acid is increased descending mist, and continuous dust-rain. No other connection with atmospheric precipitates was perceptible. These results agree, in the main, with those formerly obtained by Angus Smith and Roscoe. Smith found that the air in the suburbs of Manchester contained on the average 3·69 volumes in 10,000 volumes of air. The amount appeared to diminish slightly during long-continued westerly winds; on the other hand it increased when easterly winds prevailed. From a large number of analyses of air collected from the hill-districts of Scotland, Smith obtained, as an average, 3·36 volumes in 10,000 volumes; the extremes recorded are 3·00 and 3·60. These comparatively low numbers are probably due to the proximity of the sea, the air over which has been shown by Thorpe, from a large number of analyses made over the Atlantic Ocean and Irish Sea, to contain about 3·00 volumes of carbonic acid in 10,000 volumes of air. This amount was constant, or nearly so, in different latitudes, and, contrary to the statements of Lewy, exhibited no perceptible diurnal or seasonal variations.

THE additions to the Zoological Society's Gardens during the past week include two tigers (*Felis tigris*) from Jahore, presented by Rear-Admiral Rowley Lambert, C.B.; two Javan Chevrotains (*Tragulus javanicus*) from Java, presented by Messrs. Hill and Isaac, Lieuts. R.N.; a Malayan Bear (*Ursus malayanus*) from Sumatra, presented by Dr. F. Wicksteed; a Phatagin Manis (*Manis tricuspis*) from West Africa, a Humboldt's Saki (*Pithecia humboldti*) from the Amazons, a Red and Yellow Macaw (*Ara chloroptera*) from South America, a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, deposited; a Concave Casqued Hornbill (*Buceros bicornis*), three Yellow-billed Blue Magpies (*Urocissa flavirostris*) from India, a Pin-tailed Whydah Bird (*Vidua principalis*) from West Africa, received in exchange; two Impeyan Pheasants (*Lophophorus impeyanus*) from the Himalayas, a Mantchurian Crossoptilon (*Crossoptilon mantchuricum*) from North China, purchased.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—At a Congregation on May 17, the Vice-Chancellor, the Master of Emmanuel, Professors Cayley, Adams, Clerk-Maxwell, Stuart; Messrs. P. Frost, St. John's; J. Todhunter, St. John's; H. W. Besant, St. John's; N. M. Ferrers, Caius; E. J. Routh, St. Peters; A. Freeman, St. John's; H. H. Taylor, Trinity; W. D. Niven, Trinity; R. T. Wright, Christ's; C. H. Prior, Pembroke; W. Garnett, St. John's; and Lord Raleigh, Trinity, were appointed a Syndicate to consider the higher Mathematical Studies and Examinations of the University.

The Chancellor's gold medal, given annually to a resident undergraduate who shall compose the best English poem, has been adjudged to Edmund Whytehead Howson, Scholar of King's College. The subject of the poem is "The Heroism of Arctic Exploration."

The Moderators and Examiners for the Mathematical Tripos have presented a report of the results of the examination to the Board of Mathematical Studies, from which it appears that 110 candidates were examined. Of that number 36 were classed as Wranglers, 29 as Senior Optimes, 30 as Junior Optimes, one obtained an Ægrotat degree, and 14 were found to be not worthy of mathematical honours. The full marks were 18,643; the average obtained by the first ten Wranglers was 5,748; of the last ten Wranglers, 1,794; of the first ten Senior Optimes, 1,506; and of the first ten Junior Optimes, 721. The Additional Examiner (Mr. H. W. Watson) reports that the work done by the best men in the higher physics was very satisfactory, and proved the interest and success with which those subjects are now being studied in the University. At the same time there were indications of the tendency of the reading in this part of the course to become too diffuse and unmathematical. This tendency may be kept in check, in the first place, by framing the papers in such a manner—whether by the adoption of alternative questions or otherwise—as shall make too diffuse reading in the higher subjects unprofitable or even impossible; and, in the second place, by providing that every question set in these subjects shall be accompanied by a rider of strictly definite mathematical character, and of a difficulty proportioned to the weight assigned to the bookwork.

The Board for admitting and superintending non-collegiate students give notice that an exhibition of 50*l*. a-year, tenable for three years, granted by the Worshipful Company of Clothworkers for the encouragement of proficiency in physical science, will be awarded by means of the Certificate Examination, to be held next December, under the authority of the Oxford and Cambridge Schools Examination Board. Candidates must be either non-collegiate students in their first term of residence, or persons who have not commenced residence in the University. Full information may be obtained from the Censor of non-collegiate students, the Rev. R. B. Somerset, Cambridge.

GILCHRIST TRUST PRIZES.—The first (in London) presentation of prizes in physiology under the direction of the Gilchrist Trustees was made on Tuesday, last week, at the large room of the Society of Arts. The chair was occupied by the Rev. J. Rodgers, M.A., Vice-Chairman of the London School Board, supported by Dr. Carpenter, C.B., F.R.S., secretary to the Gilchrist Trust Fund, and others. The prizes were awarded to students who, as elementary school teachers, had attended the course of lectures on physiology recently delivered by Dr. B. W. Richardson, at St. Thomas's School, Charterhouse, and who had submitted to the examination with which the course was brought to a close. A large number of students entered into competition, and in the end prizes and certificates were awarded in the following order to four competitors:—John Pilley, George Price, W. R. Cory, and Maria J. Menzies; and certificates to Mary C. Menzies and Messrs. C. E. Marks, C. W. Shreeve, H. Steadman, J. F. Adcock, and G. Garland. In the course of the proceedings Dr. Carpenter gave a very interesting account of the origin of the Gilchrist Trust and of its founder, and the chairman delivered a very earnest and admirable address on the progress of education and on the value of the lectures such as had been delivered, and which he had himself attended.

WORKING MEN AND SCIENCE.—On Saturday afternoon the members of the Working Men's Clubs, under the auspices of the Working Men's Club Union, paid a visit, by permission of the Royal College of Surgeons, to the magnificent museum founded by John Hunter, and attached to the building of the College in Lincoln's Inn Fields. Prof. Flower, the Curator, received the visitors, who were conducted into the first great hall, where Prof. Flower gave a general description of the Museum. The visitors manifested an unmistakably genuine interest in the collection, and in Prof. Flower's descriptions, and at the conclusion of the visit one of the party, on behalf of his comrades, gave hearty thanks to the Professor and to the Council of the College, for the treat which had been afforded to them, and said it was altogether a mistake to suppose that the working men took no interest in science. The Professor said it afforded him much pleasure to show the museum, and especially so when he found his labours thus appreciated.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 3.—"On the Temperature-correction and Induction-coefficients of Magnets," by G. M. Whipple, B.Sc., Superintendent of Kew Observatory. Communicated by Robert H. Scott, F.R.S.

"Distribution of the Radicals of Electrolytes upon an Insulated Metallic Conductor," by Alfred Tribe, Lecturer on Chemistry in Dulwich College. Communicated by Dr. Gladstone, F.R.S.

May 17.—"On Hyperjacobian Surfaces and Curves," by William Spottiswoode, M.A., Treas. R.S.

Royal Astronomical Society, May 11.—Dr. Huggins, F.R.S., president, in the chair.—A gift of 500*l*. was announced from Mr. C. J. Lambert, being part of the sum bequeathed by his late father to scientific societies. The special thanks of the meeting were voted to Mr. Lambert.—The Astronomer-Royal pointed out an inaccuracy in a description of meteors by a certain "J. W. M."—Mr. Penrose read a paper (and explained a diagram) on the correction for the spheroidal figure of the earth.—Lord Lindsay spoke upon the two comets B and C of 1877. Winnecke's showed three bright lines on a weak continuous spectrum which he described. The president made some remarks thereon: there were two distinct spectra shown by comets; one was limited to two particular comets; the carbon spectrum was common to all the rest.—Lord Lindsay described the 4-inch heliometer which he had placed at the disposal of Mr. Gill for his expedition to Ascension to measure the parallax of Mars. The object glass was made by Mertz, and cut and mounted as a heliometer by Repsold; the pillar and equatorial mounting being that provided by Messrs. Cooke, of York, for an 8-inch telescope. The halves of the object-glass were moved in circular grooves by means of a handle near the eye-piece, so that they could be separated without putting the object out of focus. Several other details were pointed out, one of them being a movable wire screen adapted to equalise the light of two objects of different brightness under measurement. Mr. De la Rue admired the stability and rigidity of the instrument. The Astronomer-Royal would have had the declination axis and the polar axis twice as large. Mr. Gill vindicated the steadiness of Lord Lindsay's heliometer, and described an accident by which it narrowly escaped being smashed; which accident occurred through the instrument having been represented as an "universal equatorial," whereas it was nothing of the kind; the elevating screw having run out whilst being set to the latitude of Ascension, the polar axis was shot out of its collar on to the floor. Mr. Gill then spoke upon the positions of the planets Ariadne, Melpomone, and Iris, and their special merit of having no sensible disc.—Dr. De la Rue again referred to the axes of the heliometer, which he said were eight times as strong as Repsold thought sufficient. The Astronomer-Royal said it was perfectly adapted to the purpose intended.—A note was read from Padre Secchi on an alleged fall of a meteorite in Italy which turned out to be untrue.—Mr. Lecky related how he had made a good artificial horizon by filling a blackened trough with glycerine.—A catalogue of double stars was presented by Messrs. Wilson and Seabroke, of the Temple Observatory, measured with a parallel wire micrometer and a power of 400. Mr. Dunkin said the only fault was the omission of the R.A. and N.P.D., which necessitated the use of two catalogues.—A note was read from Mr. Proctor referring to his chart of 3,976½ stars.—Mr. Green laid before the Society some paper impressed with blank discs to aid observers in drawing the features of Mars, so prepared that lights could be taken out with ease and precision.—Mr. Christie described Prof. Zenger's solar eye-piece, which consisted of a prism with one lenticular surface, cemented to another prism of different density; the quantity of light reflected at the junction being in proportion to the difference of the density of the two glasses.

Linnean Society, May 3.—Prof. Allman, F.R.S., president, in the chair.—Three foreign members were elected, and Mr. James Paton, of the Kelvin Grove Museum, Glasgow, was likewise elected an ordinary fellow.—Specimens of abnormal primroses were exhibited and commented on by Mr. Alf. W. Bennett.—A paper on the perfoliate penny-cress (*Thlaspi perfoliatum*) was read by Mr. G. S. Boulger. This little plant has a very limited British area, viz., the neighbouring districts of Oxfordshire and Gloucestershire, and according to our author Wilts; thus equally belonging to the Thames and Severn Valley provinces. The altitude attained is from 360 to 500 feet above the sea-level.—A conjoint memoir by Prof. St. G. Mivart and the Rev. R. Clarke on the sacral plexus and sacral vertebræ of lizards was brought forward and discussed. They stated that it has of late been recognised that in any attempt to reply to the question, which vertebra of any lower animal answers to the first sacral one of man, the nervous quite as much as the bone relations require consideration. Our authors pass in review the researches of Gegenbaur and Hoffmann, and then proceed to describe their own dissections of the parts in question in the chameleon, green lizard, iguana, monitor, and others. Instituting a comparison of the parts in the Batrachia, and of the sacral region in birds, they, in a somewhat technical summary, announce that although often puzzling and complicated from occasional variations in species and otherwise, the true sacral vertebræ may be defined in all vertebrates above fishes, where hind limbs are well developed.—The Secretary read a paper on the genus *Alveolites* and some allied palæozoic corals, by Prof. Nicholson and Mr. R. Etheridge, jun. It seems from their researches that the name Alveolites covers many forms whose affinities, to say the least, are obscure. Discussing the characters and essential attributes of the genus in a historical *résumé*, they proceed by comparisons, microscopic and otherwise, to define certain groups coming under previous definitions of *Alveolites*. These are several species of the above and others of genera such as *Cœnites*, *Brachypora*, *Chætites*, &c. But moreover they state that in several instance there appears much in common between certain groups of *Alveolites* and *Favosites*, so that future investigation may further necessitate the breaking down of what at present may be regarded as but meagre lines of demarcation.

Chemical Society, May 17.—W. Crookes, F.R.S., vice-president in the chair.—The chairman announced that an extraordinary general meeting would be held on May 31 at 8 P.M. The following papers were read:—On a slight modification of Hofmann's vapour density apparatus, by M. M. P. Muir and S. Suguira. The authors propose to omit the india-rubber plate of the original apparatus, and mark off the height of the mercury by a cathetometer and a slip of gummed paper.—Note on the fluid contained in a cavity in fluorspar, by J. W. Mallet. The cavity was 6 mm. by 2·5 mm. by 1 mm.; it contained water and a bubble. On heating, the bubble became less mobile and the crystal showed signs of incipient splitting.—Examination of substances by the time method, by J. B. Hannay. The author has determined the loss sustained by various hydrates in equal and successive intervals of time, when submitted, in a Liebig's drying tube, to a current of air at various temperatures, and thus obtains evidence of the existence of hitherto unknown hydrates. Magnesium sulphate, when treated as above, loses 8 per cent. of water in five minutes at 100° C.; the loss is then much slower and regular up to 29 per cent., when the rate of loss decreases somewhat suddenly from the formation of a lower hydrate, which loses water much more slowly.—On the dehydration of hydrates by the time method, by W. Ramsay. The author examined the hydrates of alumina, iron, copper, and lead.—On the transformation of aurin into rosaniline, by R. S. Dale and C. Schorlemmer; by heating sulphuric acid and pure phenol, and gradually adding oxalic acid, pure aurin is formed; by the action of ammonia on aurin, red aurin is produced, which, by the action of alcoholic ammonia at 150° for several days is converted into rosaniline. The authors consider aurin to be identical with rosolic acid.—On certain bismuth compounds, Part VI., by M. M. P. Muir. The author describes the preparation, &c., of hypobismuthous oxide, bismuthous oxychloride and oxybromide, and sulphbismuthyl chloride.—On the theory of the luminous and non-luminous flame by J. Philippson. The author states what he considers to be the causes of the luminosity and non-luminosity of flames.

Zoological Society, May 15.—Prof. Mivart, F.R.S., vice-president, in the chair.—Mr. Sclater made some remarks on the progress and condition of the Zoological Gardens of Rotterdam, Amsterdam, Antwerp, Brussels, and Ghent, which he had just visited.—A communication was read from Mr. G. S. Brady, C.M.Z.S., containing a monograph of the fossil Ostracoda of the Antwerp Crag.—A communication was read from Dr. F. Day containing a notice of the capture of a specimen of *Coregonous oxyrhynchus*, on the coast of Lincolnshire.—A communication was read from the Marquis of Tweeddale, F.R.S., containing a memoir on the birds of the genus *Batrachostomus*. The author came to the conclusion that there were seven recognisable species of this difficult group inhabiting the Indian region, one of which yet undescribed, was from the Philippines. The rule appeared to be that the females were rufous from the nest, while the males are brown and somewhat spotted.—Mr. Edward R. Alston read the description of a shrew from Guatemala, which had been indicated without being characterised by the late Dr. Gray, and for which the name of *Sorex veræ-pacis* was now proposed.—Mr. A. H. Garrod, F.R.S., read the second portion of a series of papers on the anatomy of passerine birds.—A communication was read from Mr. T. E. Buckley containing remarks on the past and present geographical distribution of the larger mammals of South Africa.

Entomological Society, May 2.—J. W. Dunning, F.L.S., vice-president, in the chair.—Messrs. H. J. Adams, Charlestrom, Adams, and J. W. Slater were elected members of the Society.—Mr. Jenner Weir exhibited a large silken cocoon from the Cape of Good Hope, supposed to be a spider's nest. On being opened it was found to contain, among other *débris*, the skins of a number of small spiders and the elytra of beetles of the genus *Moluris*. Mr. Weir also exhibited a spider's nest from Montserrat.—Mr. F. Grut exhibited a large species of *Chelifer* from North Spain.—Sir Sydney Saunders exhibited a spider (*Atypus sulzeri*) taken on Hampstead Heath, where it is found inhabiting tubes concealed under bushes. The tubes are about fourteen inches in length and extend about ten inches beneath the surface of the ground, the remainder projecting above the surface. The same or an allied species had been observed by Mr. Jenner Weir on the South Downs.—Mr. Champion exhibited a series of *Alaus pareyssi* from Thaso Island.—Mr. C. O. Waterhouse exhibited specimens of the following insects from Tasmania:—*Dohrnia miranda* (Heteromerous beetle), *Creophilus erythrocephalus* (*Staphylinidæ*), and *Forficula erythrocephala*. The two last species bore some mimetic resemblance to each other.—A paper was read from Sir Sydney Saunders on the adult larvæ of the *Stylopidæ* and their puparia, the author exhibiting specimens in illustration.—Mr. H. W. Bates communicated a paper on *Ceratorhina quadrimaculata*, Fab., and description of two new allied species. Specimens of the new species and also of *C. morgani*, Westw., were exhibited.

Physical Society, May 12.—Prof. G. C. Foster, president, in the chair.—The following candidates were elected members of the society:—Capt. R. Y. Armstrong, R.E., Mr. W. H. M. Christie, Lieut. N. Darwin, R.E., Prof. E. Frankland, D.C.L., F.R.S., Mr. H. F. Morley, Capt. R. G. Scott, R.E., and Mr. Angus Weiss. Mr. S. P. Thompson read a paper on the chromatic observation of the eye in relation to the perception of distance. He discussed the various means of estimating distances by the eye, showing that when data for forming a judgment by the associations of visible form or visible magnitude fail, the judgment is founded on "aërial perspective," or else upon the muscular sensation of adjustment to focus. As the eye is, however, not achromatic, it cannot be in focus at the same time for red rays and blue rays proceeding from one object, but may be in focus if the blue rays come from a more remote object. This gives a definite basis to the axiom of painters that blue is a retiring and red an advancing colour. Experiments were described demonstrating the truth of this fact, and illustration was afforded of the chromatic aberration of the eye by casting beams of light through a solution of permanganate of potash upon a silvered ball, the illuminated point appearing red with a blue surrounding halo to an eye adjusted to short focus, but blue with a red halo to long focus.—Prof. Guthrie referred to the theory by which the apparent size of an object depends on the amount of nervous excitement which it occasions, whether this be due to the extent of the illuminated area or the intensity of its illumination, and he pointed out that an object always appears larger when looked at with two eyes than with one eye.—Mr. Roberts drew attention to the fact that the system ordinarily adopted in mechanical drawing of assuming the light to fall from the left hand top-corner gives an appearance of solidity, whereas if this be reversed, and the light falls from the right-hand bottom corner the object appears hollow.—The president referred to the well-known fact that if two stereoscopic pictures are taken, representing the same object in complementary colours, most people have a great difficulty in combining them so as to see a single picture of a neutral tint.—Mr. S. P. Thompson then described a curious observation of change of pitch occurring when a tuning-fork is caused to rotate rapidly round its axis; the nodal interferences at each quarter rotation ceasing to be separately heard when recurring more than about thirty times in a second. He has attempted various ways of estimating the amount of this change of pitch, including a method founded on the binaural estimation of interference beats.

Institution of Civil Engineers, May 8 and 15.—Mr. George Robert Stephenson, president, in the chair.—A paper by Sir G. W. Armstrong, C.B., F.R.S., V.P. Inst. C.E., on the history of the modern development of water-pressure machinery was read.

Cambridge

Philosophical Society, May 7.—Prof. Clerk Maxwell, president, in the chair.—Mr. J. W. L. Glaisher read a paper on expressions for the theta functions as definite integrals.—Mr. Warren's fourth "Exercise in Curvilinear and Normal Coordinates" was presented to the Society by Prof. Cayley, and will appear in the next issue of the Society's *Transactions*.

Paris

Academy of Sciences, May 14.—M. Peligot in the chair.—The following papers were read:—Isoperimetric triangles having one side of constant size and the summit at a fixed point, by M. Chasles. Rotatory action of quartz on the plane of polarisation of obscure calorific rays, by M. Desains. He has examined the action of six groups of dark rays of decreasing refrangibility. The law of thicknesses still applies to the least refrangible rays. In the symmetrical dark region of nearly extreme violet the polarised heat is so little sensible to the action of quartz that transmission through a plate 0·015 m. thick, gives hardly a rotation of 5 degrees, or $\frac{1}{3}$ degree per millimetre. This is 132 times less than for the violet of M. Biot's table. M. Desains describes his apparatus fully.—Analysis of an ancient wine, preserved in a glass vessel sealed by fusion, by M. Berthelot. This was found on the site of an old Roman cemetery near Arles, and probably dates back some sixteen hundred years.—Analysis showed in a litre, 45 c.c. alcohol, 3·6 gr. fixed acids, 0·6 bitartrate of potash, 1·2 acetic acid. There were also tartrate of lime and traces of acetic ether. It is a weakly alcoholic wine, which must have entered on acetification before being put in the tube.—M. Serret presented tome vii. of the "Œuvres de Lagrange," completing the series.—On the new navigation, by M. Villarceau.—On the origin and nature of the fever called typhoid, by M. Guerin. The object of this third memoir is to show that the toxical principle produced by stercoral fermentation causes what are looked on as the anatomical characters of the fever. M. Guerin has proved that the liquids specially poisonous are those which accumulate near the end of the ileum, and are permanently retained by the ileo-cæcal valve. The poison passes into the mesentery and to the ganglions contained in it.—New exposition and generalisation of the method of Gauss for calculating approximately a definite integral, by M. Pujet.—New meteorological maps of the South Atlantic, giving at once the direction and the intensity of the winds, by M. Brault. The general movement of the summer winds there is that of an immense cyclone with its centre about 30° or 35° south latitude, and 10° or 20° west longitude. It turns in opposite directions to the hands of a watch, and gives off the south-east trades towards Africa, &c. There is not a zone of tropical calms, nor a zone of weak and arbitrary breezes.—On a new type of simple monstrosity, omphalocephaly or umbilical hernia of the head, by M. Dareste. The head seems to come from the aperture of the umbilicus. The form has been observed in the hen, but not in man or mammalia.—Experiments made at the vitreolar station of Cognac with the view of finding an efficacious remedy against phylloxera, by M. Mouillefert. This is in favour, specially, of sulpho-carbonate of potassium.—On a modification of the pneumatic mercury machine, by M. Serret. This consists in substituting a simple valve for the glass stopcocks. In another form, even the valve is suppressed, and vacuum obtained by free circulation of mercury in simple tubes.—On solar spots, by M. Tacchini. He thinks the sun's surface at present in a true state of repose relatively to the great phenomena observed at a time of maximum sun-spots. He shows the contrast in metallic eruptions and spots between 1871 and 1876 by figures. In the first four months of 1877, he adds, there has been a diminution in the visibility of magnesium, so that the line 1474 *k* has had a marked superiority.—On the otheoscope, (a new arrangement of the radiometer), by Mr. Crookes.—Direct transformation of mechanical work into electricity, by M. Guignet. In an electromagnetic machine, having six electromagnets and a drum with six bars of soft iron, the wires are connected with a galvanometer and the drum is rotated by the hand. A continuous current is thus produced, and it is reversed on reversing the rotation. This experiment also shows the induction taking place under the influence of the earth; the soft iron is magnetised, and the magnetisation increases with the speed of rotation.—Note on work in chemistry at the Polytechnical School of Rio de Janeiro, by M. Guignet.—On work of the School of Mines of Ouro Preto, by M. Gorceix.—On some monochlorised acids of the amylic series, by M. Demarçay.—On the salts of sesquioxide of chromium, by M. Etard.—Researches on pseudopurpurine; continuance of researches on the colouring matters of madder, by M. Rosenstiehl. The remarkable instability of pseudopurpurine (he says) is a happy circumstance; as neither it nor alizarine could give a plant the extraordinary importance of madder.—On an application of the microscope to ceramic art, by MM. Fouqué and De Cessac. This refers to vases found at Santorin.—On a new larval form of Cestoides, by M. Villot.—On granular conjunctivitis in Egypt; *résumé* of observations on ophthalmias of North Africa, by M. Gayat. Eye diseases are endemic in North Africa, and have their common origin in granular conjunctivitis, which is brought on by atmospheric and terrestrial conditions.—Treatment of hypopyon, by M. Fano.—On M. Maumené's gas hydrometer, by M. Dumas.—A new arrangement of the electromagnetic induction apparatus with automatic interruption, by M. Becquerel.—On the glaciers of Greenland, by M. Malland.

Rome

R. Accademia dei Lincei, April 15.—The Age of Bronze in the piles of Peschiera in the Lago di Gardo, by M. Ferri.—On the use of the reversed siphon in the ancient conduits of water, by M. Lanciani.

CONTENTS

THURSDAY, MAY 31, 1877

THE UNIVERSITIES BILL AND UNIVERSITY MOVEMENTS

THE monotonous progress of the Oxford and Cambridge Bill through the House of Commons has never been interrupted. The Government having drawn its measure, consents to modify it in a few trivial points, but wherever it does not consent, the House accepts it and passes it as an elementary matter of party discipline. Very few of the amendments are of serious importance. Lord Edmond Fitzmaurice has added perhaps the most valuable. He enables the Universities to give a definite status and payment for any special educational work done out of the University under its control. Thus the funds of Oxford and Cambridge may be freely used in support of their missionary efforts in the large and neglected towns of England. There is no reason why permanent educational centres should not be established under this clause in any part of England. Any College with too much money can assign a sufficient portion of it to the advancement of learning in the neglected provinces. Leeds, Bristol, Birmingham, Halifax, Sheffield have had university men lecturing in their midst under the University Extension Scheme, and Lord Edmond Fitzmaur ice's amendment invites the colleges to support and endow this movement. Under it the "idle fellows" who now run off to the bar will be drawn more and more into teaching, for teaching will open to them more and more of a career. No doubt there is risk that the possibility of such grants may paralyse local effort. But as yet it is only a possibility, and the colleges may be trusted to distribute their money only in places where adequate local effort cannot be expected. Another amendment by Mr. Trevelyan enables the Commissioners to review the conditions under which university emoluments can be given, especially those relating to age. There is no doubt that the age of undergraduates has increased, is increasing, and ought to be diminished. The honour man keeps back at his school as long as possible in order to make sure of getting his entrance scholarship. Even if the age at which entrance scholarships can be taken were restricted, honour men might in many cases delay so as to have a better chance after they come up of the scholarships and fellowships which are to be gained while in residence. It is reasonable to say that the work which a man is to do under the pressure of a prize examination *ought* to be over by twenty-one. What comes after is another matter. The competitions of the University imply a discipline which is admirable for youth "under tutors and governors," but which is merely fatiguing to men of mature intellect with serious objects in life.

A clause is to be brought up by Mr. Goschen on the report which provides that the Commissioners shall first publish the main outlines of their plans before they are allowed to apply them in detail. Certainly it seems odd that Parliament should consent to throw the whole of the questions affecting the Universities into the hands of any body of Commissioners without asking for some statement from them by which they may discover the general drift of their ideas and the character they propose to give their work. It is of great importance that before any one of them is dealt with the Colleges should know on what principles it is proposed to deal with all of them, and what are the objects to which, in the opinion of the Commissioners, the money taken should be applied. In an amusing letter to the *Pall Mall Gazette* a few days ago, Mr. Dodgson, of Christchurch, represents science at Oxford as first modestly asking endowment to enable her to teach, next claiming endowment for boys to be sent to her to be taught, and lastly demanding an endowment to enable her to "think." It is an amusing travestie of the claims of the more advanced and extreme "researchers," and it is natural to ask what is the view of the Commissioners on the subject.

Since Parliament separated for the Whitsuntide holidays two things have happened in Oxford, which indicate the drift of that University opinion which in the end controls the actions even of Commissioners. The first was the Oxford scheme for new professorships. It was an echo—certainly an exaggerated one—of a similar scheme proposed some time ago by some similar board of studies in Cambridge, and they both showed that the leading members of the two Universities are not indisposed to consider very large and radical schemes of reform. Both of them will give fresh strength to the party, more powerful perhaps in sympathy than in numbers, which is suspicious not merely of proposed researchers with nothing to do but "to think," but of possible professors with very few lectures to deliver, and still fewer students to hear them. It is the commonest and the most vulgar argument against such proposals that they are really drawn in the pecuniary interest of the class of actual and possible professors who are numerous in the Universities. The Hebdomadal Board shows us at any rate one distinct way in which it is possible to utilize the endowments of Oxford and Cambridge, and they put fairly before us the question whether it is not a better way than the prize fellowship system.

The second event of the past week was the discussion in congregation of the new resolutions on natural science degrees. It is proposed that instead of there being one kind of degree and only one—that in Arts—open to ordinary undergraduates, a new degree shall be created in Natural Science. The Bachelor of Arts has to pass three examinations, at which he has to show proficiency in Latin and Greek. It is proposed that the new Bachelor of Science should be let off with Latin or Greek, the missing classical language being replaced by German or French. The Bachelor of Science was meant to know more mathematics than the Bachelor of Arts, but the mathematical men have pressed the question whether mathematics itself is not a science, and whether mathematical honour men ought not to be let off as well as experimental men with one dead language. So far as things have yet shown, Oxford is in favour of the change, and eager to consider the case of the mathematicians. These are, in fact, the proposals of the Duke of Devonshire's Commission. We desire to speak with the greatest possible respect of those who maintain the *status quo* of the two classical languages, but it seems to us impossible to ignore the fact that the Greek learned by the pass man is about as much of a "possession for ever" as the Hebrew of most clergymen. It is begun late; it is not carried far enough to give the student any real pleasure in reading a Greek book for himself; it is thrown aside as soon as its use, which is solely a "pass" use, is over, and done with. Mr. Sidgwick says, with perfect fairness, that "the study of Greek is one thing, the knowledge of the *Alcestis* and the study of Mr. Bohn's translation of it another." That the University should have voted in this sense by sixty-three votes to forty, and expressed its desire to treat the mathematicians as entitled to a similar relief by twenty-seven to fourteen is a conclusive proof that the world moves even at Oxford. Many of those who are best acquainted with that University indeed declare that it is there only that it does move—at all events, that it is only there that it moves by "leaps and bounds," as British commerce used to do in the happy days of Mr. Gladstone's ministry! Certainly the votes of Oxford are often more liberal than those of London, and we cannot doubt that whenever the new Commission sets to work it will find as much impulse as obstruction from that great University. Of Cambridge itself it has ceased to be true to say that she maintains her usual attitude of magnificent repose. The universities are anxious to reform themselves if they only know how—the Commissioners will be happy to assist them if they only get power enough—and we may perhaps hope that a few "thinkers" may get something out of the reconstruction better than the very plain living with which their "high thinking" has hitherto been so commonly coupled.

THE NEED OF MUSEUM REFORM

FEW of the many subjects now pressing themselves on the attention of the public are more important than that of museums, of the work which they are doing now in general education, and what they may reasonably be expected to do in the future. It is one which has occupied my mind for many years, and on which I venture to offer the following remarks.

The collecting instinct, the desire to accumulate what strikes the fancy, is so universal in all minds lifted above the satisfaction of the mere animal needs, that its absence is to be viewed as an infirmity or misfortune analogous to colour blindness or deafness. It is present in some form or another in most savages, and even in some birds, such as the bower-bird. It is based ultimately on the principle of curiosity combined with that of selfishness. Poor and much to be pitied is the man who has it not. The collections which result from it bear the stamp of the individual who makes them, and are as various as his tastes. They may be conveniently termed museum units, which, like molecules, have a tendency to coalesce into bodies of greater or less size, and thus constitute museums. These are of high or low organisation according as the units keep or lose the stamp of the individual, and have been moulded into one living whole or are dissociated. They are highly organised and valuable if the parts are duly subordinated to each other and brought into a living relationship; they are lowly organised and comparatively worthless if they remain as mere assemblages of units placed side by side without organic connection and without a common life.

Unfortunately in this country the provincial museums mostly belong to this latter class. It is that which takes shelter for the most part in the top rooms of Mechanics Institutes and in the holes and corners of Free Libraries and Museums. In one instance which occurs to me, you see a huge plaster cast of a heathen divinity surrounded by fossils, stuffed crocodiles, minerals, and models of various articles such as Chinese junks. In another, a museum unit takes the form of a glass case containing a fragment of human skull and a piece of oatcake labelled "fragment of human skull very much like a piece of oatcake." In a third, wax models are exhibited of a pound weight of veal, pork, and mutton chops, cod fish, turnips, potatoes, carrots, and parsnips, which must have cost the value of the originals many times over, with labels explaining their chemical constitution, and how much flesh and fat they will make—just as if the public were unacquainted with those articles of food, and required any information as to what these names really cover. Strangely enough this museum unit appears modern. In very many museums art is not separated from natural history, nor from ethnology, and the eye of the beholder takes in at a glance the picture of a local worthy, a big fossil, a few cups and saucers, a piece of cloth from the South Seas, a war club or two, and very possibly a mummy. The result of such an association as this, of articles which have no sort of relationship with the rest, is to convert the whole into rubbish, using the word in the Palmerstonian sense of being "matter in the wrong place." I do not mean to say that museums of this low order are useless. In default of better they are useful, just in proportion as they encourage the collecting instinct in the beholders. They may ultimately arrive at the higher stage of development. It is, however, a reproach to this country that museums of this low type should be found at this time, not merely in the smaller towns, but in some of the more important centres of population. They constitute a serious blot on our educational system, which we are striving to make as perfect as possible, since they are worse than useless for purposes of teaching. Instead of the natural harmony of things, they put before the mind a fortuitous concourse of atoms which is a very chaos.

While this state of things prevails largely in this country, there is no room for astonishment that museums of natural history hold the position which they do hold in the public mind. They are looked upon as haunts of the mere specialist, and as altogether outside any scheme for the advancement of the higher studies. If they are sufficiently attractive to be visited, they are treated as places of amusement, in which "a happy day" may be spent, instead of places of instruction. They are sometimes avowedly arranged for that end. It rarely enters into any one's head that collections are as absolutely necessary for the advancement of natural history studies, as books to the literary student, though it is allowed on all hands that natural history is of great importance in general education. Until this anomaly be removed by the re-arrangement of the museums which require it, and the establishment of new ones, it is hopeless to expect the natural sciences to flourish as they should flourish, or for them to assume the importance which they deserve in the studies of this country. To the obvious remark that the fruits of English natural science are not worse than those of our neighbours, it may be answered that what has been done is the result of personal effort overcoming obstacles, and succeeding in spite of disadvantages. The fact that some men can swim does not render life-belts unnecessary for those who cannot.

Well-arranged museums of every kind are now an educational necessity in every highly civilised state, and everywhere excepting in our own they are put on exactly the same footing as libraries. They are to be seen in nearly every town of any pretension on the Continent, and in cities, such as Turin, Bologna, Lyons, Brussels, and Hamburg, they exist on a scale which is only rivalled by those of London. In the United States, also, and in Australia, their value to society at large is fully recognised. They are liberally supported and largely endowed. In no museum out of Britain have I seen the chaos from which our own are now painfully and slowly emerging.

There are many highly organised museums in Britain which perform their true function as repositories of knowledge, such as those at London and the Universities, those of Leeds, Liverpool, Bristol, Taunton, Exeter, Salisbury, and others. Their numbers must be largely increased if we are to hold our own in the race for knowledge with our neighbours on the Continent and our kinsmen in Australia and America.

W. BOYD DAWKINS

FOSTER'S "TEXT-BOOK OF PHYSIOLOGY"

A Text-Book of Physiology. By M. Foster, M.A., M.D., F.R.S., Prælector of Physiology, and Fellow of Trinity College, Cambridge. (Macmillan, 1877.)

PHYSIOLOGY, like most other sciences, has been making rapid strides within the last half century, and although scarcely yet to be classed among the exact sciences, the number of well-established facts which have been accumulated is not inconsiderable, and is in several cases sufficient to serve as a substantial foundation for the building up of more or less stable theories, and the enunciation even of tolerably fixed laws. Consequently it is to-day no longer necessary to urge the importance of the cultivation of physiological science as the basis of rational medicine. Not only is this fully recognised by the medical profession but there are distinct indications that the public in general is beginning to appreciate the importance of a correct knowledge of the normal processes which are going on within the body, preparatory to the recognition and cure of such deviations from the natural processes as constitute disease. And no wonder the science should be popular the object of which is to teach us how "we live and move and have our being!"

Students of physiology in this country have long needed an advanced text-book containing the leading facts and inferences of the science set forth at length and intelligibly, the statements and deductions which are less important or less clearly established being relegated to the background of small print, or even omitted altogether. The place of such a book was supplied in Germany by Hermann's "Grundriss der Physiologie," in every respect a model text-book, and one of which it is impossible to speak too highly; and it was hoped that the production last year of a translation of Hermann's work would meet the requirements of the English student. But whether simply from the fact of its being a translation or from other causes, certain it is that the book has not fulfilled the expectations which were entertained with regard to it. It is, therefore, a matter for sincere congratulation to physiologists that one in every respect so well qualified for the task as Dr. Michael Foster should have undertaken to provide what was so much needed in the way of a text-book, and also, it may fairly be added, to himself, that he should have brought the undertaking to so successful an issue.

Dr. Foster's aim in writing the book is best given in his own words:—

"I have striven to explain, in as clear and straightforward a manner as I could, the main facts and fundamental principles of physiological science. The student before whom things both new and old are tumbled out of the physiological treasury, without adequate critical appreciation of their respective values, is simply bewildered instead of being taught. . . . And it is the duty of the teacher to bring his pupil to that which is fixed and sure, without too much display or too much neglect of that which is uncertain and loose. . . . A desire to contribute, as far as my powers will allow, to the development of physiology in the medical profession has been my guiding principle in writing the book."

The style of treatment and the mode of thought pursued throughout are characteristic of the author, and serve to indicate the originality of the book, always one of the chief merits of a work of this sort. It is often thought that a scientific text-book need be little more than a museum of facts and opinions, carefully arranged and neatly labelled, to enable them the more readily to be "got up" by the student, in order that he may be able to satisfy an examiner with a narration of whatever has been stated or conjectured about any particular subject. Were this the case, the making of a text-book would be a mere matter of scissors and paste-brush, and the task could be performed by any one who was capable of reading the language of the science. That the idea is a wrong one is so self-evident that it would be waste of words to delay in refuting it. Even an elementary text-book is never so well done as when it is taken in hand by one who is a master in the science. There is a well-known instance in this particular science of physiology, and, in fact, it is to Huxley's "Lessons" that Dr. Foster wishes his book to be regarded as the sequel.

An indication of the original character of the book before us is to be found in the fact that it is not throughout equal. All the subjects are well done, but some are better treated than others, a result to be expected from the very extended nature of the science. No one—not even a Helmholtz—can pretend to an intimate personal acquaintance with all the branches of so ramified a science, and it is casting no slur upon the rest of the work to single out a section here and there, characterised by the especial clearness with which the known facts are stated and the phenomena are discussed and explained. The articles on the coagulation of the blood and on gastric and pancreatic digestion, and the chapter on the spinal cord, may be especially mentioned as illustrations of this.

Another and a more prominent indication of originality is occasionally met with in the descriptions of observable phenomena, facts being here and there noticed which are obviously the result of personal observation, and which have not hitherto so far as we are aware, been noted down. Thus in describing the phenomena of the heart's beat in mammals the contraction of the auricles is stated to be preceded by a peristaltic contraction of all the great veins which open into the heart. And there is no doubt that Dr. Foster is right in describing this as a distinct factor in the cardiac cycle.

The manner in which the nervous system is introduced to the student calls for special comment. In treating of the various phenomena of the circulation, respiration, secretion, &c,, frequent mention must necessarily be made of the relation of the nervous system to those functions. This pre-supposes a knowledge of the mode of origination and transmission of nervous impulses, and of the changes they may undergo in transmission, and hence of the fundamental properties of the nervous tissues. It might well, therefore, be deemed proper to commence a work on physiology with the account of a system which, in the higher animals at least, dominates and directs all the other functions. But on the other hand, from its greater intricacy, it is found in the teaching of physiology by far the most convenient plan to defer the account of the nervous system until the simpler, and more obviously physical phenomena of the living body have been dealt with.

Dr. Foster has got out of the dilemma in an ingenious and effectual manner. For whilst the account of the central nervous system and its principal instruments—the sense-organs—are reserved for one of the concluding chapters of the book, a short exposition of the fundamental properties of the nervous tissues, and also, but in very general terms, of the special functions of the chief nervous centres, is introduced at quite an early stage—a mode of dealing with the subject which enables such important questions as the influence of the nervous system upon the heart, respiration, secretion, &c., to be discussed at length with their respective subjects in place of being deferred until the end of the book. We are not sure that this introduction to the nervous system might not with advantage have come in even earlier than it does; as a sequel, in fact, to the chapter with which the work is introduced.

We quote a few passages from the prefatory article on the fundamental properties of the nervous system as yielding an illustration of the gradual, easy way in which Dr. Foster leads up to a difficult subject :—

"In its simplest and probably earliest form a nerve is nothing more than a thin strand of irritable protoplasm, forming the means of vital communication between a sensitive ectodermic cell exposed to extrinsic accidents, and a muscular, highly contractile cell (or a muscular process of the same cell) buried at some distance from the surface of the body, and thus less susceptible to external influences. If in hydra we imagine the junction of the ectodermic process with the body of its cell to be drawn out into a thin thread (as appears to be the case in some other hydrozoa), we should have just such a primary nerve. Since there would be no need for such a means of communication to be contractile and capable of itself changing in form, but on the other hand an advantage in its remaining immobile, and in its dimensions being reduced as much as possible consistent with the maintenance of irritability, the primary nerve would in the process of development lose the property of contractility in proportion as it became more irritable, *i.e.*, more apt in the propagation of the waves of disturbance arising within the ectodermic cell.

"We have already seen (introductory chapter) that automatism, *i.e.*, the power of initiating disturbances or vital impulses, independent of any immediate disturbing event or stimulus from without, is one of the fundamental properties of protoplasm. In simpler but less exact language, such a mass of protoplasm as an amœba, though susceptible in the highest degree to influences from without, 'has a will of its own.' . . . . A hydra has also a will of its own; and seeing that all the constituent cells are alike, we have no reason for thinking that the will resides in one cell more than in another. . . . In both hydra and amœba the processes concerned in automatic or spontaneous impulses, though in origin independent of, are subject to and largely modified by, influences proceeding from without . . . .

"The next step of development beyond hydra is evidently to differentiate the single (ectodermic) cell into two cells, of which one, by division of labour, confines itself chiefly to the simple development of impulses as the result of stimulation, leaving to the other the task of automatic action, and the more complex transformation of the impulses generated in itself. The latter, which we may call the eminently automatic cell, will naturally be withdrawn from the surface of the body, while the other, which we may call the eminently sensitive cell, will still retain its superficial position, so that it may most readily be affected by all changes in the world without. And just as a primary *motor* nerve arises as a retained thread of communication between a sensitive cell and its own muscular process, so a primary *sensory* nerve may be conceived of as arising as a thread of communication between an eminently sensitive cell, and its twin the eminently automatic cell. . . . . Naturally the muscular process or muscular fibre would, on the splitting of the original single cell, remain in connection with the most eminently automatic. We thus arrive at that triple fundamental arrangement of a nervous system in its simplest form, viz., a sensitive cell on the surface of the body connected by means of a sensory nerve with the internal automatic central nervous cell, which in turn is connected by means of a motor nerve with the muscular fibre-cell. . . . ."

In the introductory chapter of the book the physiological processes which occur in the amœba are described, and these are taken as the basis upon which the whole superstructure of the science is to be built up. This is a wise course to pursue, for in a work on physiology the amœba cannot have too prominent a place assigned to it. It is over the amœba that the battle of physiology must eventually be fought out.

The chief organic compounds met with in the animal body are considered together in an appendix, which has evidently been carefully drawn up, and will be found not the least useful portion of the book. It is, no doubt, an advantage in many respects to have a series of similar facts thus collected and put on one side for reference. At the same time it may be questioned whether in the case of some of the bodies which have been relegated to this situation—the constituents of the blood and urine, for example—it would not have been better rather to have awarded them somewhat greater prominence in the parts of the book which treat of the special fluids or secretions in which they occur. A frequent reference to the appendix in such places might answer the purpose.

It is pleasant in a book of this sort to be able to find so little that is open to adverse criticism. It is true the latter part of the work bears traces of haste, and one or two important subjects are somewhat lightly dealt with. Moreover here and there statements which are anything but "fixed and sure" are to be found clothed in large type, while others, which are based upon a large number of exact experiments (the observations of Ludwig and

Woroschiloff upon the paths of conduction in the spinal cord, for example), are confined to small print. Exception might also be taken to the somewhat dogmatic decision of an undecided question, such as that of the cause of the pulse-dicrotism. And it may be doubted whether the introduction, if not of pictures, at least of a greater number of diagrams, would not render some of the subjects easier to the comprehension of the student. But looked at as a whole, the book must be pronounced thoroughly well done, admirably adapted for its purpose, and creditable alike to its author and to the science which it is intended to promote. E. A. SCHÄFER

WEISBACH'S "MECHANICS OF ENGINEERING"

A Manual of the Mechanics of Engineering, and of the Construction of Machines, with an Introduction to the Calculus, by Julius Weisbach, Ph.D. Vol. I.—Theoretical Mechanics. Translated from the Fourth Augmented and Improved German Edition, by Eckley B. Coxe, A.M. (London: Trübner and Co., 1877.)

THERE is, perhaps, no book on mechanics so well suited to the wants of civil and mechanical engineers as the late Dr. Weisbach's "Lehrbuch der Ingenieur und Maschinen-Mechanik." In his preface to the first edition of his work the author thus stated his design (we quote from the translation before us):—

"My principal effort has been to obtain the greatest simplicity in enunciation and demonstration, and to treat all the important laws in their practical applications without the aid of the higher mathematics. If we consider how many subjects a technical man must master in order to accomplish anything very important in his profession, we must make it our business as teachers and authors for technical men to facilitate the thorough study of science by simplicity of diction, by removing whatever may be necessary, and by employing the best known and most practicable methods. For this reason I have entirely avoided the use of the calculus in this work. Although at the present time the opportunities for acquiring a knowledge of it are no longer rare, yet it is an undeniable fact that unless we are constantly making use of it, we soon lose that facility of calculation which is indispensable; for this reason so many able engineers can no longer employ the calculus which they learned in their youth. As I do not agree with these authors who in popular treatises enunciate without proof the more difficult laws, I have preferred to deduce or demonstrate them in an elementary, although somewhat in a roundabout manner."

Weisbach was severely censured by some people for attempting to treat his subject without the higher mathematics, but he kept to his own way, saying that he intended his work not as a university text-book, but only for "practical men." In the later editions of his work, however, he gave additional demonstrations of some of the laws by the differential and integral calculus, on which he also added an introductory chapter, which surpasses in clearness anything we have seen on the subject. In judging of Weisbach's method we must not forget that few men had so much experience in teaching practical engineers, and that no one had a better knowledge of what such men really require; and we must at least acknowledge that, although in some few cases he may have carried his system too far, and have sacrificed scientific exactness of expression to mathematical simplicity, if he erred, he did so on the right side. Most English authors of books on mechanics and kindred subjects seem to forget how small is the amount of mathematical knowledge possessed by the average engineer. In the rising generation of engineers this is no doubt changing for the better, but there are still many in this country—men of ability and men who have executed works which do credit to the nation—whose ideas of the differential and integral calculus are vague in the extreme, and it is satisfactory that there is at last a standard work for their use.

The work appeared originally in two parts. The first "Theoretische Mechanik," and the second, "Statik der Bauwerke und Mechanik der Umtriebsmaschinen." To these was afterwards added a third, "Mechanik der Zwischen und Arbeits-Maschinen." The volume before us is a reprint of an American translation of the fourth German edition of the "Theoretische Mechanik." This edition was published in 1863. In 1875, after the author's death, a fifth edition was issued, which differs to a small extent from the fourth. It contains a chapter on springs, taken principally from Reuleaux's "Construction und Berechnung der für den Maschinenbau wichtigsten Federarten;" another on the general principles of dynamics, also, in the Appendix, "The Elements of Graphical Statics," none of which are in the fourth edition. We regret that the chapter on graphical statics was not added to the translation. The graphical method seems likely to come more generally into use, and a short introduction to it, giving the general rules for its application to statics, and showing the manner of using it, would have added to the value of the book.

Mr. Coxe has done the work of translation carefully, and, on the whole, well. He has avoided the blunders made by the author of the former translation, and he has given a faithful rendering of the German. He uses, however, many terms which are not in use in this country, and we are sorry that they are far from being improvements. He talks, for example, of the centre of gravity of lines and geometrical figures, of "living forces" (surely *vis viva* was quite bad enough), &c. There is room for difference of opinion as to whether Mr. Coxe has done wisely in retaining the various tables in the book on the metric system

This translation is wonderfully free from misprints, and most of those which do exist are quite apparent. On p. 479, for example, we find the following:—"REMARK.—Under the supposition that the proof strength increases and decreases with the ultimate strength, the English engineers increase the size of that portion of cast-iron girders which is subject to *compression*," &c. (the italics are ours). On p. 121, § 21, $v = \frac{\sigma}{\tau}\left(\frac{ds}{dt}\right)$ should be: $v = \frac{\sigma}{\tau} = \frac{ds}{dt}$, and "The element of time $\tau\,(dt)$" should be: The element of time $\tau = dt$. On p. 291, § 157, we have: "From this we obtain $QR = \overline{UR}.\tan.\phi = \overline{OR}$." Then on the line below "$\frac{y}{b}\,.\,\frac{V}{H}$, which is the difference," &c. This should be $QR = OR.\tan.\phi = OR.\frac{y}{b}\,.\,\frac{V}{H}$.

Weisbach's name is known in this country principally in connection with hydraulics. In this branch of mechanics he was a most laborious experimentalist, and he obtained many valuable results, many of which are incorporated in the work before us. In this first volume of his work the discharge of water is very fully treated. Unfortunately, however, his so-called theoretical formulas belong to the same category as those which Prof. James Thomson of Glasgow showed in his paper, read before the last meeting of the British Association, to be founded on assumptions which are not in accordance with known hydrodynamic principles.

On page 851 of this translation there is a formula to which we would draw attention. It is taken from "The Lowell Hydraulic Experiments," by J. B. Francis, and is for the discharge of water over a weir. This formula is "$Q = 3{\cdot}33\ (l - 0{\cdot}1\ nh)h^{\frac{3}{2}}$ English cubic feet, in which h denotes the head of water above the sill of the weir, l its length, and n either 0 or 1 or 2, according as the contraction of the vein is prevented upon both, one, or none of the sides." Prof. Thomson, in the above-mentioned paper, referred to this formula as identical, in its general form $a\,(l - \beta\,n\,h)h^{\frac{3}{2}}$, with the one which he had deduced from known principles as the true theoretical formula. Mr. Francis put it forward merely as an empirical formula which agreed with the results of his experiments, and it is curious that he should have made a guess which turned out to be more in accordance with the true theory, than all the previous so-called theoretical formulas, which had been advanced and sanctioned by the best authorities.

PATRICK EDWARD DOVE

OUR BOOK SHELF

A General Dictionary of Geography, Descriptive, Physical, Statistical, Historical; forming a Complete Gazetteer of the World. By A. Keith Johnston, F.R.S.E. New edition, thoroughly revised. (London: Longmans and Co., 1877.)

THE title of this work is somewhat misleading. The "physical" and "historical" elements are so meagre that they are scarcely worth mentioning as features of the work. To call this a "*complete* gazetteer of the world" is a misuse of the term "complete;" *incomplete* would have been more accurate. Even on the scale of the present work it would take a gazetteer at least three times its size to contain anything like a register of all the places one would naturally expect to find in a "complete" gazetteer. The work includes a selection of the more important places in the world, very few towns, for example, out of the United Kingdom being given, whose population is under 1,000. We find no fault with the publication of a selective gazetteer, but it should not pretend to be more than it is. When compared with Ritter's well-known work, *e.g.*, the proportion of places found in the latter as compared with "Johnston" is something like five to one. We believe a service would be done to the public by the issue of a gazetteer containing simply all the names omitted in "Johnston." It is not for well-known places we turn up a gazetteer, but for names that one seldom hears. During these Eastern troubles, how many names of places not to be found in "Johnston" have become of great importance, and during the war just begun how many more are likely to come prominently into notice? On the other hand, much valuable space is occupied with catalogues of streets and public buildings in the articles devoted to well-known places like London, Edinburgh, Paris, Vienna, &c. All that can be said about public buildings and similar features of a town in a gazetteer of this scale is practically useless; the space would be used to much better purpose by an enlargement of the list of names. In Russia, for example, nearly all "towns" and "villages" seem to be omitted. many of them with thousands of inhabitants, only "district towns," as a rule, being given. Poland and Finland are also very unsatisfactory; in fact these countries have never been properly "gazetteered" even in Russia. In several instances the "latest" information has evidently not been obtained. To get it, indeed, would involve a vast amount of research among official publications and travellers' narratives, but in a standard work such research is demanded. In Switzerland, we are informed by a Swiss friend, much of the information is half a century behind date. Under Chaux-de-Fonds, *e.g.*, the statement with regard to the manufacture of chains for the movements of watches has not been true for at least thirty years; and there is no lace now made at St. Imier. To arrange the wealth of information published by the United States Survey alone would involve much time and labour; we fear that for the new edition this has not been thoroughly done. Nearly two years ago Mr. W. H. Dall, of the United States Coast Survey, published a Report on the mountains in the Alaska territory. Yet no use has been made of this Report though it is quite accessible. For Mount St. Elias the height in the English Admiralty Chart, 14,970 feet is given, instead of upwards of 19,000 feet, obtained by the careful measurement of the United States Survey in 1874. The height of Mount Fairweather is set down as 14,708 (1855) instead of 15,500 (1874); Mount Crillon 13,500 instead of 15,900; Mount Cook 16,000, Mount La Perouse 11,300, and Mount Vancouver 13,100 feet, are not given. Such imperfections make one doubt if this new edition has been "thoroughly revised." It is easy to give information contained in census tables and in other gazetteers and guide-books, but even a work on the limited scale of the present cannot be made throughout trustworthy without very considerable trouble being taken.

Zoological Classification. By F. C. Pascoe, F.L.S. (John Van Voorst, 1877.)

THIS small work will be found particularly serviceable to many working naturalists. It is a concise compilation of the sub-kingdoms, classes, and orders of the animal kingdom, with lists of the families and most important genera. Specialists will be able to find fault with some of the details in many cases, nevertheless we know no volume which, in the space, contains so much reliable information. The larger groups are all succinctly defined, with many of the most modern views incorporated; and these definitions extend to the orders. Taking the mammalia for criticism, we regret to find the Sirenia included with the Cetacea, the Musk Deer with the Chevrotains, the Peccaries with the true Swine, and the Camels between the Giraffe and the other typical ruminating animals. The caecum is not "enormous" in Hyrax. "Whatever gaps there may be at the present day" between the Perrissodactyla and Artiodactyla "are *not* nearly all filled in by numerous extinct forms." Such errors may be found in many places; they do not, however, much detract from the general value of the work, which will be found more valuable as a basis for annotation, than a book of reference. There is a very complete index we are glad to say.

Tracts relating to the Modern Higher Mathematics. Tract No. 2, Trilinear Coordinates. By Rev. W. Wright, Ph.D. 77 pp. (London: Messrs. C. F. Hodgson and Son, 1877.)

DR. WRIGHT is, or was until quite recently, Professor of Mathematics at Wilson College, Pennsylvania. His object is to make his countrymen acquainted with certain branches of modern mathematics, and we learn that his first venture (Tract No. 1, *Determinants*) has met with considerable acceptance in the American universities. M. Hermite, too, has expressed himself well pleased with the author's standpoint, "Une grande transformation s'est déjà faite et continue encore de se faire dans le domaine de l'analyse; des voies nouvelles plus fécondes, et je crois aussi plus faciles, ont été ouvertes, et c'est l'œuvre de ceux qui veulent servir la science et leur pays de discerner ce que les éléments peuvent recevoir de l'immense élaboration qui s'est accomplie depuis Gauss jusqu'à Riemann."

There is in the present tract a clear exposition of the elementary applications of Trilinear and Triangular Coordinates, and just a passing glance at Polar reciprocals.

In such a work we do not look for anything original, but for clearness and correctness. These ends, we think, have been attained, and we wish Dr. Wright health and leisure to enable him to carry out his design.

Grundriss der chemischen Technologie. Von Dr. Jul. Post. (Berlin: Robert Oppenheim, 1877.)

DR. POST, who is known to chemists as an able Privat Docent at the University of Göttingen, has, like many other teachers, felt the great necessity of a manual of chemical technology, suited to the requirements of students who desire a general training in that branch of applied chemistry. A considerable number of excellent treatises, as, for example, those of Knapp, Wagner, Bolley, Kerl, and Stohmann, already exist in German, and some of them have been translated into English, but no one of them is exactly adapted to the class-room. Their excellence consists in their completeness as works of reference; indeed as such they may be said to be invaluable to the chemical manufacturer; but the mode of their arrangement renders them of comparatively little value as aids to systematic study. Dr. Post has succeeded in producing a work which, within the compass of some of our smaller chemical manuals presents a complete outline of the present position of chemical technology. His book thus serves as a fitting introduction to the larger and more special treatises above mentioned.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

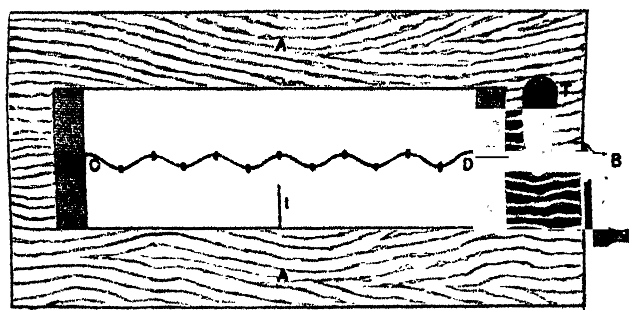
Colour-Sense in Birds

I HAVE been lately watching, with great delight, two goldfinches building their nest. They placed it nearly at the end of an outside branch of a young sycamore tree, so that there was nothing but sky above it, and the gravel path below. The window from which I observed them, being never opened, and well covered with flowers in pots and a blind, seems to have caused them no alarm, although not more than two yards distant from them; and their object appears to have been to make their nest invisible from below. To this end they chose their building materials with such skill and such colour-matching power that if one had not seen the nest built it would be quite impossible to discover it; to match the tree they took its long flexible blossoms, and to match the sky the equally long and flexible stalks and flowers of the garden forget-me-not, of which a bed was close at hand in full bloom. I watched them carefully, and, as far as I could see, they used no other materials than these flowers, though I saw one of them *attempting* to get the dirty-white cotton tie off a budded rose-tree. At all events the nest was mainly built of them. The blue of the forget-me-not has of course faded, but the general effect from below is that of a scarcely visible grey-green thickening of one of the bunches of sycamore leaves. They seemed to enjoy flinging their flower-wreaths about. And that leads to the question whether birds—who are in many ways like children—do not often out of mere playfulness and love of colour, pull to pieces yellow crocuses and other bright flowers. While my pen is in my hand I may mention, with reference to Dr. Muirhead's communication on the subject of noise causing a sensation of colour, that I have frequently observed whilst tuning a harp, that the sudden breaking of a string will cause a curious *taste* and sensation in the mouth, like that produced by a piece of silver and one of zinc placed above and beneath the tongue, when they are made to meet. J.

A Simple Wave-Motion Apparatus

IT has been suggested to me that I should publish a description of a simple and portable wave-motion apparatus, devised by me a year or two ago, which has given satisfactory results to others as well as to myself. I therefore send the description.

In the figure A A represents an ordinary wooden lantern slide, with a rectangular aperture, which may vary in size according to the size of the lantern condensers, the sketch being half size for 4-inch condensers. A small winch, B, is fitted into the slide at one end of the aperture, and held in its place by the tongue, T. The spindle, B D, is milled or otherwise roughened near the end, D. A brass stud similar in shape to the milled end of the spindle, but *smooth* and slightly smaller, is fixed in the opposite side of the aperture at C. A helix of 25-gauge hard brass wire is wound on a spit of the same size as the smooth stud, taking care to wind the coils close together; about fifteen turns of the helix are cut off, and the middle five turns drawn out till they form a perfect wave similar to the figure when held up to the light. The length of the helix should then be the same as C D. One end of the helix is pushed tight on the milled end, D, and the other end is slipped loosely over the stud, C, so as to work



on it like a swivel, to keep the end of the helix true when the winch is turned. A little bead of wax is melted on each crest and hollow of the wave to represent particles, and the essential parts of the apparatus are complete. On placing it in front of the lantern, and focussing, a distinct and striking image of a moving wave with its vibrating particles is produced by turning the winch.

If the helix is not perfectly straight the image of the wave will rise up and down more or less as a whole; the helix should then be straightened or "set" with the fingers till true. When once set thin glass plates may be placed on each side to protect it from injury. An index, I, of wire, may be fixed so as to give a means of proving that the particles *only* move up and down.

A modification I have tried by using a dark wire with bright silver beads, on a velvet back-ground in the aphengescope, is more difficult to make and use. I therefore prefer the apparatus as sketched above.

Of course the amount of finish depends on the taste of the user, &c. A pasteboard frame instead of mahogany, a wire bent twice at right angles instead of a finished brass winch, and tied to the frame by two bits of wire instead of let in, &c., may be used, thus reducing the cost to a few halfpence.

In use it will recommend itself. W. JESSE LOVETT

Birmingham

Atmospheric Currents

A CONTROVERSY was recently waged in your columns as to the course which is pursued by the hot water-laden air of the equatorial regions in its journey to the poles. Both combatants seem to adopt what I may call the sheet-theory, which regards the winds as moving in sheets or strata, and gliding over and under each other at the polar and equatorial sides of the calms of Cancer and Capricorn, a process which would inevitably result either in both opposing winds being torn to tatters, or in their commixture and neutralisation. Surely the truth is that like all other moving fluids, the air will seek equilibrium in the direction of least resistance, and will carve out for itself wide channels in accordance with local conditions from the poles to the equator, and from the equator to the poles—channels which will not intersect or interfere with one another, except when affected by disturbing causes.

One possible cause of change in this direction of least resistance or normal channel in the case of the south-west wind of these latitudes may possibly be a shifting of the thermal pole. Suppose, for instance, we have any reason to surmise that the centre of greatest cold is now on the American side of the true North Pole and at another time on the Asiatic side, we have at once a satisfactory explanation of observed variations in the prevalent direction of the main channels of the water-laden winds of the northern hemisphere.

I will now as briefly as possible state my reasons for suspecting that such is actually the case.

Since 1873 the south-west winds have prevailed very considerably over the average in Europe, and as a natural consequence we have had continued floods all over the west of this continent. In Asia, during the same period the water-laden winds have been fearfully under the average, the rainfall during the last three years having been about nine inches below the average of the previous half-dozen. Famines, of course, have been the result.

If my theory is correct we should expect to find that the thermal pole has been situated during the last three or four years on our own side of the North Pole.

Now in 1872 Capt. Hall, of the *Polaris*, saw unmistakable signs of an open polar sea where Capt. Nares, in 1875, saw nothing but a vast wilderness of ancient ice. In a former letter of mine which appeared in NATURE (vol. xv. p. 116) I attempted to reconcile these apparently conflicting observations on the supposition that this palæocrystic wilderness is in reality a vast floating island of ice some hundreds of miles in diameter. I called to mind Sir E. Parry's disappointing experiences in 1827 in the *Hecla*, when, after a toilsome journey northwards on what he believed to be the main pack, he found he was after all drifting southwards; whereupon he concluded his supposed main pack must be a loose floe of immense extent.

Is it not equally probable, to say the least of it, that he was on the main pack—on the palæocrystic island—and that he caught it on the move towards our shores of the Arctic Sea?

Be this as it may (and it is merely a suggestion) it is certain that five years later occurred the terrible famine of 1832 in India, and five years is just the time required, according to Dr. Hunter, for the effects of the proximate cause of drought (whatever that may be) to attain its maximum, according to the law of the "multiplication of effects."

Although I have examined the records of the winds at the Meteorological Office, I will add nothing more, as I fear I have already exceeded my proper limits.

WORDSWORTH DONISTHORPE

Yellow Crocuses

A LETTER in NATURE (vol. xvi. p. 43) calls attention to the destruction of the flowers of the yellow crocus by the sparrow. I have for many years been a cultivator of the crocus, both yellow, white, and purple; this spring they flowed abundantly, the white and purple blooming undisturbed, the yellow picked and torn. My gardener and I talked the matter over but could find no solution of the problem. As this has been my experience in former years, and the fact is now corroborated by general experience, can no naturalist discover the reason, or must it still be left a secret in the bosom of pert little *Fringilla domestica*? A. H.

Complementary Colours

IN connection with this subject, which was referred to in Mr. Terrill's letter in NATURE for May 17, perhaps the following homely way of illustrating the fact that the combination of two complementary colours produces white may interest your readers. If a tumbler of beer be held in front of the green glass shade of an ordinary reading lamp, it will be found on looking through the beer at the shade that the tumbler appears to be filled with an almost colourless liquid. J. ROMILLY ALLEN

Chromatic Aberration of the Eye

THERE is a slight inaccuracy in your report of my communication of May 12th to the Physical Society, wherein I am made to affirm that a blue object and a red object cannot both be in focus at once unless the blue object be the more distant. The next sentence of your report, and indeed the whole tenor of my communication imply the reverse condition, that the blue rays should come from the *less* distant source. The dispersion of the eye takes place in the same sense as its refraction; hence the adjustment of the eye to focus may be the same for blue rays proceeding from a body near the eye as for red rays proceeding from an indefinitely distant luminous source; as, indeed, Fraunhofer proved half a century ago. S. P. THOMPSON

University College, Bristol, May 25

A Correction

PERMIT me to explain that the subject of my note, read at the last meeting of the Astronomical Society, was not my chart of 324,912 stars, though I had occasion in the course of it to mention that chart. My note referred in reality to a paper read at the preceding meeting, and relating to the general subject of the distribution of stars in space. RICHARD A. PROCTOR

DR. PHILIP P. CARPENTER

WE regret to announce the death at Montreal, in his fifty-eighth year, of Dr. Philip P. Carpenter, formerly of Warrington, one of the most scientific conchologists of our time. Taking up this pursuit, in the first instance, merely as a recreative occupation, he was led by his friend, Dr. J. E. Gray, who saw his remarkable aptitude for it, to make it one of the principal objects of his life; and he brought to it a mind trained in those scientific habits which prevented him from ever becoming the mere species-monger, whilst specially delighting in that study of minute detail which is required for the true determination of specific types and their geographical distribution. It was well observed by Dr. Hooker, in his introductory essay to the "Flora of New Zealand," that "a wider range of knowledge and a greater depth of study are required to prove those dissimilar forms to be identical, which any superficial observer can separate by words and a name;" and this wide range of knowledge and thoroughness of research were the essential characteristics of all Dr. P. P. Carpenter's conchological work. The opportunity having occurred to him more than twenty-five years ago, while residing at Warrington, of studying a large collection of shells formed at Mazatlan, in California—after Mr. Cuming had selected from it what he considered the new specific types, which he caused to be described by Mr. C. B. Adams—Dr. P. P. Carpenter was impressed with the fact that Mr. Cuming had left behind him those *intermediate* forms, the study of which would prove that many of his supposed species are mere varieties; and having brought the importance of such study before the Zoological Section of the British Association, he was requested to prepare a report on the present state of our knowledge with regard to the mollusca of the west coast of North America, which was published in the *Transactions* of the Association for 1856, and at once took rank as a most able and conscientious work. A Supplementary Report on this subject, marked by the same "wide range of knowledge and depth of study," was published in 1863. Besides these, several monographs, prepared by Dr. P. P. Carpenter on particular groups of shells in the Cumingian Museum, were published in the Zoological *Proceedings*. So high was the reputation which his Reports acquired for him among American naturalists that he was invited by Prof. Henry of the Smithsonian Institution at Washington to assist him in the arrangement of its national collection of shells; and having been led in 1865 to take up his residence in Montreal, he was subsequently engaged in similar work for other museums in the Northern States. He soon acquired in the city of his adoption the character he had left behind him in Warrington, of being ever ready for any kind of philanthropic labour; and especially distinguished himself by his untiring advocacy, through evil as well as good report, of the sanitary reforms which he saw to be greatly needed. There is reason to believe that the typhoid fever which brought his useful life to a close was engendered in the foul air of the building in which he was accustomed to carry on his scientific work.

KOENIG'S TUNING-FORKS AND THE FRENCH "DIAPASON NORMAL"

HAVING had occasion to measure a series of Koenig's tuning-forks, kindly lent me for that purpose by Professors Tyndall and Guthrie, by means of Appunn's tonometer, now in the South Kensington Museum, I was much struck, and for a time puzzled, by finding that though the forks were perfectly consistent with each other, they did not answer to their names, that is, the numbers of single vibrations marked on them, did not answer at all to the double vibrations measured by Appunn's tonometer. The workmanship of Koenig's forks is so good and the intervals between them so exact, that one might be at first inclined to suspect the accuracy of the absolute numbers of the reeds on Appunn's instrument. But there can be no doubt of the accuracy of the differences of the number of vibrations between any reed and any other, for these admit of ready control by counting, and I have counted them all. Hence such a thing as this is quite certain. The difference of the vibrations of C 256 and G 384 is 128 vibrations, as on Appunn's instrument; but the difference in the vibrations of Koenig's corresponding forks is 129·2 vibrations. Now, I have no doubt about the perfection of Koenig's fifth C to G. If then his C make x vibrations, his G makes $x + 129{\cdot}2$ vibrations. Putting this $= \frac{3}{2}x$, we obtain $x = 258{\cdot}4$ as the number of the vibrations of his C, and this is the precise number furnished by Appunn's tonometer, according to a very careful measurement made by Mr. A. J. Hipkins, of Messrs. Broadwoods, who has had great experience in counting beats, and myself. The discrepancy, therefore, becomes an excellent proof of the perfection of Appunn's instrument. But how could Koenig have hit on this strange number 258·4, in lieu of 256? It was some little time before the solution presented itself to my mind, but I believe that this, which is decidedly sufficient, will prove substantially correct.

The French normal A was settled at 435, and since Lissajous superintended the publication of the fork of the French Commission in 1859, the whole world has accepted that fork as having exactly 435 vibrations. Now the French Commission gave to Messrs Broadwoods, in return for their courtesy in sending them their forks, an authorised copy of this fork, stamped with their stamp (a lyre between D and N, at the end of each prong) and made by Secretan. This fork I assume to be an authentic representative of the French diapason normal, made at the time. I have examined many others made by Secretan, and also officially stamped, and one by Koenig, and they mostly agree within two- or three-tenths of a vibration in a second. Two of Secretan's, however—one bought in Paris by the Society of Arts, and one sent to that society officially in 1869 through the Foreign Office, as representing the French pitch used in the Grand Duchy of Baden, differ as much as six-tenths of a vibration, the extreme difference observed in authorised forks. Other copies differ as much as two vibrations. But I take as my standard the copy given to Messrs. Broadwoods (which through the kindness of Mr. Hipkins I have carefully measured), and the one made by Koenig (which Dr. W. H. Stone was so obliging as to allow me to measure). These differ only by *one*-tenth of a vibration, and that tenth may be my own fault in counting. All these forks show that the real French diapason normal is A 439, that is, four vibrations sharper than was supposed. This is really a result of prime importance as brought out by Appunn's instrument, and it fully accounts for Koenig's differences as follows:—

Koenig having to make a C 256, observed (I suppose) that a major sixth above it would be A $426\frac{2}{3} = \frac{5}{3} \times 256$, and that this would beat $8\frac{1}{3}$ times in a second with A 435, which he assumed to be given by his diapason normal. Constructing such a fork by beats, which is easy enough, he necessarily obtained one exactly four vibrations too sharp, that is, A $430\frac{2}{3}$. From this, by the Lissajous figures most probably (certainly *not* by interposing new forks and counting the beats, for that would have shown him his error), he obtained first the correct major sixth below it, C $258{\cdot}4 = \frac{3}{5} \times 430\frac{2}{3}$, and then got his other forks by true intervals obtained also by Lissajous' figures. This makes all Koenig's forks harmonics of C 64·6, instead of C 64, as he intended and as he marks his forks.

Since Koenig's forks are extensively used by physicists, and also for the purpose of obtaining other pitches from them either for musical or for counting purposes, I think it will be convenient to add a little table of the harmonics of 64·6, with the marks on the forks observed (all of which had Koenig's monogram) and the pitches as actually measured by Appunn's tonometer. I am quite willing to allow the small differences to be set down to my bad counting and not to defective workmanship of either Koenig or Appunn.

No of Harmonic.	Double Vibrations of Harmonic.	Marks on Koenig's Forks V.S.	Meaning in English Notation.	Measured by Appunn's Tonometer.
1	64·6	—		
2	129·2	—

19	1227·4	—	—	—
20	1292·0	Mi_5 2560	E 1280	1292·0

The last four forks were difficult to measure. Those left blank were not found either at the Royal Institution or the School of Mines. The 11th, 13th, 17th, and 19th harmonics would not be easy to tune by Lissajous' figures. Appunn's instrument gives them with perfect ease. I may observe here with regard to the question of forks and reeds, that though forks may be the most permanent and portable records of pitch, reeds have a great advantage in the number of their upper partial tones, which allow of an extraordinary variety of verifications without any assistance beyond the instrument itself. I have found this reed tonometer easily checked and invaluable in measurements. But the above table would allow any tuning-fork maker to tune exactly to C 256, or from C 254 to C 265, by means of beats from Koenig's forks.

In trying forks to-day at King's College, Prof. Adams drew my attention to the fact that Koenig's organ-pipes are much flatter than his forks. On account of the difficulty of getting a steady blast on the organ pipes, it was not possible to measure them satisfactorily by Appunn's tonometer (a copy of which is in the physical laboratory there, and should be in all physical laboratories, as it is the best instrument for illustrating the nature of sound, partials, beats, and chords that I have yet seen), but they seemed to give very nearly C 250, about eight vibrations flatter than the forks. I cannot account for this, as this would be about Koenig's 248. ALEXANDER J. ELLIS

Kensington, May 18

HOW TO DRAW A STRAIGHT LINE[1]

II.

IN Fig. 6, Q C is the extra link pivoted to the fixed point Q, the other pivot on it C, describing the circle O C R. The straight lines P M and P′ M′ are supposed to be perpendicular to M R Q O M′.

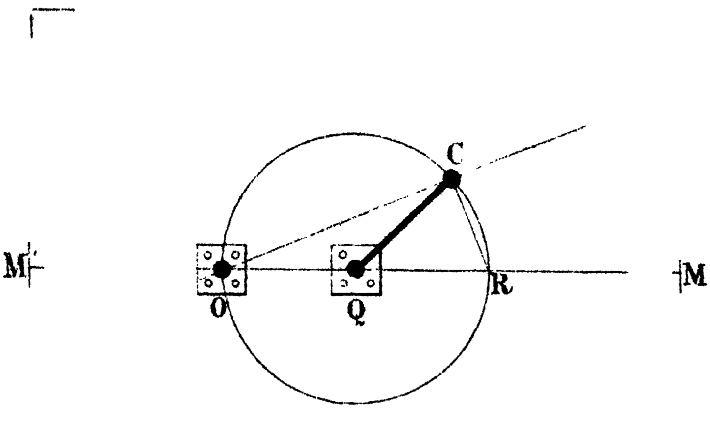

Fig. 6.

Now the angle O C R, being the angle in a semicircle, is a right angle. Therefore the triangles O C R, O M P are similar. Therefore,

$$OC : OR :: OM : OP.$$

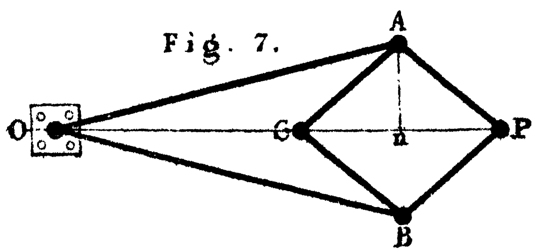
Therefore,

$$OC \cdot OP = OM \cdot OR.$$

wherever C may be on the circle. That is, since O M and O R are both constant, if while C moves in a circle P moves so that O, C, P are always in the same straight line, and so that O C · O P is always constant; then P will describe the straight line P M perpendicular to the line O Q.

It is also clear that if we take the point P′ on the other side of O, and if O C · O P′ is constant P′ will describe

Fig. 7.



the straight line P′ M′. This will be seen presently to be important.

Now, turning to Fig. 7, which is a skeleton drawing of the Peaucellier cell, we see that from the symmetry of the construction of the cell, O, C, P, all lie in the same straight line, and if the straight line A n be drawn perpendicular to C P—it must still be an imaginary one, as we have not proved yet that our apparatus does draw a straight line—C n is equal to n P.

Now,

$$OA^2 = On^2 + An^2$$
$$AP^2 = Pn^2 + An^2$$

therefore,

$$OA^2 - AP^2 = On^2 - Pn^2$$
$$= [On - Pn] \cdot [On + Pn]$$
$$= OC \cdot OP.$$

Thus since O A and A P are both constant O C · O P is always constant, however far or near C and P may be to O. If then the pivot O be fixed to the point O in Fig. 6, and the pivot C be made to describe the circle in the figure by being pivoted to the end of the extra link, the pivot P will satisfy all the conditions necessary to make it move in a straight line, and if a pencil be fixed at P it will draw a straight line. The distance of the line from the fixed pivots will of course depend on the magnitude of the quantity $OA^2 - OP^2$ which may be varied at pleasure.

I hope you clearly understand the two elements composing the apparatus, the extra link and the cell, and the part each plays, as I now wish to describe to you some modifications of the cell. The extra link will remain the same as before, and it is only the cell which will undergo alteration.

If I take the two linkages in Fig. 8, which are known as the "kite" and the "spear-head," and place one on the other so that the long links of the one coincide with those of the other, and then amalgamate the coincident long links together, we shall get the original cell of Figs. 5 and 7. If then we keep the angles between the long links, or that between the short links, the same in the "kite" and "spear-head," we see that the height of the "kite" multiplied by that of the "spear-head" is constant.

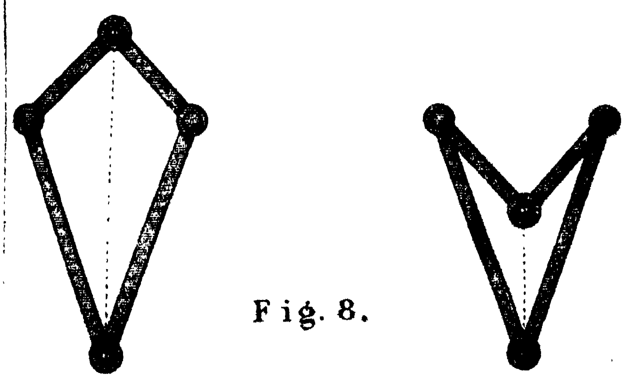


Fig. 8.

Let us now, instead of amalgamating the long links of the two linkages, amalgamate the short ones. We then get the linkage of Fig. 9; and if the pivot where the short links meet is fixed, and one of the other free pivots be

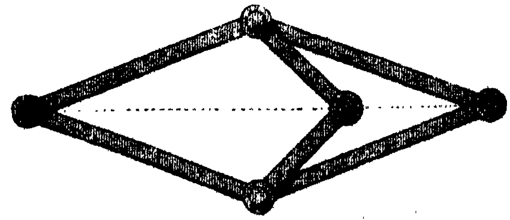

Fig. 9.

made to move in the circle of Fig. 6 by the extra link, the other will describe, not the straight line P M, but the straight line P′ M′. In this form, which is a very compact one, the motion has been applied in a beautiful manner

[1] Lecture at South Kensington in connection with the Loan Collection of Scientific Apparatus, by A. B. Kempe, B.A. Continued from p. 67.

to the air engines which are employed to ventilate the Houses of Parliament. The ease of working and absence of friction and noise is very remarkable. The engines were constructed and the Peaucellier apparatus adapted to them by Mr. Prim, the engineer to the Houses, by whose courtesy I have been enabled to see them, and I can assure you that they well worth a visit.

Another modification of the cell is shown in Fig. 10. If instead of employing a "kite" and "spear-head" of

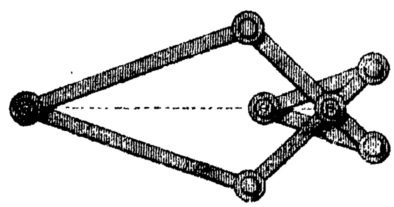

Fig. 10.

the same dimensions I take the same "kite" as before but use a "spear head" of half the size of the former one, the angles being, however, kept the same, the product of the heights of the two figures will be half what it was before, but still constant. Now instead of superimposing the links of one figure on the other, it will be seen that in Fig. 10 I fasten the shorter links of each figure together end to end. Then as in the former cases, if I fix the pivot at the point where the links are fixed together, I get

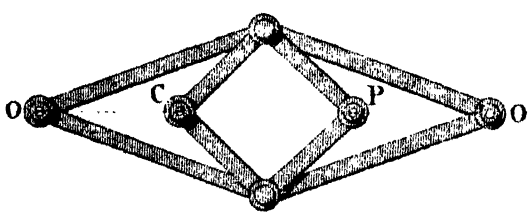

Fig. 11.

a cell which may be used by the employment of an extra link, to describe a straight line. A model employing this form of cell is exhibited in the Loan Collection by the Conservatoire des Arts et Métiers of Paris, and is of exquisite workmanship; the pencil seems to swim along the straight line.

M. Peaucellier's discovery was introduced into England by Prof. Sylvester in a lecture he delivered at the Royal Institution in January, 1874, which excited very great in-

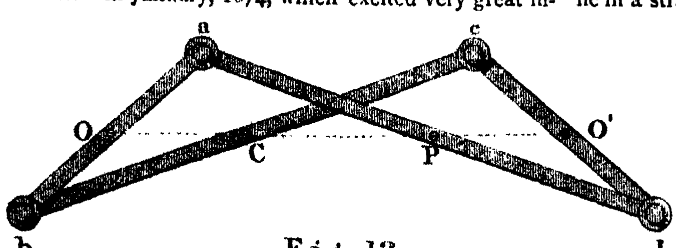

Fig. 12.

terest and was the commencement of the consideration of the subject of linkages in this country.

In August of the same year Mr. Hart, of Woolwich Academy, read a paper at the British Association meeting, in which he showed that M. Peaucellier's cell could be replaced by an apparatus containing only four links instead of six. The new linkage is arrived at thus.

If to the ordinary Peaucellier cell I add two fresh links of the same length as the long ones I get the double, or rather quadruple cell, for it may be used in four different ways, shown in Fig. 11. Now Mr. Hart found that if he took an ordinary parallelogramatic linkwork in which the

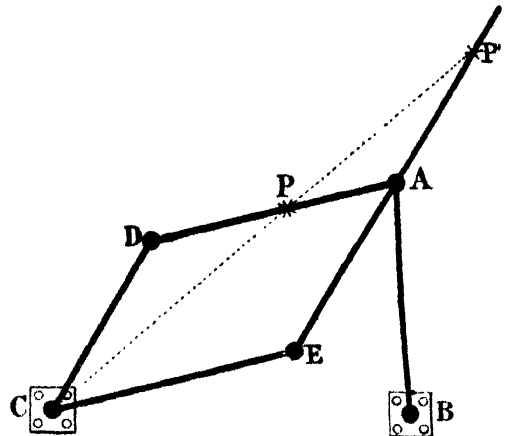

Fig. 13.

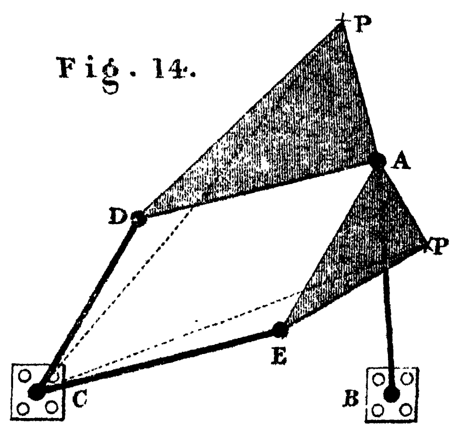
adjacent sides are unequal, and crossed the links so as to form what is called a contra-parallelogram, Fig. 12, and then took four points on the four links dividing the dis-



tances between the pivots in the same proportion, those four points had exactly the same properties as the four points of the double cell. That the four points always lie in a straight line is seen thus: considering the triangle abd, since $aO : Ob :: aP : Pd$ therefore O P is parallel to bd and the perpendicular distance between the parallels is to the height of the triangle abd as O b is to ab; the same reasoning applies to the straight line CO′, and since $ab : Ob :: cd : O'd$ and the heights of the triangles abd, cbd, are clearly the same, therefore the distances of O P and O′C from bd are the same, and O C P O′ lie in the same straight line.

That the product O C·O P is constant appears at once when it is seen that O b C is half a "spear head" and O a P half a "kite;" similarly it may be shown that O′P·O′C is constant, as also O C·C O′ and O P·P O′. Employing then the Hart's cell as we employed Peaucellier's, we get a five-link straight line motion. A model of this is exhibited in the Loan Collection by M. Breguet.

I now wish to call your attention to an extension of Mr. Hart's apparatus, which was discovered simultaneously by Prof. Sylvester and myself. In Mr. Hart's apparatus we were only concerned with bars and points on those bars, but in the apparatus I wish to bring before you we have pieces instead of bars. I think it will be more interesting if I lead up to this apparatus by detailing to you its history, especially as I shall thereby be enabled to bring before you another very elegant and very important linkage—the discovery of Prof. Sylvester.

When considering the problem presented by the ordi-

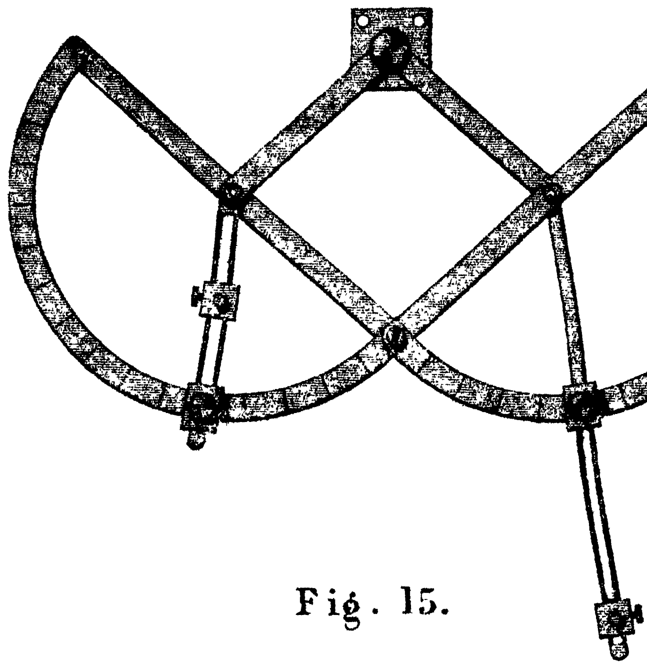


Fig. 15.

nary three-*bar* motion consisting of two radial bars and a traversing bar, it occurred to me—I do not know how or why, it is often very difficult to go back and find whence one's ideas originate—to consider the relation between the curves described by the points on the traversing bar in any given three-bar motion, and those described by the points on a similar three-bar motion, but in which the traversing bar and one of the radial bars had been made

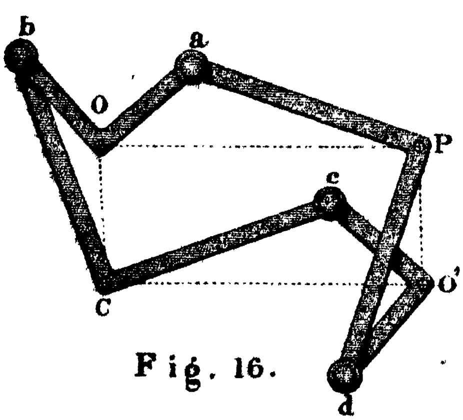

Fig. 16.

to change places. The proposition was no sooner stated than the solution became obvious; the curves were precisely similar. In Fig. 13 let C D and B A be the two radial bars turning about the fixed centres C and B, and let D A be the traversing bar, and let P be any point on it describing a curve depending on the lengths of A B, B C, C D, and D A. Now add to the three-bar motion the bars C E and E A P', C E being equal to D A, and E A equal to C D. C D A E is then a parallelogram, and if an imaginary line C P P' be drawn, cutting E A produced in P' it will at once be seen that P' is a fixed point on E A produced, and C P' bears always a fixed proportion to C P, viz., C D : C E. Thus the curve described by P' is precisely the same as that described by P, only it is larger in the proportion C E : C D. Thus if we take away the bars C D and D A, we shall get a three-bar linkwork, describing precisely the same curves, only of different magnitude, as our first three-bar motion described, and this new three-bar linkwork is the same as the old with the radial link C D and the traversing link D A interchanged.

On my communicating this result to Prof. Sylvester, he at once saw that the property was one not confined to the particular case of points lying on the traversing bar, in fact to three-*bar* motion, but was possessed by three-*piece* motion. In Fig. 14 C D A B is a three-bar motion, as in Fig. 13, but the tracing point or "graph" does not lie on the line joining the joints A D, but is anywhere else on a "piece" on which the joints A D lie. Now, as before, add the bar C E, C E being equal to A D, and the piece A E P', making A E equal to C D, and the triangle A E P' similar to the triangle P D A; so that the angles A E P', A D P are equal, and

P' E : E A : : A D : D P.

It follows easily from this—you can work it out for yourselves without difficulty—that the ratio P' C : P C is constant and the angle P C P' is constant; thus the paths of P and P', or the "grams" described by the "graphs," P and P' are similar, only they are of different sizes, and one is turned through an angle with respect to the other.

Now you will observe that the two proofs I have given are quite independent of the bar A B, which only affects the particular curve described by P and P'. If we get rid of A B, in both cases we shall get in the first figure the ordinary pantagraph, and in the second a beautiful extension of it called by Prof. Sylvester, its inventor, the *Plagiograph* or *Skew Pantagraph*. Like the pantagraph, it will enlarge or reduce figures, but it will do more, it will turn them through any required angle, for by properly choosing the position of P and P', the ratio of C P to C P' can be made what we please, and also the angle P C P' can be made to have any required value. If the angle P C P' is made equal to 0 or 180°, we get the two forms of the pantagraph now in common use; if it be made to assume successively any value which is a submultiple of 360°, we can, by passing the point P each time over the same pattern, make the point P' reproduce it round the fixed centre C after the fashion of a kaleidoscope. I think you will see from this that the instrument, which has, as far as I know, never been practically constructed, deserves to be put into the hands of the designer. I give here a picture of a little model of a possible form for the instrument furnished by me to the Loan Collection by request of Prof. Sylvester.

After this discovery of Prof. Sylvester it occurred to him and to me simultaneously—our letters announcing our discovery to each other crossing in the post—that the principle of the plagiograph might be extended to Mr. Hart's contra-parallelogram; and this discovery I shall now proceed to explain to you. I shall, however, be more easily able to do so by approaching it in a different manner to that in which I did when I discovered it.

If we take the contra-parallelogram of Mr. Hart and bend the links at the four points which lie on the same straight line, or *foci*, as they are sometimes termed, through the same angle, the four points, instead of lying in the same straight line, will lie at the four angular points of a parallelogram of constant angles—two the angle that the bars are bent through, and the other two their supplements—and of constant area, so that the product of two adjacent sides is constant.

In Fig. 16 the lettering is preserved as in Fig. 12, so that the way in which the apparatus is formed may be at once seen. The holes are taken in the middle of the links and the bending is through a right angle. The four holes O P O′ C lie at the four corners of a right-angled parallelogram, and the product of any two adjacent sides, as for example O C · O P, is constant. It follows that if O be pivoted to the fixed point O in Fig. 16, and C be pivoted to the extremity of the extra link, P will describe a straight line, not P M, but one inclined to P M at an angle the same as the bars, are bent through, *i.e.*, a right angle. Thus the straight line will be parallel to the line joining the fixed pivots O and Q. This apparatus, which for simplicity I have described as formed of four straight links which are afterwards bent, is of course strictly speaking, formed of four plane links, such as those employed in Fig. 1, on which the various points are taken. This explains the name given to it by Prof. Sylvester, the "Quadruplane." Its properties are not difficult to investigate, and when I point out to you that in Fig. 16 as in Fig. 12, O *b*, *b* C form half a "spear-head," and O *a*, *a* P half a "kite," you will very soon get to the bottom of it.

I cannot leave this apparatus in which my name is associated with that of Prof. Sylvester without expressing my deep gratitude for the kind interest which he took in my researches, and my regret that his departure for America to undertake the post of Professor in the new Johns Hopkins University has deprived me of one whose valuable suggestions and encouragement helped me much in my investigations.

(*To be continued.*)

METEOROLOGICAL NOTES

NOTES OF THE WEATHER IN SCOTLAND, FARÖ, AND ICELAND.—It appears from the meteorological returns for the eight principal towns in Scotland, that the weather of last April has been distinguished by low temperature, 3°·7 under the average, great fluctuations in the barometric pressure, large rainfall distributed among the towns with unusual uniformity, much wind and that more persistently from the eastward than has been before chronicled for any month of any year since the Scottish Meteorological Society was founded. At the monthly meeting of the Edinburgh Botanical Society, held on Thursday, May 10, Mr. McNab stated that the present spring is later than any other during the last twenty-eight years, when systematic observations on the flowering of plants began to be made in the Royal Botanic Garden of Edinburgh. In Farö the winter and early spring have been among the worst ever known, high easterly and northerly winds and snowstorms being very prevalent. In March and April snow fell on no fewer than thirty-one days. The mean barometric pressure at 32° and sea-level at Thorshavn during April, was 29,945 inches. On the other hand the winter, until Easter, was one of the finest ever known in Iceland, particularly in the north of the island. There was little snow, any frost that occurred was of short continuance, and fine calm weather prevailed. But about Easter-day a series of northerly snowstorms began, accompanied by severe frosts, which lasted with little intermission for about a week, causing the loss of many ships, and snowing up the pastures. Since these storms sunshine prevailed up to May 6. When the steamer left Reykjavik the Greenland and Spitzbergen ice had appeared off the northern coasts about the middle of March, but only stray icebergs neared the land, the ice becoming "land-fast" nowhere in any quantity. The season has also been singularly mild in Canada. Spring set in there fully three weeks earlier than usual, and as very little rain had fallen up to the close of April and the thaw was very gentle, the rivers were unusually low for the time of the year.

METEOROLOGY OF HOLLAND.—A highly-important work on the annual march of the thermometer and barometer in Holland, deduced from observations made from 1843 to 1875, has been published by Dr. Buys Ballot, the distinguished director of the meteorological system of that country. The monthly means for each meteorological lustrum of five years, as well as for the whole period during which the observations have been made, are given for each of the hours of observations. From these general averages, the normal values for each of the ten stations have been determined by the process of differentiation, so that the normals are substantially the averages which would have been obtained if the observations at each of the stations had been made during precisely the same terms of years. The normals are calculated for very extended periods by a comparison of the results arrived at for the Dutch stations, with the long averages for Copenhagen, Paris, and Greenwich. Thermometric and barometric normals have also been determined for each day of the year for all the stations, which cannot but prove to be of considerable value in framing forecasts of the weather and in some other practical matters. We hope, however, that Dr. Buys Ballot may be enabled soon to calculate the arithmetic means of the temperature of each day of the year at all his stations, and thus complete what must be regarded as an able and exhaustive discussion of the two most important elements of the meteorology of Holland. Tables are also added, showing the mean temperature of each month during the whole period of observations, and an exceedingly valuable table of the monthly mean barometric measure at Maestricht for sixty-nine years, beginning with 1807 and ending with 1875.

TYCHO BRAHE'S METEOROLOGICAL JOURNAL.—The Royal Academy of Sciences and Letters of Copenhagen has laid scientific men generally under a debt of gratitude in publishing *in extenso*, the Meteorological Journal, kept at Uraniborg in the Isle of Hveen by Tycho Brahe from 1582 to 1597. To the journal is appended a clear and interesting *résumé* of the observations by M. Paul la Cour. The results of the observations made on clouds, rain, snow, hail, fog, winds, frost, thunder, halos, and auroras, by the celebrated astronomer nearly 300 years ago, are compared with similar observations made at Copenhagen and other stations in Denmark in recent years. The results of the different sets of observations are fairly accordant when the different positions and times of observing are taken into consideration. The most noteworthy difference is in the monthly curve of thunder, the maximum at Hveen being strongly pronounced in June, whereas the recent observations at fourteen stations in different parts of Denmark have the maximum extending equally over June, July, and August—a difference perhaps due to a different seasonal distribution of thunder in different parts of Denmark. Of the seventy-eight auroras which were noted by Tycho Brahe, seventy-six occurred during the ten years from 1582-1591, and only two during the six years immediately following. From the detailed descriptions given of certain auroras and auroral arches, M. Paul la Cour concludes that the magnetic inclination at this observatory during 1584 was somewhere between 72° 25′, and 73° 25′.

"ATLAS MÉTÉOROLOGIQUE" OF THE OBSERVATOY OF PARIS, 1875.—A rapid glance through the *Atlas Météoro-*

logique for 1875 is enough to show that it more than sustains the high character of the publications of previous years. The thunderstorms and hailstorms of France for 1875 are elaborately and ably discussed, and to these discussions are appended no fewer than twenty-six memoirs on different meteorological subjects, by such well-known meteorologists as the two Becquerels, R. P. Denza, Brault, Crova, Moritz, Belgrande, Lemoine, Raulin, Coumbary, Brito-Capello, and Fron. Several of the more important of these memoirs not yet noticed by us, we shall bring before our readers on an early occasion, particularly those dealing with the climatology of Asia Minor and of Portugal, and with the rainfall of Algiers.

WEATHER MAPS IN AUSTRALIA.—Mr. Russell, of the Sydney Observatory, began a few months ago to issue daily weather maps for Australia. The plan of preparing the maps, which possesses some novel features, is briefly this:—There is a block of type metal with an electro of the coast-line and mountains fixed on it, and at the position of each station there is a slot in the metal block for the placing of the wind and weather symbols and figures which show the force of the wind, height of the barometer, and the temperature. The sea symbols, arrows, curves, words descriptive of the state of the weather, and in short everything which may be required on the map as varying from day to day, are glued on to the face of the metal block and held so fast that printing from an ordinary letter-press may be begun at once. The whole map is prepared in about two hours, and after a few copies are printed off for the use of the observatory, the block is sent to the *Herald* newspaper and by them stereotyped with their other matter. Copies of several weeks' weather maps, thus prepared and printed, have been forwarded to us. A note in manuscript on the map is sent to the *Herald* every day giving remarks on the weather of that day, and forecasts of coming weather. A system of exchange has been already effected with Melbourne, will soon be completed with Adelaide, and it is expected that all the other colonies will join in the effort to make the system as complete as possible so as to secure for this region of the globe effective warnings of coming storms. The colonial governments will no doubt see that this system of weather telegraphy, so admirable in itself and calculated to be highly beneficial to large public interests, will be furnished with the funds necessary for its efficient maintenance and further development.

STONEYHURST METEOROLOGICAL AND MAGNETICAL OBSERVATIONS, 1876.—This publication maintains the high character of its predecessors for the care and exhaustiveness with which the results are worked out and detailed in each of the monthly reports, and its value is further enhanced by the notes and tables of agricultural and horticultural results which have now been introduced. We are glad to see that observations of cirrus clouds are sent monthly to Dr. Hildebrandsson, of the Upsal Observatory; and we hope that, from the great importance of these observations in questions affecting atmospheric circulation, Father Perry will be enabled to add them to his future monthly reports. It was pointed out by us last year that in discussing the hours of occurrence of the minimum temperatures, the double inflexion in the curve which was obtained was solely due to the adoption in the discussion, of the civil day, beginning with 1 A.M., and that while the civil day must be employed in discussing the maximum temperatures, the astronomical day must be employed for the minimum temperatures. The minimum temperatures have now been discussed afresh, the astronomical day being adopted, with the result that there is only one inflexion in the time curve of the minimum temperature, the hour of lowest daily temperature falling in the annual curve between 4 and 5 A.M.

CLIMATE AND INFANT MORTALITY IN TASMANIA.—A carefully prepared paper on this subject, by Mr. E. C. Nowell, Government Statistician, has been published in the *Report of the Royal Society of Tasmania for* 1875, in which the statistics for Tasmania are compared with those for South Australia, Victoria, Queensland, and New South Wales for the five years 1869-73. Among the interesting results arrived at, the most important are these two, viz., first, the average number of deaths of infants under one year to 100 births for each colony was—South Australia 14·24, Victoria 11·86, Queensland 11·07, New South Wales 9·57, and Tasmania 9·45; and secondly, the proportions which the deaths of children under five years of age bore to 100 deaths at all ages were—South Australia 54·17, Queensland 46·33, Victoria 45·50, New South Wales 42·14, and Tasmania 28·08. These interesting and instructive results, showing the advantages possessed by Tasmania in regard to the low rate of mortality among infants and children, Mr. Nowell considers to be chiefly due to the remarkable salubrity of its climate. It is highly probable that it is to the climate that this low infant mortality must be ascribed, seeing that the summer heat of Tasmania is not nearly so great as that of the other colonies, and consequently the mortality from bowel complaints may be expected to be much less, whilst in all these colonies the temperature does not fall so low in the winter months as to prove so seriously fatal to the very young, as is the case in such climates as that of Great Britain. Mr. Nowell would do a very valuable piece of work if he extended the inquiry he has so well begun, in the directions we have indicated, so as to ascertain the particular diseases, the mortality from which is unusually low in Tasmania, and the seasonal distribution of the deaths from different diseases.

ON THE PROPER LENGTH OF THE GYMNASIUM SWING

MANY of the evolutions performed upon the gymnasium swing can be made equally well upon swings of any length; with others it is different. When the evolution is such that the swing in one direction marks a period of exertion, while the return is comparatively a period of rest, then the evolution cannot be equally well performed with swings of all length.

One of the most useful exercises is made as follows:—Reaching up and grasping the rings let the swing be started, and at the beginning of a forward swing the feet are thrown above the head, the legs being flexed. As the forward swing closes the legs are extended and the arms flexed, the body being thus thrown upward and outward. Here, also, by some practice, one learns to accomplish the swing with a minimum of exertion, which a good gymnast always does; nevertheless, the number of swings before exhaustion takes place varies with the length of the ropes, as is shown in the following series of experiments made upon myself:—

Nipher.

l	t	n
12	4·5	10·0
11	4·3	12·2
10	4·1	12·8
9	4·0	15·4
8	3·9	15·2
7	3·8	13·0
6	3·7	10·6

l = distance from point of suspension to centre of hands; t = time of one complete oscillation (forward and back); n = No of oscillations before exhaustion.

It will be observed that n reaches a maximum where l = about 8·5 feet, or where the time of a full swing is between 3·9 and 4·0 seconds.

Another series of experiments was made upon Mr. Cunningham, a young man about 5 feet 2 inches in height, and of light build. The maximum value of n is here reached when the length of the rope was about ten feet, and here the time of a full swing was about 4·1 seconds.

My own height being about five feet eleven inches, it will be observed that these two cases are sufficiently representative.

Cunningham.

l	t	n
12	4·3	14·0
11	4·3	16·3
10	4·1	17·0
9	3·8	14·6
8	3·7	12·6

The swing was shortened by drawing the rings up from the ground, and in the latter table the values of n for short ropes are a little too small, as he seemed fearful of falling. Hence we may affirm that in order that this and similar evolutions may be elegantly performed, the time for the full swing should be four seconds.

The cause of rapid fatigue with long ropes is that the body must be held in a constrained position for too long a time. With very short swings the muscles are forced to work with too great a velocity.

The muscular action is here too complex to allow of any mechanical discussion, but the general results are exactly what the discussions of Prof. Haughton might have enabled us to predict. FRANCIS E. NIPHER

Washington University

NOTES

THE demise of such veterans in biology as Von Baer, Ehrenberg, &c., during the past year has left gaps in the lists of honorary fellows of our scientific societies which come to be filled up with men almost of a different generation, yet worthy successors of the great masters departed. We understand the three subjoined *savans* have recently been elected foreign members of the Linnean Society—viz., Pierre Du Charte of Paris, highly distinguished for his researches in teratological, physiological, and other branches of botany; Prof. Carl Gegenbaur of Heidelberg, whose labours in zoology and the comparative anatomy of the vertebrates and invertebrates are acknowledged as of the highest standard; Prof. Rudolph Leuckardt of Leipzig, by whose philosophical investigations into the morphology and physiology of the lower forms of animals and establishment of the group coelenterata, zoologists of all countries are highly indebted.

WE are glad to hear that Dr. Dohrn's Zoological Station continues to make satisfactory progress. The number of naturalists who have availed themselves of the institution, we are informed, has reached eighty, from almost all parts of Europe. The summer dredging with the small steamer will now shortly commence, and we may hope that besides the important physiological work which is there done, that a complete knowledge of the rich fauna of this bay will be a further result furnished by this station. The institution is carried on under the direction of Dr. Dohrn, the detail management being in the hands of Dr. H. Eisig, who is backed up by two assistants. The aquarium belonging to the station has in their hands for some time been the most successful in Europe, and naturalists we do not doubt will find the experience gained by some years working enables their wants to be more readily provided for. A statement has appeared in an English paper which might lead one to think some change had been made, but we are in a position to state that no alteration has been made, and that with increased opportunity of collecting material the institution will become each year more useful.

ALTHOUGH M. Leverrier's health is so unsatisfactory he continues to attend to his professional duties as persistently as ever. The number of stations oraganised by him in connection with the international service now exceeds 1,200. He is preparing instructions to be sent to each correspondent on the method of better utilising warnings from the Observatory. He confesses that the agricultural service is in a period of uncertainty, and that some time must elapse before it can render much service to the commonwealth. He urges strong reasons why the service—not conducted by military men, as in America—should be conducted by men accustomed to military discipline.

THE primary clock of the Paris Observatory is now regulating the motion of the clocks of the Conservatoire, St. Sulpice, and the Luxembourg. M. Leverrier proposes to adapt the same system to a number of other public clocks, and even to those which are used in the cab stations. But the application of the system is delayed for want of funds.

PROF. RUPERT JONES, F.R.S., is preparing a new edition of Dixon's valuable "Geology of Sussex" for Mr. W. J. Smith, of Brighton. The work will be brought up to the present state of knowledge. The descriptions and lists of Sussex fossils will be carefully revised in this new edition, and a full account will be given of the Sub-wealden boring and its results, of the Warren-Farm Well, and of the archæological discoveries at Cissbury and elsewhere in Sussex. It is also arranged that a selection of the original quarto plates of Mantell's "Fossils of the South Downs; or, Illustrations of the Geology of Sussex" (1822), with descriptions according to our latest knowledge of the subjects, shall form part of the new volume.

A NEW application of the principle of the magic-lantern has been lately introduced into London for drawing attention after dark to the names of restaurants and shops. At present it is only used where the establishment has a lamp overhanging the pavement. The lenses are fitted into the bottom of the lamp, the words to be read are painted on the "slide," which has an opaque ground, and thus the advertisement is thrown in letters of light on to the pavement. Ordinary gas lamps are used, and when the apparatus is once fixed the announcement appears every time the lamp is lighted without any further trouble.

THE anniversary meeting of the Geographical Society was held on Monday, and as usual, a large increase of numbers was reported, as well as the prosperity of the Society generally. The president, Sir Rutherford Alcock, reviewed the progress of geographical science during the year, a year remarkable by the return of three important expeditions to England—the *Challenger*, the Arctic, and that under Lieut. Cameron. The medals, the award of which we have already announced, were presented to Sir George Nares, the Pundit Nain Singh, and Capt. Markham. The president, in concluding his address, announced that the Society's African Exploration Fund Committee were about to appeal to the Society and the public for support and co-operation in the prosecution of continuous and systematic African exploration. In view of the interests concerned in this work, the Council felt confident that their appeal would meet with a ready response, not only in the United Kingdom, but in all our colonies.

ON the evening of June 5 the first trial, in this country, of the Jablochkoff electrical light will be made at the West India Docks. The object of this trial is to test the applicability of this new light to purposes of lighting up of docks, warehouses, &c., in order that work may be continued during the night.

"SUMMER Schools" are becoming a regular institution in America, and no more pleasant way could be devised of combining the *dulce* and the *utile* than that of a proposed aquatic summer school of natural history, which, under the direction of Prof. Theodore B. Comstock, of Cornell University, expects to charter a large steamer, and spend the summer around the shores of Lake Superior in the study of the geology and natural history of that region. The steamer will accommodate from seventy-five to one hundred passengers, to be made up of students and professors. Regular instruction will be given in the form of lectures during the voyage, and every facility afforded by the examination of mining localities and the like. The vessel will probably start from Cleveland or Detroit on July 7, and proceed thence to Lake Superior, making its full circumnavigation. The coast of Georgian Bay, on Lake Huron, will be investigated on the return voyage. The expense will probably amount to about 125 dollars for each person. In addition to the aquatic summer school mentioned above, Harvard University announces two special summer courses of instruction, one in zoology and the other in geology.

THE progress of industry in France (denoting by industry the working of raw material) has been very rapid, much more rapid, proportionally, than that of agriculture. We learn from *La Nature*, that in half a century, the employment of cast iron, so necessary to industry, has been multiplied tenfold, and that of coal twenty-fold. The total power of steam-engines has increased in still greater proportion; it is at least thirty times greater than it was in 1840. Going further back, the proportion would be less interesting, as steam was used in but few establishments. In 1820 there were only sixty-five steam-engines in the whole of France. As an acquisition of material force these engines represent in value at least 25 million workmen, added to the 10 million who labour in workshops, and to the motor forces furnished by nature gratuitously, air and water. There are in France nearly 40,000 weirs, the falls from which work more than 80,000 mills of every kind, and this number might be doubled. In some parts, lastly, they are beginning to utilise the force of the tide.

AT a recent meeting of the French Physical Society M. Gouy gave an account of experiments he had made on flames produced by a mixture of air and coal-gas, holding in suspension pulverised metallic salts. The salts, dissolved in water, were introduced by a pulveriser, acting with air compressed to half an atmosphere. In these flames the blue surface of the interior cone, which gives the spectrum of carbon, gives also the lines proper to the salt which the flame contains. These lines are not visible beyond this part, and they coincide with the principal lines of the metal in the electric spark. The metals sodium, strontium, magnesium, lithium, manganese, iron, cobalt, bismuth, cadmium, zinc, and osmium give this phenomenon distinctly. Platinum gives a special spectrum formed of regular bands. These experiments seem to prove that there is at the base of the flame a very fine layer which has a temperature much higher than the flame properly so-called.

THE exploration of the Angara, proposed by the Russian Geographical Society, has taken a yet larger extension. M. Sibiryakoff, who has presented a gift of 2,000 roubles, proposes to undertake also the exploration of the water-parting between the Obi and Jenissei, to solve the question of the practicability of a canal between the two rivers. Owing to the great commercial importance of such a canal, the Geographical Society has agreed to the proposal of M. Sibiryakoff, and will send an expedition for that purpose.

NEAR Lake Ourmia (N.W. Persia), a hill near Digala is irregularly excavated by a number of galleries for its nitrous earth, strongly impregnated with saltpetre. This loose, friable soil, of brownish colour, in irregular horizontal beds, includes layers of a mostly amber-brown earth, with layers of bone-ash, intermixed with large and small fragments of human bones, charred remains of straw, and thin seams of carbonised seeds of cereals. Fragments of burnt earthenware are scattered through this bed, and through the whole of the hill. Nearly in the middle of the hill is a conical hollow, cylindrical above, and becoming narrower upwards, like the inside of a high furnace. The inner wall shows four or five ranges of repositories, several feet distant from each other, and made of slabs of eocene sandstone, about 1½ ft. broad. These slabs of a rust-brown colour, bear evident traces of having been exposed to a fierce fire; and the whole chamber may thus be inferred to have served for a furnace to burn dead bodies. This view is confirmed by the traditions still extant among the surrounding people. Fragments of large pot-like vases, and of coffins made of slabs of sandstone, both inclosing an earthy residuum, mixed with fragments of skulls and bones show that in the same place, burials have been effected without cremation. The abundance of saltpetre in the soil of the hill has probably been derived from the nitrogen set free by the decomposition of organic remains.

THE *Phormium tenax* or New Zealand Flax, is, it is said, being largely planted in St. Helena, on behalf of a fibre company, who propose so to plant all the Government waste lands in the island.

WE have received from Dr. Petermann a very useful map issued in connection with the Russo-Turkish war. Its purpose is to show at a glance the relative position of the boundaries of Russia, Turkey, Persia, and British India. It extends from Bosnia to Central Asia, and from the north of the Black and Caspian Seas to the Indian Ocean, and includes enlarged special maps of the Nile Delta and of Crete.

THE first field-day of the Liverpool Geological Society was held on Saturday last. The members and their friends proceeded to Crosby by rail and from thence by 'bus through Little Crosby, Hightown, Altcar, Downholland, Has Rayne, to Hallsall, and back again through Lydiate and Maghull to Sefton, where they had tea and examined the church. The object of the visit was to examine the great post-glacial deposits of the West Coast of Lancashire. The party was guided by Mr. T. Mellard Reade, C.E., F.G.S., who described the succession of the beds and their superficial extension. He explained that what they had seen was only a part of a very extensive series of deposits surrounding our coasts and found at most estuaries. The society last May examined a portion of the same series disclosed by the North Dock excavations, and the present excursion would enable them to better understand this most interesting part of the geology of Lancashire. At the Alt Mouth was found a peat and forest bed between high and low water-mark washed daily by the tide. The moss land between the inland edge of the 25-feet plain was only an extension of this submarine forest which passes under the sand hills and joins the moss. Under the moss lies the main silts with here and there some freshwater deposits on the surface.

SOME interesting disclosures were made last week at the Marlborough Street Police Court as to the method on which certain war maps are constructed. A certain publisher, whose name is probably unfamiliar to most of our readers, has published one of those exaggerated pictorial maps of the seat of war so attractive to the indiscriminating public. We have seen the map, and a very misleading and rude specimen of cartography it is. Its natural defects are bad enough, but it came out during the proceedings that intentional errors—names of non-existing places and wrong positions of existing places, were introduced for the purpose of detecting imitations. The magistrate, Mr. Newton, was therefore to a considerable extent justified in stating that the designer of the map seemed to have constructed it out of his own brain, and he virtually dismissed the summons.

FROM the report read at the annual meeting of the Nottingham Literary and Philosophical Society, we see that it now has 352 members of various classes. The Society has had several scientific lectures during the session, and we are specially glad to see that the Natural Science Section is in a flourishing condition, having had twenty-nine meetings and excursions during the session, at which papers were read on various subjects of scientific interest.

THE Société Française de Navigation Aërienne, an institution which has been approved by the Minister for Public Instruction, is to organise a collective exhibition at the Champ de Mars. It will include any means of propelling and governing in the air. Any instrument which has proved efficacious in some degree will be admitted if its dimensions are not too large, or by model, if otherwise. Any apparatus for making aërial observations, or helping aëronauts in any way will be admitted. The collection will also include maps, books, manuscripts, and newspapers relating to aërial navigation.

WE have received from Dr. Warren de la Rue a small pamphlet containing two sets of tables which must prove of great use to most scientific workers. There are tables for the reduction to 0° centigrade of a mercury column observed with a glass scale divided into millimetres, and tables for the reduction of millimetres (mercurial pressure) to thousandths and millionths of an atmosphere, and *vice versâ*. These tables are printed for private circulation.

AN important Russian work has just been published by Prof. Inostrantsef—"Geological Sketch of the Povyenetz District, Government Olonetz, and of its Mines." This large volume (750 pp.), being the result of seven years' explorations, contains detailed reports on the travels of the author, an orographical description of the district (the surface of which exceeds that of Switzerland), an interesting chapter on the metamorphism of the green slates, and a sketch of the glacial formations. It is accompanied by maps, engravings, and chromolithographed plates representing microscopical cuttings of rocks.

THE additions to the Zoological Society's Gardens during the past week include an African Turkey Buzzard (*Buteo tachardus*) from Africa, presented by Mr. A. Anderson, F.Z.S.; two Rendall's Guinea Fowls (*Numida rendalli*) from Bogos Country, Abyssinia, presented by Capt. Burke, s.s. *Arcot*; three Carpet Snakes (*Morelia variegata*) from Australia, presented by Mr. J. Moseley; a Guianan Crested Eagle (*Morphnus guianensis*) from the Upper Amazons, a Green-necked Pea-fowl (*Pavo spicifer*) from Java, two Barred-tailed Pheasants (*Phasianus reevesi*) from North China, a One-wattled Cassowary (*Casuarius uniappendiculatus*) from New Guinea, a Great-headed Maleo (*Megacephalon maleo*) from the Celebes, purchased; an Inconvenient Curassow (*Crax incommoda*) from South America, deposited; a Derbian Wallaby (*Halmaturus derbianus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN

COMETS OBSERVED BY HEVELIUS.—Of the eight comets observed by Hevel, better known as Hevelius, at Dantzic, with such degree of precision as could be attained with his instruments, the observations of two only have been reduced with the aid of modern places for comparison stars, &c., and in these two cases only have we other orbits than those calculated by Halley, which appear in his *Synopsis Astronomiæ Cometicæ*. The observations of the comet of 1664 have been discussed by Herr Lindelof, with the view of ascertaining whether any support were afforded by them, to a conjecture of identity of the comet, with the first comet of 1853; and those of the comet of 1683, were similarly reduced by Mr. W. E. Plummer, in his examination of the elliptical tendency of the orbit indicated by the computations of Prof. Clausen, who had previously recalculated a few of the observations. There remain the comets of 1652, 1661, 1665, 1672, 1677, and 1682; Mechain's reduction of the observations of the second of these bodies nearly a century since, will hardly be considered final.

The observations of the comets of 1672 and 1677 were published in the second volume of the *Machina Cœlestis*, and in small special treatises. This second volume of the great work of Hevelius, as is well known, is extremely scarce, the whole of the impression, with the exception of such copies as had been already presented to astronomers having been lost in the fire which destroyed the observatory, library and papers of Hevelius on September 26, 1679. The copies thus saved were so few in number, that as Lalande remarks "On peut regarder cet ouvrage comme un manuscrit;" and the special treatises to which we have alluded are perhaps of equal difficulty of access. The observations of the comets of 1652 and 1661 were printed in the *Cometographia*, not a work of very great rarity, as well as in the scarce volume of the *Machina Cœlestis*; those of the comet of 1665 also appear in this volume, in a special treatise, and in the *Prodromus Cometicus*, while those of the comet of 1682 (Halley's comet) are found in *Annus Climactericus*, and have been fully utilised.

A new reduction and discussion of the observations of the comets of 1652, 1661, 1665, 1672, and 1677, is certainly a desideratum, and important assistance in this direction might be afforded by a republication of the original observations of Hevelius from some quarter where the scarce volume is accessible. Mädler remarks upon a certain degree of resemblance between the elements of the comet of 1672 and those of the comet of 1812, which is shortly expected to return to perihelion; and it has been pointed out in this column that Halley has given the descending in place of the ascending node, for a comet observed in 1686—an oversight which has found its way into all catalogues of cometary orbits hitherto published, so that a re-computation of the orbits of the five comets we have mentioned, which now rest upon the figures of the *Synopsis Astronomiæ Cometicæ* is wanted, if only for verification.

"THE OBSERVATORY."—The second number of this new periodical is before us. Mr. David Gill continues his paper on "The Determination of the Solar Parallax;" we have the first part of an article giving the substance of a lecture recently delivered at Gresham College, by the Rev. E. Ledger, on "The Scintillation or Twinkling of the Stars," which has long been an obscure subject; Mr. Marth continues his Ephemerides for aiding physical observations of the Moon, Mars, and Jupiter; and there is also a report of the proceedings at the last meeting of the Royal Astronomical Society, including the discussion on the papers read, which, as was mentioned in a previous notice, it is intended should form a feature of the publication. We think every one who is competent to judge of the actual state of the case will agree in the opinion expressed at p. 55, while remarking on Mr. Todd's extension of Damoiseau's Tables of Jupiter's Satellites to the end of the present century, that "the time has hardly yet come for the formation of entirely new Tables." So far as regards the necessary observations, it must be admitted that they are being followed up with vigour at several observatories. The first binary star orbit on p. 58, refers to ξ Scorpii (ξ Libræ of Flamsteed), not to ζ Libræ; the error, however, is made in the *Astron. Nachrichten*, whence the orbit is taken.

L'ÉTÉ DE LA SAINT-MARTIN ET LES ÉTOILES FILANTES.—In No. 493 of the *Bulletin Hebdomadaire* of the French Scientific

Association, the Abbé Lamey, under the above heading, endeavours to explain by a new theory, certain abnormal temperatures which in one case, at least, has formed the subject of popular tradition. "The Summer of St. Martin," as the common phrase runs, presented itself, according to the Abbé, in a very definite manner in the last year; the month of November commenced colder than usual, but on the 12th it suddenly became warmer than from the sun's altitude could have been expected. Long-continued notice of a similar rise in temperature about the feast of St. Martin the Abbé considers is a proof that our ancestors were excellent observers, while the existence of a tradition upon the point shows clearly that the phenomenon has not been confined within restricted limits; it has been exhibited, he says, simultaneously in Europe and in the United States, and this without being materially affected by the climacteric conditions of the places of observation. One circumstance only he thinks appears to influence it, viz., the latitude; it vanishes as the equator is approached, and is not yet known to be recognised in the southern hemisphere.

The anomalous thermometric effect is not, however, perceptible only about St. Martin's Day. There is an analogous phenomenon according to the Abbé, in August: "une chaleur torride qui règne subitement après quelques jours de refraîchissement de l'air," and a similar effect, though in an opposite direction, has been noticed at the end of April or at the beginning of May, when vernal frosts so disastrous at this season occur, and have often been preceded by "une douce chaleur précoce," as the Abbé terms it, which has hastened forward the vegetation.

After remarking that the cause of such abnormal changes of temperature is not to be sought in any influence residing either in the sun or in the earth's atmosphere, it is suggested by the Abbé that it may be more probably found in what he calls cosmical meteorology, or as we are more accustomed to term this branch of science, meteoric astronomy. In November, August, and April meteors are more numerous than usual, and two of the greatest periodical showers yet observed, fall in November and August. His theory is that when a large number of meteors are passing between the earth and the sun, the solar rays are intercepted to a sufficient extent, to cause a diminution of temperature on the earth's surface, while, when a similar large number of meteors are so placed that they might reflect the heat derived from these rays, and so produce an effect of the opposite nature, that, to use his own words, those calorific rays "qui viendront frapper l'essaim météorique encore voisin de la terre seront *réverbérés* sur notre planète, de façon à recevoir alors un surcroît de chaleur." The Abbé lays some stress also upon another point of apparent coincidence: the intensity of the periodical meteoric showers of November varies from year to year, and "the summer of St. Martin" does not present itself under the same circumstances in every year.

In thus noticing the Abbé Lamey's attempt to explain a phenomenon which has been so long remarked as to have become a popular belief, at least in France, it will be understood that we are by no means advocating the probability of such a theory.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—In a Convocation held May 23 a decree was carried, without opposition, to the effect that the Vice-Chancellor and Proctors be authorised to nominate a delegate to represent the University at the 400th anniversary celebration of the University of Upsala, in September next.

In a Convocation to be held on June 5 it will be submitted to the House that the Curators of the University Chest be authorised to expend a sum not exceeding 7,000*l*. on the construction and fittings of new chemical laboratories at the University Museum. Also that a sum not exceeding 2,400*l*. be expended on certain additions to the University observatory.

An examination will be held in common at Magdalen, University, and New Colleges, on Tuesday, June 26, for election to the following mathematical scholarships:—One demyship at Magdalen College, of the annual value of 95*l*., inclusive of allowances; one scholarship at University College, of the annual value of 80*l*., tenable for five years during residence; one scholarship at New College, of the annual value of 100*l*., tenable for five years during residence. Testimonials of conduct, &c., to the President of Magdalen College, Mr. C. J. Faulkner, of University College, or the Sub-Warden of New College, between 4 and 6 or 8 and 9 P.M., June 25.

The commemoration fixed for June 13 will, it is understood, be held in the Sheldonian Theatre, although no official notice to that effect has appeared. There will be the usual round of festivities attendant on the event, though it has not transpired if the University will confer any honorary degrees on distinguished persons at the commemoration.

CAMBRIDGE.—The Museums and Lecture-rooms Syndicate, in their Eleventh Annual Report, just issued, state that the buildings are in an efficient state of repair, and the collections, to which many valuable additions have been made during the past year, are in good order. They draw attention to the munificence of the Chancellor of the University, the Duke of Devonshire, who has now completely furnished the Cavendish Laboratory with the instruments required by the present state of science. Profs. Liveing, Dewar, and Stuart complain of want of suitable accommodation for the work of their several departments, and the Syndicate concur in the reasonableness of their complaints.

An important report has been issued by the Musical Examinations Syndicate, which states that under existing regulations for obtaining a degree in music no provision is made for testing the literary and scientific qualifications of the candidates. They therefore recommend that no candidate be admitted to the examination for the degree of Mus. Bac. unless he have passed Parts I. and II. of the Previous Examinations, or one or other of their equivalent examinations. As to the examination for the degree of Mus. Bac., it is proposed to divide it into three parts—1, a preliminary examination, consisting of acoustics, harmony, counterpoint; 2, the exercise; 3, a more advanced examination in musical science; and that no person be accepted as a candidate for the second or third parts until he has qualified in the previous part or parts. In order to encourage the study of music, that it be recognised as the subject of an additional special examination for the ordinary B.A. degree, and that a student who has passed the Previous and the General Examinations, and is in his ninth term of residence at least, having previously kept eight terms, shall, on passing the preliminary examinations in acoustics, harmony, and counterpoint, be entitled, when he has kept nine terms, to receive the degree of Bachelor of Arts.

The "Rede" lecture was delivered on May 25 in the Senate House by Sir C. Wyville Thomson, who gave a brief sketch of the main results obtained by the *Challenger* expedition.

LONDON.—A new and additional Chair of Clinical Surgery has been created at King's College, which is to be filled by Prof. Lister of Edinburgh. The Chair of Systematic Surgery is thus still vacant.

EDINBURGH.—The students at the University have, during the past session, taken a step which it seems surprising they have not taken long ago. There is, in the Scotch universities, no college life as in England, the students appearing at their classes at the proper hours, and then dispersing to their respective lodgings in various parts of the town. While this system has undoubtedly its advantages, it is attended with not a few social, moral, and physical drawbacks, so that we are glad to learn that the Edinburgh students have started a Students' Club which has been thoroughly successful, and calculated we believe, if prudently conducted, to be productive of considerable benefit to the raw and lonely Scotch youth "when first he leaves his father's fields," to get what training and equipment for the future fight Edinburgh can give him.

By the transference of Prof. Lister to London, the Chair of Clinical Surgery in the University becomes vacant.

SIR JAMES KAY-SHUTTLEWORTH.—The death took place on Saturday last of Sir James Kay-Shuttleworth, a name well known in connection with educational and social reform. The deceased baronet, who was born at Rochdale on July 20, 1804, was for some time secretary to the Committee of Council on Education, and whilst fulfilling the duties of this post he was mainly instrumental in establishing a system of school inspection by officers appointed by the Government. On his resignation he was succeeded by Mr. Lingen, now permanent secretary of the Treasury, who was succeeded in his turn by Sir Francis R. Sandford. Under Sir James's scheme teachers were divided into nine grades, and received money grants, not according to the number of their scholars or of their passes, but largely, according to the grade they had obtained by examination or service. He was hostile to the Revised Code, which was introduced, about twelve years after his resignation, by Mr. Lowe and his successor. It is undoubtedly to Sir James that we owe the training colleges and the pupil teacher system, without which it would have been impracticable for us to advance educationally even as we have done. At the close of the year 1849 he received a baronetcy at the recommendation of Lord Russell, then Prime Minister. In 1870 he received the honorary degree of D.C.L. from the University of Oxford.

Spelling Reform.—An influential Conference on English Spelling Reform was held on Tuesday at the Society of Arts, under the presidency of the Rev. A. H. Sayce and Sir Charles Reed. Many weighty reasons were urged against the present system, and a deputation consisting of Prof. Max Müller, the Rev. A. H. Sayce, Dr. Morris, Mr. Ellis, Mr. Sweet, Dr. Murray and others, was appointed to wait upon the Education Department in reference to the subject. A proposal having the support of such names as we have mentioned deserves at least serious consideration.

A Siberian University.—It has been finally decided that the New Siberian University, to which we referred some time since, is to be established at Omsk. So long ago as 1803 a wealthy Uralian landowner named Demidoff gave 100,000 roubles to the Treasury, to be expended in the establishment of a University. This sum has now swollen to 150,000 roubles, to which a Siberian merchant has added 100,000 roubles more. Orders have been issued to begin the construction of the university buildings at once, so as to have them ready for occupation by July, 1880. The estimated cost of the future professional staff, together with other incidental expenses connected with the university, is 307,000 roubles yearly.

SOCIETIES AND ACADEMIES

London

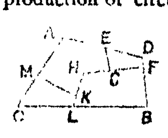
Mathematical Society, May 10.—Lord Rayleigh, F.R.S., president, in the chair.—Mr. Tucker communicated a short account of a paper by Dr. Hirst on the correlation of two planes. In a former paper on the subject (*Proceedings*, vol. v., p. 40), the nature and properties were described first, of an ordinary correlation satisfying any eight given conditions; secondly, of an exceptional correlation of the first order, possessing either a singular point or a singular line in each plane, and satisfying seven conditions; and thirdly, of an exceptional correlation of the second order, having in each plane not only a singular point but also a singular line passing through that point, and satisfying six conditions. Moreover, the two following numerical relations were established between the (π, λ) exceptional correlations of the first order, with singular points and singular lines respectively, which satisfy any seven conditions, and the (μ, ν) ordinary correlations, which, besides satisfying these same conditions, possess a given pair of conjugate points or conjugate lines respectively $(2\nu = \mu + \pi, 2\mu = \nu + \lambda)$. It was by means of these relations that the number of ordinary correlations was determined which satisfy any eight elementary conditions. Before they could be applied, however, the exceptional correlations of the first order which satisfy any seven elementary conditions) had to be directly determined, and this determination not unfrequently necessitated the consideration of the projective properties of curves of high order. In the present paper the writer shows that the object just referred to can be attained in a very much simpler manner by means of two general relations, hitherto unobserved, connecting the number of exceptional correlations of the second order, which satisfy any six conditions, with the numbers of exceptional correlations of the first order which, besides satisfying the six conditions in question, possess a given pair either of conjugate points or conjugate lines.—The University of Adelaide, on the free motion of a solid through an infinite mass of liquid. Suppose that we have a solid body of any form immersed in an infinite mass of perfect liquid, that motion is produced in this system from rest by the action of any set of impulsive forces applied to the solid, and that the system is then left to itself. The equations of motion of a body under these circumstances have been investigated independently by Thomson and by Kirchhoff, and completely integrated for certain special forms of the body. The object of the present communication is, in the first place, to examine the various kinds of permanent or *steady* motion of which the body is capable, without making any restrictions as to its form or constitution; and, in the second, to show that when the initiating impulses reduce to a couple only, the complete determination of the motion can be made to depend upon equations identical in form with Euler's well-known equations of motion of a perfectly free rigid body about its centre of inertia, although the interpretation of the solution is naturally more complex. Free use is made throughout the paper of the ideas and the nomenclature of the theory of screws as developed and established by Dr. Ball.—Herr Weichold (Head-master of the Johanneum, Zittau, Saxony) sent a paper (read in part by the secretary) containing a solution of the irreducible case, *i.e.*, of the problem to express the three roots of a complete equation of the third degree, in the case of *all* these roots being *real*, directly in terms of its coefficients, by means of purely algebraical and really performable operations, whose number shall always be limited, except in the case where all these roots are incommensurable.—Mr. H. Hart made three communications: First On the "Kinematic Paradox."—Prof. Sylvester has described a system of Peaucellier's cells, the poles of which all move in a straight line, but two of which not directly connected always remained at a constant distance. Such a result is very easily obtained by means of the following relations connecting six points A, B, C, D, E, F, lying on a straight line. If

$$\left.\begin{aligned} AB \,.\, AC &= a^2 \\ BC \,.\, BD &= 4a^2 \\ EB \,.\, ED &= a^2 \\ FA \,.\, FE &= 2a^2 \end{aligned}\right\} \text{ then } FB = a.$$

He then spoke on the solution of the algebraical equation $f(x) = 0$ by linkwork, considering three points, the preparation of the equation (put under the form $\frac{A}{x+a} + \frac{B}{x+b} + \ldots = k$), the representation of the terms of this equation, and the method of adding these terms. He showed that for the solution of the cubic $x^3 + px^2 + qx + r = e$, treated under the form—

$$x + p + \frac{\left(q - \frac{r}{p}\right)x}{x^2 + \frac{r}{p}} = 0,$$

two reciprocators alone are required. He then spoke on the production of circular and rectilinear motion. The particular problem considered, he thus enunciated "to find if possible the relations that must exist between the fourteen segments of the bars placed as in the figure in order that the system may be capable of free motion."



He showed that seven equations can be obtained connecting the fourteen quantities only, so that any seven being given, the remaining seven can be determined in terms of them.—Mr. Hart then proceeded to the application to the cases of 5-bar motion, laid before the Society at its April meeting. Mr. Kempe stated that the cases submitted by Mr. Hart at the previous meeting had also occupied some of his attention, and he proceeded to remark that he had determined the positions that the lines GE, KM must have, and that the determination of one involved the determination of the other, as the position of either turned upon the fact that the angles at A and H must be equal. Prof. Cayley also made a few remarks on the subject. Mr. J. W. L. Glaisher stated that he had had all the cases in which there are more than fifty consecutive composite numbers looked out from Burckhardt's and Dase's tables, which cover six millions, and that he had found that in the first million there is a stretch of 111 numbers without a prime (about 370,000), and a stretch of 113 numbers without a prime (about numbers in the first million, and these are longer, he thought, than anyone would have supposed likely. He exhibited the lists from which he drew the above results. Questions were put to the meeting, for information, by Profs. Cayley and Clifford.

Geological Society, May 9.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—James Dorrington, Rev. E. R. Lewis, Edward Penton, Henry Rosales, and Henry White were elected fellows of the Society.—On the Agassizian genera *Amblypterus*, *Palæoniscus*, *Gyrolepis*, and *Pygopterus*, by Ramsay H. Traquair, F.R.S.E. The author's object in this paper was to discuss the characters by which the above genera of fossil fishes have been supposed to be distinguished in the case of specimens from the carboniferous series.—On the circinate vernation, fructification, and varieties of *Sphenopteris affinis*, and on *Staphylopteris* (?) *peachii*, Etheridge and Balfour, a genus of plants new to British rocks, by C. W. Peach, A.L.S., communicated by Robert Etheridge, F.R.S., V.P.G.S.—On the occurrence of a Macrurous Decapod (*Anthrapalæmon woodwardi*, sp. nov.) in the red sandstone, or lowest group of the carboniferous formation in the south-east of Scotland, by Robert Etheridge, jun., F.G.S. After giving a detailed bibliography of the palæozoic malacostracous crustacea, the author described the remains of a small crustacean from the lower group of the carboniferous formation near Dunbar, and discussed its affinities and systematic position, which he regarded as being among the Macrurous Decapods, although the absence of the eyes in the preserved specimens, and some other characters, rendered it doubtful whether it might not in some respects approach the Stomapoda. Its position among the Macrura seemed, however, to be established by the well-developed abdominal somites and telson. He referred the fossil to Salter's genus, *Anthrapalæmon*, and named the species *A. woodwardi*.—On the stratigraphical position of the corals of the Lias of the Midland and Western Counties of England and of South Wales, by R. F. Tomes, communicated by R. Etheridge, F.R.S., V.P.G.S. The object of this paper was to give the precise stratigraphical position of the species of liassic corals collected by the author and his friends in the districts above mentioned. He noticed forty-one species, of which fifteen were described as new.

Paris

Academy of Sciences, May 21.—M. Peligot in the chair.—The following papers were read:—Meridian observations of small planets at the Paris Observatory during the first quarter of 1877, by M. LeVerrier.—On Gay-Lussac's law of volumes, by M. H. St. Claire Deville. He considers recent researches have neither invalidated nor added to the law.—On an algebraic method for obtaining the *ensemble* of the fundamental variants and co-variants of a binary form, and of any combination of binary forms (continued), by Mr. Sylvester.—Report on M. Roudaire's project of making an interior sea in the south of Tunisia and the Province of Constantine. M. Favé reports favourably; but on the points, whether the sea would not dry up, whether the vapours would benefit neighbouring lands and not be carried to the sea by winds, and whether the eastern Algerian and Tunisian climate would recover its old fertility, and be improved hygienically, MM. Daubrée and Dumas (while adopting the general conclusions) express hesitation, and desire further researches.—Report on a memoir of M. Stanislas Meunier, entitled "Composition and Origin of the Diamantiferous Sand of Toit's Pan (in South Africa). M. Meunier has separated several mineral species not before noticed there, and offers an ingenious explanation of the way of filling up those vertical pits.—On the employment of oxygen of high tension as a process of physiological investigation; poisons and virus, by M. Bert. There is in anthracic blood a toxical and virulent principle which resists the action of compressed oxygen and alcohol, and which can be isolated like diastase. M. Bert is studying its nature and its relation to the bacteria. Lymph, too, and the pus of glanders, by resisting compressed oxygen, show that their virulent action is not due to living beings or cells.—On the employment of rotatory discs for the study of coloured sensations, by M. Rosenstiehl.—Dehydrated oxalic acid may serve to characterise polyatomic alcohols; chemical function of inosite, by M. Loria.—Decomposition of chlorhydrate of trimethylamine by heat, by M. Vincent. This substance might be utilised to give ammoniacal products and pure chloride of methyl, the latter yielding the methylated aniline colours or pure methylic alcohol.—Observations of a disease of the vine known commonly as *white*, by Mr. Schnetzler.—New spectroscopic method, by Mr. Langley. Two spectra from the north and south poles of the sun respectively are put in juxtaposition (a considerable dispersion being used); let the instrument be adjusted so that the lines in both are continuous. On turning the spectroscope round its axis of collimation till the light comes from the east and west extremities of the equator the solar lines are displaced, while the atmospheric remain continuous. On turning 180° the spectra glide on one another like a Vernier on a scale. The point is, *simultaneous* observation of the *different* displacement of the solar and the atmospheric lines in the two spectra.—On a transmission of motion, by M. Rozé.—On the spectrum of the electric spark in a compressed gas, by M. Cazin. From experiments on air and nitrogen he concludes that the electric spark in a gas is similar to an ordinary hydrocarbon flame. In each there are luminous particles giving a spectrum of lines, and solid or liquid particles giving a continuous spectrum. The latter (in the case of the spark) come from the electrodes and the walls. When the pressure is increased these particles are more abundant; the continuous spectrum becomes more brilliant, and finally makes the linear spectrum disappear. The luminous spark called an *aureole* is of gaseous particles, and is to the total spark what the blue base of a candle flame is to the entire flame.—Studies on organ pipes, by M. Philbert.—On some new models of radiometers, by Mr. Crookes.—Thermo-chemical study of aniline and some other bodies of the same group, by M. Louguinine.—On the nitrates of bismuth, by M. Yvon.—On the properties of resorcine; molecular volumes, by M. Calderon. Resorcine in solution behaves as if it were solid and isolated from the solvent. In presence of water and potash it absorbs oxygen, though very slowly.—Anatomical characters of the blood in new-born infants during the first days of life, by M. Hayem. *Inter alia*, the red corpuscles are much more unequal in size than in the adult, and seem of a different composition. The number (in a cubic metre) is nearly as high as in the most vigorous adult. The number of white corpuscles is three or four times as great as in an adult. When the infant has reached its minimum weight (about the third day) the number of these suddenly falls; various fluctuations ensue (which are described).—On a process for estimation of alcohol in liquids, by M. Fleury.—On the filling of fissures in chalk with silex, by M. Robert.—M. Vinot presented a celestial map of the equatorial region.

THURSDAY, JUNE 7, 1877

THE ANTIQUITY OF MAN

THE Conference on the Antiquity of Man lately held by the Anthropological Institute, and reported in these columns, has led to a result by no means unsatisfactory, when all the conditions of the problem are duly weighed. The result is merely negative, but in arriving at it several misconceptions and errors of fact seem to us to have been swept away. In its discussion there were two parties represented, one eager to show that the antiquity of man has been proved by modern discovery to be far older than the date which had been arrived at by the labours of Falconer, Lyell, Prestwich, Evans, Boyd Dawkins, and others, while the other contended that the subject had not advanced in the least degree during the last few years, and that the so-called discoveries were either errors of observation, or resulting from premises which were altogether unsatisfactory. The field of the discussion lay in matters geological rather than archæological, and the caution which the president urged upon the conference was certainly not urged in vain.

The chief interest of the debate turned upon the question as to whether there was any evidence in this country of man in the caves or river deposits older than post-glacial times. The readers of the works of Messrs. Croll and James Geikie will remember that they ascribe all the traces of palæolithic man in this country either to a pre- or inter-glacial age, basing their conclusions principally upon the fact that in the river deposits and caves some of the associated animals, such as the hyæna, lion, and hippopotamus are now only to be found in hot climates; and seeing that no traces of a warm climate are presented by any post-glacial deposit in Britain, they infer that those in question are of a much higher antiquity. They account for the association of southern and northern animals by the supposition that they occupied the country at different times, during glacial or interglacial æons of from five to twelve thousands years in length. To this it was objected that the intimate association of forms prove that both sets of animals inhabited the country at the same time, and were the result of the overlapping of different faunas during seasonal changes. The reindeer formed a large portion of *the prey* of the hyæna, and must therefore have been a contemporary. It was also pointed out by one of the speakers, that there is no evidence from the animals that there ever was anything like "the perpetual summer," advocated by Mr. Geikie at any time in the pleistocene age. The hippopotamus in Regent's Park takes his tub regularly in spite of the east winds so prevalent in the spring, which remind one of the glacial period; and the tiger crosses the frost-bound rivers of the Amoor to prey upon the reindeer. The lion, now found only in the south, lived in the days of Herodotus in the inclement mountains of Thrace. It seems, therefore, to us, that any argument based upon fossil animals as to a warm inter-glacial period, is worthless. And further, it is obviously unfair in treating of the fauna associated with man to adopt the forensic device of choosing some witnesses to the exclusion of others. It would be as easy to prove the climate in question to have been temperate from the associated remains of bison, stag, and horse, as it would be to prove it to have been arctic from the associated musk sheep, lemmings, and reindeer. It was probably a varying climate, with great extremes, similar to that in Central Siberia, in which the summer heat and winter cold are very severe.

The fossil mammalia of the pleiostocene tell us nothing as to the relation of man to the glacial period. The Arctic species invaded Europe probably from Asia, while the ice was finding its way southwards from the mountains of Scandinavia, and occupied the area north of the Alps and the Pyrenees, *while* the confluent glaciers covered the area north of the valley of the Thames. When the ice ultimately retreated they followed it, and thus were both pre- and post-glacial. Nor do the survivals from the pleiocene age tell us anything, such as the hippopotamus, the *Rhinoceros leptorhinus*, and the *Elephas antiquus*, since they belong both to the earlier and later pleistocene strata, and are also associated with remains of reindeer, and other northern species. The presence of the reindeer in all the palæolithic caverns stamps the age of man as late pleistocene, according to Prof. Boyd Dawkins, but it does not afford any clue as to his pre- or post-glacial age. The glacial period is not a hard and fast line dividing one fauna from another. One palæolithic cave, however, in this country, that of Pont Newydd, in the valley of the Elwy, near St. Asaph, is of well-ascertained post-glacial age.

The argument urged in favour of palæolithic man being pre- or inter-glacial, based upon the distribution of the mammalia in southern and eastern England, and in France, while they are conspicuous by their absence in the glaciated areas of Scotland, Cumberland, and Wales, was met by the view that the barren areas were covered with ice, *while* other districts further to the south were occupied by the animals. The hypothesis that the uplands of Wales and Northern Britain were ever stocked by the same animals as the fertile river-bottoms of the south, seems to us little less than absurd. Yet this is necessary for the view that their remains have been removed from the barren areas by the subsequent grinding of the ice-sheet.

In the course of the discussion the reputed cases of the occurrence of palæolithic remains in the deposits older than the post-glacial were minutely criticised. Prof. Busk stated that the fibula of the Victoria Cave, formerly supposed to be human, was altogether too insignificant a fragment to base any conclusion upon as to man's antiquity. Two small cut-bones, however, of goat were brought forward by Mr. Tiddeman in support of the pre- or inter-glacial age of man in the Victoria Cave. On the other hand, it was urged that these were derived from the superficial stratum containing Roman coins and pottery, &c., in which they were very abundant. From the nature of the cuts it seems to us that if it be established that they were discovered in the undisturbed stratum along with the hyænas, they would prove not only the presence of man, but of a user of a knife or chopper of bronze or iron. The absence of the goat, also (probably a domestic animal) from all undisturbed pleistocene deposits in this country, and in France, Belgium, and Germany, renders it very probable that the animal was introduced into those regions after the close of the pleistocene age. But even supposing that these difficulties be got over, the age of the deposit in which these fragments are stated to have been found is a matter of dispute in which the authorities are about equally balanced on either side.

The asserted inter-glacial age of the river gravels containing palæolithic implements proved equally unsatisfactory. The cases supposed to be decisive of the question in the neighbourhood of Brandon and Thetford, were considered by Prof. Hughes to throw no light upon it, since the deposits above them, supposed to be boulder clay, are not boulder clay *in situ*. It was forcibly urged by several speakers, and especially by Prof. Prestwich, that the flint implement-bearing strata are proved by their position in the valleys to be later than the glaciation of the district, in every case where it has been glaciated, or in other words, that they are decidedly of post-glacial age.

The general question of the antiquity of man in Europe was not discussed, although we gathered that the evidence of the presence of man in the Italian pleiocenes was not considered satisfactory. The general impression left upon our minds is that in Britain there is no evidence of any palæolithic men, either in caves or the river-deposits of an age older than post-glacial, and that the discoveries of the last fourteen years have merely given us interesting details as to the palæolithic savage, without telling us anything of his relation to the glacial period.

THE VALUE OF NATURAL HISTORY MUSEUMS

WELL-arranged museums are valuable to the state in many ways. The technological department ought to show in what new directions capital may and may not be invested; the geological and mineralogical should point out in what kind of rock and in what parts of the earth's crust ores and minerals are to be sought, and should save the expenditure of money in useless trials. The museum of the Royal School of Mines in Jermyn Street performs these functions. But they are valuable in a still higher sense as encouraging a love of knowledge for its own sake apart from any selfish aims. The visitors to the British Museum, however frivolous they may be, leave it all the better for having been there. It is impossible that they should not carry away some sort of idea, which otherwise would not have occurred to them, even if it be merely the recognition that outside their daily lives there is a world of knowledge vast and indefinite, but real and tangible. In this respect museums are educators of the masses, offering them a means of culture which would otherwise be out of their reach. And lastly, as instruments of training in natural history they are, as I have already observed, as necessary to the student as collections of books to the student in arts.

Natural history pursuits are in themselves one of the forms of higher education, and one that is especially adapted for the culture of the lower, sometimes falsely termed the working classes—as if the higher classes worked neither with head nor hand. In proof of this I may quote the following example, which I am free to mention by the death of the man to whom it relates. Some years ago a mechanic, one of the evening class students at Owens College, took me to see a collection of fossils made by "a hand" in a cotton-mill at Oldham. To my astonishment I found that it consisted not merely of fossils *au naturel*, shells, and the like, but of those of coal plants, polished, and in many cases cut into slices so as to show their minute structure. This had been done by rubbing them down on the kitchen floor, cementing them to a piece of glass, and then grinding them until they became transparent. The care and labour implied in a process of this kind can only be estimated by those who have tried it. But it was necessary to have a microscope to see them, and I actually discovered that the instrument which was given me to use was made by the man himself, who could not afford to buy more than the lenses, which he mounted in tubes that were made to slide in each other after the manner of a telescope. He was also a good local botanist. His collection of fossils, along with another made by a friend of his under similar circumstances, furnished the materials on which Prof. W. C. Williamson has to a great extent founded his admirable memoirs on the coal-plants, now being published by the Royal Society. From time to time I saw a good deal of my friend, and a man more completely lifted out of the usual level of his class into what I may call the unselfish horizon I never met. This could be traced directly to the scientific pursuits to which he was led by seeing somebody one day pick up a piece of coal shale, and hearing him say that there was a fish scale in it. He disbelieved this, examined for himself, took to collecting, and ultimately became what he was, devoting his early mornings and his late evenings not merely to collecting but to knowing. His knowledge embraced other things than natural history. James Whittaker, of Oldham, may be taken as a type of the effect of natural history in elevating a man's character. He is the representative of a small, though very important, body in the Northern Counties, a body which would be largely increased by the foundation of museums of the right sort. From personal contact with men like him I have arrived at the conclusion that in this direction we have a means of spreading culture among the intelligent mechanics, artisans, and mill-hands, who go neither to church nor chapel, who do not read very much, and very often have no aims higher than those of the mere animal life. Had they access to museums on holidays and in the evenings, I am sure that the receipts of public houses would ultimately be lessened. At present they have few recreations and little chance of self-improvement; for the so-called mechanics' institutes, which were originally intended for them, have generally passed into the hands of the class immediately above them.

W. BOYD DAWKINS

PHYSIOLOGICAL ÆSTHETICS

Physiological Æsthetics. By Grant Allan, B.A. 8vo. (London: Henry S. King and Co., 1877.)

WE have here a little work of some 300 pages, which deals with the philosophy of æsthetics almost exclusively on its physiological side. Of course, in thus restricting his subject, the author neglects all the more subtle and intricate parts of that philosophy; but every competent reader will agree with him that it is desirable, for the purpose of analysis, to separate as distinctly as possible the physiological from the psychological elements of æsthetics. For although the two classes are intimately blended in reality, this only makes it the more desirable to eliminate the one from the other in our analysis; so that we may perceive, as clearly as we can, how much of the total effect which our æsthetic consciousness supplies admits of being resolved into simple constituents, and how much remains over as complex constituents. Now in this respect Mr. Allan has profited well by the experience of previous writers; for while he treats his subject very thoroughly so far as it can be treated on the lower basis of physiology, he never permits himself to be tempted into the alluring superstructure of pure psychology. So rigidly, indeed, does he "stick to his text," that an uninformed reader might peruse the whole essay, and scarcely receive a hint that there is such a thing as "the association theory" in existence; while the names of Burke, Reynolds, Alison, Knight, Stewart, and Jeffrey are not even once mentioned.

The scope of the treatise being thus carefully confined to the more simple factors of our æsthetic emotions, space is afforded for a full exposition of numerous facts and theories relating to this important sub-division of psychological science. And, on the whole, the work has been well done. The arrangement is good, the style admirably lucid, and the spirit throughout scientific. True, there are no ideas of a strikingly original character; but a judicious compilation of facts already known, and a philosophical discussion of the more important theories which have been raised upon them, would be features in a work sufficient of themselves to make the latter a valuable addition to the literature of æsthetics. Mr. Allan, however, has done more than this. In his dedication he characterises his work as a "slight attempt to extend in a single direction the general principles which he (Mr. Herbert Spencer) has laid down;" and in this attempt we must allow that our author has been successful.

Setting out with the object of "exhibiting the purely physical origin of the sense of beauty, and its relativity to our nervous organisation," Mr. Allan begins by "investigating the nature of Pleasures and Pains generally." The most important part of this discussion is that in which he criticises the law thus enunciated by Prof. Bain: "States of pleasure are concomitant with an increase, and states of pain with an abatement, of some, or all, of the vital functions." On this law it is remarked, with justice, "in its endeavour to be antithetical, it misses the real relationship between the two states. If pleasures were the psychical concomitants of an *increase* of the vital functions, then our two greatest, if not our only pleasures ought to be digestion, and repose after exertion. . . . Mr. Bain has sighted this difficulty, but, not perceiving its full force, has endeavoured to avoid it by a supplementary theory of stimulation, which appears to me far more important than his main law. I believe the true principle of connection to be this: Pleasure is the concomitant of the healthy action of any or all of the organs or members supplied with afferent cerebro-spinal nerves, to an extent not exceeding the ordinary powers of reparation possessed by the system. And just as the two laws are not exactly antithetical, so too the feelings themselves are not directly and absolutely opposed to one another as will be seen in the sequel . . . In short, it will be seen that while Prof. Bain refers pleasure to an *increase* in the efficiency of the organism, it may better be regarded as the concomitant of a *normal amount of activity* in any portion or the whole of the organism." Thus "every activity when not excessive nor of a sort to prove destructive of the tissues, is doubtless in itself faintly pleasurable . . . but owing to the commonness and faintness of the feeling, we habitually disregard it." Nevertheless, when the whole organism is "under the influence of abundant food and good rest, the general stimulation of the nerves produces a consciousness of massive pleasure." Moreover, "the special stimulation of a single organ whose periods of activity are long intermittent, and which is at the culminating point of its nutrition, produces consciousness of acute pleasure." From considerations such as these, illustrated by a large number of subsequent examples, there is deduced the general formula, that "the amount of pleasure is probably in the direct ratio of the number of nerve fibres involved, and in the inverse ratio of the natural frequency of stimulation." Hence it is that the possible intensity of pleasures can never approach the possible intensity of pains; for while the organism, or parts of it; may be reduced or injured to a large extent before loss of sensibility supervenes, "efficient working cannot be raised very high above the average." Hence, too, "the æsthetically beautiful is that which affords the maximum of stimulation with the minimum of fatigue or waste, in processes not directly concerned with vital functions."[1]

Such may be said to be the foundation on which the present system of "Physiological Æsthetics" is raised. Thus, to select a few among the copious illustrations which are offered:—"The vulgar are pleased by great masses of colour, especially red, orange, and purple, which give their coarse nervous organisation the requisite stimulus; the refined, with nerves of less calibre but greater discriminativeness," require delicate combinations of *complementaries*. Similarly in music, the complex *harmony* of a Bach's fugue pleases the cultured ear, while a chorus of Offenbach, or the boisterous *melody* of a comic song, is more gratifying to the common people. Again, the æsthetic superiority of musical tones over mere noises is naturally explained by the fact, that "while the nervous apparatus for the perception of the latter receives frequent stimulation, each portion of the nervous apparatus for the perception of the former is comparatively seldom stimulated." Similarly, of course, simple tones are musically "poor," because they "can only arouse a sympathetic vibration in a single one of Cortis's organs;" while tones rich in harmonics are musically "full," because they stimulate a correspondingly greater number of Cortis's organs. *Beats*, again, are disagreeable, because "the ear is conscious of each separate interruption of the tone, and each subsequent reinforcement," thus receiving a *destructive* amount of intermittent stimulation. Similarly, though in a lesser degree, with *dissonance*: and similarly, too, with the optic nerve, when flashes of intermittent light follow one another too rapidly for the receptive material

[1] The latter qualification arises from a lengthy discussion in which Mr. Spencer's view as to the origin of the Play-instinct from a superfluity of nervous energy is explained. This is explained in order that the æsthetic feelings, which by the theory are supposed to have a similar origin, may be analytically differentiated from the playful feelings—the distinction between Art and Play being supposed to consist largely in the fact that while the latter has reference to the over-fed motor fibres, the former has reference to the over-fed sensory fibres, "the organs of sight, hearing, &c.," or "the passive side of our nature"

to undergo repair during the intervals of darkness. The æsthetic superiority of the analytic colours over black, white, and grey is explained by considerations analogous to those which have just been mentioned in the case of musical tones and noises; while harmony of colours is treated in the same way as harmony of sounds. A somewhat curious speculation is ventured to explain the apparent deficiency of the red-perceiving elements. "It is clearly desirable that the eyes of the frugivorous animals should be *pleasurably* stimulated by reds, oranges, and purples; and the simplest contrivance for effecting this end would be to give the greatest possible rest to such elements as answer to stimulations of these orders. Accordingly, they ought only to be excited by comparatively powerful stimulations of their proper kinds."

Adopting Mr. Spencer's view[1] as to the ideal being a faint central stimulation of such nerve-fibres as would receive strong peripheral stimulation by the reality, Mr. Allan carries his analysis to the limit where "Physiological Æsthetics" must end, and where Psychological Æsthetics ought only to begin. Space, however, will not allow us to follow him into this division of his subject. Enough has been said to show that his work deserves the attention of psychologists; and it may be added that as he throughout clearly explains both the physics and the physiology of his subject, his entertaining little treatise will prove instructive to any general readers who may be desirous of observing the intimacy of those relations between psychology and the lower sciences, which the magnificent generalisations of recent years are now every day bringing into clearer prominence.

GEORGE J. ROMANES

[1] Here, as indeed in most other places, Mr. Allan does not express his obligations. Doubtless, having a psychological public in view, he thought it superfluous to state the sources from which such well-known conceptions have sprung; but as his work is in all other respects adapted to badly-informed readers, it would have been desirable, on their account, to have supplied these omissions.

OUR BOOK SHELF

Select Plants readily Eligible for Industrial Culture or Naturalisation in Victoria, with Indications of their Native Countries and some of their Uses. By Baron F. von Mueller, C.M.G., F.R.S., &c. (Melbourne: McCarron, Bird, and Co.)

THIS is another form of Baron Mueller's numerous and widely-spread contributions to the Acclimatisation Society of Victoria—numerous we say, because the Baron's pen is always at work upon botanical matters, the consideration of useful plants being apparently one of his favourite themes, and widely spread, because these papers on "select plants" seem to have been freely distributed not only in Australia and in this country, but also in America, where indeed some portion, if not all, have been republished. The present issue, Baron Mueller tells us, is a rearranged and largely supplemented form, which has been taken up by the Government of Victoria, and published under their authority. The book, which numbers some 293 pages octavo, contains references to an immense number of plants, the information attached to each being brief but withal accurate. The generic and specific names are arranged alphabetically from beginning to end, and this arrangement is perhaps the best for general use. After the scientific name, the vernacular name is given, then the geographical distribution or habitat, followed by a note as to the nature of the plant, whether a tree, shrub, or what not, and finally a brief description of its properties and uses. As a proof that Baron Mueller has corrected this latest issue of his papers, down quite to the present time we may mention that under *Nicotiana tabacum*, Lattakia tobacco is included, and it is only within a comparatively recent date that Mr. Thiselton Dyer has shown this to be right, nearly all previous writers having attributed it to *N. rustica*. At the conclusion of the book a very good plan is adopted of classifying the plants mentioned under distinct heads referring to their uses; thus, under alimentary plants, the generic names of all such are placed; the same under dye plants, fibrous plants, and so on. A good index is given of vernacular names only, which is quite sufficient when it is remembered that the scientific names are arranged alphabetically throughout the book.

Notes on the Ancient Glaciers of New Zealand. With Map. By J. C. Russell. Reprinted from the "Annals of the Lyceum of Natural History." (New York: November, 1876.)

MR. RUSSELL was attached to the U.S. Transit of Venus Expedition, and finding himself stationed on the shores of Lake Wakatipu among the snow-fields and glaciers of the South Island of New Zealand he read what had been written on the ice-work of that region and supplemented his reading by the personal observations recorded in these notes. Though he does not add any important new fact to our previous knowledge he gives an interesting *résumé* of the physical geography of the glacier region, pointing out the evidence for the former greater extension of the ice-fields of New Zealand, and dwelling especially on the proofs of enormous erosion shown by the valleys and lake-basins.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Nectar-secreting Glands

I HAVE briefly described in vol. xv. of the Linnæan Society's *Journal*, the nectar-glands found at the base of the fronds of the brake fern (*Pteris aquilina*) which are visited by ants for the sake of their sweet secretion. This case seemed to me to show in a striking manner that extra-floral nectar-glands are not necessarily protective in function, because the fern has, in England at least, extremely few enemies. The following extract of a letter lately received from Fritz Müller (of St. Catharina, Brazil) is of considerable interest in relation to this subject. He states that "the honey-glands on our *Pteris aquilina* serve, without doubt, to protect the ferns from the depredations of the leaf-cutting ants (Œcodoma), as is the case with Passiflora, Luffa, and many other plants. The glands of the Pteris are eagerly visited by a small black ant, Crematogaster, of which the Œcodoma seems to stand in great dread. On the other hand, when no protecting ants are present, I have seen Œcodoma gnawing the young fronds; here, as in other cases, it is only the young leaves that stand in need of protection, the older ones not being attacked by the leaf-cutting ants." This fact might, no doubt, be used as an argument by those who believe that all nectar-glands were originally developed as protective organs, and this argument would have great force if it could be shown that *Pteris aquilina* is a form which has arisen in countries where protection is needed; but even in that case there would remain the difficulty of accounting for the continued functional activity of the glands in districts where no such protection is required. Or it may be said that in past ages the glands on our European Pteris served as a protection against enemies which have now become extinct. But here we are again met by the difficulty of accounting for the continued activity of the glands. It is characteristic of evolution that great changes occur in the functions of organs, and I think that it will generally be allowed that even the most beautifully adapted apparatus must have originated in an organ performing some comparatively simple function. The question at issue may perhaps be stated as follows:—In the cases where the nectar-glands are now well developed has there been a special course of structural development in close relation with the need of the plant for protection? Has there been a course of evolution such as we may believe has taken place in the formation of the food-bodies in *Acacia sphærocephala* and *Cecropia peltata*, or should we not rather believe that the sweet secretion has been developed in connection with some unknown process of nutrition; according to this view, a well developed system of glands may continue merely performing some obscure excretory function, and consequently, although the presence of nectar-glands has undoubtedly been of the utmost importance in determining the survival of certain species, yet it is hardly fair to assume that all nectar glands were originally protective in function. For many plants secrete large quantities of sweet fluid, which serves no such purpose. This argument is given by my father in his "Effects of Cross and Self-Fertilisation" (p. 402). In addition to the facts there given in support of this view, a curious case described by Prof. H. Hoffmann may be mentioned ("Ueber Honigthau," 1876). He states that numerous large drops of sweetish fluid appeared on the under-surface of the young leaves of a camellia. He also alludes to a similar abnormal production of honey-dew on an ivy plant.

In the case of introduced plants, we see how an already existing quality may, without any special course of development, become of vital importance to its possessor. Thus, Mr. Belt shows ("Naturalist in Nicaragua," p. 74) that the lime, *Citrus limonum*, is able to exist in a wild state, because its leaves are, from some unknown reason, distasteful to the leaf-cutting ants; whereas the orange, *C. aurantium*, and the citron, *C. medica*, can only survive with the help of man.

Fritz Müller concludes his letter with some curious facts on kindred subjects:—

"The extreme variability of the nectar-glands on the leaves of many plants, is a somewhat remarkable fact. Thus our Citharexylon has normally two large glands at the base of the leaves, but sometimes there is only one, and sometimes none at all; besides these there are small glands scattered over the surface of the leaf, the number of which varies from twenty to none. Similar variations occur in the nectar-glands of *Alchornea erythrospermum*, and of a Xanthoxylon. It seems to me probable that in all the cases at present known, these glands serve to attract protecting ants; and I here agree with Delpino, although I do not hold with him that caterpillars are the chief enemies which are guarded against by Pheidole and Crematogaster; but I think with Belt that these latter ants protect the plant against the leaf-cutting species. Indeed it is precisely those plants which are free from the attacks of ants that seem to be especially well fitted for caterpillars. Thus the larvæ of Gynaeria live on *Cecropia peltata*, those of *Epicalia numilia* on *Alchornea erythrospermum*. On the Cayien (?) whose leaves are furnished with nectar-glands, and are visited by protecting ants, the caterpillars of many species of Callidryas are found. Finally, as far as I know, all the larvæ of the genus Heliconius feed on Passiflora. Moreover, the same relation holds in the case of plants protected in other ways, for instance, by stinging hairs or by poisonous sap. How numerous are the larvæ found on the European stinging-nettle. In this country we find the caterpillars of 'Ageronien' on the stinging Dalechampia; and again those of some species of Danais on Asclepias, which is protected by its milky juice." FRANCIS DARWIN

Down, Beckenham, May 21

Quartzite Implements at Brandon

AT the recent conference held by the Anthropological Society on the present state of the question of the antiquity of man, the president, Mr. John Evans, referred to the finding of implements made of quartzite at Brandon, and remarked that as that rock did not exist in the neighbourhood excepting in the glacial drift, the implements must have been made from pebbles obtained from the glacial beds, and were therefore of post-glacial age. This statement was made at the end of the meeting when there was no opportunity of replying to it, and as its effect must have been great, I shall be obliged if you will allow one who believes that none of the palæolithic implements are of post-glacial manufacture to make some remarks upon it.

For a full description of the implement-bearing deposits near Brandon I must refer to an able paper by Mr. J. W. Flower in the twenty-fifth volume of the *Quarterly Journal of the Geological Society*. Gravel Hill, near Brandon, is an isolated hill rising to a height of 91 feet above the river, from which it is nearly a mile distant. It is covered with gravel which is mostly, and in some places entirely, composed of quartzite pebbles. Mr. Flower estimates that three-fourths of the whole are of quartzite. In this the gravel differs from that of other pits in the neighbourhood of Brandon, as for instance, that at Bromhill, which contains only one thirtieth part of quartzose pebbles.

At Gravel Hill, along with some hundreds of flint implements, four made of quartzite, similar to that of the pebbles, have been found. All the implements are usually found at the bottom of the gravel, and occasionally lie on the chalk. On the supposition that the quartzose pebbles, from which some of the implements have been made, were brought by ice in the glacial period, some such succession of events as the following must have occurred. 1. Ice, from the north, carried thousands of quartzite stones and deposited them in immense abundance over a limited area. 2. Man afterwards made implements from some of them. 3. The whole of the pebbles were rearranged and formed into beds of gravel with the implements at the bottom, whilst the distinctive character of the deposit was retained.

This ingenious but complicated theory is not necessary, for quartzose boulders and pebbles are found in deposits much older than the glacial period not very far away from the locality, and may exist beneath the drift close to it. It has long been known to geologists that there are many fragments of old crystalline rock in the upper greensand. They have been described by Mr. Bonney in his geology of Cambridge, and very fully by Messrs. Sollas and Jukes Browne, who state that fragments of gneiss, mica, and hornblende schists, talcose schists, granites, vein quartz, grits, quartzites, and slates are very numerous in this bed. It ranges northward from Cambridge, and is lost beneath the surface gravels and boulder clays, but it is not at all improbable that it may run along to the west of Brandon, and there contain even more quartzose fragments than in Cambridgeshire.

I may remark in conclusion that Mr. Flower, in his description, states, that he is disposed with the French geologists, to ascribe the outspread of the gravels to some powerful cataclysmal action, and that he does not know of any boulder clays in the course of the river from which such a mass of pebbles could have been derived. THOMAS BELT

Cornwall House, Ealing

The Migration of the Swiss Miocene Flora

WITH reference to the route the plants took which formed the European miocene flora, I should be glad to know *why* Dr. Unger considers it to have been from America to Europe. He says: "There is more than *one* reason for thinking that the centre from which our lignite flora has sprung was far away from Europe—in the southern parts of the United States" (*Journ. of Bot.*, iii. 17). He thinks that the living flora of that part of America is the lineal descendant of that which gave rise, by aid of "Atlantis," to the Swiss miocene flora. But is enough known of the miocene flora of the United States to infer this? Prof. Heer says that the methods of comparison he employed "incontestably prove that Switzerland was inhabited by types now scattered over every part of the world [agreeing in that respect with the existing Arctic flora], but of which the majority correspond with species of South U.S. of America; the Mediterranean region of Europe ranks second; Asia Minor, the Caucasus, and Japan third; the Atlantic Isles fourth, and North Holland fifth" (*Nat. Hist. Rev.*, 1862, p. 154, quoted by Oliver). Prof. Oliver and Sir Charles Lyell think that the route was by Japan, and not by the Atlantis; but still (Sir Charles, at least) *from* America *to* Europe. Heer, in his "Primæval World of Switzerland" (vol. i. p. 325, Eng. ed.), says the *Glyptostrobus heterophyllus* of Japan "has probably been derived from the tertiary species" [of Europe]. Similarly, in comparing the *Taxodium distichum miocenum* with that of America, he observes: "It is very interesting to find that the ancestors of the existing American swamp-cypresses were formerly spread over the whole of Europe, as far as 78° N. lat. Again, of *Sequoia Langsdorfii*, he observes: "It probably formed a zone round the whole earth in high northern latitudes."

Instead, then, of regarding either Switzerland or the South U.S. as a "centre," I would suggest that the miocene flora was uniformly spread over the whole of the regions bordering the entire Arctic circle, just as the Arctic flora is now; Asia, Japan, and North-West America being then continuous; that as the climate became cooler in the pliocene epoch, it was driven southwards along every meridian, its descendants now existing in the localities above mentioned. It will be seen that these form a belt all round the globe, roughly speaking, between the 30th and 40th parallels of latitude. Migration to some extent might have taken place along that belt, but the great migration I suggest was probably from north to south, and not from east to west, or *vice versa*.

The above theory is simply an adaptation of that given by Dr. Hooker for a similar dispersion of the existing Arctic flora, which replaced the temperate floras of Europe, Asia, and America; but which on the return of a temperate climate retreated northwards as well as up temperate and even tropical mountains, perishing, however, in the low lands.

GEORGE HENSLOW

The Fertilisation of Orchids

WHILE botanising this spring in Portugal, I was struck with the fact that scarcely one of the orchids—species of Ophrys principally—that I had collected for my herbarium, or examined in the field, seemed to be fertilised, for none presented the least indication of having had pollen applied to its stigmatic surface; and I examined flowers in every stage of expansion, from the opening of the bud to the withered and shrunk up floral envelopes. Each one, I remarked besides, contained its own pollinia, their caudicles in their respective glands and in their natural position. I was so struck with this, that one day (March 31) I gathered and examined forty-five different flower-heads, and of all these only one was found to have pollen-grains on its stigma, and all, the fertilised one included, had their pollinia intact. The locality was the Tapada d'Ajuda, or Royal Park, situated just outside the city walls of Lisbon, an inclosure containing many acres of land, clothed in spring with a rich flora, and a favourite entomological hunting ground, teeming with Coleoptera, Hymenoptera, and the commoner Lepidoptera. Several of the orchids contained aphides, and a few harboured a species of small red ant.

On April 21 I again made similar observations, selecting the same place, as it was most accessible to me, and because several orchideæ grew there in the greatest profusion. On this occasion I examined over thirty flowers—none of them the same as I had examined in March, for I had plucked these at the time, but there was not one that did not possess its pollinia, and, as on the previous occasion, none of them showed any appearance of having had pollen-grains in contact with their stigmas.

Yet the Tapada, during the spring, produces these orchids by the thousand, vigorous, healthy, sweet-smelling plants, and in sunny days its air is perfectly alive with insect life, as I have said, of every kind.

HENRY O. FORBES

Old Hall, Highgate, N.

New Meteor Radiant

THE "two remarkable meteors" closely following each other, observed by Mr. Hope on May 13 (NATURE, vol. xvi. p. 43), proceeded most probably from a shower in the small southern constellation Crater. Your correspondent describes the point of first appearance as a *little* south of Arcturus. If this means about 7° or 8° below that star, then the observed courses accord well with the centre indicated, which is apparently quite a new radiant. From the Italian catalogue of 7,512 meteor paths (observed by Schiaparelli, Denza, and others in 1872) which I have lately been reducing, I found this shower at R.A. 170°, Dec. 10° S. (near $\epsilon - \theta$ Crateris) for May 3–15 from nine meteors.

Ashley Down, Bristol, May 27 W. F. DENNING

OUR ASTRONOMICAL COLUMN

ANTHELM'S STAR OF 1670.—The small star which is very close to the position of this object, as determined from the observations contained in Lemonnier's "Histoire Celeste," deserves to be closely watched, as there is more than a suspicion of its variation within narrow limits. Thus in August, 1872, it was exactly equal to a star which follows it 12·5s. in R.A., 4″·9 to the north; while in November, 1874, it was as certainly fainter by half a magnitude. This small star precedes the variable S. Vulpeculæ 43·6s., and is north of it 2′ 11″; two other small stars follow less than 2′ from the parallel, 22·4s. and 30·6s. respectively.

Prof. Schönfeld found the place of Anthelm's star from the observations of Hevelius and Picard,

R.A. 19h. 41m. 37s. N.P.D. 63° 2′·3 for 1855·0.

The place of the suspicious star alluded to above is, for the same epoch,

R.A. 19h. 41m. 43·5. N.P.D. 63° 2′ 7″.

It was meridionally observed at Greenwich in 1872.

D'ARREST'S COMET.—As yet we hear nothing of observations of the short-period comet of D'Arrest, for which M. Leveau has worked so laboriously, with the view to facilitate its discovery at the present return. The intensity of light was at a maximum about May 22, but diminishes gradually during the summer. Nevertheless, early in August it is still of the same amount as when Prof. Schmidt discontinued his observations at Athens in December, 1870, at which time he stated he could have followed it longer but for the want of an ephemeris. Subjoined are the comet's calculated positions during the absence of moonlight in the present month, for Paris noon:-

	Right Ascension. h. m. s.		North Polar Distance. ° ′		Distance from the Earth.
June 7	1 18 58	...	85 26·2	...	1·613
9	1 25 14	...	85 11·8	...	—
11	1 31 27	...	84 58·2	...	1·611
13	1 37 35	...	84 45·2	...	—
15	1 43 40	...	84 33·0	...	1·609
17	1 49 41	...	84 21·5	...	—
19	1 55 38	...	84 10·7	...	1·607

Though the comet will not arrive at its least distance from the earth during the present visit (1·396) until October 20, it passed its perihelion on May 10. The period of revolution is now 2,434 days, or 35½ days longer than at its last appearance in 1870.

THE D'ANGOS COMET OF 1784.—Perhaps no person who has been occupied in astronomical observation and calculation has obtained for himself, rightly or wrongly, a more unenviable notoriety than the Chevalier D'Angos, who, in the latter part of the eighteenth century, was possessed of a small observatory in the island of Malta. From the unusual character of some of his statements his name came to be associated with anything in the way of observation that appeared to be apocryphal, and we find not only Zach was in the habit of terming doubtful assertions "*Angosiades*," but even Pastorff, who himself put upon record more than one suspicious statement, appeared to consider that he was establishing the good faith of an observation of a comet in transit across the sun's disc by declaring that it was not an observation made "à la D'Angos." We pass over on this occasion the reported observations by D'Angos in 1784 and 1798 of a comet or planet upon the sun, with the view to presenting the reader with a brief outline of the actual state of a case that has been open to still greater suspicion, viz., his observation and calculation of what appears in some of our catalogues as the second comet of 1784; and we may be pardoned for bringing together here particulars which though probably known to those who have access to a good astronomical library, are not so likely to be within the cognisance of those who cannot command such a collection. And further, it is almost essential to bring the main points in the case into one view, to enable the reader to judge for himself whether D'Angos is deserving of the opprobrium which has been cast upon him or not.

Writing from Malta on April 15, 1784, D'Angos apprised Messier at Paris that he had discovered a comet in Vulpecula on April 11, and he inclosed two approximate positions observed on the mornings of these days. He stated that the comet was very small, without tail, and with only "a slight appearance of nebulosity." Messier did not receive this letter until May 14, when he sought in vain for the comet. Pingré who wrote before any suspicion had been raised with respect to D'Angos, attributed this to its having in the interval receded to too great a distance from the earth, or having attained too great south declination. It appears that Messier did not receive any further observations from Malta, but D'Angos some time afterwards communicated to him elements of the orbit, calculated by himself, and it was to be presumed with the aid of further positions. The observatory at Malta was burnt at a subsequent period, and the whole of the papers, &c., of D'Angos were stated to have fallen a prey to the flames, so that it was supposed in France that the observations were irrecoverably lost. Burckhardt had endeavoured by successive hypotheses to extract some idea of the nature of the orbit from the two rough observations which he had received, and as his results differed widely from those of D'Angos, and even the elements of the latter did not represent these observations, Delambre, at the instance of Burckhardt, wrote for further particulars. In reply, D'Angos stated that he had only saved from the fire his meteorological journal, in which, under date April 22, was mentioned an observation of the zodiacal light, without any reference to the comet, whence he concluded that on this date the latter was no longer visible.

This assertion will appear a most extraordinary one when it is stated that so far from the observations being lost, they had appeared in a memoir drawn up by D'Angos himself, in a periodical conducted by Bernoulli and Hindenberg, entitled—*Leipziger Magazin für reine und angewandte Mathematik*, Leipzig, 1786, where they were discovered by Olbers, as he mentions in a letter to Encke, inviting his discussion of them. Positions of the comet in longitude and latitude are there given for fourteen nights between April 10 and May 1, and they are followed by the elements of the orbit, which D'Angos says he had calculated from them.

Zach in 1812 had suspected that the observations of the second comet of 1784 were imaginary, and had suggested that the orbit should be omitted from the catalogues, but he adds as he had only great probabilities and moral, not mathematical, proofs to support his view, he did not insist upon it. To provoke an explanation, however, he states he had enveloped "ce mystère d'iniquité" in a problem in vol. iii. of his *Correspondance Astronomique*, where he printed a series of positions of a body, which he invited his readers to explain, and which puzzled Olbers and Bessel who failed, like others, to discover Zach's meaning. Burckhardt also on receiving intimation from Olbers of his having brought to light what purported to be the observations of D'Angos, remarked upon the importance attaching to the circumstance, since it might lead to proof that they had been fabricated.

It remains to describe in a future note or notes, the results of Encke's investigation and of later inquiries relative to the comet of D'Angos.

PROF. SYLVESTER ON TEACHING AND "RESEARCHING"

IN the address of Prof. Sylvester at the Johns Hopkins University, to which we have already referred, he spoke as follows on the above subject:—

Let me take this opportunity of making my profession of faith on a subject much mooted at the present day, as to whether the highest grade of university appointments should be conferred with or without the condition of teaching annexed.

I hesitate not to say that, in my opinion, the two functions of teaching and working in science should never be divorced. I believe that none are so well fitted to impart knowledge (if they will but recognise as existing, and take the necessary pains to acquire, the art of presentation) as those who are engaged in reviewing its methods and extending its boundaries—and I am sure that there is no stimulus so advantageous to the original investigator as that which springs from contact with other minds and the necessity for going afresh to the foundations of his knowledge, which the work of teaching imposes upon him. I look forward to the courses of lectures that I hope to deliver in succession within the walls of this university as marking the inauguration of a new era of productivity in my own scientific existence; nor need I consider any subject too low (as it is sometimes foolishly termed) for me to teach, when I remember to have seen the minutes of the conversation held between the delegates of the Convention, at the time of the French Revolution, and the illustrious Lagrange, the son of the pastry-cook of Turin, possibly the progenitor of the Marquis Lagrange, of turf celebrity (Citoyen Lagrange, as he is styled in the record), who, when asked what subject he would be willing to profess for the benefit of the community, answered meekly, "I will lecture on Arithmetic."

At this moment I happen to be engaged in a research of fascinating interest to myself, and which, if the day only responds to the promise of its dawn, will meet, I believe, a sympathetic response from the Professors of our divine Algebraical art wherever scattered through the world.

These are things called Algebraical Forms. Prof. Cayley calls them Quantics. These are not, properly speaking, Geometrical Forms, although capable, to some extent, of being embodied in them, but rather schemes of processes, or of operations for forming, for calling into existence, as it were, algebraic quantities.

To every such Quantic is associated an infinite variety of other forms that may be regarded as engendered from and floating, like an atmosphere, around it—but infinite in number as are these derived existences, these emanations from the parent form, it is found that they admit of being obtained by composition, by mixture, so to say, of a certain limited number of fundamental forms, standard rays, as they might be termed in the Algebraic Spectrum of the Quantic to which they belong. And, as it is a leading pursuit of the Physicists of the present day to ascertain the fixed lines in the spectrum of every chemical substance, so it is the aim and object of a great school of mathematicians to make out the fundamental derived forms, the Covariants and Invariants, as they are called, of these Quantics.

This is the kind of investigation in which I have, for the last month or two been immersed, and which I entertain great hopes of bringing to a successful issue. Why do I mention it here? It is to illustrate my opinion as to the invaluable aid of teaching to the teacher, in throwing him back upon his own thoughts and leading him to evolve new results from ideas that would have otherwise remained passive or dormant in his mind.

But for the persistence of a student of this University in urging upon me his desire to study with me the modern Algebra I should never have been led into this investigation; and the new facts and principles which I have discovered in regard to it (important facts, I believe,) would, so far as I am concerned, have remained still hidden in the womb of time. In vain I represented to this inquisitive student that he would do better to take up some other subject lying less off the beaten track of study, such as the higher parts of the Calculus or Elliptic Functions, or the theory of Substitutions, or I wot not what besides. He stuck with perfect respectfulness, but with invincible pertinacity, to his point. He would have the New Algebra (Heaven knows where he had heard about it, for it is almost unknown in this continent), that or nothing. I was obliged to yield, and what was the consequence?

In trying to throw light upon an obscure explanation in our text-book, my brain took fire, I plunged with re-quickened zeal into a subject which I had for years abandoned, and found food for thoughts which have engaged my attention for a considerable time past, and will probably occupy all my powers of contemplation advantageously for several months to come.

OUR INSECT FOES

AN important conference was held at the Society of Arts on Tuesday afternoon on the subject of insects injurious to agriculture and methods of stamping them out. Its origin was a proposition by Mr. Andrew Murray (who has had the arrangement of the collection of economic entomology made by the Science and Art Department), which he laid before the Lord President of the Council. The proposition was printed by order of the president, and copies were sent to the agricultural societies and chambers of agriculture of the country. After the proposition had been before them for two months and there was no indication of any notice being taken of it, it was arranged that a conference of delegates of agricultural societies should be held at the Society of Arts. The Duke of Buccleuch, K.G., took the chair, and there were present representatives of the Scottish, Cheshire, Warwick, Hampshire, and Banbury Chambers of Agriculture; the Farmers' Club, Dr. Maxwell Masters, representing the president of the Royal Society, Prof. Voelcker (chemist to the Royal Agricultural Society), Mr. Sewell Reed, M.P., &c. The conference was opened by a paper read by Mr. Murray.

The paper commenced by assuming as an axiom that, besides the occasional great injury done by insects, by which whole districts are ravaged, a continual drain is constantly kept up by them, which constitutes a very perceptible percentage of deduction from the cultivators' profits; and, further, that where this loss can be prevented at less cost than the loss it occasions, it should be prevented.

It next maintained that, if we wish to rid a district or a country of an injurious insect, to be effective, any attempt to do so must be simultaneous and combined, for to what purpose would it be if one man cleared his farm if his neighbour did not clear his; or if the one cleared his one year, and the other cleared his another? A central authority, therefore, is needed to secure united action.

It next considered the various ways in which the insects injurious to agriculture might be extirpated. The first, the simplest, the most powerful, and the most efficient of these is county or district rotation of cropping. Farmers know well enough the advantage of a rotation of cropping (or its equivalent) on their own farms. By long-continued growth of the same crop on the same land the soil becomes exhausted of some of the elements necessary for the proper development of that kind of crop, and a change of crop brings other elements into use, and relaxes the demand upon those that have been too much drawn upon.

Exactly the converse of this takes place with regard to certain insects. The great majority of vegetable-feeding insects do not feed on all kinds of plants indiscriminately; most of them are restricted to one kind of plant, and if by cultivation of that plant its numbers are enormously increased, so will naturally be the number of the insects that feed upon it; while, if we should cease to grow that plant, the number of the insects would correspondingly diminish. Thus, for instance, if a district is almost entirely in pasture, there will be very few wheat-feeding insects in it, but if it is turned into a wheat country they will be myriads. If these numbers reach such a pitch as to deteriorate the crops the remedy is plain. Change the rotation, and grow some other crop instead of wheat. Most of the wheat insects are only annuals. If they could be banished for one year they would be banished entirely, or until re-introduced. Now, if there were a controlling authority, what would be easier than to say to the farmers, "Gentlemen, in the common interest you will substitute barley for wheat in your next year's rotation." The insect, deprived of its proper nidus, must then either lay its eggs in an unsuitable place where they will perish, or have recourse to the pasture fields for *Triticum repens*, or other suitable grasses. By this, of course, the fly would not be exterminated, but its numbers would be so reduced as to render it comparatively harmless, at all events for a time, when, if it again reappeared in force, the same means of defence would be resorted to. Nay, it might be so arranged that two or more counties might brigade themselves together, so as to establish a permanent see-saw by which they should play into each other's hands. But no single man can carry out such a rotation. He may try it upon his own fields, but they will be replenished continually from the fields of his neighbours, unless they at the same time are compelled to follow the same rotation.

Mr. Murray then went over the various other means of extirpation—picking and burning infected plants, the collecting caterpillars, poisons, and local remedies, in relation to which he drew attention to the destruction of what are called ticks and lice upon sheep. Everyone knows how readily such vermin can be communicated by contact or even proximity, and it does seem a very hard case that a man, who has kept his flock clean by taking proper precautions, should be liable to have them infected by a neighbouring neglected flock, by stray sheep, or even by sheep passing along the road. It is said that, *cæteris paribus*, the difference in value between a sheep that has been kept clean for the season and one that has been worried by vermin will be 20*s*. If that is so it is a wonder that sheep farmers have not long since clamoured for some supervision.

At the conclusion of the paper the following resolution was put from the chair and carried:—"That thanks are due to the President and Lords of the Council for having brought the subject of insect damage under the consideration of the agricultural bodies of the kingdom."

Dr. Maxwell Masters moved the next resolution, and in doing so said he was charged to express the regret of the President of the Royal Society that he was unable to be present. He spoke of the great ignorance throughout the country on the subject of insect damage, and as an indication of the amount of damage done, said that half the time of the Scientific Committee of the Royal Horticultural Society was occupied with answering inquiries from all parts as to how to deal with insect foes. The resolution he moved was,—"That much of the loss occasioned by insects is preventible, and ought to be prevented." This was seconded by Mr. Maclagan, and carried.

Mr. Mechi then moved—"That it properly belongs to Government to provide the necessary means for protecting cultivators from this loss, as it is only by combined and simultaneous action over considerable districts that it can be effectually done, and Government alone possesses or can obtain the requisite means of enforcing such action."

Both Mr. Mechi in moving it and Prof. Voelcker in seconding it, spoke of the want of knowledge throughout the country on the subject. Mr. Sewell Reed urged it was not a question for government but for agricultural societies. The resolution was declared carried, though many hands were held up against it.

The last resolution was—"That the President and Lords of the Council and the Agricultural Societies of the United Kingdom be informed of the opinion of this Conference, and urged to take the subject at once into their consideration, with a view of providing a remedy," which, after a long discussion, was carried.

THE VOLCANOES OF ICELAND

DURING the past year the Danish Government despatched the well-known geologist, Prof. Johnstrup, to Iceland, for the purpose of making a thorough scientific investigation of the scene of the recent volcanic disturbances. A short time since he laid before the Danish Parliament a report of his journey, with a brief account of the results so far obtained. The first part of the expedition was devoted to the volcanoes in the Dyngju Mountains, encircling the valley of Askja, and was accompanied with many difficulties resulting from the conformation of the region and the prevalence of violent snow-storms. The mountains themselves are not of volcanic origin, but consist of basalt and palagonite-breccia. In former times the Askja Valley was evidently much deeper than at present. Repeated flows of lava have gradually filled it up, and these Prof. Johnstrup believes to have occurred within the historic period, although no mention of volcanic disturbances in this district is to be found in the annals of the island. Along the outer edge of the Dyngju Mountains are numerous craters, some of considerable size, which have contributed most of the lava covering the plain of Odadahrann to the extent of sixty square geographical miles. Part of this enormous quantity of lava had its origin in the neighbouring volcano of Trölladyngja. It is, however, sharply distinguished from the twisted, contorted, masses of the former, by its more regular character and smooth crusts. In the neighbourhood of the newly-formed craters the earth is covered to the distance of over a mile with the bright yellow pumice-stone ejected during the eruption of March 29, 1875. Most of the pieces are seven to eight inches in diameter; many contained two to three cubic feet. In places where the pumice-stone is several feet in depth, it covers a layer of snow twenty-five

The Oskjagja. (From Watts's "Across the Vatna Jökull.")

feet deep, which fell in the winter of 1874-1875, and has been protected from the effects of solar warmth by the feeble conductive power of the pumice-stone. It is fortunate for the land that the outbreak was of this nature, for from its lightness the pumice-stone can be easily removed from the surface of the country. The party examined the most northerly of the craters, which was 300 feet wide and 150 feet deep. It was filled with steam, which was driven out with such force as to give rise to a most deafening roar. No solid matter, however, was borne along with the vapour. Not far from the crater an extensive depression in the valley of Askja has taken place, and the fresh surfaces of rock exposed thereby give a clear picture of the peculiar formation of the valley by successive deposits. It presents a remarkable similarity to the basalt and dolerite formations so prevalent in the mountain ranges of Iceland.

The most surprising feature of these late eruptions was the ejection of such enormous masses of pumice-stone, while not a trace of a lava stream is to be found. A similar outbreak is not mentioned in the records of the island. On account also of the vast development of steam, which gave rise to the pumice-stone formation, they are without a parallel amongst volcanic phenomena. At present the craters are to be regarded as gigantic steam escape tubes, the activity of which will continue for an uncertain period, but with gradually decreasing intensity. As long as these safety valves remain open it is not probable that a repetition of the eruptions will occur in the immediate future.

The volcanoes in Myvatns Öræfi were found to present entirely different characteristics. This barren plain is about thirty-five miles long and thirteen miles wide. Suddenly, on February 18, 1875, a volcano appeared in the centre. Four others appeared at subsequent dates, all of the craters falling into a straight line north and south. No eruptions have occurred here within historic times. The mass of lava which issued from these various craters is estimated at 10,000,000,000 cubic feet, eighteen times the amount supposed to have been emitted by Vesuvius in 1794 and 1855. The lava was basaltic and viscous when emitted, and crystals of chloride of ammonium were found in the vicinity of the craters. Only slight traces of the volcanic action remain now, where warm air arises from the thicker layers of lava.

Prof. Johnstrup is engaged at present in the preparation of maps showing the successive deposits of lava from the older eruptions, as well as from the more recent. The Hlidar range, hitherto regarded as a palagonite formation, was found by him to consist of trachytic masses, a more ancient, and in Iceland rarer, formation than palagonite.

In connection with Prof. Johnstrup's Report we may refer to Mr. Watts's interesting narrative of his journey across the Vatna Jökull.[1] Mr. Watts's name is already well known in connection with recent exploration in Iceland. He has for long had a strong desire to cross the Vatna Jökull, and at last succeeded. We infer—for his narrative is almost innocent of dates—that the feat took place in the summer of 1875. The preparations made remind one of those necessary before setting out on an Arctic expedition, and the whole journey bore a strong resemblance to those sledge journeys we read of in connection with the recent polar expedition. There were sledges, tent, sleeping bag, pemmican, and similar stores; frost-bites, snow-storms, and weary detentions for favourable weather and ground. The Vatna Jökull, we learn from Mr. Watts, is a vast accumulation of volcanoes, ice, and snow, covering an area of over 3,000 square miles in the south-east of Iceland. It is a plateau of from 4,000 to 6,000 feet high, is surrounded on all sides by volcanic mountains, and gives birth to glaciers on various sides. On the south especially it seems to be advancing, and there the glacier may soon reach the sea and give birth to miniature icebergs. Mr. Watts crossed at the east side, and after suffering considerable hardships he and his party reached the farm of Grimstadr, in the north of Iceland. From here Mr. Watts returned southwards to the northern edge of the Vatna Jökull for the purpose of examining the Oskjagja, a huge and active crater on the south of the Askja, or Dyngjufjall, referred to by Prof. Johnstrup. Mr. Watts gives many interesting and important details concerning this mountain and the desolate country in its vicinity, covered with pumice dust and other products of eruption. Mr. Watts also visited the region around the Myvatn Lake, near which are the sulphur deposits which a company was started to work. After visiting one or two places on the north coast he returned to Reykjavik right across the centre of the country. Notwithstanding the defects of style, the want of dates, and occasional vagueness, Mr. Watts's narrative is a really valuable and interesting contribution to a knowledge of the physical geography of Iceland, and he has the honour to be the first, so far as known, to have crossed the great Icelandic waste.

[1] "Across the Vatna Jökull; or, Scenes in Iceland," by William Lord Watts. (London: Longmans and Co.)

THE ANTIQUITY OF MAN

IN the number for May 24 we gave abstracts of the papers read by Professors Dawkins and Hughes, and Mr. Tiddeman at the Conference on the subject of the Antiquity of Man at the Anthropological Institute, and this week we give a report of the discussion which followed the reading of these papers, the remarks of the various speakers, we may state, having been revised by themselves.

Prof. Busk wished to explain, before the discussion commenced, the circumstances connected with the interesting fragment of bone, for the determination of which he was personally responsible. This "bone of contention" was represented by the cast which he held in his hand. He was surprised that such a large superstructure had been raised upon that particular piece. It was merely a fragment, evidently of a fibula, one of the most variable bones in the body. It was received by him, together with a large collection of other remains from Mr. Tiddeman, and for a long time remained an insoluble problem. At last, after many conjectural determinations by himself and others, Mr. James Flower, the well-known articulator to the Royal College of Surgeons, discovered in the College a human fibula of unusual size, and with which, as he pointed out, the Victoria Cave bone corresponded in many particulars. This determination, with the reasons for it, and illustrated by figures, was published in the *Journal* of the Institute. At the same time Mr. Busk was perfectly open to be convinced that it might be ursine. But although Prof. Boyd Dawkins had been good enough to show him bones of fossil bears of surprising size, none of them quite came up to the one in question. Nor at Toulouse, where there is such an enormous collection of ursine remains, did Mr. Busk observe any of corresponding dimensions. He was himself still disposed to regard the specimen as a fragment of an abnormally large human fibula, but thought that at present it would be unsafe to build any strong conclusions upon it.

Prof. Rolleston stated that in digging out a British skeleton he came upon a fibula standing vertically. They went on and he took out every bone with his own hands and they came to a skeleton, contracted in the ordinary British way, which was whole, minus that one fibula. A man is put into the ground with his flesh and bones all upon him, the flesh decays, the stones get upon him, the bones are loose and consequently the fibula gets disturbed. Even granting that the one before them was a human fibula he would lay less stress upon it than on any other bone. In the Gibraltar Cave series the fibulæ, owing to their liability to displacement, were very often missing. He did not in the least dispute the antiquity of the deposits in the Victoria Cave. With respect to the reindeer and the hippopotamus, they might judge something from what they saw in the life and in the flesh. He had seen the hippopotamus walking about in very cold weather in the Zoological Gardens seeming extremely comfortable, and the rhinoceros and reindeer the same. Mr. Evelyn, of Wotton, had kept reindeer alive for considerable periods in England. At the time of Julius Cæsar the reindeer lived in Germany. At the present time the reindeer was the food of the tiger in the Isle of Saghalien, North of Japan. There the tiger, which has a black and thick fur, crosses the ice after the reindeer. The skull of a young hippopotamus was found in England, showing that the hippopotamus really did live here and breed here too. Hence, mammals were not good indicators of temperature.

Prof. Prestwich referred to the observation of the president, that to consider the present subject thoroughly required the knowledge of the palæontologist, the anthropologist, the archæologist, and the geologist. He thought that it specially concerned the geologist with regard to the sequence of events. The palæontological evidence hardly presented sufficient differences. We had to deal with the sequence of man from his first appearance in time geologically to the present period. He would confine himself to the evidence in the south of England and in the north of France. In the south of England it was particularly clear and decisive; the datum line was distinct. It was afforded by the deposit of the boulder clay, which ranged as far south as London. That represented the glacial period. The post-glacial period he considered to be subsequent to the period of the deposit of the boulder clay. Most of the discoveries made in this country have been made in the districts of the south which have been covered by the boulder clay, and it is in the drift and gravel of the valleys excavated in the boulder clay of those districts that the flint implements have been so largely found; therefore he believed that in all that area man is of post-glacial age. If we got two levels on either side of a valley, so many feet above sea-level, with the boulder clay cut off on either side, then of course the *débris* at the bottom of the valley would consist of gravel, and so on, derived from materials which had been formed by the destruction of the several strata which originally traversed that valley. The materials so spread out were necessarily newer than the boulder clay; consequently man in the valleys was post-glacial. There were sometimes two or three successive levels of gravels in those valleys. If a valley was excavated to a certain depth, and a deposit was formed in which they could find no traces of the existence of man, whilst at another and deeper level flint implements were found, then man was introduced in that place only when the valley was excavated to its greatest depth and the gravel was spread out on the site now nearly occupied by our present rivers. Unfortunately the mammalian remains of those nearly connected periods were so alike that it was impossible to determine from the distinction of age. Bone caves were also found on the sides of valleys and in districts where there was scarcely any boulder clay, and we were then left to the palæontological evidence. With regard to the possible correlation of other deposits found in the south of England with the deposits which preceded the glacial period in the north, there was evidence in both areas of the land having been inhabited previous to the boulder clay period by animals which were likely to serve as the food of man. There was no *à priori* reason why man should not have existed before that period. Much would have to depend upon that complete palæontological evidence which possibly Mr. Tiddeman might have at some future period to bring before them rather than upon geological position. He was disposed to consider with Mr. Tiddeman that the cave he was now investigating might be of pre-glacial age. He thought that the evidence rather tended to show it was pre-glacial, but it was not conclusive. What might be decided upon that particular point must, however, depend upon further research. Taking again the valley of the Thames, we found flint implements in terraces raised some twenty, thirty, or forty feet above the present level of the river. At Reculver we found such evidence of the existence of man in a gravel eighty feet high, but as we ascended the valley we found the flint implements confined to the lower levels. At Reading no flint implements or mammalians are found in the high-level gravel. So also in the neighbourhood of Oxford mammalian remains and implements are found in the low-level gravel but none in the higher. Thus at the entrance of the Thames valley near to France we find evidence of man in the later high-level gravels, but man had not then penetrated into the Upper Thames valley. It was evident that at the period that those higher terraces were deposited in the upper valley of the Thames as far down as Maidenhead, very cold conditions pervaded, though post-glacial to the boulder clay. In the neighbourhood of Oxford there have been found in this upper gravel boulders of several tons in weight which had been carried from a very long distance, and he had recently observed in the neighbourhood of Reading some high-level gravel resting upon an ice-pitted surface of stiff clay in which there was no calcareous matter, presenting that sort of section (drawing it on the black board). A surface the size of that room was exposed. It seemed to him, however, that with respect to pre-glacial man there was an important "suspense account" now accumulating. In France an large series of observations had been made by competent observers, and it would not do to ignore the points they had brought forward. He had some reason now to believe from his own observations that there was evidence of man being pre-glacial even in the north of France. He also produced one specimen from the Red Crag which had been in his possession for many years. He could not answer for the labelling but only for the locality and the condition of the bone, but from the peculiar way in which it had been cut and then broken it had all the appearance of having been artificially worked, but he should certainly only put it to a suspense account. With respect to one observation of Prof. Dawkins, that the oldest implements were ruder than the newer ones, he would remark that one cause why the implements of Creswell Cave were so rude was because they were made of quartzite, which could not be finished in the same way as flint. At Amiens the older high-level implements were often more finished and finer than those of the low-level gravel.

Col. Lane Fox wished to say a few words upon a point not yet touched upon in any of the papers which had been read, viz., the means by which valleys had been eroded, and the time necessary to accomplish it. The uniformitarian theory, by which it was assumed that all the work of excavating valleys had been performed by means of their rivers flowing under the same conditions as at present, had been a good deal modified of late years, and he thought he could add a few facts from personal observation tending to show that some modification of the theory was necessary. With respect to the valley of the Somme, there was evidence afforded by relics of the Roman and bronze age found in the peat in the bottom of the valley, that the river had not materially lowered its bed since those relics were deposited, and therefore it must have taken an enormous time to work out the whole valley by means of a river which flowed with the same eroding power as at present. The valley of the Somme, however, was so comparatively narrow that it was possible the whole of it might have been eroded by such means, if sufficient time were allowed. But if it could be shown that the same conditions prevailed in other very much larger valleys where the work to be done was much greater, that would afford fair presumptive evidence that the eroding force must have been greater. He could mention one or two facts which showed that the Thames like the Somme had never shifted its bed since the bronze period. The first of these was that the river some way below Oxford, at the village of Dorchester, made a great bend; the ground on one side was high, and on the other, in the space inclosed by the bend perfectly, flat and low; there was an ancient intrenchment running across this low ground from bank to bank, and converting the promontory formed by the bend of the river into a fortress. It had been ascertained by means of the relics, consisting of pottery, flints, bronze implements, &c., associated with this intrenchment, that it was certainly as early as the bronze period, and perhaps earlier, no relic of Roman work having been found there, although Dorchester, close by, was a Roman station. The intrenchment in order to serve its purpose must have rested its flanks on the river at the time it was made, and the fact of their resting on the banks at the present time, although they are only a foot or two in height, showed that the river had not shifted or lowered its bed since the bronze age. Other evidence giving the same results was found in the same river lower down. Between Richmond and Battersea the Thames makes three or four bends in the comparatively flat bottom of the valley which is here more than four miles wide. He had found flint implements of the drift type deposited in sedimentary sand and gravel at Acton eighty feet above the present river, the discovery of which was communicated by him to the Geological Society and published in their journal. The river then since these implements were deposited must not only have lowered its bed eighty feet, but, according to the uniformitarian theory, must at each successive level have shifted its bed repeatedly so as to work out the valley here more than four miles wide. Yet bronze and stone implements have been found in considerable numbers in all the various bends of the present river dredged up from the gravel at the bottom by the dredging machines that have been employed of late years, and proving that the river had neither lowered nor shifted its bed since the bronze period, but if anything it had risen since that time. Was it possible, he would submit, that at this rate of progress, if progress it could be called, the erosion of the valley could be attributed to the present river flowing under the same conditions as at present? But if, as believed by Prof. Boyd Dawkins and Mr. Tiddeman, man existed in these parts during the subsidence of the glacial epoch, that would account, he thought, for a much greater flow of water having passed down these valleys in palæolithic times than was the case at present. In the valley of the Solent the same class of evidence was obtained. Mr. Evans had shown what a large amount of depression and erosion must have taken place in this valley since drift implements were deposited on the hill at Southampton. The valley of the Solent, from Portsdown to the Isle of Wight, is nine miles wide, and we have evidence in the Roman fortress at Porchester how little it has changed in modern times; yet in the centre of this valley near Southsea common, Col. Fox had some years ago discovered a flint station of the neolithic age, including celts, scrapers, and flakes in great abundance, the site of which was less than ten feet above the present high-water mark, showing that flint implements continued to be fabricated in the valley after land and water had assumed its present distribution. All these facts, he thought, favoured the opinion that powerful eroding forces must have been at work before that time. The very valuable papers which had been read treated only the geological aspects of the question, but as the President had observed there were ethnological and sociological problems to be solved, how long would it have required for the various races of man to diverge, and the earliest traces of culture to be evolved? He trusted that even if no other result came of the conference it would show that we had not yet exhausted the subject.

Prof. A. H. Sayce had to confess that the evidence of language as regarded the antiquity of man was not so decisive as that of geology. Under certain conditions the vocabulary of a language changed rapidly, under other conditions it changed slowly. The grammar of a language may be said to change never, and its structure to change very rarely. If these conclusions were applied to two or three of the principal families of speech, the results would be something like this: Take the Semitic class of languages; by means of the Assyrian monuments we are able to get back to 2000 B.C. for a starting point, when those languages were pretty much as they are to-day. Scarcely any of the structure, or grammar, or vocabulary has changed, but it is plain enough that they pre-supposed several earlier stages of existence, and when compared with the grammar of the old Egyptian there was a time when the parent language seems to have been the parent also of the old Egyptian. But in order to allow for the changes that had taken place in the structure of the Semitic languages, and the structure of the Egyptian language, we must assume a very great period of time. With regard to the Aryan family, the different dialects could be traced back to the parent speech spoken in some part of Western Asia. That parent language could be restored by comparison with the later languages and dialects. In all points that parent speech was as fully developed as Sanscrit, or Greek, or Latin, the people who spoke it were in an advanced stage of civilisation, and the language itself was in a highly advanced condition. When the grammatical details of the language were analysed, it became quite plain that it was the product of a long series of successive stages of growth. Take another language, the old language of Chaldea. The earliest monuments that contained that language were between 3000 and 2000 B.C. On these monuments the language appeared in a stage of the most utter decline and decay. Therefore there was evidence of a language which had behind it a long and undetermined past. If, as several scholars believed, that language belonged to the Ural-Altaic family, in order to get back to a period when those languages were one and the same, they must suppose an enormous period of time. There was another consideration connected with the evidence of language. It would seem that most languages, whatever their present structure might be, were at one time in a condition similar to that of the Esquimaux language at the present time, that is to say, a time when as yet the single word is not distinguished from the sentence as an independent unit, but forms part of the sentence in which it is embodied. In the case of languages so highly developed as, say, the Aryan languages, in order to get back to a time when those languages were in a condition similar to the present condition of the Esquimaux language, they must allow not hundreds but thousands of years. Those were the conclusions to which the present investigations of language would appear to point.

Mr. T. K. Callard, referring to the outline of the head of a horse, drawn upon a bone represented as belonging to the palæolithic age, found in association with extinct animals, said they had always been led to think that palæolithic man was a rude savage who could only chip his flint implement, but who could not smooth it (that would indicate the neolithic period), but they were now getting evidence of a different character. They had heard of a bone needle being found in the cave-earth, which at once suggested a step in civilisation, as men did not make bone needles unless they intended to use them, and that would lead their thoughts to a palæolithic tailor. In that very cave were found traces of a no mean artist, for not one man in three at the present time could make a sketch like that of the horse. It struck him that that Royal Academician of the palæolithic age had for his model a horse with his mane *clipped*, which indicated another stage of civilisation. Were they justified in saying that because the remains of mammoth and woolly rhinoceros were found in close proximity to the remains of man, therefore man lived at such a remote period? He was inclined to think that it proved not so much the antiquity of man, as that the extinct mammalia were more modern than they are supposed to be. The works of man being found with the remains of the extinct mammalia, tells nothing of the period of man's existence, unless it is also proved when the mammalia referred to became extinct; of this there was no proof adduced, and therefore, to his mind, the argument for man's antiquity based on the contemporaneity of man and the extinct mammalia has not been sustained.

Mr. Harrison said the palæolithic character of the flint implements found at Cissbury in connection with the remains of existing fauna, including goat and pig, showed that the form and finish of prehistoric tools and weapons were not of themselves a safe criterion of age. Though the earliest implements would necessarily have been the rudest, the converse was by no means true. There were doubtless art-centres in early times, as there are now, and Cissbury would not appear to have been one of them, but rather belonged to the far larger class of village manufactories. Some of the pits, he wished to say as the result of personal observation, may have been opened but a short period before our era. Their age does not directly affect the question of the antiquity of man in this country, which depends for its solution on geological facts.

The President, Mr. Evans, in summing up, said the questions principally discussed were—In the first place were they to assign any implement found in this country to a pre-glacial or inter-glacial period? or must they restrict them to a post-glacial period? Some of the implements found in the river gravels were made from stones derived from glacial drift, and were therefore clearly post-glacial. The characteristic forms of the implements gave a guide by which they might fairly argue that others of a similar character belonged approximately to the same date. Some implements were very persistent in their type; but if in a certain part of England post-glacial implements were found associated with a certain fauna, and in another part the same forms of implements were found alone, these also would appear to be post-glacial. There were certain distinctions to be pointed out in cave-deposits. In the cave described by Prof. Dawkins there were a succession of beds, and he thought it was in the upper beds of more recent date that the relics of the tailor and the artist were found. Looking at the enormous lapse of time comprised in the palæolithic period, which was evidenced by the amount of time requiste for the erosion of river valleys, he thought they would eventually be able to establish some chronology. If they could form any idea of the amount of time requisite for the excavation of a valley such as the valley of the Thames, they could approximately estimate the antiquity of man in this country, but for the last 2,500 years the variation of the river bed and its level were practically nothing, and therefore they were entirely at a loss without falling back on some hypothesis as to variations in the climate. It was difficult to say with certainty whether the implements discovered abroad in reputed miocene and pliocene beds were of necessity worked by the hand of man, and whether they had in all cases been found under the circumstances which were attributed to them. With regard to the other deposits by which the early existence of man had been traced, such as the skull alluded to by Prof. Rolleston, if it was found with a highly-finished spear-head, he (the speaker) could not regard it as of pleistocene date. The evidence of cut bones was by no means satisfactory. Some of those incisions were probably induced by natural causes. Some present might remember a pair of horns of an Irish elk which by mere pressure were embedded in each other. Still, all such evidence should be carefully collected, and it would become to a certain extent accumulative. The question as to the distinction between the glacial period in the South of England and that of the North was of very great importance. If geologists carried back the early appearance of man in this country to a time but little removed from the glacial period, they might safely infer that he must have existed in other parts of Europe at a much earlier period.

As this interesting discussion could not well be postponed, and as the time at the disposal of the Conference was necessarily brief, it now only remained for the three principals to reply to any objections that may have been raised to their statements and arguments.

Prof. Boyd Dawkins said that the first point to be considered was the antiquity of man in the Victoria Cave, based upon a small fragment of fibula, and two fragments of goat's bones which presented the appearance of having been cut. The fibula seemed to him to be ursine rather than human, and in size came within a very little (two-tenths of an inch) of the circumference of one of *Ursus spelæus* from Lozère. With regard to the goat's bones, he shared the opinion of Mr. Davies, of the British Museum, that they are not fossil, but recent, in other words, he did not believe that they were originally imbedded in the stratum containing the remains of the hyænas, but were derived from an upper stratum of post-Roman age in the cave, in which they are exceedingly abundant. The goat hitherto has not been found in any pleistocene strata in this country or in France, all the repeated cases of its occurrence turning out on examination to be the result of the mixing of two suites of animal remains, the one pleistocene, and the other historic or pre-historic. This is very generally done by the workmen, and this was probably the case in the Victoria Cave. But if these equivocal data be assumed to prove that man was living in this district while hyænas occupied the cave, the evidence is still unsatisfactory as to their pre- or post-glacial age. The hyæna stratum itself appeared to him, while the explorations were under his direction, not to be of clearly defined pre- or inter-glacial age; and his doubts as to this point were, he believed, shared by Prof. Hughes. He further remarked that the reindeer found in the hyæna stratum had been omitted from Mr. Tiddeman's list of species. The rudeness of the palæolithic implements in the Cresswell caves from the lower strata as compared with the more highly finished ones found above them, seemed to him to imply a progress in the arts in that district.

A priori, the more highly finished should succeed the ruder implements, although of course many cases of their being mixed together were on record. Into the other avenues of discussion he would forbear to enter.

Prof. Hughes, in reply, said that he wished the subject had been divided, so that they might have considered separately the different parts of the evidence and the different sources of error which had still to be eliminated. For instance, he thought it would be very well if they could have an exhibition of, and discussion on, the various ways in which nature breaks, cuts, and otherwise marks bone and stone as well as of various ruder forms known to be the result of human agency, so as to get clearer ideas as to what might really be taken as evidence of design. He pointed out that the measure of the antiquity of the deposits containing the remains of man depended chiefly upon the time it would take to bring about certain geographical changes, either assuming that surrounding conditions had practically remained the same, or allowing for such differences as must have occurred, and of which we can estimate the effect. Applying this, while he agreed with Col. Lane Fox's remarks on the slow rate of waste of the Thames valley, he felt that we must make a very considerable allowance for the probability that during the period from the bronze age to our own man had interfered far more with the free course of the river than during all previous time. Nature might also entirely change the rate of waste in such a case by a gentle upheaval or depression causing the more rapid or slower cutting back of the stream. With regard to the existence of depressions in non-calcareous strata he thought we could detect two ways in which they were formed. One by the forcing out of the plastic material all round the mass of gravel or clay thrown on it, and another when the gravel worked down into the puddled surface of a clay, the softer portions of which oozed up between the sinking stones. In all the cases which had come under his observation in which such phenomena occurred above palæolithic beds, the last appeared to be the explanation, as also in most cases where it was the only evidence for the more southerly extension of glacial phenomena.

With regard to the Victoria Cave, he thought that the evidence was as yet decidedly against the pre-glacial age of any of the deposits containing even a suspicion of man. He believed that the deposits along the sides and in the side chambers of a limestone cave were frequently newer than those in the main cave, as the carbonated water, being thrown off the clay, must work the sides down. Whatever might be the age of the boulder clay on the floor at the mouth of the cave, he believed that the thin layer which occurred in the talus had fallen out of a pipe of which there were plenty in the limestone above, and that this clayey bank had ponded back the flood-waters and caused the accumulation of mud in the talus inside and the formation of the laminated clay.

Mr. Tiddeman[1] had thought it unnecessary on this occasion to call attention to geological minutiæ at the cave mouth, but as Prof. Hughes had raised the question of the age of the boulder clay there he was bound to follow him. Prof. Hughes said the boulder clay fell from the cliff at a time long subsequent to the date when the bones were deposited, but in drawing his section he had omitted a very important feature. They had to dig through twenty feet of talus before they came to the boulder clay, at the back of which was the hyæna bed; that represented a very considerable lapse of time since the boulders were deposited there. If the boulder clay fell at a subsequent period how was it that it was at the base of all the talus and not mixed up with it. If it fell before the talus began to form it might practically be considered of glacial age. As regards the reindeer in the lower bed, only one very doubtful specimen had been found since he had had charge of the excavations. The chief matter to be considered was whether this fauna which had been found in Europe and in England with human handiwork, occurred at a time which could be correlated with certain great physical events. All the facts which he had noticed seemed to harmonise with the idea that there had been in England two well-marked glacial periods, and these both prior to the much lesser event of the upper boulder clay of Lancashire. For instance, the boulders made into implements which Prof. Hughes had referred to in Pontnewydd Cave, need not have belonged to the latest glaciation of that [illegible] Rolleston's experience, but in the Victoria Cave it would have great difficulty. If it were soft mud it might have a chance of getting down, but if it were modern other modern things would go down with it unless it had a start. [Prof. Rolleston said it was pointed at both ends.] Mr. Tiddeman did not think there was a possibility of its working its way down. There were large blocks of stone and beds of stalagmite which had to be blasted in getting down to it. He hoped geologists would bear in mind as new facts cropped up, the suggestion that we had had two glacial periods.

[1] In the abstract of Mr. Tiddeman's paper, p. 70, line 40, *non-gravels* should be *river-gravels*; line 44, *then* post-glacial should be *there* post-glacial.

THE GREENWICH OBSERVATORY REPORT

THE Report of the Astronomer-Royal at the annual visitation on Saturday contained nothing extraordinary with respect to the ordinary work of the Observatory. With reference to extraneous work, there are one or two points worthy of notice.

First, as regards the operations for the transit of Venus, the Astronomer-Royal reports as follows :—

The computing staff under Capt. Tupman has by degrees been reduced to two junior computers within the Observatory; and one or two computers external to the Observatory, who are employed on large groups of systematic calculations, for which they are remunerated by tariff. The principal part of the calculations remaining at the last report was that applying to the determination of the geographical longitudes of fundamental stations. At the moment of my writing, the last of these (the longitude of Observatory Bay, Kerguelen) is not absolutely finished; but I trust that it will be so before my presentation of this report; and then I shall be in position to offer the first determination of correction to parallax from eye-observations of the transit.

The method of determining the geographical longitude of the principal station in each group by vertical transits of the moon has been found very successful at Honolulu and Rodriguez. For stations in high south latitude, horizontal transits are preferable; for Kerguelen, as I have mentioned, the work is not quite completed. (It will be remembered that the longitude of Mokattam, the principal Egyptian station, was determined by telegraph.) The corrections to the moon's tabular places have been determined with much care from meridional observations at the principal European observatories.

The differences of longitude, or the relations of clock-times, within the groups of stations, are ascertained.

These calculations must be followed by the preparation of the factors of errors of various elements. Little progress is made in these; the work will not be heavy.

No further advance is made in the photographic reductions. The work is large, but it is simple, and will not be oppressive.

Second, as regards the numerical lunar theory :—

In the algebraical theory an alteration has been made, by the substitution of the equation of radial forces for the equation of *vis viva*. Nearly all the numbers had been computed, and the additional numerical operation was small.

The numerical calculations of the factors of symbolical variations are advancing; and the computations of the perturbing side of the equations, with due attention to the terms requiring extension of decimals, are in progress.

The numerical errors to which I alluded in the last report are corrected; and I do not think that any systematic error now remains.

With the view of preserving, against the ordinary chances of destruction or abandonment, a work which is already one of considerable magnitude, I have prepared and have printed as Appendix to the Greenwich Observations (with additional copies as for a separate work) the ordinary equations of lunar disturbance, the novel theory of symbolical variations, and the numerical developments of the quantities on the first side of the equations. The last of these will ultimately require some additions for the terms whose magnitude is increased (in algebraical development).

The work is perhaps somewhat larger than I anticipated, and the regularity of its progress has been disturbed by very frequent interruptions of my own attention, occasioned chiefly by annoying occupations on the transit of Venus. I trust that it will in future go on in a more orderly and more rapid way.

Sir George Airy concludes his report with the following general remarks :—

The subject which, I think, must first present itself to the mind of anyone who has traced the history of the observatory is the increase in the number and the fulness of our occupations.

Of these one in particular (altazimuth-observations of the moon) has originated with myself; others, from the suggestions of the Board of Visitors, or from the obvious demands of the scientific world.

This increase is felt even in our buildings and grounds; every corner of every room is or will shortly be occupied; and the form of the ground almost forbids extension.

The printing of the steps of the reductions of observations (which originated with myself more than forty years ago) naturally increased the labour within the observatory, as well as the expenses without it. This printing, however, must never be abandoned. But there is another part, of which the policy still appears to me somewhat doubtful, namely, the printing *in extenso* of every figure of original observations, it being remarked that the originals or extracts are always open to astronomers. I brought the question of suppressing these before the Board of Visitors many years ago; but the opinions of astronomers (I cite in particular the honoured name of M. Biot and that of Mr. Johnson) were so strongly adverse to it, that I laid aside all further thoughts of it; and I do not even now profess to entertain a decided opinion.

The three points, however, to which I have alluded (the extent of scientific occupations, the enlargement of buildings, and the amount of printing) must before long engage the attention of the Visitors.

RECENT RESEARCHES AMONG THE LOWER SARCODE ORGANISMS

THE customary annual address on the occasion of the anniversary of the Linnean Society was, on Wednesday, the 24th May, delivered by the President, Prof. Allman, F.R.S. In continuation of his last year's summary of the progress in this department of biology, he dwelt upon the important additions to our knowledge of these organisms, due to the investigations of Archer in our own country and of Hertwig and Lesser, Franz Eilhard Schulze, and Greeff in Germany.

The discovery of many new monothalamic Rhizopods of fresh water and the important additions made by the British and German investigators to our knowledge of their protoplasmic bodies were brought in review before the meeting. These monothalamic forms may be divided in accordance with the nature of their pseudopodia; in some these processes being short, thick, and finger-shaped (*Lobosa*); in others long, slim, and filiform (*Filifera*). The former were illustrated by *Hyalosphenia*, with its smooth, transparent shell, and by *Quadrula*, with beautifully sculptured shell; and the latter by *Gromia*, with its very long filiform reticulated pseudopodia; and by *Microgromia socialis*, which has the curious habit of forming colonies by the association of numerous individuals, which become united to one another by the mutual fusion of their pseudopodia. The remarkable form of reproduction discovered by Hertwig in *Microgromia* was also described. Hertwig had shown that in this Rhizopod the protoplasm divides by spontaneous fission into two segments, one of which remains in the shell, while the other forces its way out, assumes an oval shape, develops, instead of pseudopodia, two vibratile flagella, and becomes a free-swimming flagellate Zoospore, capable of ultimate development into the form of the adult. The very interesting discovery by Haeckel, that the contents of the so-called "yellow cells" of the Radiolaria become of a deep violet colour under the action of iodine, and are therefore mainly composed of starch, was also referred to among recent additions to our knowledge of the lower organisms. An account was then given of the remarkable and very significant researches of Messrs. Dallinger and Drysdale among the so-called "Monads,"—microscopic organisms which become developed in putrifying solutions of organic matter, and which, in their ordinary and apparently adult state swim about by the aid of vibratile flagella. These laborious and trustworthy investigators have shown that the flagellate monads may acquire an amœboid condition and move about by the aid of pseudopodia; that two such amœboid forms when they come in contact with one another become instantly blended together at the point of contact, that this blending becomes more and more intimate until the two individuals become completely fused together, when their mingled protoplasm assumes the form of a spherical sac filled with particles of immeasurable minuteness. These particles are germs destined for the reproduction of the individual. Their form can be demonstrated only by the highest powers of the microscope; and by following them by means of a one-fiftieth of an inch object glass, Messrs. Dallinger and Drysdale were enabled to trace their gradual development into the form of the adult. They further proved the remarkable and unexpected fact that these minute germs may be subjected to a temperature of from 258° F. to 300° F. without losing their vitality and power of development, a fact of vast significance in its bearing on experiments connected with the question of spontaneous generation. Finally attention was drawn to the quite recent discovery of Hertwig and F. E. Schulze of a nucleus in the Foraminifera. By this discovery the true systematic position can now be assigned to the Foraminifera, which must accordingly be removed from the region of Cytodes or non-nucleated protoplasm masses (to which they had been hitherto relegated), and placed on a much higher stage in the great division of the Rhizopoda. Resting on these facts F. E. Schulze has attempted to represent by the aid of a genealogical tree the mutual affinities and derivation from one another of the various members of the Rhizopoda. The base of the tree where its stem is as yet undivided, consists of the primitive forms—mere non-nucleated Cytodes represented by Haeckel's Monera (*Protogenes*, *Protamœba*, &c.). From these by the differentiation of a nucleus in their protoplasm are evolved the nucleated forms (*Amœba*, fresh-water Monothalamia, Foraminifera, Heliozoa, &c.) which constitute the sub-divisions into which the stem branches off. These repeat the various modifications of pseudopodia (Lobose, Filiform, &c.) which had already existed in the primitive forms, and which they thus derive by inheritance from their non-nucleated progenitors. Finally through the branch of the Heliozoa we are conducted to the ultimate twigs formed by the families of the Radiolaria, in which we find not only nuclei but a "central capsule" indicating the highest grade of differentiation attained by any member of the group.

THE NORWEGIAN DEEP-SEA EXPEDITION

THE Norwegian Deep-Sea Expedition will have started from Bergen on its second summer cruise in the steamer *Bæringen*. It has been decided by the proper authorities that the expedition, like last year's, shall be commanded by Capt. Wille with Lieut. Petersen as first officer. The scientific staff of the expedition is also the same as the previous year with the exception of the chemist, whose post is this year filled by Herr H. Tornœ.

The following is the approved plan of the expedition of the present year.

The equipment of the vessel and the determination of its magnetic constants were to be completed by June 1. In studying the temperature in the deep sea over the banks off the West Coast, it has become evident that accurate observations are wanting in the Norwegian Rende. In order to obtain these the vessel will go from Bergen direct to sea, and following the bottom of the Rende, take accurate observations there. Farther to the north several of last year's observations may also be verified.

The first proper field of work is the Norwegian coast banks to the north of Ramdalen. From existing observations it is probable that the "Havbro," where the bank sinks toward the depths of the Polar Sea, and where the ice-cold water begins at the bottom, lies at least twenty-five geographical miles from the coast. Between Rœst and the point off Ramdalen, where the expedition last year found a depth of about sixty fathoms with a rocky bottom ten miles from land, it is considered probable that there runs a more or less continuous ridge of rock.

The position and characteristics of the "Havbro" and the supposed ridge form main points in the examination of the banks. This goes on by forming cross-sections perpendicular to the coast. The sections, like last year's, are to be at a distance of twelve or thirteen geographical miles asunder. Their inner boundary is to be the outermost line of the special hydrographical survey. Their outer boundary is where the temperature at the bottom of the sea is ÷ 1° C., or thereby. In each section besides the observation of the temperature at each sounding, at least three other series of observations are required, one at the inner boundary, one at the "Havbro," at its inner edge, and one at the outer limit of the section. The number of soundings will depend on the bottom being found more or less even as the work goes on.

In order to leave as much time as possible for work in the depths of the Polar Sea, and at Jan Mayen and the Greenland ice, there will be carried on, along with the survey of the banks, the examination of the Umbellularia region to a depth of 1,000 fathoms in every third cross-section. If circumstances permit several other bank-sections may also be extended to this depth. While working in this region it will be proper to call at Bodoe.

A series of observations of temperature made in West Fiord with the newest deep-water thermometers will be carried out both during the voyage northwards in June and during the return voyage in August, in order to examine the abnormal state of things found there in the summer of 1875, the minimum temperature being at a depth of seventy fathoms. As the zoological surveys in West Fiord have hitherto only embraced the fauna of the coast, the opportunity will be sought to be utilised for zoological work in this fiord at a greater distance from land.

Magnetic absolute observations will be carried out at Rœst, where circumstances, from Lieut. Petersen's observations in 1875, appear favourable, and where the most projecting point is found for comparison with the proposed observations on the Greenland ice.

In the course of June it is supposed, with average weather, and with the experience gained last year, that the survey of the banks and of the Umbellularia Region according to this plan will have reached the latitude of Tromsœ.

The expedition will in the end of June or beginning of July, be equipped for a cruise to the westward, going first along the line Andœ, Jan Mayen, surveying it and its neighbourhood on both sides. Round the north-east end of Jan Mayen as a centre, several series of soundings are to be taken towards the north-east, the north, and the north-west. For in that neighbourhood where the outermost mountain of the Iceland volcanic region is supposed to be, the bottom appears to sink very rapidly towards the deep sea in the directions named.

Provided Jan Mayen can be reached, it is proposed to land on it for the purpose of undertaking an examination of its geography, geology, hydrography, zoology, botany, &c. It is also intended to make a survey of the sea on the west and south sides of Jan Mayen, for there is ground for supposing that Jan Mayen is connected with Iceland by a sub-oceanic ridge.

In order to examine the phenomena at the boundary between the warm surface current from the Atlantic and the cold polar current in the Greenland sea, the Greenland ice north-west of Jan Mayen will be visited. When the examination of a part of the Greenland ice is completed the course will be taken to a point about midway between Iceland and Jan Mayen, and the cross-section is to be examined from this point in the direction of Ranen with the view of discovering and exploring the supposed sub-oceanic ridge. When this cross-section is worked out to the Norwegian Umbellularia region, previously examined, the expedition will sail to Tromsœ to carry on work to the northward, if time permit.

As July is supposed to be devoted to the Jan Mayen cruise, the first half of August will be employed in a survey of the banks, the "Havbro," and part of the Polar Sea between Norway and South Spitzbergen. The eastern limit will be the line North Cape, Bear Island, South Cape. The latter half of August will be devoted to the return voyage to Bergen and dismantling. The scientific work will be carried out mainly in the same way as in 1876. In the zoological work, along with the use of the dredge, the trawl, and the swab, special weight is laid on the use of nets in the intermediate depths and fishing on the banks. On Jan Mayen the capture of birds ought to be an object of importance, and on the Greenland ice possibly seal and bear-hunting, &c.

In taking soundings the form and extent of the banks is to be determined, and the way in which the bottom falls off from these to the greatest depths of the polar sea. It is of fundamental importance for understanding the orography and geology of this sea and the neighbouring land and for the distribution of animal life, whether the bottom falls off towards the deep sea with an even slope or in terraces and escarpments with plateaus lying between. The position and number of the soundings is therefore to be determined with this view.

The measurements of the temperature in the deep sea are to be carried out to the extent necessary for a certain determination of the isotherms in the deep water of the cross-sections. It is also to be kept in view that the points in the cross-sections may be used for longitudinal sections. The newest deep-sea thermometers are to be used as frequently as possible, along with those employed last year.

At every sounding a specimen of water is to be taken from the bottom, and at chosen places at intermediate depths. The specific gravity of all specimens is to be ascertained. At every sounding, also, specimens of the bottom are to be taken and preserved for future examination, which is also to be done with the material of the bottom brought up by the dredge and trawl.

The chemical work is to be carried on mainly as last year. The specific gravity of the surface-water is to be determined once or twice a day, and oftener at places where the state of the currents or other circumstances render it desirable. Observations of the currents in the sea are to be carried out where circumstances make it desirable, and the weather permits.

Magnetic observations are to be carried out on board at sea, special weight being laid on obtaining declination observations. Absolute determinations are to be carried out at Rœst, and on the Greenland ice, besides the determination of the ship's magnetic constants at Husœ, and elsewhere where possible.

A geological survey is to be made of Jan Mayen, if a landing there is possible, to the extent circumstances may permit. It would be of great interest to carry out astronomical determinations of geographical position, topographical and hydrographical surveys on Jan Mayen. A determination of geographical position at Rœst, in connection with the magnetic observations, is also desirable, as the place is not connected with the trigonometrical net.

Botanical observations and collections are to be carrried out on Jan Mayen to the greatest possible extent.

The meteorological observations on board are to be carried out in all essential points as in 1876. H. MOHN.

NOTES

AMONG those on whom honours were conferred on the occasion of Her Majesty's birthday, was Dr. J. D. Hooker, President of the Royal Society and Director of the Royal Gardens, Kew. Dr. Hooker has been made a K.C.S.I.

THE twenty-sixth annual meeting of the American Association for the Advancement of Science commences at Nashville on August 29. Our own association meets at Plymouth this year on August 15, under the presidency of Prof. Allen Thomson, of Glasgow.

WE have received the programme of an Anthropological Exhibition to be held in connection with the Paris International Exhibition of 1878, under the superintendence of the Paris Anthropological Society. That Society has nominated a large Commission to organise the exhibition, with Prof. de Quatrefages as president. M. Krantz has placed at the disposal of the Society a spacious and fine position in the central pavilion of the Trocadero Palace. The Commission makes a warm appeal to all interested in the progress of the anthropological sciences, both in France and abroad. It wishes to prepare a complete inventory of the present state of these sciences. The following are the classes under which the exhibition will be arranged:—1. Crania and bones, mummies, and specimens relating to the comparative anatomy of the human races; 2. Instruments, methods of education; 3. Prehistoric and ethnological collections; 4. Photographs, paintings and drawings, sculpture, and modelling; 5. Geographical maps and tables relating to ethnology, prehistoric archæology, linguistic, demography, medical geography, &c.; 6. Books, journals, brochures. In order to facilitate the work of collection and arrangement, the Commission has appointed the following members to superintend the special departments named:—Dr. Broca, 1, rue des Saints-Pères, for what concerns Anthropological Societies; Dr. de Ranse, 4, place St. Michel, Anthropological Instruction; Dr. Topinard, 97, rue Rennes, General Anthropology and Craniology; M. Gabriel de Mortillet, Château de St. Germain-en-Laye (Seine-et-Oise), Prehistoric Archæology and Anthropology; M. Girard de Rialle, 64, rue de Clichy, Ethnography of Europe; M. Abel Hovelacque, 35, rue de l'Université, Linguistic Anthropology; Dr. Dureau, 16, rue de la Tour-d'Auvergne, Bibliography; Dr. Bertillon, 20, rue Monsieur-le-Prince, Demography, or the Statistical Study of Population, and Medical Geography; M. Louis Leguay, 3, rue de la Sainte-Chapelle, for all concerning the general management and arrangements. Each of the gentlemen named should be communicated with in relation to all concerning his special department. The programme is a very inviting one, and if successfully carried out the result must be highly interesting and valuable. We hope British anthropologists will do all in their power to help the Commission to carry out their aims.

THE Maritime and Piscatorial Exhibition, which was opened at the Aquarium on Monday, contains a large collection of stuffed river fish—the largest collection, probably, ever brought together. Fourteen angling clubs, and many private individuals, have sent contributions. The Prince of Wales has also lent his collection of Indian fish obtained during his tour, and there is also a collection from the Indian Museum. As the exhibition includes, among other things, all subjects connected with fishing, there is a good show of fishing-tackle, and with them a fine set of flies. Those by Mr. Ogden Smith are quite works of art. Messrs. Sotheran and Co. have, at considerable trouble, made a collection of books on fish and pisciculture, which deserves attention.

A HUNGARIAN prelate, the Archbishop Louis of Haynald, has constructed an astronomical observatory at his own expense at Kalocsa, lat. 46° 31′, long. 16° 32′. Among the instruments are a Browning telescope, a small (4-inch) Merz refractor, and a Cooke transit instrument. The arrangement of the new observatory is superintended by M. de Konkoly, already known as having built on his own property, O-Gyalla, a well-furnished observatory. We may add that the Archbishop of Haynald has already devoted considerable sums to botanical researches.

THE *conversazione* of the Society of Arts is fixed to take place at the South Kensington Museum, on Wednesday, June 27.

THE Commission appointed by the U.S. Government to examine Capt. Howgate's proposal for the establishment of an exploring colony within 400 miles of the North Pole recommend that 50,000 dollars be granted for the purpose.

AT the meeting of the Zoological Society of France on June 1, M. Perier, Professor of Conchology at the Paris Museum, explained that the number of specimens was far too large to be properly exhibited in the galleries, and that consequently it had been resolved to exhibit only specimens of each genus, and to have the types of species arranged systematically in drawers. Each species is to be entered in an alphabetical and systematic catalogue, so carefully compiled that the information it contains may be got at instantly. Any visitor wanting to inspect a particular species will have only to make an application to the galleries for conchology. The work is immense, but it is supposed that in ten years it will be completed.

THE French Society of "Amis des Sciences," instituted twelve years ago for distributing pensions to the families of deceased men of science or to *savants* themselves when incapacitated by old age, has held its anniversary meeting under the presidency of Prof. Berthelot. The report was read by M. Pasteur. It shows that the assets of the Society amount to 19,000*l*. The sum spent in pensions was 1,200*l*. last year. An *éloge* of M. Charles Sainte Claire Deville was read by M. Fouquier, his successor as professor at the Collége de France.

WE have received the yearly report for 1876–7 of the new Scientific Club of Vienna, and its perusal is well calculated to fill a cultured Londoner of moderate means with envy. For an entry money of five florins and a yearly contribution (payable quarterly !) of sixteen florins all the advantages of a good London club can be obtained combined with those of the Royal Institution. The club possesses a spacious building with lecture-halls, reading and conversation-rooms for smokers and non-smokers, writing-rooms, refreshment-rooms, splendid library, all the best journals of every kind from all parts of the world. During the greater part of the year there are scientific and other lectures, entertainments and receptions, excursions during summer, and it is contemplated to publish a weekly journal connected with the affairs of the club. The members, numbering already upwards of 500, belong to all classes of society and to all professions, their only bond of union being a desire for cultured intercourse. The only institution in London at all approaching to this Vienna club is the modest German Athenæum.

UNDER the care of Dr. P. P. C. Hoek there has been published in German a *catalogue raisonné* of zoological works and papers that have appeared in the Netherlands during 1875–6. There are in all eighty-seven titles. The title is "Die Zoologie in den Niederlanden," and the publishers are E. J. Brill, of Leiden, and C. F. Winter, Leipzig.

INTELLIGENCE received at New York, June 1, from the Sandwich Islands announces that simultaneously with the earthquake at Iquique, Peru, a tidal wave struck the group of islands on May 10, between 4 and 5 A.M. The sea suddenly receded and returned with great violence in a wave sixteen feet high, which entered the harbour at Hilo, and swept away the wharves and storehouses in the front part of the town. All the houses at Waiakin within 100 yards of the shore were destroyed. Five persons were drowned; many were picked up in the harbour. The earthquake undulations continued during the day, the difference between the highest and lowest water-mark varying from three feet to thirty-six feet in various parts of the islands. Cocoanut (*sic*, but probably Molokai) island was entirely submerged, and the hospital at that place was swept away. A fresh eruption of the Kilauea volcano commenced simultaneously with this oceanic disturbance. The same earthquake wave was also felt all along the Mexican Pacific Coast. Late particulars announce that great devastation and loss of life were caused by the tidal wave which swept the Peruvian coast. Six hundred persons are reported to have perished.

IN connection with the above the following is of interest :—A Press despatch from Washington, of May 12, states that Assistant-George Davidson telegraphs to C. P. Patterson, Superintendent of the Coast Survey, in relation to the earthquake waves registered in the tide-gauge at Fort Point, at the entrance of San Francisco Harbour, to the following effect :—"Sharp earthquake waves commenced on Thursday, May 10, at 6.18 a.m., five rises and falls of 9 in. in 80 minutes; then nine *maxima* or crests 48 minutes apart, with secondary *maxima*, the largest of which were 15 in.; then six sharp rises of 14 in. each to irregular broken crests one hour apart; then to 5 A.M. Friday, double *maxima* as at the commencement, the largest rise being 18 in. From 5.20 A.M. Friday, to 1.15 P.M., irregular *maxima*, then a sudden fall of 16 in., and action, continuing until 5 P.M. No well-defined *maximum* of action, but exhibitions of markedly different character. It may be stated that the earthquake wave of the great earthquake in Japan some years ago was twenty-three minutes in traversing the Pacific to San Francisco."

ON Monday afternoon, about 3.30, a tornado partially destroyed Mount Carmel, a flourishing town of 3,000 inhabitants on the Wabash River, South-Eastern Illinois. It struck the town on the southern quarter and passed north, destroying almost everything in its path. Three churches, two newspaper offices, two schools, the Court-house, and 120 buildings were demolished. The ruins caught fire, burning almost till midnight before the flames were extinguished. Many persons were killed or injured.

ON the vote in Parliament last Thursday to complete the sum of 24,569*l*. for the Patent Office, Dr. Playfair remarked that while the Government derived a revenue of 180,000*l*. from the inventors of this country, it made them a very insignificant return. Only about 2,000*l.* was spent upon a Patent Museum. The Patent Museum at South Kensington was very inferior to the corresponding institutions in France and America, and if we had such a museum at all it ought to be a good one, and such as would promote invention. He wished to ask whether the Government had bought or rented a large building for the purposes of an efficient Patent Museum? Mr. W. H. Smith explained that the space intended for the Patent Museum at South Kensington had been taken up by the collection of scientific apparatus, but that the Government still intended to arrange for a suitable exhibition of inventions.

A NOTE has been circulated in German papers, warning parents against the use of india-rubber toys manufactured in France and sold largely on the north of the Rhine. They were said to be poisonous owing to a certain quantity of oxide of zinc which was mixed with vulcanised india-rubber. The French Minister of Agriculture and Commerce ordered an inquiry to be made by the Council for Public Health, and the result is a declaration that these objects are quite harmless.

ACCORDING to recent news received by M. Sidoroff as to the mammoth discovered in Siberia, the carcass was found in the gold-bearing sands of a gold-washing on the river Kundola, at a depth of five mètres. The flesh was very soft and of a light red colour when freshly dug out, but soon hardened, becoming like a white clay. It seems to be much impregnated with lime. The digging out of the whole body will be very difficult because of the access of water. M. Polyakoff has already left St. Petersburg for the excavation of the body.

A TASHKEND telegram, dated May 10, announces that the Russian embassy, sent last spring to Kurl, has made a thorough survey of the route it followed, together with numerous barometrical measurements of heights. Capt. Kuropatkin and the naturalist M. Wilken, have explored the lake Bastan-nor and the route to Karashar, twenty-seven miles east of Kurl, whilst Lieut. Senorguroff has explored and surveyed the route from Aksu to Karakol, following the Babel pass.

AT the last meeting, May 16, of the Russian Geographical Society, it was agreed to postpone the exploration of the Angara river until next year, whilst the exploration of the water-parting between the Obi and the Yenissei will be made during this summer. Besides, M. Sonirnof undertakes a tour in Russia for magnetical measurements.

WE learn from the *Gardeners' Chronicle* that Prof. Boulger, the Professor of Natural History at the Royal Agricultural College, Cirencester, is preparing a "Flora" of Gloucestershire, and will be glad of any information as to rare species, localities, &c.

A COMMITTEE has been formed having for its object the presentation of a testimonial to Mr. F. W. Wilson, whose connection with the Crystal Palace, after twenty-five years' service, has just terminated. During the past quarter of a century Mr. Wilson, by his genial disposition, obliging manners, and thoroughly zealous efforts to promote and successfully carry out the various interesting natural history and other exhibitions held at the Crystal Palace, has earned the respect both of his colleagues and the general public.

OUR Paris correspondent writes: We were present at the Alliance Electric Works to witness an experiment on the new caolin-light, which we had seen in operation at the Physical Society, and which was recently described in NATURE. The Ruhmkorf machine was fed by a more powerful primary current given out by an Alliance electro-motor of three-horse power. The bar of caolin, ignited by induction-spark, was eight centimetres long, and fully equal to eight gas-burners. At the same time three so-called electric candles were in operation, each of them giving about forty gas-burners, and fully equal to five caolin lights. Consequently not less than twenty-five lights could be fed at once in separate parts of the same building or at any distance. The light is admirable for its constancy and duration; the quantity of caolin destroyed is quite insignificant—no more than 1 mm. per hour; the thickness of the caolin plate or bar used is not more than 4 millimetres. The electric candles are formed, as is known, by two graphite bars separated by a caolin bar. It was proved that the agitation of the candlestick produces no interruption of the current. Consequently a single Alliance-work machine can feed the three lights required by the regulations for steamers. The graphite pencils are consumed at the rate of eight centimetres per hour, which is a difficulty; but it is expected that any length required may be supplied by means of a proper clock-work. Experiments were tried on the same day at the Palais de l'Industrie for the purpose of illuminating the exhibition of pictures with electric light. The ordinary Gramme machines were set into operation. The light was found steady, but the effect was not quite favourable artistically. It is expected that with the system of light division, an improvement may be effected. The experiments were made in order to test whether electric light may be utilised on the occasion of the forthcoming International Exhibition.

IN connection with the above we may state that the experiment with Jablochkoff's electric light at the West India Docks on Tuesday night, was not quite successful, owing to some part of the apparatus going wrong. The experiment is, however, we believe, to be repeated.

THE destruction of agricultural and garden produce by the systematic attacks of insects is yearly becoming more and more serious. The gravity of this subject has been felt of late years not only by the growers of food crops themselves, but by scientific men, especially entomologists, and it is therefore with satisfaction we notice that some steps have been taken to obtain accurate records of the habits and conditions most favourable to the development and increase of certain well-known insects that devastate our crops. A little pamphlet called "Notes for Observations of Injurious Insects" has recently been issued by Mr. T. P. Newman, of 32, Botolph Lane, E.C. In these notes the necessity of such observations is pointed out, not only on scientific grounds, but also with a view to diminish the yearly losses of food crops to the country. The "Notes" are illustrated with woodcuts of many well-known insect depredators as a guide to their identity, and a ruled sheet is furnished for entering the records and any remarks that may appear desirable. These, as well as the "Notes" themselves, are to be obtained *free* on application to the printer, as above, and any information required will be furnished by the Rev. T. A. Preston, the Green, Marlborough, or by Mr. E. A. Fitch, Maldon, Essex.

MR. OSCAR BROWING, in lecturing on Friday evening last at the Royal Institution on the history of education, drew attention to the science of teaching being in advance of the art. He urged that, like medicine, pædogogics should be made a science of observation on results obtained. Teachers should interchange experiences on results as well as on theory.

THE additions to the Zoological Society's Gardens during the past week include a Mesopotamian Fallow Deer (*Cervus mesopotamicus*), an African Leopard (*Felis pardus*), a Cheetah (*Felis jubata*) from South Africa, a Humboldt's Lagothrix (*Lagothrix humboldti*) from South America, deposited; a Prevost's Squirrel (*Sciurus prevosti*) from Malacca, purchased; a Black-backed Jackal (*Canis mesomeles*) from South Africa, presented by the Earl of Guildford.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE, May 30.—The Sheepshanks Astronomical Exhibition has been adjudged to John Edward Aloysius Steggall, scholar of Trinity College.

The twenty-second annual report of the Botanic Garden Syndicate has been issued. It is stated that during the past year much attention has been paid to the labelling of the arranged trees, shrubs, and herbaceous plants in the open ground, and it is believed that they all, or nearly all, are correctly and legibly named. There has not been time, without neglecting other important work, to name with similar completeness the plants scattered in the belt. It is believed that very few of the plants in the houses are without names, although a few duplicate specimens may be in that condition. About 1,700 new labels have been written. The culture of the plants is such as to give satisfaction to the syndicate. About 170 species of herbaceous plants have been raised from seed to supply the places of those which have died. Among the presents acknowledged are packets of seeds from the Indian Botanic Gardens, from Baron F. v. Mueller, and five large ferns from Australia from the last-mentioned gentleman.

OXFORD.—At the ensuing commemoration the honorary degree of D.C.L. will be conferred upon Mr. J. Evans, the distinguished antiquary; Dr. Harold Browne, the Bishop of Winchester; and Lord Coleridge. It is probable that degrees will be conferred on certain other distinguished persons, whose names, however, it would be premature to announce at present.

On November 23 next there will be an election to a Brackenbury Natural Science Scholarship at Balliol College, worth 80*l.* a year, tenable during residence for four years, open to all such candidates as shall not have exceeded eight terms from matriculation. Papers will be set in (1) Mechanical Philosophy and Physics, (2) Chemistry, (3) Physiology; but candidates will not be expected to offer in more than two of these.

DURHAM.—The University Mathematical Scholarship has been awarded to Mr. F. W. Sanderson, Hatfield Hall.

THE UNIVERSITIES BILL.—The attempt was made twice on Monday in the House of Commons to get a clause inserted in the Universities Bill abolishing Clerical Fellowships. As might have been expected, the attempt failed, though in the case of Mr. Goschen's motion by a very narrow majority—only 9.

UNIVERSITIES AND NATIONAL LIFE.—The following forcible remarks on universities and national life occur in the address of Prof. Sylvester at the Johns Hopkins University, to which we have already referred:—"The mention of Germany brings to my mind the importance of universities to the maintenance or development of a national spirit in the countries in which they are fostered and carried on with an animus free from local or sectarian prejudices. I think that there can be little doubt that the greatest fact in modern history, the consolidation of the German empire, the resurrection of the German people, is mainly to be attributed to the feeling of brotherhood and the spirit of nationality kept alive in those ganglions of thought, those centres of intellectual activity, the German universities. It is the university professors who have made German unity a possibility, and I cannot but deplore the unpatriotic short-sightedness of those in my own country who, until so late a period, have struggled, and still covertly struggle, to make our universities in England not the representatives of the universal English mind, but the monopoly of a party and the appanage of a sect."

SCIENTIFIC SERIALS

American Journal of Science and Arts, May.—On vortex rings in liquids, by J. Trowbridge.—An account of the discoveries in Vermont Geology of the Rev. Augustus Wing, by J. D. Dana.—Notes on the history of *Helianthus tuberosus*, the so-called Jerusalem artichoke, by J. H. Trumbull and Asa Gray. —A new investigation of one of the laws of friction, by A. S. Kimball.—Examination of American columbic acid minerals, by J. Lawrence Smith.—On the sensitiveness to light of various salts of silver, by M. Carey Lea.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 31.—"On the Amplitude of Sound-Waves," by Lord Rayleigh, M.A., F.R.S.

Scarcely any attempts have been made, so far as I am aware, to measure the actual amplitude of sound-bearing waves, and indeed the problem is one of considerable difficulty. Even if the measurement could be effected, the result would have reference only to the waves actually experimented upon, and would be of no great value in the absence of some means of defining the intensity of the corresponding sound. It is bad policy, however, to despise quantitative estimates because they are rough, and in the present case it is for many reasons desirable to have a general idea of the magnitudes of the quantities with which we have to deal. Now it is evident that a superior limit to the amplitude of waves giving an audible sound may be arrived at from a knowledge of the energy which must be expended in a given time in order to generate them, and of the extent of surface over which the waves so generated are spread at the time of hearing. An estimate founded on these data will necessarily be too high, both because sound-waves must suffer some dissipation in their progress, and also because a part, and in some cases a large part, of the energy expended never takes the form of sound-waves at all.

The source of sound in my experiment was a whistle, mounted on a Wolf's bottle, in connection with which was a syphon manometer, for the purpose of measuring the pressure of wind. This apparatus was blown from the lungs through an india-rubber tube, and with a little practice there was no difficulty in maintaining a sufficiently constant blast of the requisite duration. The most suitable pressure was determined by preliminary trials, and was measured by a column of water 9½ centimetres high.

The first point to be determined was the distance from the source to which the sound remained clearly audible. The experiment was tried in the middle of a fine still winter's day, and it was ascertained that the whistle was heard without effort at a distance of 820 metres. In order to guard against any effect of wind, the precaution was taken of repeating the observation with the direction of propagation reversed, but without any difference being observable.

The only remaining datum necessary for the calculation is the quantity of air which passes through the whistle in a given time. This was determined by a laboratory experiment. The india-rubber tube was put into connection with the interior of a rather large bell-glass open at the bottom, and this was pressed gradually down into a large vessel of water in such a manner that the manometer indicated a steady pressure of 9½ centimetres. The capacity of the bell-glass was 5,200 cubic centimetres, and it was found that the supply of air was sufficient to last 26½ seconds of time. The consumption of air was therefore 196 cubic centimetres per second.

In working out the result it will be most convenient to use consistently the C. G. S. system. On this system of measurement the pressure employed was $9\frac{1}{4} \times 981$ degrees per square centimetre, and therefore the work expended per second in generating the waves was $196 \times 9\frac{1}{4} \times 981$ ergs. Now the mechanical value of a series of progressive waves is the same as the kinetic energy of the whole mass of air concerned, supposed to be moving with the maximum velocity of vibration (v); so that, if S denotes the area of the wave-front considered, a be the velocity of sound, and ρ be the density of air, the mechanical value of the waves passing in a unit of time is expressed by $\frac{1}{2} S . a . \rho . v^2$, in which the numerical value of a is about 34,100, and that of ρ about ·0013. In the present application S is the area of the surface of a hemisphere, whose radius is 82,000 centimetres; and thus, if the whole energy of the escaping air were converted into sound, and there were no dissipation on the way, the value of v at the distance of 82,000 centimetres would be given by the equation—

$$v^2 = \frac{2 \times 196 \times 9\frac{1}{4} \times 981}{2\pi(82000)^2 \times 34100 \times \cdot 0013},$$

whence

$$v = \cdot 0014 \text{ centimetres per second.}$$

This result does not require a knowledge of the pitch of the sound. If the period be τ, the relation between the maximum excursion x and the maximum velocity v is

$$x = \frac{v\tau}{2\pi}.$$

In the present case the note of the whistle was f^{iv}, with a frequency of about 2730. Hence

$$x = \frac{\cdot 0014}{2\pi \times 2730} = 10^{-8} \times 8 \cdot 1,$$

or the amplitude of the aerial particles was less than a ten millionth of a centimetre.

I am inclined to think that on a still night a sound of this pitch, whose amplitude is only a hundred millionth of a centimetre, would still be audible.

Linnean Society, May 24.—Annual General Meeting.—Prof. Allman, F.R.S., president, in the chair.—The Senior Secretary (Mr. Currey) read his report, among other items, mentioning that twelve fellows and five foreign members had died during the past year. On the other hand forty-three fellows, three foreign members, and one associate had been elected. Of active scientific workers that had passed away, J. Scott Bowerbank, Edward Newman, and Alfred Smee called for special mention; the labours of the first named, in a previously little-worked department, the sponges, marking an epoch in British natural history. A passing tribute was due to the memory of the foreign members that had died during the year, for von Baer, Braun, De Notaris, Ehrenberg, and Hofmeister in their several departments worthily represented biological science in its broad aspects.—Mr. Gwyn Jeffreys, treasurer, in his financial statement, showed an increased balance in favour of the Society, and this, notwithstanding extra outlay in valuable additions to the library, improvements in the Society's scientific publications, &c. The demise of the late Charles Lambert, F.L.S., had brought the handsome bequest of 500*l*. to the funds of the Society.—The president and officers were re-elected and the following gentlemen, viz., Lieut.-Col. Grant, C.B., W. Carruthers, R. Hudson, Dr. J. Millar, and Dr. R. C. A. Prior were elected into council in lieu of the subjoined, who retired by rotation:—G. Bentham, Gen. Scott, C.B., R. B. Sharpe, H. T. Stainton, and C. Stewart. We elsewhere give an abstract of the presidential address, devoted to a *résumé* on "Recent Researches among the Lower Sarcode Organisms," a subject of daily increasing interest.

Meteorological Society, May 16.—Mr. H. S. Eaton, M.A., president, in the chair.—Messrs. Stephen Bretton, J. Gulson Burgess, David Milne Home, and F. Gartside Tippinge were elected fellows of the Society.—The following papers were read:—An improved form of mercurial barometer, by Mr. R. E. Power, F.M.S. The improvement consists in the use of a double column of mercury, so that in the event of a vacuum being formed by the escape of some mercury into the cistern, the shock is no longer felt by the tube but in the first place is received by the mercury alone and then reflected much diminished into the cistern, where it is modified by the presence of the atmosphere. At the same time, owing to the peculiar construction of the cistern, the probability of any mercury leaving the tubes is much less than in the case of the standard barometers at present in use. It is also believed that the employment of the double tube will do away with the necessity of boiling the mercury.—The relation between the upper and under currents of the atmosphere around areas of barometric depression, by the Rev. W. Clement Ley, F.M.S. This paper gives a description of the mean directions of the movements of cirrus clouds over the different segments of areas of depression. The subject is treated on its observational side, as it is not yet considered ripe for much theoretical discussion, but one or two points seem likely to throw some light on the theory of the movements of the atmosphere. The direction of the upper currents round a depression is found to be most intimately related to the direction in which the depression itself is progressing. In the rear of a depression where the mean direction of the surface winds is nearly parallel to the isobars, or at right angles to the radius, the cirrus current almost coincides with the surface wind, except near the central calm. In the front of the depression on the other hand, where there is the greatest indraught near the earth's surface, the upper currents flow greatly away from the centre. The current in the rear of a depression has therefore the greatest, and that in the front the least vertical depth. The majority of our depressions travel towards some point between N. and E., and so far as the author has been able to calculate, the mean height of our south-easterly winds is not half that of our north-westerly winds, even supposing the latter to extend no higher than the stratum of cirrus. The angle of deviation increases with the increase of friction; and it is possible, therefore, that the great incurvation of the surface winds in the front of a depression is closely related to the greater amount of friction which they encounter, for they are comparatively shallow currents, and experience resistance above as well as at their base. The contrast between the upper currents on the right and those on the left of the trajectory is quite as remarkable as that between the upper currents in the front and in the rear, and it is very constant and well-marked in its general character. As regards the centre, the upper-current, when traceable over this district, commonly coincides, or very nearly, with the wind previously felt at the earth's surface.—Contributions to the meteorology of the Pacific—the Island of Rapa, by Robert H. Scott, F.R.S. Rapa is a small island, eighteen miles in circumference, in the South Pacific, in latitude 27° S. and longitude 144° W. The observations were made by Capt. D. E. Mackellar, on board the depôt ship *Medas*, during the period extending from 1867, December 15, to 1869, May 27. The climate appears to be an equable one.

Physical Society, May 26.—Prof. G. C. Foster, president, in the chair.—The following were elected members of the Society:—Lieut.-Col. A. C. Campbell, Dr. H. Debris, F.R.S., Mr. W. T. Thiselton Dyer, M.A., B.Sc., W. Jack, M.A., and Capt. Sale, R.E.—Lieut.-Colonel Campbell explained and exhibited a double slit which he has employed for measuring the distances between the lines in the spectrum and finds of great service in cases where the illumination is so slight as to preclude the possibility of using the ordinary micrometer. One slit remaining stationary the other can be moved at right angles to its direction by means of a very delicate micrometer screw of 200 threads to the inch, the graduated head of which is capable of distinctly indicating one-five-millionth of an inch in the motion of the slit. If now a reading of the micrometer be taken when the slits are superposed and form one continuous slit, and a second reading when any given line has been superposed upon any other line at a moderate distance from it, the difference between these readings will enable us at once to ascertain the distance between the lines if the micrometer be calibrated in terms of the spectrum as seen in the observing telescope. The author has made several measurements with this apparatus, and finds it to be capable of extreme accuracy, but it is of course essential that the movable slit remains within a moderate distance of the axis of the collimator. He then described a simple arrangement for automatically fixing a prism, when placed on the table of a goniometer at the angle of minimum deviation when different coloured rays are under examination. To the arms which support the telescopes of the goniometer are attached two short links of equal lengths connected at their extremities with a nut sliding freely on an arm which is fixed radially to the centre table of the instrument. The prism is held on this table with its base at right angles to this arm, and it thus remains adjusted for all the rays of the spectrum.—Mr. O. J. Lodge then read two papers by Profs. Ayrton and Perry, jointly, of the Imperial College of Engineering, Japan. The first contains an account of an elaborate series of experiments on ice as an electrolyte. They state as a result of their experiments that the capacity per cub. cent. of ice at $-13°\cdot5$ C. is 0·002 micro-farad, and the specific inductive capacity is 22,160 (that of air being called unity), while that of water at $8°\cdot7$ C. is about 2,240 times this amount. Commencing with ice at $-13°\cdot6$ C the temperature was allowed to rise and the conductivity determined by galvanometer readings. From these a very regular curve was deduced which shows that the conductivity increases regularly, and that there is no sudden rise in passing from the solid to the liquid state. The apparatus was also employed for determining the electromotive force of polarisation currents at different temperatures by replacing the copper by a zinc disc.—The second communication contained suggestions for experiments on the viscosity of water and other liquids. It is accompanied by working drawings of an apparatus which the authors have designed for determining the relation between the viscosity of a liquid and the velocity of a surface moving in contact with it. They have, however, no facilities for making such an apparatus, and therefore place it at the service of any one who may be willing to study the subject.

Victoria Institute, June 4.—At the Annual Meeting of this Institute, the address was delivered by Mr. J. E. Howard, F.R.S.—Capt. F. Petrie (the honorary secretary) read the eleventh annual report; 107 members and associates had joined during the year, and the total number had risen to over 700, two-thirds of whom were country and foreign members.

Institution of Civil Engineers, May 29.—Mr. George Robert Stephenson, president, in the chair.—A paper was read on an economical method of manufacturing charcoal for gunpowder, by Mr. George Haycraft, F.C.S.

PARIS

Academy of Sciences, May 28, M. Peligot in the chair.—Some remarks were made on M. Roudaire's Algerian scheme. M. de Lesseps thought it practicable and useful; M. d'Abbadie desired that study might be given for a whole year to the quantity of evaporation and the *régime* of the winds in that region, &c.—The following papers were read:—Reply to M. Tacchini's note inserted in last *Comptes Rendus*, by M. Janssen. While accepting M. Tacchini's figures in comparison of maximum and minimum years, he yet holds that the numerous and rapid appearance and disappearance of spots witnessed during the past year indicates very violent movements of matter.—On Gay Lussac's law of volumes, reply to M. Saint Claire Deville, by M. Wurtz. The system of chemical equivalents which prevailed about 1840 over the atomic notation of Berzelius, has not taken account of Gay Lussac's discoveries on the combinations of gases, and the maintenance of the principle of equivalence in chemical notation would bring science back to the times of Dalton, Wollaston, and Richter, which would be an anachronism.—Reply to M. Wurtz's note on the law of Avogadro and the atomic theory, by M. Berthelot.—Experimental critique on the glycogenetic function of the liver, by M. Cl. Bernard. He proves the function directly during life, laying bare the liver in a dog, cutting off a piece of it, which is then put into boiling water. The tissue contains a proportion of sugar varying from 1 to 3 per 1,000. The influence of vivisection does not cause variation in the quantity, unless the circulatory and respiratory functions are greatly disturbed. M. Bernard also demonstrates that the saccharine matter continues to be formed in the liver after death.—Observations on the work presented to the Academy by M. Villarceau, entitled the "Nouvelle Navigation," by M. Mouchez. He objects to the title; and the analytic method proposed (application of Taylor's series in place of the old formula) though good in theory, is found impracticable. The graphic method is nearly the same, according to M. Mouchez, as he has himself long practised and recommended. Lastly there is but rare need to use M. Villarceau's new process for determining *the most probable point*.—On an algebraic method for obtaining the *ensemble* of the fundamental invariants and covariants of a binary form, and of any combination of binary forms (continued), by Prof. Sylvester.—Description of new manœuvres executed with the economising apparatus at the dam of Aubois, by M. de Caligny.—Experiments made in order to appreciate the diffusion of the vapours of sulphide of carbon introduced into the ground as an insecticide, by M. Gastine. In permeable soil the diffusion reached a maximum radius of about 1 metre about the hole of injection (which received 20 grammes of the sulphide). The vapours persisted at 30 cm. distance from March 1 to 5, or about 100 hours; nearer the hole, 150 hours. In clayey soil the diffusion was as extensive, and the persistence was about twenty-four hours more.—Historical remarks on the theory of movement of one or several bodies of constant or variable forms, in an incompressible fluid; on the apparent resultant forces and on the experiments relating thereto, by M. Bjerknes.—On Gauss's formula of quadrature, by M. Callandreau.—Thermal researches on the substituted anilines, by M. Longuinine.—Electrolysis of ordinary pyrotartaric acid, by MM. Reboul and Bourgoin. This acid is very stable; it is electrolysed like mineral acids, and is in this respect quite unlike succinic acid, which is decomposed easily.—Researches on the synthesis of acids of the series $C_nH_{2n-2}O_2$ and $C_nH_{2n-4}O_2$; allylic and diallylacetic acids, by M. Reboul.—On the decomposition of carbonic acid in the solar spectrum by the green parts of plants, by M. Timiriazeff. A spectrum was formed with a bisulphide of carbon prism and a trough containing chlorophyll solution was put in the path of the rays. Next were interposed in a row five vessels inverted over mercury, each containing air with about 5 per cent. carbonic acid, and these vessels received green organs of plants (pieces cut from a bamboo leaf). The vessels, being in different parts of the spectrum, were left there six to ten hours on fine days in July, and the gas was afterwards analysed. The maximum of decomposition of CO_2 was always found in the vessel corresponding to the position of the characteristic absorption band of chlorophyll; in orange, yellow, and green, the amount of decomposition showed successive decrease, and in red there was even production of CO_2 through respiration.—On the nature and signification of the small red corpuscles of the blood, by M. Hayem. He concludes that they are young corpuscles incompletely developed.—On the changes of volume, and the delivery of the heart, by M. François-Franck. His method was to connect the cavity of the pericardium (in live dogs) with one of Marey's registering apparatuses. The heart increasing in volume in diastole drove a certain quantity of air into the tambour, while the contraction in systole permitted return of this air.—On the histological alterations of the uterus in their relations to the principal diseases of this organ, by M. Courty.—Statistical Researches on the Sologne, especially with regard to recruiting and movement of the population, by M. Coste.—On a process for recognising the presence of fuchsine in wines, by M. Baudrimont. A drop of fuchsinated wine left a few seconds on the skin of the hand, produces a mark which cannot be washed out with water.

GÖTTINGEN

Royal Academy of Sciences, January 31.—Report on the Botanical Institute of Göttingen University for 1876.

February 21.—A contribution to the theory of reflection-phenomena, by M. Rethy.

March 21. Separation of arsenic from nickel and cobalt.

April 4.—On the electric conductivity of aqueous solutions, especially of salts of the alkalies and alkaline earths, caustic alkalies, and some acids, by M. Kohlrausch.

CONTENTS

THURSDAY, JUNE 14, 1877

THE ENDOWMENT OF RESEARCH

We are authorised to publish the accompanying list of the sums to be paid by the Government, on the recommendation of the Royal Society, during the present year in aid of Scientific Research.

We might well leave the list to speak for itself, but it would be ungrateful not to point out that the Duke of Richmond and Lord Sandon have by their action, beyond all doubt, inaugurated a new era in the scientific activity of our country, and one which is sure to be fostered by corporate bodies and individuals now that the Government has set so noteworthy an example.

Personal Payments.

Mr. J. A. Broun.—For Correction of the Errors in the published Observations of the Colonial Magnetic Observatories . . . . 150*l.*

Dr. Joule.—For Experimental Investigations into the Mechanical Equivalent of Heat . . . . 200*l.*

Prof. Parker.—For Assistance in Researches on the Morphology of the Vertebrate Skeleton and the Relations of the Nervous to the Skeletal Structure, chiefly in the Head . . . . 300*l.*

Rev. W. H. Dallinger.—For Microscopic Investigations of Monads, Bacteria, and other Low Forms of Life 100*l.*

Rev. F. J. Blake.—For compiling and publishing a "Synopsis of the British Fossil Cephalopoda" . 100*l.*

Prof. A. H. Garrod.—For Aid in preparing for Publication an Exhaustive Treatise on the Anatomy of Birds . . . . 100*l.*

Dr. Murie.—For completing and publishing three Memoirs:—"Anatomy of the Kingfisher," 4to., with five plates; on "Extinct Sirenia," 4to., with six plates; "Osteology of the Birds of Paradise," folio, three plates 150*l.*

Mr. H. Woodward.—For Continuation of Work on the Fossil Crustacea, especially with reference to the Trilobita and other Extinct Forms, and their Publication in the Volumes of the Palæontographical Society. . 100*l.*

Prof. Schorlemmer.—For Continuation of Researches into (1) the Normal Paraffins, (2) Suberone, (3) Aurin . 200*l.*

Dr. H. E. Armstrong.—For Continuation of Researches into the Phenol Series, and into the Effect of Nitric Acid on Metals . . . . 300*l.*

Profs. King and Rowney.—For Researches to Determine the Structural, Chemical, and Mineralogical Characters of a Certain Group of Crystalline Rocks represented by Ophite . . . . 60*l.*

Mr. W. J. Harrison.—Towards the Expense of collecting and describing Specimens of the Rocks of Charnwood Forest . . . . 50*l.*

Non-Personal Payments.

In aid of Apparatus, Materials, and Assistance.

Dr. J. Kerr.—For aid in Electro-Optic and Magneto-Optic Researches . . . . . . 200*l.*

Mr. J. E. H. Gordon.—For Experimental Measurements of the Specific Inductive Capacity of Dielectrics 50*l.*

Prof. Guthrie.—For Apparatus and Assistance in (1) the Determination of the Latent Heats of the Cryohydrates and the Vapour Tensions of Colloids; and (2) the Examination of Heat Spectra and Radiant Heat by means of varying Electrical Resistance in Thin Wires . 150*l.*

Mr. J. T. Bottomley.—To aid in carrying out a Series of Experiments for determining the Conductivity for Heat of Various Liquids and Solutions of Salts . . 100*l.*

Sir William Thomson.—For Assistance and Materials for a Continuation of Experiments on the Effects of Stress in Magnetism . . . . . . 100*l.*

Mr. W. Crookes.—For Assistance in continuing his Researches connected with "Repulsion resulting from Radiation" . . . . 300*l.*

Messrs. Rücker and Thorpe.—For a Comparison of the Air and Mercurial Thermometers . . . 50*l.*

Mr. F. D. Brown.—For an Investigation of the Physical Properties, the Specific Gravity, Expansion by Heat, and Vapour Tension, of the Homologous and Isomeric Liquids of the $C_nH_{2n}+1$ Series . . . 100*l.*

Prof. Roscoe.—For Continuation and Extension of the Experiments on the Self-registering Method of measuring the Chemical Action of Light . . . 100*l.*

Sir William Thomson.—For Investigation and Analysis of Tidal Observations and Periodic Changes of Sea Level . . . . 200*l.*

Dr. J. B. Balfour.—For the Expense of Illustrations for a "Monograph of the Pandanaceæ" . . 50*l.*

Mr. H. T. Stainton.—For Aid in publishing the "Zoological Record" . . . . . 100*l.*

Dr. J. G. M'Kendrick.—For Apparatus for a Research into the Respiration of Fishes . . . 75*l.*

Prof. Gamgee.—For a more Complete Survey than has yet been made of the Physiological Action of the Chemical Elements and their more Simple Compounds, with the Object, in the first instance, of establishing a Physiological Classification of the Elementary Bodies . 50*l.*

Dr. Brunton.—For Researches into the Physiological Action of the most important Compounds of Nitrogen, and into the Action of certain Poisons, and for Apparatus . . . . 80*l.*

Mr. E. A. Schäfer.—To pay the Wages of an Assistant to give Mechanical Aid in Histological and Embryological Research . . . . 50*l.*

Dr. Burdon Sanderson.—For an Investigation of the Normal Relation between the Activity of the Heat-producing Processes, and the Temperature of the Body 70*l.*

Prof. Schorlemmer.—For continuation of Researches into (1) the Normal Paraffins, (2) Suberone, (3) Aurin . 100*l.*

Mr. W. N. Hartley.—For Researches into the Photographic Spectra of Organic Substances, into the Phosphates of Cerium, the Conditions under which Liquid Carbonic Acid is found in Rocks and Minerals, the Double Salts of Cobalt and Nickel, and for other Investigations, and for Assistance . . . . 100*l.*

Dr. Burghardt.—For a Research into the Origin of the Ores of Copper and (if possible) of Lead, their Mode of Formation, and the Chemical connection (if any) between the Ore and its Matrix . . . . . 50*l.*

Prof. Church.—For a Research into the colouring matters of Colein, of Red Beet, and for the Study of Plant Chemistry . . . . . . 50*l.*

THE "CHALLENGER" COLLECTIONS

The preliminary steps have been taken for the completion of the great work of the *Challenger*, and the vast collections made during the voyage are now being distributed among experienced workers for determination and description.

The director of the scientific staff has been at great pains in endeavouring to secure the services of men most competent for the task, and we are sorry to see that some of our English naturalists, and notably the president of the Geological Society, have thought it necessary to remonstrate against the course which the director has taken in the selection of the men to whom he is about to entrust the examination of the collections. We have already had occasion to refer to what we felt obliged to characterise as an unwarranted attack on Sir Wyville Thomson, and it is with much regret that we observe an attitude of hostility to the mode of distribution which has been deemed most conducive to the reputation of the expedition and to the interests of science.

It would seem that while almost all the great zoological groups which the *Challenger's* dredges have brought to light have been handed over for examination to naturalists in this country, a few have been placed in the hands of American and German workers; and it is this association of foreign zoologists with the men to whom in this country by far the largest portion of the work has been assigned that has excited the indignation of the individuals referred to.

Now every one who has kept himself *en rapport* with recent zoological research, must know that the foreign zoologists, to whom Sir C. Wyville Thomson has intrusted these collections, stand before all others in the amount and thoroughness of their work in the special departments of zoology for which their aid is asked, and the narrowest nationalism cannot deny that it was the duty of the director to see that the specimens were placed in the hands of men most competent to secure for science the results which have been obtained at the cost of so much labour, skill, and public expenditure.

If this country can be shown to enjoy the unique distinction of possessing in every department of zoological research men at least as good as can be met with elsewhere, the advocates of a national science may find an argument in favour of having the work absolutely confined to Englishmen; but if we cannot assume a position which no other nation in the world would think of claiming, it is plainly for the interests of science that we should supplement from abroad those departments of research in which foreign workers may excel us.

That the naturalists to whom we have referred will not receive much support from their fellow-workers will be evident from the subjoined letter to the Editors of the *Annals* now in process of signature, which has already received the adhesion of the presidents and secretaries of the Royal, Linnean, and Zoological Societies, and of other leading men in this department of knowledge:—

"*Zoology of the 'Challenger' Expedition.*

"As in a letter upon this subject in the number of the *Annals of Natural History* for May last Dr. P. Martin Duncan, writing as president of the Geological Society, has stated that he speaks 'at the instance of a very considerable number of members of learned societies,' we, the undersigned, wish to state that we do not agree in the strictures passed by Dr. Duncan upon the manner in which Sir C. Wyville Thomson has distributed the specimens collected by the *Challenger* Expedition for description. So far as we have had an opportunity of judging we are perfectly satisfied that Sir C. Wyville Thomson, in the arrangements which he has made as regards these collections, has acted consistently with the best interest of science.

"It was, in our opinion, Sir C. Wyville Thomson's duty to secure the aid of the most competent naturalists without regard to their nationality; and, even if it were proper that national jealousies should be imported into science, Sir C. Wyville Thomson can hardly be reproached on this score, when it is considered that two-thirds at least of the naturalists whose aid he has obtained are Englishmen.

"J. D. HOOKER.	W. H. FLOWER.
T. H. HUXLEY.	P. L. SCLATER.
CHARLES DARWIN.	OSBERT SALVIN.
ST. GEORGE MIVART.	A. H. GARROD.
FRANCIS DAY.	GEO. A. ALLMAN.
GEO. BUSK.	TWEEDDALE."
WILLIAM B. CARPENTER.	

It is of importance that no misunderstanding should exist as to the real state of the controversy which has arisen on a subject in which zoological science is so deeply interested, and we believe we cannot do better than lay before our readers the correspondence which had taken place between Sir Wyville Thomson and Dr. P. Martin Duncan before a word of hostile criticism had as yet shown itself in print.

"Scientific Club, Savile Row, London, W.
"24th March, 1877

"MY DEAR SIR WYVILLE THOMSON,

"You can hardly imagine the strong feeling of disappointment which has arisen amongst a very large section of the naturalists and palæontologists who study the invertebrates, in consequence of a letter which was published in the *Ann. and Mag. of Nat. Hist.* for March, 1877. In this letter the scientific world is informed by our mutual friend, A. Agassiz, that the Echini, Ophiurans, Radiolaria, and a part of the Spongida collected in the expedition of the *Challenger* have been given to American and German naturalists for description, and that the United States have a 'fair share' of the work. So great is the feeling that English workers should have been thus passed over, that a conference has been held on the subject, and I have been asked to write to you in the friendliest spirit of remonstrance. I need hardly state that I should not have taken this liberty did I not happen to hold a position which entails action in everything relating to the progress of geological science. Writing then on the part of many men whose capabilities as naturalists and palæontologists I am well aware of, I express their and my own opinion that in this distribution your amiability and want of personal acquaintance with English workers have led you astray. We recognise the great merits of those foreign gentlemen to whom you have sent collections and the exceeding liberality of A. Agassiz; but we do not think that you are justified in giving them the results of the greatest natural history expedition which has ever sailed from this country, unless there is a want of that power amongst English workers which will enable them to treat the subjects in the broadest sense, and to compare the recent and geological faunas satisfactorily. There is no such deficiency. I am asked to urge upon you a reconsideration of the matter, and to leave a fair portion of work in the hands of our friends, giving the rest to men of your own country. Assuring you that we appreciate your difficulties, and that we will assist you in every way consonant with the dignity of English science, I remain,

"Yours sincerely,
(Signed) "P. MARTIN DUNCAN

"Sir C. WYVILLE THOMSON"

"MY DEAR DR. MARTIN DUNCAN,

"I must ask you to consider this note as written to yourself personally, for I cannot, of course, in any way recognise this nameless 'Conference.' I may mention, however, at starting, that in this matter I have consulted several of the first English naturalists, and that they entirely approve of my selection.

"I take up my pen rather hopelessly, for your letter does not touch any of the considerations on which I have acted. My duty was to have prepared an official account of the voyage to the best of my power within a certain time. I endeavoured to select to assist me in this (1) those who had most successfully made certain branches their special study and were generally regarded as *authorities*; and (2) those whom I knew by experience to be likely to do the work within the time to which I was tied down, and to return the specimens in good order to be lodged in the British Museum. In all cases where I considered that these conditions were fairly fulfilled by Englishmen I at once and fully recognised the great advantage of avoiding the risk of sending things abroad, but except for this consideration I confess I saw and see no objection, but rather the reverse, to making a great work of this kind somewhat more catholic. The result has, however, been, that by far the greater part of the work will be done in England. I do not mean to go into special cases, but I give a general sketch of the arrangements as they now stand:—

Sea Mammals	Prof. Turner.
Birds	Dr. Sclater.
Fishes	Dr. Günther.
Cephalopoda	Prof. Huxley.
Gastropoda	Rev. R. B. Watson.
Lamellibranchiata	Rev. R. B. Watson.

Brachiopoda	Mr. Davidson.
Higher Crustacea	Probably Prof. Claus.
Ostracoda	Prof. G. Brady.
Copepoda	Prof. G. Brady.
Isopoda	Mr. Henry Woodward.
Cirripedia	Mr. Darwin.
Annelida	Dr. McIntosh.
Gephyrea	Prof. Ray Lankester.
Bryozoa	Mr. Busk.
Echinoidea	Mr. A. Agassiz.
Ophiuridea	Mr. Lyman.
Crinoidea	Dr. Carpenter and myself.
Hydromedusæ	Prof. Allman.
Corals	Mr. Moseley.
Sponges	Prof. Oscar Schmidt and myself
Rhizopods	Mr. Henry Brady.
Radiolarians	Prof. E. Haeckel.

"Now the only foreigners in this list are Dr. Günther, Prof. Claus, Prof. Agassiz, Mr. Lyman, Prof. Oscar Schmidt, and Prof. Haeckel. If there is a better English authority than Dr. Günther on fishes, I beg his pardon for having overlooked him. The crustaceans were to have been done by the late Dr. v. Willemöes-Suhm and certain considerations come in as to the use of his plates and notes, which I need not discuss. I am not aware that there is any one in this country who can be considered at present an authority on recent Echinoidea. The choice perhaps lay between Agassiz and Lovén, but the reference collection at Cambridge is the best in the world in this department. There is, so far as I know, no English authority on Ophiurids at present. I prefer Oscar Schmidt's mode of treating the sponges to that of any other author. I am not aware that any Englishman knows the Radiolarians so well as Haeckel. There are a good many departments not yet settled, and one or two other foreigners may be added to the list. I should of course have most heartily asked your assistance with the corals had Moseley not undertaken them, but he has the preference as one of our staff, and he has done excellent work.

"I have submitted the principles on which I am working to the best of my ability to the Treasury, and they have received their sanction and that of the Council of the Royal Society. I cannot recognise the importance of the geographical distribution of naturalists, and with all respect for the dignity of British science I must say I think that in this selection, which I considered entirely open, I have done it ample justice.

"Believe me, very truly yours,

"C. Wyville Thomson

"20, Palmerston Place, Edinburgh, March 27"

To this letter no reply has been received, and the subject might well have ended here.

The objectors to the course pursued by Sir Wyville Thomson would hardly advocate our assumption of a spirit more narrow and illiberal than that of any other country, and they will perhaps be interested in knowing how a foreign Government has acted under quite similar circumstances.

The results of the two great recent scientific expeditions fitted out in the United States, that of the "Haslar," and the Exploration of the Gulf Stream, have been distributed among special workers without any regard to nationality. Of this we need no further evidence than that afforded by the arrangements which have been adopted for the examination of the very rich collections made during the Gulf Stream Expedition. These collections have been allocated as follows:—

Halcyonaria ...	A. Kölliker	Würzburg.
Annelides	E. Ehlers	Göttingen.
Sponges (part) ...	O. Schmidt	Strassburg.
Sponges (part) ...	E. Haeckel	Jena.
Holothurians ...	E. Selenka	Leiden.
Polyzoa	F. A. Smitt	Stockholm.
Mollusca	J. Gwyn Jeffreys	London.
Hydroids	G. J. Allman	London.
Starfishes	E. Perrier	Paris.
Crustacea	Alph. Milne Edwards ...	Paris.
Fishes	F. Steindachner	Vienna.
Cephalopods ...	J. P. Steenstrup	Copenhagen.
Brachiopods ...	W. H. Dall	Washington.
Corals	L. F. Pourtales	Cambridge, U.S.
Ophiurans	T. Lyman	Cambridge, U.S.
Echini	A. Agassiz	Cambridge, U.S.

It will be thus seen that out of the twenty-two zoologists among whom the collections of the *Challenger* have been distributed *seventeen are English;* while out of the sixteen to whom the American collections have been assigned, *four are American.*

ELEMENTARY PHYSICS

Matter and Motion. By J. Clerk-Maxwell. (Society for Promoting Christian Knowledge. London, 1876.)

THE recent appearance of a swarm of elementary books on physics, some of which at least are written by well-known authors, leads to some very curious inquiries and speculations: for, though treating in the main of the same parts of the same subject as does the work we are specially dealing with, and addressed professedly to the same class of readers, they have comparatively little in common with it. To a certain, even a considerable, extent, this difference is of course due to the idiosyncrasies of the authors; but, after all allowance is made for these, there is still a most notable divergence. It will be both interesting and profitable carefully to consider in what this divergence consists, and what is its probable origin. For it is not too much to say that an intelligent reader of Clerk-Maxwell's book, had he no other source of information, would be utterly unable to answer any one of hundreds of questions which might be framed (without "dodge" or "trap") by a qualified examiner, *directly* from the text of the others. It is true that such questions would be artificial rather than natural—bearing more upon old and cumbrous dogmatic fallacies than upon the actual facts of science. But if the reader of Clerk-Maxwell's book would be at a loss when examined from any of the others, the student who relies merely upon one (or even *all*) of these would hardly even understand the meaning of a question put directly from Clerk-Maxwell's. The main origin of this divergence is to be found in the steady progress of knowledge in all departments of true science; even the most elementary. And, bearing this in mind, we may give an almost complete statement of the case by saying that Clerk-Maxwell's book properly belongs to the second half of the present century, while his rivals give us that of the first half only. These give us again the elementary "*Mechanics*" of our student days (more than a quarter of a century ago) very little changed—though where changed, often changed for the better—the first gives us what is emphatically the science of *to-day.* Possibly enough, in the beginning of the twentieth century even Clerk-Maxwell's book may appear a little antiquated; but it is hardly to be imagined that the text-book of that not very distant future will differ from Clerk-Maxwell's to anything like the extent to which that differs from its competitors. At least if there be anything like so a great difference it will depend upon some wholly new information as to the intimate nature of matter or energy, certainly not upon a mere difference in the mode of treatment.

The immense steps taken by Galileo and Newton (to mention only two of the chief workers) in the simplification and orderly arrangement of the fundamental conceptions and laws of physical science are too often lost sight of in comparison with the vast extensions which these men gave to our knowledge—though their actual *value* is probably little inferior. No doubt it is scarcely possible for any one (except by accident, of which some notable instances will occur to every reader) to make real extensions of our knowledge unless he possesses a clear conception of elementary principles. But great discoverers are generally too much engrossed with their higher studies to bestow much time on the explanation or co-ordination of the more elementary parts of their science. All the more honour, then, to those who, like Galileo and Newton, have made every step of their progress clearly intelligible to the student from its very foundations.

Immediately after Newton's time the progress of physical science was almost arrested in Britain (mainly, it seems, from the want of men of a high order of genius), and the really great foreign Mathematicians and Physicists of the time were entirely absorbed in the rapid development of their subjects. The disastrous consequence was that the elementary parts of science were left almost entirely to the second-rate men, or to the mere sciolists, men whose representations of science, even at the best, were mere caricatures—in the sense in which an orrery mimics the solar system, or an automaton a living animal;—and though, since that time, really first-rate men (*e.g.*, Cavendish and Young) have occasionally appeared in Britain, the pernicious influence of generations of smatterers was not easily shaken off. Thus an absurdly artificial, and unnecessarily complex system, based to a certain extent on Newton, but altogether devoid of his wonderful precision, simplicity, and completeness, came to be generally adopted here. This artificial system may be said to have reached its climax in the works of the late Dr. Whewell, perhaps the only brilliant writer of what is known now as *Paper Science*, by far the most pestilent weed against which the true scientific cultivator has to contend. The omniscient Master of Trinity might quite probably have been able to hold his own with Aristotle, had he lived in days when science had but a scanty development; but it is impossible for any one nowadays to hold relatively to human knowledge any such position. And he who tries to do so, even had he the genius of Newton to start with, will simply *do nothing*.

Clerk-Maxwell (wisely, we think) appears to prefer Newton and Rowan Hamilton to Whewell, on whom or the like of whom his rivals mainly rely. And this alone accounts for a great deal of the extraordinary dissimilarity between the works to which we have alluded. What is Whewell, the universal genius, with all his book-learning, in comparison with Newton, the special genius, with his close and patient study of material phenomena themselves? Nothing. Men consulted Whewell as they would a dictionary or an encyclopædia, simply to save themselves trouble. But when was an encyclopædia ever seen to add a volume of new matter to itself as an appendix? To use an old comparison, Newton, as it were, studied Chinese metaphysics in China itself, at head-quarters; Whewell and those who do like him read all the European works on China and all the European works on metaphysics, and "combine their information." Thus almost all Clerk-Maxwell's rivals—whom therefore we need not specially name—give us the sacred *Three Classes of Levers*, the various *Systems of Pulleys*, the altogether imaginary *gold* shell of the Florentine Academicians, the *Principle of Repulsion*, the *Transmissibility of Fluid Pressure*, and what not. Weight and specific gravity are usually put forward in preference to mass and density—the accidental property before the inherent or essential one! We have the old confusing statements about a co-efficient of *elasticity* in the impact of balls. In one of the most pretentious of these works we are told that the "strict" definition of a *level surface* implies that "at all points of it the force of gravity has the same value, and its direction is at right angles to the surface." That is to say, the author here uses the word "force" in two different senses. It means the "potential energy of a given mass," when its *value* is spoken of; but it means the "weight of a given mass" when its *direction* is spoken of. For it is inconceivable that the author could have meant to state that the weight of a body is the same at all points of a level surface. We could give without practically any limit instances of a similar kind (not mere slips of the pen, from which no man's work can be free), but we will be merciful, and simply extract the following passages, putting a word or two in italics, and leaving the reader to exercise himself in finding what is erroneous:—

"An arrow shot upwards from a bow reaches to a certain height: show that if the weight of the arrow be doubled, *other circumstances remaining the same*, the height reached will be *one-fourth* of its former value."

"Gravity and distance together represent the *force* employed from the beginning in putting things where they are, and whenever they come together by attraction they develop a corresponding *force or heat*."

"When heat is continually applied to water it is found that if the water is in an open vessel its *heat cannot be raised* beyond a certain point."

"The *forces* of heat, electricity, magnetism and light are now considered to be all *species of motion*, discoverable and measurable only by the amount of *movement* they can produce or counteract."

". . . water is boiled by placing a lamp beneath the flask so that the upper part of the flask becomes full of steam, the air being expelled. The flask is now stopped with a cork, removed from the lamp, and allowed to cool. . . . By pouring cold water . . the water begins to boil again. *The experiment requires great care to prevent accidents*."

"Matter in motion is FORCE."

"Electrical attraction is *the name given to some cases* resembling magnetic attraction, in which electricity is the agent."

"Liquids possess a *small but very perfect* elasticity, which differs in amount in different liquids."

". . . gold, which *in the case of a sovereign* falls as fast as anything which we have commonly in view, may be beaten out to a thin leaf which *almost floats on* the air . . ."

"*It is sometimes stated incautiously*, that the weight of a body may always be supposed to be collected at the centre of gravity, but the present case shows that *such a statement is too wide*."

There is no justifying the existence of a new way of doing anything except by showing that it is better than the old one; but, if that can be done, the new way is justified. And, as it is not our interest to become Encyclopædias, when we get a good new way, let us adopt it, and at once drop the old. And we are not without hope that Clerk-Maxwell's book may effect the complete abolition of the older methods, which are already sadly shattered. Perpetual "distinctions without a difference," like the three classes of levers above alluded to, can only confuse and irritate the student—often making him doubt whether he really understands the gist of an explanation or no. And to give rules for calculating results without explaining how to obtain these rules, or what they imply physically, is, in the vernacular, simply CRAM:—call it euphemistically what you will. To learn how to do this is not, in any sense, to acquire knowledge.

Clerk-Maxwell's book is not very easy reading. No genuine scientific book can be. But the peculiar characteristic of it is that (while any one with ordinary abilities can read, understand, and profit by it) it is the more suggestive the more one already knows. We may boldly say that there is no one now living who would not feel his conceptions of physical science at once enlarged, and rendered more definite by the perusal of it. Short and (on the whole) simple as it is, it is one of the most suggestive works we have ever met with. The following extract needs no comment of ours: let us see how the metaphysicians will digest it :—

"But, as there is nothing to distinguish one portion of time from another except the different events which occur in them, so there is nothing to distinguish one part of space from another except its relation to the place of material bodies. We cannot describe the time of an event except by reference to some other event, or the place of a body except by reference to some other body. All our knowledge, both of time and place, is essentially relative. When a man has acquired the habit of putting words together, without troubling himself to form the thoughts which ought to correspond to them, it is easy for him to frame an antithesis between this relative knowledge and a so-called absolute knowledge, and to point out our ignorance of the absolute position of a point as an instance of the limitation of our faculties. Any one, however, who will try to imagine the state of a mind conscious of knowing the absolute position of a point will ever after be content with our relative knowledge."

We can afford space for only one other quotation; but, as it is very important, we quote *in extenso* :—

ARTICLE CXIV.—CENTRIFUGAL FORCE.

"This is the force which must act on the body M in order to keep it in the circle of radius v, in which it is moving with velocity V.

"The direction of this force is towards the centre of the circle.

"If this force is applied by means of a string fastened to the body, the string will be in a state of tension. To a person holding the other end of the string this tension will appear to be directed towards the body M, as if the body M had a tendency to move away from the centre of the circle which it is describing.

"Hence this latter force is often called Centrifugal Force.

"The force which really acts on the body, being directed towards the centre of the circle, is called Centripetal Force, and in some popular treatises the centripetal and centrifugal forces are described as opposing and balancing each other. But they are merely the different aspects of the same stress."

This is one of the few passages in the work to parts of which exception may fairly be taken. Of course, the *physical* statements are correct, and they are very clearly put. But it is hardly fair to a junior reader to begin by telling him that Centrifugal Force means *the force which must act* on a body in order to keep it moving in a circle, and then to say that *the force which really acts* is called Centripetal Force! That force is required *to produce change of direction* of a body's motion, and that when this is applied by means of a string held in the hand the impression on our "muscular sense" is the same as if the body were *pulling* at the other end of the string, are facts: but they no more justify the use (however guarded) of the word "centrifugal" than the tension of the couplings, just before a train starts, proves that the carriages have a tendency to run *backwards*.

There is one very great blemish in Clerk-Maxwell's book, from which those of his rivals are comparatively free. Some of the woodcuts are simply atrocious. This must be looked to in future editions, for passages of great importance are at present rendered totally unintelligible to the beginner: and from this cause alone.

Clerk-Maxwell's work, then, is simply Nature itself, so far as we understand it. The peaks, precipices, and crevasses are all there in their native majesty and beauty. Whoso wishes to view them more closely is free to roam where he pleases. When he comes to what he may fear will prove a dangerous or impassable place, he will find the requisite steps cut, or the needful rope attached, sufficiently but not obtrusively, by the skilful hand of one who has made his own roads in all directions, and has thus established a claim to show others how to follow.

In the rival elementary works the precipice and the crevasse are not to be seen: there are, however, many pools and ditches; for the most part shallow, but *very* dirty. You are confined to the more easily accessible portions of the region. In the better class of such books these are trimly levelled—the shrubs and trees are clipped into forms of geometrical (*i.e*, unnatural) symmetry like a Dutch hedge. Smooth straight walks are laid down leading to old well-known "points of view,"—and, as in Trinity of ormer days, undergraduates are warned against walking on the grass-plats.

These "royal roads" to knowledge have ever been the main cause of the stagnation of science in a country. He would be a bold man indeed who would venture to assert that the country which, in times all but within the memory of many of us, produced such mighty master-minds as Lagrange, Fourier, Ampère, and Laplace, does not now contain many who might well have rivalled the achievements even of men like these. But they have no chance of doing so; they are taught, not by their own struggles against natural obstacles, with occasional slight assistance at a point of unexpected difficulty, but by being started off in groups, "eyes front" and in heavy marching order, at hours and at a pace determined for all alike by an Official of the Central Government, along those straight and level (though perhaps sometimes rough) roads which have been laid down for them! Can we wonder that, whatever their natural fitness, they don't now become mountaineers?

I still vividly remember the horror with which I watched the the struggles of a former class-fellow of my own, whose friends had just sent him to another school that he might learn geometry a little earlier than was the custom with us. For him there was no longer any play—

all his spare time was devoted to the committing of Euclid to memory! I shuddered as I thought of what was to be my own fate in a few short months, when I too must be subjected to this fearful imposition. But the first hour or two which Dr. Gloag (a name strange, perhaps, to southern ears, but very high indeed on the roll of successful teachers—Clerk-Maxwell, indeed, was one of his pupils) devoted to geometry showed those of us who had any taste for the subject that it was one to be learned by head, not "by heart" (the idiotic phrase in common use)—and that my friend's parents had simply taken him from a good teacher and sent him to an exceedingly bad one—for it came to be discovered after some time that he had really considerable aptitude for geometry.

But if he had been in fact quite unfit for the study, otherwise than in learning to repeat Euclid by rote, what object beyond mere torture would have been attained by forcing it upon him? This leads to another remark of great importance in connection with the mass of elementary text-books.

What sort of students are those who require to be told to *take the square of the velocity, divide it by the radius, and find the proportion of this quotient to* 32 . . . :—without farther explanation or proof? What the better are they of the information? Call you this "teaching science?" Has it improved their minds? Will they be able to make any use of it in after life? I do not see how these questions and many other connected ones can be answered except by a prompt negative. One of two things. The pupil who requires to be taught in this way is either as yet too young, or is one who will never become old enough, to learn even the rudiments of science.

To our metaphor once more. Grass-plats, moss, and flower-beds for the happy sports of children—the bare rock and rough moor for the stern work of men. Your gravel-walks and Macadamised roads are excellent things in their way, but keep them to their legitimate users, the carriage and the perambulator for the invalid and the infant who can neither work nor even play.

My reasons for writing on this subject are very serious ones. I have to consider each year how best to instruct some couple of hundred students in the elements of physics, and have to be constantly on the out-look for a really good text-book of an elementary character. In the higher branches of the subject there is, happily, little difficulty, but that a really good, short, and simple treatise on the merest elements has been (at least till very lately) wholly unprovided is, I think, clear from the ridiculous discussions about *Centrifugal Force*, and other connected ideas, which are even now constantly to be found in our more practical periodicals.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Nectar-Secreting Glands

MR. FRANCIS DARWIN has made an interesting addition to his important discovery of nectar-bearing glands on the young fronds of *Pteris aquilina*, supplied from the ever-welcome experience of Mr. Fritz Müller. The latter gentleman finds that in Brazil the *Pteris aquilina* is protected from the leaf-cutting ants by those attracted to the nectar, and Mr. Darwin adds some speculations on the origin of the glands and their continued functional activity in Europe where they now appear to be useless. On this part of the question I should like to make the following remarks:—

Prof. Heer has shown that in the Miocene plant-beds at Œningen and Radoboj, ants are the most numerous amongst the fossil insects, and in 1849 as many as sixty-six species had been described from these two localities. In 1865 the number found at Œningen alone is recorded as forty-four. I do not know what the total number of species is that have been recorded from the two places up to the present time, but it probably does not fall short of eighty. Amongst the fossil ants from Radoboj there are species of the Tropical American genera *Atta* and *Ponera*. One of the fossil species of *Atta* resembles in general form and in the venation of the wings the curious *Atta cephalotes* of Tropical America.

As there are only about forty species of ants existing now in the whole of Europe it is evident that in the Miocene epoch they must have played a much more important part in Europe than they do now. Plants may then have been exposed to the attacks of enemies that have become extinct along with the general impoverishment of the fauna and flora of Europe that took place in Post-pliocene times; and the protection afforded by ants attracted to the nectar-bearing glands at the critical stage of the unfolding of the young and tender leaves may have been as important to some plants in Europe, then, as it is to many in Tropical America now.

With regard to the persistency of the nectar-producing glands up to the present time in Europe, it is to be remarked that many plants are identical with those living in the Miocene period and the world-wide distribution of *Pteris aquilina* seems to indicate that it is of very ancient origin. If a plant has not otherwise varied there is no reason apparent why it should do so in this respect so long as the secretion of nectar is not positively injurious to it. I have recently noticed in my garden that the ants that attend the glands at the bases of the leaves of the cherry, the plum, the peach, and the apricot, stroke with their antennæ some of the glands that are not excreting when they arrive at them, just as they do the bodies of the aphides. I have not actually noticed that this promotes a flow of nectar, but ever since I became a disciple of Darwin I have been convinced that the most trivial circumstance is worthy of notice; and it may be that the slight irritation of the glands kept up by the ants is sufficient to ensure the perpetuation of a function of the plant now useless to itself. It is, however, perhaps too soon to assume that the glands are entirely useless to the plants in Europe. Darwin states that there is good evidence that the absence of glands in the leaves of peaches, nectarines, and apricots leads to mildew ("Animals and Plants under Domestication," vol. ii. p. 231).

Darwin refers at the same place to the variation of the glands of the leaves in the above-mentioned fruit trees and I may add that they are extremely variable on the cherry, being sometimes absent, sometimes on the stalk and sometimes on the blade of the leaf. The young leaf in its earliest stage, before it expands, has a complete fringe of them, thus bearing out Mr. Francis Darwin's theory that they are homologous with the serration-glands of Reinke.

May I suggest to some of your correspondents that information as to how far north in Great Britain or in Europe the glands on the above fruit trees are attended by ants and especially if the wild cherry (which I have not had an opportunity of observing) is so attended, would be of great interest.

THOMAS BELT

Cornwall House, Ealing, June 8

On Time

"The fact is, that we have not yet quite cast off the tendency to so-called metaphysics."—Tait, "Rec. Adv. in Phys. Sc.," p. 11.

IN Thomson and Tait's "Natural Philosophy," of which I have only the German edition in my possession, I find, § 246: "Die Zeiten, während welcher irgend ein besonderer Körper, der durch keine Kraft angetrieben wird, die Geschwindigkeit seiner Bewegung zu ändern, gleiche Wege durchläuft, sind einander gleich." And § 247: "Dieser Satz drückt bloss die für die Messung der Zeit allgemein getroffene Uebereinkunft aus."

These quotations quite express what is generally understood

Yet in the definition of the equality of two lapses of time there is a logical fault. It is not allowed implicitly to introduce in a definition what is to be defined. There is no body of which we know *à priori* that no force tries to alter its velocity; in order to ascertain this, we must find out in consistency with the usual definition of force, given in § 217, whether it moves through equal spaces in equal times.

The definition of § 246, therefore, really says: The times, in which a body that goes through equal spaces in equal times moves through equal spaces are equal. It is evident that we are reasoning in a circle.

I am very well aware of the objection which will be made. We have it in § 245: "Auch werden wir später sehen, dass ein vollkommen glatter sphärischer Körper, welcher aus concentrischen Schalen besteht, deren jede von gleichförmiger Material und überall von derselben Dichtigkeit ist, sich, wenn man ihn in eine Drehung um eine Axe versetzt hat, trotz hinzutretender einwirkender Kräfte mit gleichförmiger Winkelgeschwindigkeit dreht, und seine Rotationsaxe in einer absolut festen Richtung erhällt." Thereupon it is said in § 247 that the earth is a body which fulfils these conditions very nearly, and that therefore its rotation gives us the means to measure time. But this assertion is not at all proved.

I now request my readers to be so good as to follow the exposition of *my* view. I assume that we are able to decide whether two lapses of time are equal. How this is done I shall dwell on afterwards.

When the conception of time is combined with the conception of motion we arrive at the building up of kinematics, in which the ideas of velocity and of acceleration are introduced. In abstract dynamics the idea of force is first introduced, wholly separated from any definite physical sense. As soon as the state of motion of a body (which is determined by the magnitude and the direction of its velocity) undergoes a change, we think of a cause of this change, and call this cause a force. We ascribe to a force magnitude and direction. If a body, which primarily is in rest, acquire a rectilinear motion, the force has constant direction. The magnitude of a force of constant direction is judged by the increase of velocity, which it gives in a definite time to a body primarily in rest. If the increases of velocity in equal times be equal, the force has constant magnitude. Two forces of constant direction and magnitude are in the same proportion as the increases of velocity which they give in equal times to the same body. Unity of force is the force which in unity of time gives to a particular body unity of increase of velocity.

It is conceivable that equal forces acting on different bodies cause different accelerations. Therefore another idea is introduced—the idea of mass. It is settled by definition that the masses of two bodies are in inverse proportion to the accelerations which they receive from equal forces. To a particular body unity of mass is ascribed. Unity of force is the force giving to unity of mass unity of acceleration.

I need not dwell on other ideas which are introduced, *e.g.*, moment, work, energy, &c. The whole building can be constructed, and there is room for every investigation which belongs to so-called theoretical mechanics. So it is demonstrated that a centrobaric body, which has kinetical symmetry in respect to its centre of gravity, and which has been brought in rotation about an axis going through the centre of gravity, retains constant angular velocity, when no forces are acting on the surface, and on the component parts only central forces which are in the same proportion as the masses of the parts.

Before kinematics and abstract dynamics can be applied in interpreting phenomena, we must be enabled to measure time.

What is time? There are mental conceptions which cannot be described by words, and I reckon "time" amongst them. But I shall try to answer the question how the conception of time originates with us.

The formation of the conception of "time" is preceded by the formation of the idea of "lapse of time." The idea of "lapse of time" we arrive at by the simultaneous observation of two phenomena, in conjunction with the observation of two phenomena not occurring simultaneously, in such a manner that we receive the impression of the second phenomenon when the impression of the first one is not yet effaced from our memory.

A lapse of time, from the nature of the idea, is limited. If we abstract the *definite* limits, we have the conception of time.

It is clear that in speaking of the measuring of time we properly mean the measuring of lapses of time.

In order to measure lapses of time we must know when a lapse of time is twice as long as another. We easily come to this on its having been established which lapses of time are equal.

If we wish to compare the length of two bodies we place the one beside the other, or if circumstances prevent us from doing so, we successively place a third object beside each of them.

For the comparison of two lapses of time we lack such means and have to follow another way.

In nature phenomena present themselves that persistently return. *Now we simply settle by definition that the lapses of time between the first occurrence of a particular phenomenon and the second is equal to that between the second and third occurrence.* Which phenomenon is to be chosen? Flux and reflux? Earthquakes? For the application of kinematics and abstract dynamics in interpreting phenomena, the choice is no indifferent matter.

I confine myself to the phenomenon which is still the usual base of the measurement of time. It is settled by definition that the lapses of time between the successive culminations of a definite fixed star in a definite place are equal. To divide these lapses of time themselves into equal parts, it is settled that the apparent motion of the fixed star, and therefore of all fixed stars, is uniform.

The results arrived at in the attempts at interpreting phenomena show that a very good hit has been made. But it is not impossible that after greater development of science we may have to make the measurement of time independent of the rotation of the earth. The application of abstract dynamics to the theory of the motion of the earth round the sun and of the moon round the earth has furnished admirable results. But in comparing the results of calculation with the accounts of eclipses found in ancient chronicles, a difference is met with, and in the opinion of some it is too considerable to be accounted for by the imperfection which may adhere to ancient descriptions. Therefore the theory of the motion of the earth and of the moon is incomplete. But hitherto no omission can be pointed out. For this reason some men of science are inclined to *settle by definition* that the theory of the motion of the earth and of the moon is complete, and to make it the base of the measurement of time. Then, of course, the former definition must be abandoned, and two arbitrary intervals between successive culminations of a fixed star no longer are equal.

Prof. Clerk Maxwell says ("Theory of Heat," second edition, p. 81): "This shows that time, though we conceive it merely as the succession of our states of consciousness, is capable of measurement, independently, not only of our mental states, but of any particular phenomenon whatever." In my opinion this assertion is erroneous. If we reject the rotation of the earth as the base of the measurement of time, we must have recourse to the motion of the earth round the sun or to that of the moon round the earth, or to any other phenomenon. Thomson and Tait, in § 406, already allude to a metal spring oscillating *in vacuo*. It should then be *settled by definition*, for example, that such a spring has a harmonical motion. If we proclaimed the lapses of time between the successive arrivals of flux and reflux at a particular station to be equal, and if we admitted, in order to divide these lapses of time into equal parts, *e.g.*, that the water sinks and rises uniformly, *then the whole of kinematics and abstract dynamics would retain the same form*; even then a centrobaric body with kinetical symmetry in respect to its centre of gravity, would show the peculiarity already mentioned. But it would be seen that our kinematics and abstract dynamics were but a highly deficient aid for the interpretation of phenomena; and the earth would not at all be a body with the same motion round its axis, as if it were a centrobaric body with kinetical symmetry in respect to its centre of gravity.

Of course it is wise to maintain provisionally the definition by which the earth in equal times rotates through equal angles.

In applying abstract dynamics to the interpretation of phenomena, we are led to identify the idea of mass with the idea of quantity of matter, and this has furnished excellently satisfying results. From this, in conjunction with experiment, it follows that two bodies which have equal weight, possess equal quantities of matter; that no matter is annihilated or created, &c.

This article is already too long for me to dwell on other consequences which follow from my view. Only a few words on the conservation of energy. This law threatens to be considered an axiom. Yet I believe it desirable that we should always remember that it is the result of experiment. If the measuring of time were founded on a different basis, it would not hold. Still the experiments do not give perfectly satisfying results. Usually this is ascribed to the imperfection of our methods and instruments, which really may be the cause. But, probably, if in future times it be found by improved methods and instruments that the law does not hold, it would be advantageous to proclaim by definition the conservation of energy and to deduce from it the measurement of time. Then we should have the analogon of the absolute scale of temperature of Thomson.

If any one after the perusal of this article asserts that my views are at variance with the historical development of science, I answer that often in the reasoning of man there are gaps, which by contemporaries are not perceived; but that we must try to find them out and to fill them.

I hope my readers will not be too much annoyed by the defective manner in which I may have expressed myself in English; it is always difficult to make use of a foreign language.

Before closing I am bound to state that I have particularly mentioned the assertions of Sir W. Thomson, Prof. Tait, and Prof. Clerk Maxwell, because in their works I found most emphatically stated what in my opinion is erroneous. These eminent men stand so high that it is unnecessary for me to express my profound respect for them. V. A. JULIUS

Roermond, Holland

OUR ASTRONOMICAL COLUMN

THE D'ANGOS COMET OF 1784.—Encke's investigation relating to this reported comet appears in Zach's *Correspondance Astronomique*, as an "Imposture Astronomique grossière du Chevalier D'Angos, dévoilée par J. F. Encke, à Gotha." Olbers, in a letter addressed to him, had, as already stated, asked his attention to the subject, saying, "I would invite you to the examination of a doubtful comet of which the result will be either the knowledge of the yet unknown orbit of a very remarkable comet, or the discovery of a most shameful imposture," and adding particulars to which allusion is made in our previous note.

Encke remarks at the outset that, contrary to all general usage amongst astronomers, D'Angos had given the Malta observations with mean times for Paris, and the comet's positions expressed in longitudes and latitudes, which confirmed the suspicion that he had computed from the elements of an imaginary orbit and had not taken the trouble to convert the results into right ascensions and declinations, in which astronomers are accustomed to present them. If it is demonstrable that according to the observations (at least without supposing them erroneous to the amount of many minutes) the comet could only have moved in a very improbable orbit, in fact almost as a satellite of the earth and at a distance less than that of the moon, and if further it can be shown that by a very simple error of calculation D'Angos was misled in deducing the places of the comet from the imaginary elements, then, Encke urged, there remains no longer the smallest doubt that he had invented all these observations. Making use of the positions given for April 15, 22, and 29, Encke assuming arbitrarily a value of the comet's curtate distance from the earth at the first date, finds the corresponding value for the same at the third date in order to represent precisely the longitude on April 22, and compares with the corresponding latitude. Thus if the curtate distance on April 22 be taken as 0·42 (we somewhat contract Encke's figures) the third distance is 0·55, the error on the middle latitude, − 16′, and the resulting conic section is a hyperbola; the same form of orbit is deduced when the comet's distance on April 22 is diminished to 0·25. If this distance be further diminished to 0·146, the orbit becomes an ellipse, but the error on the middle latitude is still − 12′·8, and it was found necessary to reduce the curtate distance to 0·00126 in order to represent this latitude with no greater error than − 2″·5; the resulting orbit being also an ellipse. Taking the solar parallax at 8″·86, this distance corresponds to 116,000 miles, or about half the moon's distance from the earth, and under the condition named above, on April 29 it still be less than 160,000 miles. Thus Encke found it was necessary to assume the comet's distance from the earth, almost incredibly small if the errors of calculation are to be brought within the limit assigned by D'Angos to the differences between the places computed from his elements and his observations, or about 1½′; and, he continues, a celestial body under such circumstances remaining for so long a time in immediate proximity to the earth, would assuredly have been retained within its sphere of activity, and D'Angos if he were the first would certainly not have been the only observer of this second moon. Rejecting then as beyond probability the conclusions necessarily drawn from an investigation in the manner here briefly described, Encke proceeded to examine the calculation of geocentric longitudes and latitudes of the comet from the elements assigned by D'Angos.

Taking for example the observation of April 15, the logarithm of the radius-vector calculated from the orbit of D'Angos is found to be 9·8208333, and continuing the computation the resulting position differs from the observation 47° in longitude and 15° in latitude, but supposing that by an error of the pen D'Angos had used a log. radius-vector ten times greater, or 0·8208333, with the same heliocentric longitude and latitude, the errors are reduced to 56 seconds and 34 seconds respectively, and making the same change in the log. radii-vectores at the other dates of observation, Encke arrived at the extraordinary result that the whole of the reputedly-observed places were represented within about the limit of error mentioned by D'Angos, and he insisted that with such proof there could be no possible doubt that the observations and the orbit of the comet, "ne soient entièrement fausses et controuvées, et que par conséquent il faut les rayer de tous nos catalogues des comètes, comme un astre chimerique qui n'a jamais existé;" while at the same time he acknowledged himself ready to do justice to the accused and to make the most ample satisfaction if he could be opposed by arguments as strong and apparently conclusive as those upon which he had founded an adverse verdict.

THE TOTAL SOLAR ECLIPSE, 1889, DECEMBER 22.—In continuation of notices of future total eclipses of the sun which have appeared in this column, the elements of the eclipse of 1889, December 22, are subjoined:—

G.M.T. of Conjunction in R.A. Dec. 22, at 0h. 24m. 50s.

	° ′ ″
R.A.	271 0 10·4
Moon's hourly motion in R.A. ...	41 20·7
Sun's ,, ,, ,, ...	2 46·6
Moon's declination	23 14 1·8 S.
Sun's ,, ...	23 27 10·3 S.
Moon's hourly motion in decl. ...	3 4·2 S.
Sun's ,, ,, ,, ...	0 1·1 N.
Moon's horizontal parallax	61 17·1
Sun's ,, ,, ...	9·1
Moon's semi-diameter	16 42·0
Sun's ,, ...	16 16·1

The central and total eclipse commences in long. 78° 52′ W., lat. 15° 22′ N., and ends in long. 60° 55′ E. and lat. 6° 53′ N., and it occurs with the sun on the meridian in long. 6° 27′ W., lat. 11° 5′ S.

At a point on the coast of Africa in 10° 6′ S. lat., totality commences at 2h. 8m. 55s. local time, and continues 3m. 34s. At Bridgetown, Barbadoes, totality begins at 6h. 47m. 6s. A.M. local time, and continues 1m. 48s., but the sun's altitude is only 6°. The following are points upon the central line, which will show that with a fair duration where the sun is near the meridian, the course of the eclipse is not a favourable one for observation:—

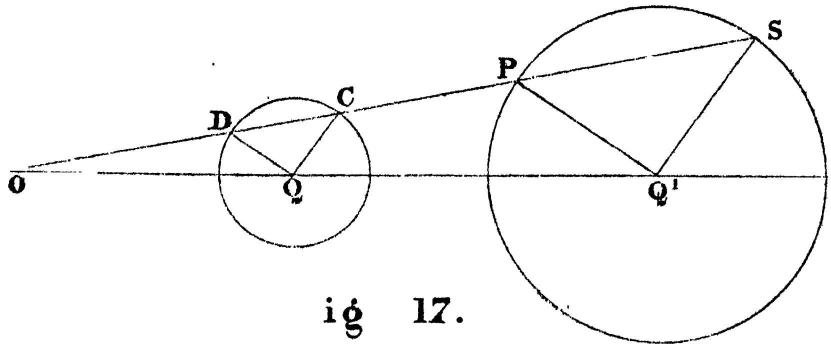
32 28 W.	0 23 S.	18 32 E.	8 27 S.

HOW TO DRAW A STRAIGHT LINE[1]

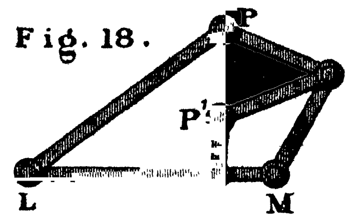
III.

BEFORE leaving the Peaucellier cell and its modifications, I must point out another important property they possess besides that of furnishing us with exact rectilinear motion. We have seen that our simplest linkwork enables us to describe a circle of any radius, and if we wished to describe one of ten miles radius the proper course would be to have a ten mile link, but as that would be, to say the least, cumbrous, it is satisfactory to know that we can effect our purpose with a much smaller apparatus. When the Peaucellier cell is mounted for the purpose of describing a straight line, as I told you, the distance between



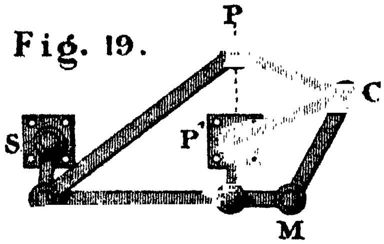
ig 17.

Fig. 18.



the fixed pivots must be the same as the length of the "extra" link. If this distance be not the same we shall not get straight lines described by the pencil, but circles. If the difference be slight the circles described will be of enormous magnitude, decreasing in size as the difference

Fig. 19.



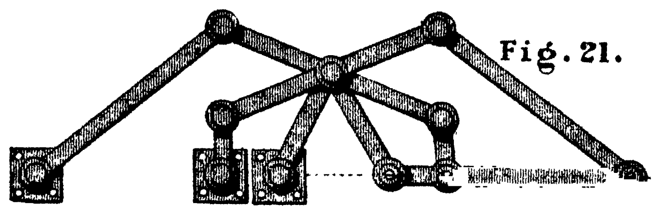


Fig. 21.

increases. If the distance Q O, Fig. 6, be made greater than Q C, the convexity of the portion of the circle described by the pencil (for if the circles are large it will of

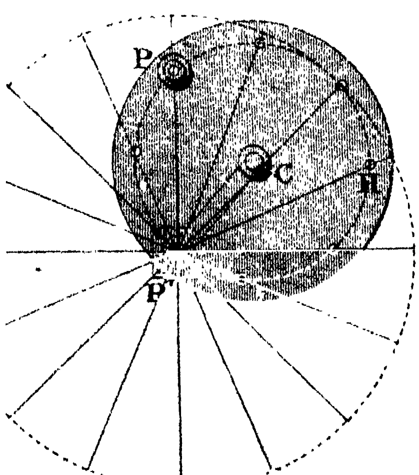

Fig. 20.

course be only a portion which is described) will be towards O, if less the concavity. To a mathematician, who knows that the inverse of a circle is a circle, this will be clear, but it may not be amiss to give here a short proof of the proposition.

In Fig. 17 let the centres Q, Q′ of the two circles be at distances from O proportional to the radii of the circles. If then O D C P S be any straight line through O, D Q will be parallel to P Q′, and C Q to S Q′, and O D will bear the same proportion to O P that O Q does to O Q′. Now considering the proof we gave in connection with Fig. 7, it will be clear that the product O D · O C is con-

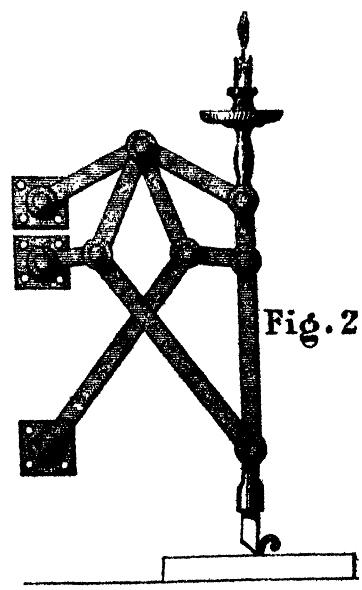

Fig. 22.

stant, and therefore since O P bears a constant ratio to O D, O P · O C is constant. That is, if O C · O P is constant and C describes a circle about Q, P will describe one about Q′. Taking then O, C, and P as the O, C, and

[1] Lecture at South Kensington in connection with the Loan Collection of Scientific Apparatus, by A. B. Kempe, B.A. Continued from p. 89.

P of the Peaucellier cell in Fig. 7, we see how P comes to describe a circle.

It is hardly necessary for me to state the importance of the Peaucellier compass in the mechanical arts for drawing circles of large radius. Of course the various modifications of the "cell" I have described may all be employed for the purpose. The models exhibited by the Conservatoire and M. Breguet are furnished with sliding pivots for the purpose of varying the distance between O and Q, and thus getting circles of any radius.

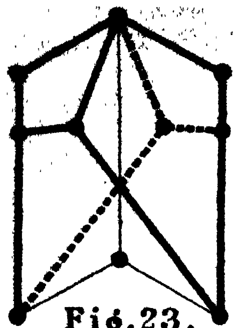

Fig. 23.

My attention was first called to these linkworks by the lecture of Prof. Sylvester, to which I have referred. A passage in that lecture in which it was stated that there were probably other forms of seven-link parallel motions besides M. Peaucellier's, then the only one known, led me to investigate the subject, and I succeeded in obtaining some new parallel motions of an entirely different character to that of M. Peaucellier. I shall bring two of these to your notice as the investigation of them will lead us to consider some other linkworks of importance.

If I take two kites, one twice as big as the other, such that the long links of each are twice the length of the short ones, and make one long link of the small kite lie on a short one of the large, and a short one of the small on a long one of the large, and then amalgamate the coincident links, I shall get the linkage shown in Fig. 18.

The important property of this linkage is that, although we can by moving the links about, make the points P and P′ approach to or recede from each other, the imaginary line joining them is always perpendicular to that drawn through the pivots on the bottom link L M. It follows that if either of the pivots P or P′ be fixed, and the link L M be made to move so as always to remain parallel to a fixed line, the other point will describe a straight line perpendicular to the fixed line. Fig. 19 shows you the

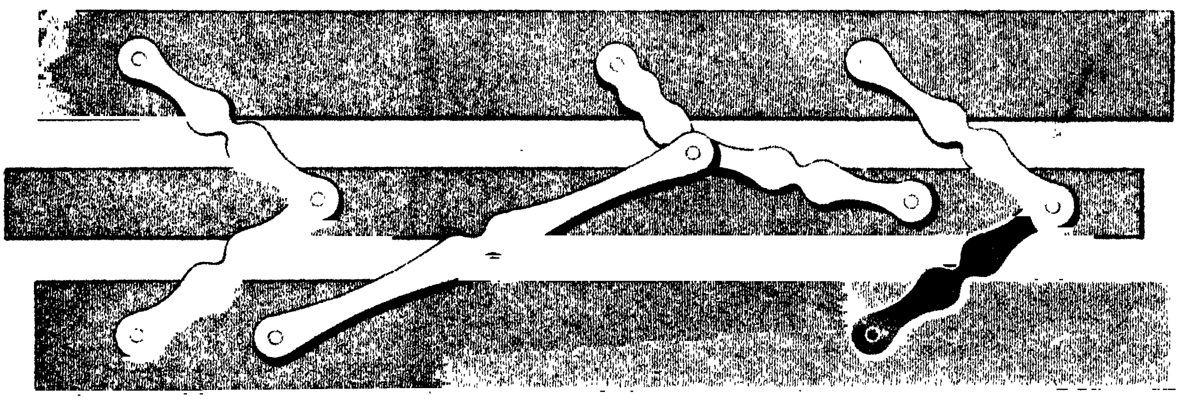

Fig. 24.

parallel motion made by fixing P′. It is unnecessary for me to point out how the parallelism of L M is preserved

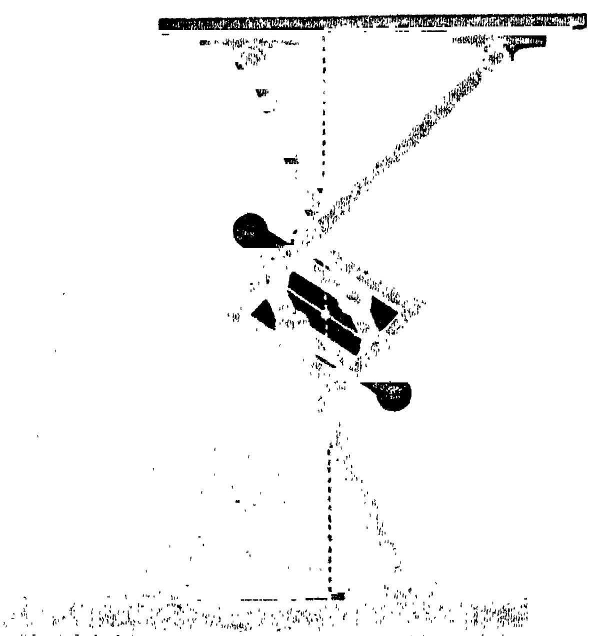

Fig. 25.

by adding the link S L, it is obvious from the figure. The straight line which is described by the point P is perpendicular to the line joining the two fixed pivots; we can, however, without increasing the number of links make a point on the linkwork describe a straight line inclined to the line S P at any angle, or rather we can, by substituting for the straight link P C a plane piece,

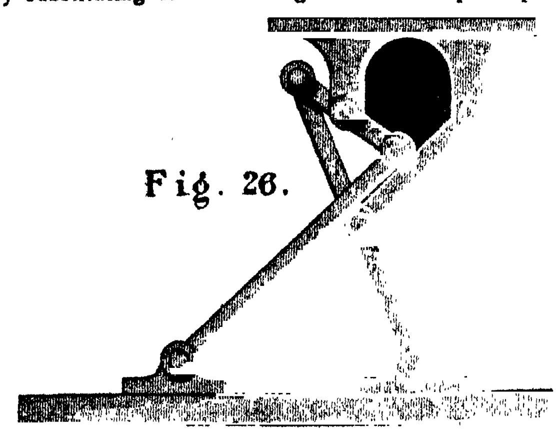

Fig. 26.

get a number of points on that piece moving in every direction.

In Fig. 20, for simplicity, only the link C P′ and the new piece substituted for the link P C are shown. The new piece is circular and has holes pierced in it all at the same distance—the same as the lengths P C and P′ C—from C. Now we have seen from Fig. 19 that P moves in a vertical straight line, the distance P C in Fig. 20 being the same as it was in Fig. 19; but from a well-known property of a circle, if H be any one of the holes pierced in the piece, the angle H P′ P is constant, thus the straight line H P′ is fixed in position, and H moves along it; similarly all the other holes move along in straight lines passing through the fixed pivot P′, and we get straight line motion distributed in all directions. This species of motion is called by Prof. Sylvester "tram-motion." It is worth noticing that the motion of the circular disc is the same as it would have been if the dotted circle on it rolled inside the large dotted circle; we have, in fact, White's parallel motion reproduced by linkwork. Of course, if we only require motion in one direction, we may cut away all the disc except a portion forming a bent arm containing C, P, and the point which moves in the required direction.

The double kite of Fig. 18 may be employed to form some other useful linkworks. It is often necessary to have, not a single point, but a whole piece moving so that all points on it move in straight lines. I may instance the slide rests in lathes, traversing tables, punches, drills, drawbridges, &c. The double kite enables us to produce linkworks having this property. In the linkwork of Fig. 21, the construction of which will be

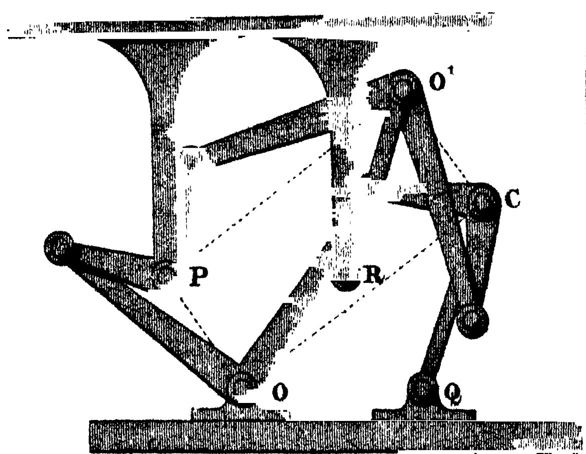

Fig 27.

at once appreciated if you understand the double kite, the horizontal link moves to and fro as if sliding in a fixed horizontal straight tube. This form would possibly be useful as a girder for a drawbridge.

In the linkwork of Fig. 22, which is another combination of two double kites, the vertical link moves so that all its points move in horizontal straight lines. There is a modification of this linkwork which will, I think, be found interesting. In the linkage in Fig. 23, which, if the thin links are removed, is a skeleton drawing of Fig. 22, let the dotted links be taken away and the thin ones be inserted; we then get a linkage which has the same property as that in Fig. 22, but it is seen in its new form to be the ordinary double parallel ruler with three added links. Fig. 24 is a figure of a double parallel rule made on this plan with a slight modification. If the bottom ruler be held horizontal the top moves vertically up and down the board, having no lateral movement.

While I am upon this sort of movement I may point out an apparatus exhibited in the Loan Collection by Prof. Tchebicheff which bears a strong likeness to a complicated camp-stool, the seat of which has horizontal motion. The motion is not strictly rectilinear; the apparatus being, as will be seen by observing that the thin line in the figure is of invariable length, and a link might therefore be put where it is, a combination of two of the parallel motions of Prof. Tchebicheff given in Fig. 4, with some links added to keep the seat parallel with the base. The variation of the upper plane, from a strictly horizontal movement is therefore double that of the tracer in the simple parallel motion.

Fig. 26 shows how a similar apparatus of much simpler construction employing the Tchebicheff approximate parallel motion can be made. The lengths of the links forming the parallel motion have been given before (Fig. 4). The distance between the pivots on the moving seat is half that between the fixed pivots, and the length of the remaining link is one-half that of the radial links.

An *exact* motion of the same description is shown in Fig. 27. O, C, O′, P are the four *foci* of the quadriplane shown in the figure in which the links are bent through a right angle, so that O C · O P is constant, and C O P a right angle. The focus O is pivoted to a fixed point, and C is made by means of the extra link Q C to move in a circle of which the radius Q C is equal to the pivot distance O Q. P consequently moves in a straight line parallel to O Q, the five moving pieces thus far described constituting the Sylvester-Kempe parallel motion. To this are added the moving seat and the remaining link R O′, the pivot distances of which, P R and R O′, are equal to O Q. The seat in consequence always remains parallel to Q O, and as P moves accurately in a horizontal straight line, every point on it will do so also. This apparatus might be used with advantage where a very smoothly-working traversing table is required.

(*To be continued.*)

SPONTANEOUS GENERATION[1]

THE investigation embodied in the memoir now submitted to the Society was opened in the summer of 1876 by a series of tentative experiments on turnip-infusions, to which were added varying quantities of bruised or pounded cheese. I was soon, however, drawn away from them to other experiments on infusions of hay. With this substance no difficulty was encountered in my first inquiry. Boiled for five minutes, and exposed to air purified spontaneously or freed from its floating matter by calcination or filtration, hay infusion, though employed in multiplied experiments at various times, never showed the least competence to kindle into life. After months of transparency, I have, in a great number of cases, inoculated this infusion with the smallest specks of animal and vegetable liquids containing *Bacteria*, and observed twenty-four hours afterwards, its colour lightened, and its mass rendered opaque by the multiplication of these organisms.

But in the autumn of 1876, the substance with which I had experimented so easily and successfully a year previously, appeared to have changed its nature. The infusions extracted from it bore in some cases not only five minutes' but fifteen minutes' boiling with impunity. But on changing the hay a different result was often obtained. Many of the infusions extracted from samples of hay purchased in the autumn of 1876, behaved exactly like those extracted from the hay of 1875, being completely sterilized by five minutes' boiling.

To solve these discrepancies, numerous and laborious experiments were executed with hay derived from different localities, and by this means in the earlier days of the inquiry, it was revealed that the infusions which manifested this previously unobserved resistance to sterilization were, one and all, extracted from old hay, while the readily sterilized infusions were extracted from new hay, the germs adhering to which had not been subjected to long-continued desiccation.

I then fell back upon infusions whose deportment had

[1] "Further Researches on the Deportment and Vital Resistance of Putrefactive and Infective Organisms, from a Physical Point of View." By John Tyndall, LL.D., F.R.S., Professor of Natural Philosophy in the Royal Institution.—Abstract.

been previously familiar to me, and in the sterilization of which I had never experienced any difficulty. Fish, flesh, and vegetables were re-subjected to trial. Though the precautions taken to avoid contamination were far more stringent than those observed in my first inquiry, and though the interval of boiling was sometimes tripled in duration, these infusions, in almost every instance, broke down. Spontaneously purified air, filtered air, and calcined air,—calcined, I may add, with far greater severity than was found necessary a year previously,—failed, in almost all cases, to protect the infusions from putrefaction.

I had the most implicit confidence in the correctness of my earlier experiments; indeed, incorrectness would have led to consequences exactly opposite to those arrived at. Errors of manipulation would have filled my tubes and flasks with organisms instead of leaving them transparent and void of life. By the unsuccessful experiments above referred to a clear issue was therefore raised: Either the infusions of fish, flesh, and vegetable had become endowed in 1876 with an inherent generative energy which they did not possess in 1875, or some new contagium external to the infusions, and of a far more obstinate character than that of 1875, had been brought to bear upon them. The scientific mind will not halt in its decision between these two alternatives.

For my own part the gradual but irresistible interaction of thought and experiment rendered it at first probable, and at last certain that the atmosphere in which I worked had become so virulently infective as to render utterly impotent precautions against contamination, and modes of sterilization, which had been found uniformly successful in a less contagious air. I therefore removed from the laboratory, first to the top, and afterwards to the basement of the Royal Institution, but found that even here, in a multitude of cases, failure was predominant, if not uniform. This hard discipline of defeat was needed to render me acquainted with all the possibilities of infection involved in the construction of my chambers and the treatment of my infusions.

I finally resolved to break away from the Royal Institution, and to seek at a distance from it a less infective atmosphere. In Kew Gardens, thanks to our President, the requisite conditions were found. I chose for exposure in the Jodrell laboratory the special infusions which had proved most intractable in the laboratory of the Royal Institution. The result was that liquids which in Albemarle Street resisted two hundred minutes boiling, becoming fruitful afterwards, were utterly sterilised by five minutes' boiling at Kew.

A second clear issue is thus placed before the Royal Society:—Either the infusions had lost in Kew Gardens an inherent generative energy which they possessed in our laboratory, or the remarkable instances of life development, after long-continued boiling, observed in the laboratory are to be referred to the contagium of its air.

With a view to making nearer home experiments similar to those executed at Kew, I had a shed erected on the roof of the Royal Institution. In this shed infusions were prepared and introduced into new chambers of burnished tin, which had never been permitted to enter our laboratory. After their introduction the liquids were boiled for five minutes in an oil-bath.

The first experiment in this shed resulted in complete failure, the air of the shed proving to be sensibly as infective as the air of the laboratory.

Either of two causes, or both of them combined, might, from my point of view, have produced this result. First, a flue from the laboratory was in free communication with the atmosphere not far from the shed; secondly, and this was the real cause of the infection, my assistants in preparing the infusions, had freely passed from the laboratory to the shed. They had thus carried the contagium by a mode of transfer known to every physician.

The infected shed was disinfected; the infusions were again prepared, and care was taken, by the use of proper clothes, to avoid the former causes of contamination. The result was similar to that obtained at Kew, viz., organic liquids which in the laboratory withstood two hundred minutes' boiling, were rendered permanently barren by five minutes' boiling in the shed.

A third clear issue is thus placed before us, which I should hardly think of formulating before the Royal Society, were it not for the incredible confusion which apparently besets this subject in the public mind. A rod thirty feet in length would stretch from the infusions in the shed to the same infusions in the laboratory. At one end of this rod the infusions were sterilized by five minutes' boiling, at the other end they withstood two hundred minutes' boiling. As before, the choice rests between two inferences:—Either we infer that at one end of the rod animal and vegetable infusions possess a generative power, which at the other end they do not possess; or we are driven to the conclusion that at the one end of the rod we have infected, and at the other end disinfected air.

The second inference is that which will be accepted by the scientific mind. To what, then, is the inferred difference at the two ends of the rod to be ascribed? In one obvious particular the laboratory this year differed from that in which my first experiments were made. On its floor were various bundles of old and desiccated hay, from which, when stirred, clouds of fine dust ascended into the atmosphere. This dust proved to be both fruitful and in the highest degree resistant. Prior to the introduction of the hay which produced the dust, no difficulty as regards sterilization had ever been experienced; subsequent to its introduction my difficulties and defeats began.

In these and numerous other experiments a method was followed which had been substantially employed by Spallanzani and Needham; and more recently by Wyman and Roberts, the method having been greatly refined by the philosopher last named. The flasks containing the infusions were only partially filled, the portions unoccupied by the liquids being taken up with ordinary unfiltered air. Now as regards the death-point of contagia, we know that in air it is higher than in water, the self-same temperature being fatal in the latter and sensibly harmless in the former. Hence my doubt whether, in my recent experiments, the resistance of the contagium did not arise from the fact that it was surrounded, not by water but by air.

I changed the method, and made a long series of experiments with filtered air. They were almost as unsuccessful as those made with ordinary air.

One source of discomfort clung persistently to my mind throughout these experiments. I was by no means certain that the observed development of life was not due to germs entangled in the film of liquid adherent to the necks and higher interior surfaces of the bulbs. This film might have dried, and its germs, surrounded by air and vapour, instead of by water, might on this account have been able to withstand an ordeal to which they would have succumbed if submerged.

A plan was, therefore, resorted to by which the infusions were driven by atmospheric pressure through lateral channels issuing from the centres of the bulbs. As before, each bulb was filled with one-third of an atmosphere of filtered air, and afterwards heated nearly to redness. When fully charged, the infusion rose higher than the central orifice, and no portion of the internal surface was wetted save that against which the liquid permanently rested. The lateral channel was then closed with a lamp without an instant's contact being permitted to occur between any part of the infusion and the external air. It was thus rendered absolutely certain that the contagia exposed subsequently to the action of heat were to be sought, neither in the superjacent air nor on the interior surfaces of the flasks, but in the body of the infusions themselves.

By this method I tested in the first place the substance which, at an early stage of the inquiry, had excited my suspicion—without reference to which the discrepancy between the behaviour of infusions examined in the winter of 1875-76 and those examined in the winter of 1876-77 is inexplicable, but by reference to which the explanation of the observed discrepancy is complete—I mean the old hay which cumbered our laboratory floor.

Four hours' continuous boiling failed to sterilise bulbs charged with infusions of this old hay. In special cases, moreover, germs were found so indurated and resistant, that five, six, and in one case even eight hours' boiling failed to deprive them of life. All the difficulties encountered in this long and laborious inquiry were traced to the germs which exhibited the extraordinary powers of resistance here described. They introduced a plague into our atmosphere—the other infusions, like a smitten population, becoming the victims of a contagium foreign to themselves.[1]

It is a question of obvious interest to the scientific surgeon whether those powerfully resistant germs are amenable to the ordinary processes of disinfection. It is perfectly certain that they resist to an extraordinary extent the action of heat. They have been proved competent to cause infusions, both animal and vegetable, to putrefy. How would they behave in the wards of a hospital? There are, moreover, establishments devoted to the preserving of meats and vegetables. Do they ever experience inexplicable reverses. I think it certain that the mere shaking of a bunch of desiccated hay in the air of an establishment of this character might render the ordinary process of boiling for a few minutes utterly nugatory, thus possibly entailing serious loss. They have, as will subsequently appear, one great safeguard in the complete purgation of their sealed tins of air.

Keeping these germs and the phases through which they pass to reach the developed organism clearly in view, I have been able to sterilise the most obstinate infusions encountered in this inquiry by heating them for a minute fraction of the time above referred to as *insufficient* to sterilise them. The fully developed Bacterium is demonstrably killed by a temperature of 140° F. Fixing the mind's eye upon the germ during its passage from the hard and resistant to the plastic and sensitive state, it will appear in the highest degree probable that the plastic stage will be reached by different germs in different times. Some are more indurated than others and require a longer immersion to soften and germinate. For all known germs there exists a period of incubation during which they prepare themselves for emergence as the finished organisms which have been proved so sensitive to heat. If during this period, and well within it, the infusion be boiled for even the fraction of a minute, the softened germs which are then approaching their phase of final development will be destroyed. Repeating the process of heating every ten or twelve hours, and before the least *sensible* change has occurred in the infusions, each successive heating will destroy the germs then softened and ready for destruction, until after a sufficient number of heatings the last living germ will disappear.

Guided by the principle here laid down, and applying the heat discontinuously, infusions have been sterilised by an aggregate period of heating, which, fifty times multiplied, would fail to sterilise them if applied continuously. Four minutes in the one case can accomplish what four hours fail to accomplish in the other.

If properly followed out the method of sterilisation here described is infallible. A temperature, moreover, far below the boiling point suffices for sterilisation.

Another mode of sterilisation equally certain, and perhaps still more remarkable, was forced upon me, so to speak, in the following way:—In a multitude of cases a thick and folded layer of fatty scum, made up of matted *Bacteria*, gathered upon the surfaces of the infusions, the liquid underneath becoming sometimes cloudy throughout, but frequently maintaining a transparency equal to that of distilled water. The living scum-layer, as Pasteur has shown in other cases, appeared to possess the power of completely intercepting the atmospheric oxygen, appropriating the gas and depriving the germs in the liquid underneath of an element necessary to their development. Above the scum, moreover, the interior surfaces of the bulbs used in my experiments were commonly moistened by the water of condensation. Into it the *Bacteria* sometimes rose, forming a kind of gauzy film to a height of an inch or more above the liquid. In fact, wherever air was to be found, the *Bacteria* followed it. It seemed a necessity of their existence. Hence the question, What will occur when the infusions are deprived of air?

I was by no means entitled to rest satisfied with an inference as an answer to this question; for Pasteur, in his masterly researches, has abundantly demonstrated that the process of alcoholic fermentation depends on the continuance of life without air—other organisms than *Torula* being also shown competent to live without oxygen. Experiment alone could determine the effect of exhaustion upon the particular organisms here under review. Air-pump vacua were first employed, and with a considerable measure of success. Life was demonstrably enfeebled in such vacua.

Sprengel pumps were afterwards used to remove more effectually both the air dissolved in the infusions and that diffused in the spaces above them. The periods of exhaustion varied from one to eight hours, and the results of the experiments may be thus summed up:—Could the air be completely removed from the infusions, there is every reason to believe that sterilisation *without boiling* would in most, if not in all cases, be the result. But, passing from probabilities to certainties, it is a proved fact, that in numerous cases unboiled infusions deprived of air by five or six hours' action of the Sprengel pump are reduced to permanent barrenness. In a great number of cases, moreover, where the unboiled infusion would have become cloudy, exposure to the boiling temperature for a single minute sufficed completely to destroy the life already on the point of being extinguished through defect of air. With a single exception, I am not sure that any infusion escaped sterilisation by five minutes' boiling after it had been deprived of air by the Sprengel pump. These five minutes accomplished what five hours often failed to accomplish in the presence of air.

The inertness of the germs in liquids deprived of air is not due to a mere *suspension* of their powers. They are *killed* by being deprived of oxygen. For when the air which has been removed by the Sprengel pump is, after some time, carefully restored to the infusion, unaccompanied by germs from without, there is no revival of life. By removing the air we stifle the life which the returning air is incompetent to restore.

[1] A hard and wiry hay from Guildford, which I have no reason to consider old, was found very difficult to sterilise.

AGRICULTURAL EXPERIMENTS AT WOBURN

IN the autumn of 1875 Mr. C. Randell proposed to the Council of the Royal Agricultural Society that it be referred to the Chemical Committee to consider the propriety, and the manner, of instituting a series of experiments, to test the accuracy of the estimated value of manure obtained by the consumption of different articles of food, as given in Mr. Lawes' paper, in the Spring Number of the Journal of the Society.

As it was decided that experiments by practical farmers in different districts could not be relied on, the Duke of

Bedford very kindly offered to afford facilities for making new experiments at his own cost.

Mr. Lawes and Dr. Voelcker were requested to draw up a scheme for carrying on, at Woburn, such experiments as they, in communication with the Chemical Committee, might determine on. His grace offered to give up for the purpose Crawley Mill Farm, comprising about ninety acres, with the house and buildings. But, on examination, it was found that there was no sufficient area on that farm so even in character, and in condition, of soil, as to render it available for a considerable series of comparative field experiments. Eventually, after inspection of many others, a large field of much more suitable land was selected, on Birchmoor Farm. Crawley Mill Farm is, however, also retained, as a means of providing a residence for the Superintendent of the experiments, the requisite buildings, and the opportunity of having at command the necessary horse and hand labour for the experiments. Mr. P. H. Cathcart, formerly at the Royal Agricultural College, Cirencester, has been appointed the Resident Superintendent of the experiments.

As experiments to determine the value of the manure obtained by the consumption of purchased foods obviously involved the necessity of feeding animals under conditions in which the manure could be collected with as little loss as possible, the Duke of Bedford has erected eight very complete feeding boxes, in which the manure for the experimental barley and root crops recently sown has been made.

The field devoted to the field experiments has an area of twenty-seven acres; the soil has been carefully tested all over, and an account taken of the history of the field since 1874.

It was considered important, especially with reference to valuations under the Agricultural Holdings' Act, to add, if possible, to our knowledge of the manure-value of both artificial manures and consumed feeding stuffs; and it was decided, therefore, both to compare the effects of the manure obtained by the consumption of selected purchased foods, with those obtained by artificial manures estimated to supply the same constituents, and also to determine the effects of dung and artificial manuring substances, applied year after year, on the Woburn soil, and to compare these with the results obtained for so many years, with the same manures, on the very different soil at Rothamsted. Accordingly, 2¾ of the six acres where wheat had been grown in 1876, after tares and turnips, each fed with cake, are devoted to the continuous growth of wheat, and 2¾ acres to the continuous growth of barley. In each case the area is divided into eleven plots, of a quarter of an acre each.

The description and quantities of the manures for these experiments have been so carefully selected that in the end valuable results must be obtained as to the comparative value of various kinds of artificial manure as compared with farmyard manure, the constituents of which are accurately known. Two of the plots are unmanured; seven are manured with artificial manure of more or less complicated composition, and two with farmyard manure estimated to contain different proportions of nitrogen. In connection with the farmyard manure an accurate record is kept of the kinds and quantities of food from which it is produced, as also of the increase in the live-weight of the stock thus fed.

Besides these continuous experiments a series of rotation experiments—seeds, wheat, roots, barley, in successive years from 1877 to 1881—are to be carried out. The stock which is to supply the farmyard manure for these experiments is to be fed with decorticated cotton-cake, which among purchased feeding stuffs has a very high manure value, and maize-meal, which has a very low manure value. The effects of the manures obtained by the consumption of these foods will be compared with those of artificial manures supplying, in one case the same amount of nitrogen, potass, phosphoric acid, &c., as is estimated to be contained in the manure from the cotton-cake consumed, and in another the same as in that from the maize-meal consumed. Accordingly, four feeding experiments have been conducted, in each of which the same amount of litter has been used, and the same amount of roots, and the same amount of wheat-straw chaff consumed. In Experiment 1, 1,000 lbs. decorticated cotton-cake were given in addition; and in Experiment 2, 1,000 lbs. maize-meal. In Experiments 3 and 4 no purchased food was given; but in Experiment 3 artificial manures estimated to contain the same amount of the chief constituents as the manure from 1,000 lbs. of cotton-cake, and in Experiment 4 the same as from 1,000 lbs. maize-meal, will be applied to the land, in addition to the root and chaff manure.

Four areas of four acres each have been devoted to these rotation experiments, eight of them coming into exact experiment this year, and the remaining eight in 1878. Each area of four acres is again divided into four plots, each of the latter sub-divisions bearing the same crop during the rotation of four years, but undergoing different treatment in the way of manure. For example, rotation No. 1, now under seeds, is treated as follows. Each plot is being separately fed by sheep. Plot 1 with cotton-cake; Plot 2 with maize-meal; and Plots 3 and 4 without purchased food. But, for the succeeding wheat, artificial manure estimated to contain nitrogen, and other constituents, in amounts equal to those in the manure from the consumed cotton-cake, will be applied to Plot 3, and artificial manure, equal to that from the consumed maize-meal will be applied to Plot 4. For the roots in 1879 (succeeding the wheat), the 4 acres will be manured as already described, and barley will complete the course in 1880. The other rotations are so treated as at the end of the four years to yield a collection of data that must be of the highest value in agricultural chemistry, and therefore to practical agriculture. In a "Statement" as to the objects and plan of the experiment which lies before us, full details are given on all points, and carefully constructed tables relating to every stage of the experiments, which show that all possible care has been taken to secure accuracy and practical utility in the results. The experiment will no doubt be anxiously watched by all interested in scientific agriculture.

NOTES

PROF. FRANKLAND, D.C.L., F.R.S., has now in the press a volume containing his collected researches in Pure, Applied, and Physical Chemistry, dedicated to Prof. Bunsen, of Heidelberg. The section on Pure Chemistry treats, amongst other matters, of the Isolation of the Organic Radicals, and the Discovery of Organo-Metallic Bodies, and their Application to the Synthetical Production of Organic Compounds. In the section devoted to Applied Chemistry, the author describes his Investigations on the Manufacture of Gas for Illuminating Purposes; on the Qualities of Potable Waters; and on the Treatment of the Sewage of Towns. Physical Chemistry includes his Experiments upon Flames, and upon the Source of Muscular Power, together with those on the Spectra of Gases and Vapours. Each chapter is preceded by introductory remarks, having reference to the scope, object, and future development of the subject treated of. Mr. Van Voorst is the publisher.

A MOVEMENT has been commenced in Spain for the formation of an association similar to the British Association. The Madrid Societies of Natural History, Anthropology, and Geography have appointed a joint commission to consider how best to organise an annual meeting in different parts of the kingdom for the purpose of investigating matters of scientific interest within the domain of these societies, and also to arrange for the publication of the results that may thus be obtained. A movement like this leads one to hope that a fair future is yet in store for Spain.

It is probable that the Sixth Congress of Russian Naturalists will not be held this year, the Government not having granted a sum of money for the expenses of the Congress, and private help being unlikely to be forthcoming on account of the war.

The fifth session of the International Congress of the Medical Sciences will be held at Geneva, from September 9 to 15. In connection with the Congress there will be an exhibition of new apparatus and instruments used in medicine, surgery, physiology, &c. Articles for exhibition should be sent free of all charges to the "Direction de l'Exposition du Congrès Médical; Dr. J. L. Reverdin, place du Lac, Geneva." Intending exhibitors should intimate before August 15 what space they are likely to require.

We hope shortly to give an account of the proceedings which took place in connection with the recent Gauss centenary celebration. We may here state that the festival speech was delivered by Prof. Dr. Sommer, that a sketch for a monument by the Berlin sculptor, Schæfer, was exhibited in the Festival Hall, and that his Majesty, the Emperor of Germany, was a contributor to the Memorial Fund. The following pamphlets have appeared:—"Briefe zwischen A. von Humboldt und Gauss. Herausgegeben von Dr. K. Bruhns;" "Gauss. Ein Umriss seines Lebens und Wirkens. Von F. A. T. Winnecke;" "Über die Anzahl der Ideal-Classen in den verschiedenen Ordnungen eines endlichen Körpers. Von R. Dedekind." The committee also intend to publish an account of Gauss's relations with Brunswick.

France appears to be becoming more and more anxious to do honour to her science worthies by the erection of statues. A statue to Arago is being erected at Perpignan, in the department of Orientales Pyrénées. Another to Niepce de Saint-Victor, a name well known in connection with improvements in photography, will be erected at Chalons, his native place, by public subscription, at the instance of the Municipal Council of the city. It is also stated that a public subscription will be opened at Lyons on behalf of Ampère, the inventor of the electro-magnet, and the precursor of Faraday in the invention of the inductive electricity. Ampère was born in that city in 1775, and his father was guillotined there on the Place des Terraux for having been active in the great royalist rebellion against the Convention, which ended in the famous siege of Lyons and his capture by Dubois-Crancé.

At the usual fortnightly meeting of the Royal Geographical Society on Monday, a paper on "Journeys up the Niger and Notes on the Neighbouring Countries," by Bishop Crowther, was read. The paper, which dealt with the journeys of Bishop Crowther in Western Africa, between 1841 and 1871, described the character of the river Niger, the villages of the natives upon its banks, the tribes scattered about the neighbouring countries, &c. It was remarked that the actual extent of the delta of the river was still uncertain, but the lecturer inclined to the opinion that the affluents of the river, and particularly the Bénuwé, on the south bank, if traced to their source would lead to a rich field of discovery. What might be called the delta of the river was a vast tract of marshy country extending along a coast line of 120 miles, and probably in parts some 150 miles in breadth. In the course of the journey of some 700 miles no less than thirteen tribes, speaking as many different languages, were met with. Ten of the tribes appeared to be of the same family, and might be classed as aboriginal. The Houssas were a tribe spread in the widest direction, and the territory in which their language was spoken appeared to be more considerable than any in Africa. It was a beautiful language, and had become to Africa what French is to Europe. The other important language of that part of Africa was the Fulah. The Filanis were a remarkable people who had conquered extensive parts far to the south of the river Bénuwé. Dr. Barth stated that he had been told by natives of the interior that in bygone days an ancient kingdom called Ghanata had existed. The trade routes which meet the Egga on the Niger were important; the chief came from the north, from Tripoli, across the Sahara, with European produce on camels to the Nupe kingdom, where it was distributed in the neighbouring countries. It has been resolved by the Church Missionary Society to send out a small steamer, drawing only three feet of water, to push further into the interior, and afford assistance to Bishop Crowther to carry the missionary work more completely among the natives.

A Museum of Science and Arts has been established at St. Louis, U.S.

We are glad to learn that the experiments with Jablochkoff's Electric Light are to be repeated at the West India Dock to-morrow evening. We hope all will go well and fairly on this occasion so as to allow a real test to be made of the practical utility of the invention.

An Italian optician established in Paris has constructed a very sensitive metallic thermometer on a new principle. The dilations of a small sheet of platinised silver are amplified by means of a system of levers, and the motion is communicated to a needle on a dial, on which degrees are marked. The motion of the needle is almost instantaneous. The apparatus has been tested in the "Ville de Paris," a new balloon sent up on June 3 at Paris.

The St. Petersburg Society of Naturalists has intrusted Professors Fr. Schmidt and Inostrantseff with a geological exploration of the Valley of the Neva, from Schlüsselburg down to the Finnish Gulf. From the interest possessed by the glacial accumulations in this valley, as well as the qualifications of both professors for this special subject, we may expect much new light on the question of the glaciation of Northern Russia.

The *Turkestan Gazette* gives the latest news from M. Prshevalsky, dated from Lob Nor, February 22. After having reached this lake by the valley of the Lower Tarim, M. Prshevalsky advanced 130 miles east of the lake. The survey and the astronomical measurements of latitudes and longitudes he has made give a totally new aspect to the map of the country. The population on the banks of the Tarim and around the Lob Nor is very sparse; the people speak almost the same language as that of Eastern Turkestan. The flora and fauna of the locality are very poor; some vegetation is found only in the Tarim valley, the neighbourhood being a true desert. During February and March M. Prshevalsky was to stay in the Lower Tarim, during May at Yuldus, and during June at Kunghes. About the beginning of July he proposes to return to Kuldsha to begin in August his journey to the Tibet.

The *Gardener's Chronicle* learns that it is proposed to erect at Ootacamund, in the Neilgherry Hills, a statue of the late Mr. MacIvor, to whom the successful cultivation of Cinchona on those Indian slopes is so pre-eminently due.

We see from the Report of the Auckland (New Zealand) Institute for 1876-7, that that society is in a flourishing condition, and that during the year thirteen papers on subjects of scientific importance in connection with the Colony were read. About a year ago a fine new museum was opened, the cost of building having been 4,000*l*., half of which was raised by private subscription and half obtained as a grant from the New Zealand Government.

At a recent meeting of the St. Petersburg Technical Society, M. Chikolef made an interesting communication as to the experiments recently made at St. Petersburg for determining the lighting power of the electrical light at great distances. The power of the light is notably increased by covering the carbon of the lamp with a thin sheet of copper (one-sixteenth of the diameter of the carbon at its upper part, and from one-forty-eighth to one-sixty-fourth in its lower part). It depends also upon the direction given to the carbon, the best being to turn the cup towards the object to be lighted. The great machine of Alteneck, with a carbon of 12 millim. of diameter, gave a *maximum* of light equal to 10,210 candles, and a mean of 5,739 candles; whilst with a carbon of 10 millim., but galvanised, it gave a maximum of 16,255 candles (20,275 when the cup is turned as above) and a mean of 14,039 candles. The light was sufficient to make objects visible (for military purposes) at a distance of 3,080 yards. Of many machines used, the most economical proved to be the great one of Alteneck.

THE Society for Improvement of Public Health in Utrecht, offers a prize of 100 gulden for the best work on the liquid manure of stables, giving (1) an accurate account of the literature of the subject; (2) a description of original experiments on the means of obtaining from horse urine diluted with water, products which, either as manure or as a chemical preparation, may be brought into commerce in comparatively large quantities; (3) full numerical tables on quantitative chemical analyses made; (4) a thorough treatment of the financial side of the question. The memoirs may be written in Dutch, German, French, or English, and are to be sent, with sealed envelope and motto, to Prof. Dr. Th. Mac Gillvory, Director of the Veterinary School in Utrecht, before September, 1878.

THE very interesting discoveries in prehistoric archæology made by M. Kibalchich at Kief, were the subject of his last communication at the Russian Archæological Society. The numerous caves in the limestone on the banks of the Dnieper seem to have been a favourite haunt of men, even during the first ten centuries of our era. Very important objects have been found in these caves dating from the time of the introduction of Christianity in Russia, showing a remarkable mixture of articles used in Pagan and in Christian worship, establishing a link between Christian and Indian religious symbols. We notice especially those caves at Kief which date from the earliest stone period. They are very long, sinuous, but narrow, and contain great quantities of the plainest stone weapons and stone pearls, together with burned bones of various animals. Some facts lead us to infer the existence of lake-dwellings in the vicinity. Close to these oldest dwelling-places there exists a profusion of conic mounds of boulders and *koorganes* (high mounds of earth), or burial-places, coming from times anterior to the introduction of Christianity in Russia. They contain skeletons, often without skulls, which are buried separately, and a variety of weapons and utensils. The number of such burial-places at Kief and in its neighbourhood is very large. One cemetery of that epoch occupies twenty-three acres in the Fundukley Street, without reckoning the numerous "kitchen-mounds." The objects excavated by M. Kibalchich will form, it is hoped, the nucleus of an archæological museum to be opened at Kief. The excavations are to be continued.

THE *Panama Star and Herald* of the 21st ult., states that the destructive tidal wave experienced at Callao and the ports to the north of that place extended as far south as the northern boundary of Chili, but how much further south was not known, as the telegraph communication had been interrupted. The almost complete destruction was reported of Antofagasta, Iquique, Arica, Tambo do Moro, Pabellon de Pica, and Ilo. Severe shocks of earthquake were felt, but they caused little damage. The destruction of life and property was caused by the frightful upheaval and ingress of the sea. At Arica the sea washed over the town to the hill at the back of the church and destroyed much valuable property. The wreck of the United States steamer *Wateree*, carried inland a couple of miles by the tidal wave of 1868, was again floated, and carried a mile or two further up the coast. The sea in some places rose over sixty feet, and the destruction of life and property is believed to have been enormous.

THE final report of the Sub-Wealden Exploration has just been issued by Mr. H. Willett. He reports that the depth attained on December 21 last year was 1,823 feet, and on April 12, 1,905 feet. On the last-mentioned date a letter was sent by the Diamond Boring Company, stating they used the best endeavours to reach a depth of 2,000 feet and had failed, owing to the want of lining permitting the hole to fall in on the rods and jambing them. Mr. Willett writes:—"The Sub-Wealden exploration is, therefore, brought to a close, and has proved conclusively that in the lowest part of the Wealden area no palæozoic rocks exist within 1,900 feet of the surface. That the search was justified, and that the scientific deductions of Prof. Prestwich, F.R.S., were entitled to the highest consideration may be found in the fact that palæozoic rocks of the Devonian period have been discovered (containing spiriferæ) in the boring made at the brewery of Sir Henry Meux and Co., at the corner of Tottenham-Court Road London." Mr. Willett adds: "The search should undoubtedly be further promoted in the valley of the Thames and at other points in the south-east of England."

M. FERDINANDO TOMMASI has recently constructed a "thermodynamic motor," in which work is done by the mere dilatation of a liquid (oil) without change of state.

MR. SAMUEL HIGHLEY writes us:—"In connection with Mr. Atkinson's letter as to the phenomena connected with Japanese mirrors, and the question as to their method of manufacture, a few years ago Prof. Pepper exhibited the reflected figure formed by these specula when illuminated by a beam of oxyhydrogen light upon the screen at the Polytechnic Institution. In his 'Cyclopædic Science' the question of the method of the production of such mirrors is fully discussed. During the time the Japanese mirrors were being exhibited at the Polytechnic, an English brass-worker tried to solve the problem and apparently discovered the secret of the Japanese makers. He found that taking ordinary brass and stamping upon its surface with any suitable die, not once, but three times in succession, upon exactly the same spot, grinding down and polishing between each act of stamping, a molecular difference was established between the stamped and unstamped parts, so that images of the pattern could be reflected from the finally-polished surface, just as with the Japanese specula, though no difference of surface could be detected by the eye. One operation did not produce this result. Mr. James Princeps published an account of his investigations on this subject in the *Journal* of the Asiatic Society, vol. i., p. 242. He gives as the result of his anylysis of the Japanese alloy, copper, 80 parts; tin, 20—100; with no traces of silver or arsenic, but a slight indication of zinc. He supposed that the phenomena resulted from difference of *density* produced by means of stamping, and that the thinnest parts, from being the hardest, should give the stronger reflection."

IN the last number of the *Transactions* of the Institution of Engineers and Shipbuilders in Scotland is a paper read April 24, by Sir Wm. Thomson, on Compass Adjustment on the Clyde, the aim of the paper being to show that the Clyde is pre-eminently suitable for the adjustment of the compasses of ships under way.

THE ninth annual report on the noxious, beneficial, and other insects of the State of Missouri, by Chas. V. Riley, the State Entomologist, contains descriptions (with woodcuts) of the following insects:—The gooseberry span-worm (*Eufitchia ribearia*, Fitch), the imported currant worm (*Nematus ventricosus*, Klug.), the native currant worm (*Pristiphora grossulariæ*, Walsh), the strawberry worm (*Emphytus maculatus*, Norton), Abbot's white pine worm (*Lophyrus abbotii*, Leach), and Le Conte's pine worm (*Lophyrus le contei*, Fitch). There is an account of the progress of the Colorado beetle, the army worm, the wheat-head army worm, and the Rocky Mountain locust.

MUSCULAR contraction, it is known, is always accompanied with electric phenomena; the difference of electric potential between two points of a muscle, undergoes a diminution, which, according to Bernstein, precedes by about $\frac{1}{150}$ of a second, the contraction of the muscle. This *electric variation* has been observed on various muscles, and in particular on the heart (by Du Bois Reymond and Kühne), and recently M. Marey has represented it graphically by photographing the indications of a Lippmann capillary electrometer. We learn from the *Journal de Physique*, that M. De la Roche has tried the experiment on the heart of a living man. Two points of the epidermis of the chest were connected with the poles of a capillary electrometer, by means of electrodes, formed each of a bar of amalgamated zinc, with a plug of muslin at its lower end saturated with sulphate of zinc. Held with insulating handles, the bars were applied, one with its plug opposite the point of the heart, under the left nipple, and the other to another point of the chest. The mercurial column was then seen to execute a series of very distinct periodical pulsations synchronous with the pulse; each pulsation even marked the double movement of the heart (of the auricles and ventricles). The amplitude corresponded to about $\frac{1}{1000}$ Daniell.

WE have received from Perthes of Gotha a special map of Eastern Turkey, by Dr. Petermann, so full of details that for the war operations on and beyond the Danube, should the Russians succeed in crossing, we know of no better.

A RUSSIAN work, by M. Bogolubsky, on Gold and Gold Mining in Russia, is worthy of notice. It contains very interesting information upon that industry in Russia and Siberia. We observe that the area of gold mines occupies in the Russian empire about 2,100,000 square miles, and now yields yearly about 80,000 lbs. of gold, in value upwards of 3,000,000*l.* sterling. The total amount of gold produced in Russia since 1752 has been upwards of 2,500,000 lbs.

A VERY thorough and exhaustive investigation of the Alaska region may now be expected, through the agency of Mr. E. W. Nelson, a well-known naturalist, who has lately proceeded to Norton Sound, by way of Alaska, to relieve Mr. Turner. He has been provided with the necessary outfit by the Smithsonian Institution, and will probably greatly increase the amount of our knowledge of that interesting country.

WE have received from Mr. Stanford "Botanical Tables for the Use of Junior Students," by Miss Arabella B. Buckley. There are two tables—one of some common terms used in describing plants, and the other a table of the chief natural orders of British plants, arranged according to Bentham and Oliver. Both tables are well arranged, and seem to us well calculated to serve the purpose for which they are intended.

M. MEGUIN has lately been making important researches on Acarians, and on that strange asexual form called Hypopes, a form which is not absolutely necessary for reproduction, but which seems to occur under certain biological conditions, for the indefinite conservation of the species. In the aërial reservoirs of birds, especially Gallinaceæ, there breeds an inoffensive species, which M. Meguin calls *Kytodites glaber*, which sends colonies even into the bronchial branches, and into the marrowless bones of the limbs in communication with the air vessels in birds. Another harmless acarian is found in the cellular tissue of birds living and dying there, and persisting after death, surrounded by a calcareous tubercle. A third species, which lives normally between the barbs of the feathers, produces at the time of moulting, and in the skin of the birds, especially domestic and wild pigeons, a hypopial vermiform nymph. Without this precaution of nature, the species would be annihilated, by reason of the fall of the feathers in the moulting season.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mrs. Cleaver; a Common Buzzard (*Buteo vulgaris*), European, presented by Mr. F. Buckland; a Smooth Snake (*Coronella lævis*) from Hampshire, presented by Lord Lilford, F.Z.S.; three Crested Guinea Fowls (*Numida cristata*), two Vulturine Guinea Fowls (*Numida vulturina*) from East Africa, an Imperial Eagle (*Aquila imperialis*) from Turkey, deposited; four Summer Ducks (*Aix sponsa*), bred in the Gardens.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—In a Convocation held June 5, the decree authorising the expenditure of 7,000*l.* on the construction and fittings of new chemical laboratories at the University Museum, to which we referred p. 94, was introduced by Prof. H. Smith, and carried on a division by 64 against 42.

A second proposal to grant a sum of 2,400*l.* for additions to the University Observatory was carried on a division by 46 placets to 27 non-placets.

The Trustees of the Johnson Memorial Prize for the encouragement of the study of astronomy propose the following subject for an essay:—"The History of the Successive Stages of our Knowledge of Nebulæ, Nebulous Stars, and Star-Clusters from the Time of Sir Wm. Herschel." The prize is a gold medal of the value of ten guineas, with what remains of the dividends of four years on 338*l.*, reduced annuities, after deducting cost for medals, and other expenses. The essays must be sent to the Registrar of the University on or before March 31, 1879, under the usual conditions.

CAMBRIDGE.—A curatorship in the Department of Zoology at the Museum of the University of Cambridge has just been established by the Senate, to which Mr. J. F. Bullar, B.A., of Trinity College, has been appointed. Mr. Bullar graduated in the first class of the Natural Sciences Tripos of 1875, and has been twice nominated by the University to study at the Zoological Station at Naples, where he is at present working.

The various special examinations for the Ordinary B.A. Degree were held on Friday and Saturday week, when the total number of candidates was 204, while at the corresponding period of 1876 the number was 190. Candidates can select one of the following subjects for this final examination, viz., Theology, Law, Modern History, Natural Sciences, Moral Sciences, Mechanism, and Applied Science. The number in each branch of study is as follows:—Theology, 95, Law, 31, Political Economy, 29; Modern History, 24; Natural Sciences, 21—viz., 13 in Chemistry, 5 in Botany, 2 in Zoology, 1 in Geology. In Mechanism and Applied Science there are four candidates.

Mr. William Napier Shaw, B.A., has been elected a fellow of Emmanuel College. He graduated as 16th Wrangler in the Mathematical Tripos of 1876, and obtained a first-class in the Natural Sciences Tripos, 1877, being distinguished in physics.

LONDON.—The Council of University College have elected Mr. G. D. Thane Professor of Anatomy for two years.

DORPAT.—The Annual Report of the Dorpat University for 1876, gives the number of students at the University as 815, of whom 86 study theology, 173 jurisprudence, 121 history and philology, 363 medicine, and 72 physics and mathematics. The number of professors is 67. The library of the University numbers 138,924 volumes.

RUGBY SCHOOL NATURAL HISTORY SOCIETY.—The Report of this Society for 1876, shows that it is in a "fairly healthy condition," to use the words of the preface. A considerable proportion of the papers are by members of the Society, as are also several of the illustrations. The papers are on very varied subjects and all up to a creditable standard. The preface complains that so few members take an active part in the Society's proceedings, but, in this respect, the Society is no worse than others of much greater pretension. Still it would be to the advantage of the youthful members if the patrons and office-bearers made every effort to increase the number of actual workers. We regret that our space prevents us making special reference to any of the papers. The Botanical Section has issued a list of local plants, by H. W. Trott, the result of many years' observation; this last, we daresay, may be obtained by any one desiring it. The price is only 9*d.*

LONDON SCHOOL-BOARD DISTRICTS.—Mr. Stanford is preparing for the School-Board of London a series of maps of the various School-Board districts of the metropolis, which are likely to possess considerable interest. These maps are on the scale of six inches to a mile, show the various School-Board subdivisions, the positions of the schools which have been erected by the Board, and, in a different colour, of those which are under the Board's inspection. We have seen the sheet of the Hackney district, and no better evidence could be produced of the thoroughly good work done by the Board since its institution.

SCIENTIFIC SERIALS

Memorie della Società degli Spettroscopisti Italiani, January.—Note from Prof. Draper on photographing the spectra of Venus and α Lyræ; a 28-inch reflector and a 12-inch refractor are the instruments used, and an exposure of from ten to twenty minutes. In the photograph of the spectrum of α Lyræ bands or broad lines appear in the ultra-violet region totally different to anything in the solar spectrum.

February.—Letter on the comet Borelly, 1877, Brorsen-Bruhns, 1857, and the eclipse of the moon of February 27, 1877. The spectra of the first appears, according to him, to consist of some carbon compound.—Tables of statistics of protuberances and spots observed at Rome in the months of January and February, 1877.—List of positions on the solar limb in which the vapour of magnesium was observed from February 20, 1876, to July 4 of the same year.—In the appendix to this number appears an article explaining the construction of the several different forms of aneroid barometers.

March.—List of positions on the solar limb in which the vapour of magnesium was observed from July to November, 1876, by Prof. Tacchini, and a table for the year showing the frequency of visibility of the *b*-line and 1,474-line, from which it appears that the latter line is more frequently visible than the former. Table of positions and size of protuberances observed at Rome in 1876, by Father Secchi.—Some observations of the zodiacal light, by Prof. A. Serpieri.—Note by Prof. Tacchini on Mr. Le Verrier's researches on the intra-Mercurial planet.—Drawings of chromosphere for September and October, 1875, made at Rome and Palermo.

April.—Spots and facula observed spectroscopically and directly at Palermo in 1876. This paper consists of the daily notes of observations of the chromosphere for last year.—Table of spots and faculæ observed in February and March, 1877, by Prof. Tacchini.—Drawings of the chromosphere for October, November, and December, 1875, by Secchi, Ferrari, and Tacchini, observed at Rome and Palermo.

Journal de Physique, April.—On the cause of the motion in the radiometer, by M. Gaffie.—On the capillary theory of Gauss and its extension to the capillary properties of liquid lines, by M. Lippmann.—New electric lamp, by M. Jabloschkoff.—On the quadrant electrometer of Sir W. Thomson, by M. Benoit.—Complement to the theory of the microscope and the dark chamber, by M. Neyreneuf.—Experiments of static electricity, by M. Grisson.

May.—On the observation of the infra-red part of the solar spectrum by means of the effects of phosphorescence, by M. Edm. Becquerel.—Determination of the polar distance in magnets, by M. Benoit.—Electric variation produced by contraction of the heart in the living man, by M. De la Roche.—On a new industrial application of heat, called the thermo-dynamic motor, by M. Ferd. Tommasi.—On the absorbent power of moist air, by M. Hoorweg.—On refrigerating mixtures of snow and sulphuric acid, by M. Pfaundler.

Morphologisches Jahrbuch, vol. iii. Part 1.—Oscar Hertwig, contributions on the formation, fertilisation, and cleavage of the animal ovum, part second (*Hæmopis*, *Nephelis*, *Rana temporaria*, and *R. esculenta*), 86 pages, 5 plates.—A. Rauber, the fixation of long bones in joints, and the form of the bones.—W. Moldenhauer, the development of the middle and outer ear, 56 pages, 4 plates.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. x. Fasc. vii.—Two new mycetes parasitic on vines, by M. Cattaneo.—On a cause little estimated in the pathogenesis of some female diseases, by M. de Giovanni.—The molecular velocity of gas and the corresponding velocity of sound, by M. Brusotti.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, June 7.—Dr. Gladstone in the chair.—The following papers were read:—On the gases inclosed in lignite coal and mineral resin from Bovey Heathfield, by J. W. Thomas. Four samples were examined, two of which contained much hydrated oxide of iron in the cleavages. The gases consisted chiefly of carbonic acid, carbonic oxide, nitrogen, and sulphuretted hydrogen. In one case sulphur sublimed off in yellow crystals; organo-sulphur compounds, mercaptan, sulphide of allyl, &c., were also present in the gases. The lignites resemble cannel coal more than any other of the true coals as regards the occluded gases, but are far less stable, decomposing, *in vacuo*, below 200° C., whilst the true coals resist a temperature of 300° C. It seems probable that the iron pyrites of true coal have derived their sulphur from that existing in organic combination in the plants from which coal is produced.—On apparatus for gas analysis, by Dr. Frankland. The author proposes to substitute for the india-rubber cork, which has several disadvantages, at the bottom of the water-cylinder, a cast-iron base through which the two glass tubes pass, and are firmly clamped by a wooden clamp; the latter is screwed to the cast-iron base. The most important improvement is, however, the removal of the steel clamps which connect the laboratory and measuring tubes. These are replaced by a glass cup at the top of the measuring tube into which fits the drawn-out end of the laboratory tube, covered with thin sheet-india-rubber; this flexible joint, when wetted and covered with mercury, is quite air-tight.—On narcotine, cotarnine, and hydrocotarnine, Part V., by Dr. Wright. The preparation of bromhydrocotarnine hydrobromide, bromocotarnine hydrobromide, and tribromhydrocotarnine hydrobromide is described; the second of these bodies, when heated to 200° splits into a new base, tarconine, and a large amount of an indigo-blue substance; the latter body is very insoluble, but dissolves in strong sulphuric acid, forming a magnificent intense purplish solution. Bromocotarnin crystallises in fine scarlet crystals. Noropianic acid and other substances were also prepared and their properties examined.—On otto of limes, by C. H. Piesse and Dr. Wright. A terpene-like body boiling at 176° C. was obtained which yielded but little cymene. The residue in the retort, after standing two to three months, formed a quantity of crystals. These crystals were investigated and their composition determined.—On primary normal heptyl alcohol and some of its derivatives, by C. F. Cross. Pure œnanthol was prepared with a specific gravity of 0·823 at 16° C. Pure heptyl alcohol is colourless, has an agreeable odour, sp. gr. at 0° 0·833, boils at 175°. Heptyl chloride, bromide, iodide, acetate, and œnanthylate were prepared and examined; their boiling-points closely agree with those calculated by Schorlemmer.—On the transformation of aurin into rosanilin, by Messrs. Dale and Schorlemmer. The authors find the spectra of the hydrochlorides of their new base, and rosaniline quite identical; they have also prepared from their base Hofmann's violet, aniline blue, and aniline green.

Geological Society, May 23.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Richard George Coke, Robert Slater, and William Swanston were elected fellows of the Society.—The president read a letter from Mr. C. J. Lambert, announcing that he had allotted the sum of 500*l.* to the Geological Society out of the 25,000*l.* left by his father for distribution. The president further announced that the sum of 500*l.* had already been paid to the Society, and would be invested for its benefit.—The following communications were read:—Remarks on the coal-bearing deposits near Erekli, the ancient Heraclea, Pontus Bithynia, by Rear-Admiral T. A. B. Spratt, C.B., F.R.S.

—On the structure and affinities of the genus *Siphonia*, by W. J. Sollas, F.G.S. This paper contained, first, a full account of the history of the genus *Siphonia*, including a complete list of its described species, and, next, a description of its general and minute structure. Its skeletal network was shown to consist of spicular elements belonging to the Lithistid type of sponges, and most closely allied in generic details to the recent form *Discodermia polydiscus*. Not only in this character but in every other, *Siphonia* was shown to approach *Discodermia* so closely as to be almost identical with it. The mineral replacements which have affected the siliceous skeleton of *Siphonia* were then considered. The paper concluded with a systematic description of the genus.—On the serpentine and associated rocks of the Lizard district, by Rev. T. G. Bonney, F.G.S., fellow and late tutor of St. John's College, Cambridge. The author stated that considerable doubt appeared still to exist as to the true relations of the lizard serpentine and the associated hornblende schists, and as to the origin of the serpentine. He had carefully examined all the junctions accessible on the Cornish coast (inland they are generally obscured). Some of them are concealed by *débris*, &c., but the majority prove beyond doubt that the serpentine is intrusive. Further, almost everywhere large fragments of hornblende schist are caught up and included in the serpentine. Besides the serpentine there is a large mass of gabbro at Crousa Down, and many dykes and veins along the east coast almost to the extremity of the serpentine region. At Coverack Cove, near the above mass, are gabbros of two ages, the older much resembling a kind of troktolite. On microscopic examination it proves to be chiefly plagioclase felspar, augitic minerals (including diallage), and olivine partially converted into serpentine. There is a red and a green variety. The newer, a coarser variety, appears to be of the same age as the other veins on the coast, and connected with the main mass. Some remarkable changes have taken place in this also. In certain places it exhibits a separation of its mineral constituents, causing it to resemble a foliated rock. This is proved to be due to pressure at right angles to the structure. The minerals also are often changed. The felspar is replaced by a white granular mineral resembling saussurite; the diallage (which occurs sometimes in very large crystals) is often partially, or even wholly, converted into rather minute crystalline hornblende. In these specimens there is no olivine to be distinguished. The great mass, however, is rich in olivine, yet a weathered specimen from it, resembling in aspect the gabbro of the veins, does not show olivine. Hence the author believes that in certain cases the olivine, instead of being converted into serpentine, aids in forming the hornblende. Further, there are dykes and veins over the same area of a dark trap. Some of these are augitic, others hornblendic. The author believes that at any rate in certain of these the hornblende is of secondary formation. On the west coast are veins of granite; those on the east coast, said to be granite, prove, on careful examination, to be altered rock, remarkably like granite veins, but not really such. In discussing the origin of the serpentine the author called attention to a structure commonly seen, which appeared to be a true "fluidal structure." He then described the result of microscopic examination of many specimens of the lizard and some other serpentines. Commencing with slightly altered lherzolite (from the Ariége), he traced the change through the older gabbro of Coverack to the serpentine rock of that place, which contains a large quantity of unaltered olivine; and so to other serpentines in which the olivine is quite replaced by the mineral serpentine. He described also the mode of the change. The other minerals found in the serpentine rock are enstatite, varieties of augite, and occasionally a fair quantity of picotite, with, of course, oxides of iron. Hence he concluded that, as had been already shown as regards some other serpentines, that of the lizard was the result of the hydrous alteration of an olivine rock, such as lherzolite.—On certain ancient devitrified pitchstones and perlites from the Lower Silurian district of Shropshire, by S. Allport, F.G.S.

Physical Society, June 9.—Prof. G. C. Foster, president, in the chair.—The following candidates were elected members of the Society:—Mr. W. H. Northcott and Mr. L. J. Whalley.—Mr. S. P. Thompson read a paper on interference fringes within the Nicol prism. After referring to the original paper by the inventor in 1828, in which this phenomenon was referred to, he gave a general description of it prior to explaining the cause. If the "field" of a Nicol be explored by the eye it will be seen to be bordered on one side by a margin of violet-blue light, and on the other, when the light passes obliquely through the prism, by an orange band within which lie a series of coloured fringes; these latter are very clearly seen with monochromatic light, when a second set, within the blue band, also appears. The author showed that these two sets are due to interference taking place within the film of balsam at the critical angle of total reflexion for ordinary and extraordinary rays respectively; they are therefore analogous to the interference bands in a thin film, placed beneath a prism of a more highly refracting substance and occurring just within the limit of total internal reflection, as first observed by Sir W. Herschel. At the conclusion of the scientific business of the Society, a special general meeting was held.

Royal Microscopical Society, June 6.—Dr. Robt. Braithwaite, vice-president, in the chair.—Six new fellows were elected, and M. L'Abbé Renard was elected an honorary fellow of the Society.—A paper by the Rev. J. Delsaulx on the thermodynamic origin of the Brownian motion was read by the secretary, and described the observations of the author with regard to the motion of fluid in rock cavities and molecular motion generally, with a view to establish the theory that it was due to the action of temperature. The observations had been suggested by the study of Crookes's radiometer.—A letter from Mr. H. C. Sorby on the subject was also read to the meeting, and Mr. Hartley described his experiments which led to the same conclusions. The meeting was then adjourned until October.

EDINBURGH

Royal Society, June 4.—Prof. Kelland in the chair.—Sir C. Wyville Thomson read a paper on the structure and relations of the genus Holypus.—Mr. Alexander Buchan, M.A., secretary to the Scottish Meteorological Society, communicated the second part of his investigations of the diurnal oscillations of the barometer. He stated that the summer months of the northern hemisphere as indicated by the barometer were May, June, and July, the winter months being November, December, and January, both corresponding with the sun's declination. He has now results of the daily barometric readings from upwards of 110 stations at different parts of the earth's surface. His investigations showed that a long-continued series of observations was absolutely necessary to show the peculiarities of the barometric curve. For instance, three years' observations gave in the case of Great Britain only the broadest characteristics. He found that no theory as yet propounded would explain the diurnal oscillations of the barometer, and that as more facts were obtained the difficulty of framing a satisfactory theory was greatly increased.—In his paper on the air dissolved in sea-water, Mr. J. Y. Buchanan stated that the result of the analysis he has as yet made of the specimens of the air dissolved in sea-water which were collected in the recent *Challenger* expedition, tends to show that as regards surface-water least air was dissolved where the temperature was highest, *e.g.*, near the equator, and most where the temperature was least, as in the polar sea. As regards the percentage of oxygen present at different depths it diminishes from the surface to a depth of 300 fathoms and increases from that point to lower depths. Prof. Tait communicated two laboratory notes; (1) Two plates either of the same or different metals were placed very close to one another but insulated and one of them raised in temperature: a difference of potential was produced, which was capable of producing a current measurable by a sensitive galvanometer. (2) He had seen in Dr. Blair's "Scientific Aphorisms" a hypothesis to account for gravitation very like that of Lesage's ultramundane corpuscles, which Blair stated was suggested to him by Newton's works, and Prof. Tait was anxious to ascertain if any part of it was due to Lesage or was entirely original. Prof. Tait laid on the table an algebraic identity which could be used to sum various series.

DUBLIN

Royal Society, May 21.—Prof. J. Emerson Reynolds, M.D., in the chair.—The following papers were read:—On some measurements of the polarisation of light coming from the moon and from the planet Venus, by Earl Rosse, F.R.S. Lord Rosse gave the results at which he had already arrived from a very large number of observations on the polarisation of light from particular parts of the moon's surface made in the years 1872, 1873, 1874, and 1875, and which are still in progress. The observations indicate that the polarisation of the light coming from the plains is greater than that of the light coming from the mountainous regions.—Notes on the crustacea of Ireland, by Mr. William Andrews. An account of the rarer of other countries, in many ways worse off than our own. The subject is well worth the attention of all who have at heart the higher education of the people.

W. BOYD DAWKINS

THE CARBONIFEROUS FLORA OF CENTRAL FRANCE

Flore Carbonifère du Département de la Loire et du Centre de la France. Par Cyrille Grand' Eury, Ingénieur à St. Étienne. (Imprimerie Nationale, Paris.)

THIS work consists of three quarto volumes, the first of which is devoted to the plants, the second to the geology of the districts under consideration, and the third forms an atlas with thirty-four plates of fossil plants and four large "tableaux," in which the author has "restored" the plants he has described according to his own ideas of their morphology.

It is very obvious that the carboniferous plants of one district cannot be received as altogether typical of those occurring at other and distant localities. Hence such publications as those of Dr. Dawson and Prof. Newbury in America, and the volumes of M. Grand' Eury, are extremely valuable to the English palæo-botanists. They tend to preserve him from the one-sided habit of viewing the subject which he is apt to contract when only studying the types occurring in his own coal-fields. But apart from this M. Grand' Eury's work has an independent value, especially in some departments in which he has made important additions to our stock of knowledge. This is especially the case with his investigations amongst the hitherto obscure plants known as Flabellariæ and Cordaites, as well as amongst some remarkable sporange-bearing ferns.

Our knowledge of Cordaites has hitherto been most vague; but M. Grand' Eury has fortunately obtained some beautiful specimens in which not only the leaves are attached to the stems of several species, but in some he also finds what he believes, I think justly, to be male and female organs of reproduction, thus establishing the point that these plants were monœcious Phanerogams. These organs are slender spikes, some of which support small scaly buds lodged in the axils of bracts, and which the author believes to have been antheriferous. Others bear single seeds in each axil. Some of the spikes are affirmed to be those of Antholithes, and the seeds to be identical with Cardiocarpus. The stems which bear these reproductive structures have a Sternbergian pith, surrounded by an exogenous woody zone inclosed within a distinct bark, which latter appears to have consisted of more than one layer. M. Grand' Eury concludes that these plants were Conifers, of which the well-known Dadoxylons were the ligneous axes, and that the type which survived for a time in some of the Ulmanniæ of the Lechstein, and in the Albertia of the Triassic rocks. I see nothing, however, in his figures and descriptions leading me to conclude that they are identical with our British Dadoxylons.

The new ferns described by the author are equally remarkable. They include numerous forms of Pecopteris, with very peculiar sori approaching those of the Marattiaceæ. Some of these fronds he associates unhesitatingly with Psaronius and other stems of tree-ferns. The author's researches on the above subjects have been conducted under most favourable conditions, of which he has availed himself in a praiseworthy manner.

When we come to the debateable subjects of Calamites, Lepidodendron, Sigillariæ, and Asterophyllites I am obliged to use different language. On these points the author adopts substantially the ideas of Brongniart. Thus he distinguishes between Calamites and Calamodendron, making the former an equisetaceous plant and the latter a gymnospermous one. I cannot understand how any one can do this in the face of our present knowledge of the facts.

In external form the supposed Calamites and Calamodendra exhibit precisely the same appearances. All these appearances are explained in the most exact manner by the internal structure of the many illustrative specimens which we now possess, and which demonstrate that we only have one type of organisation. Further, what are called Calamites by the school to which our author belongs are amongst the most abundant of the plants furnished by our coal-shales, and there is nothing to prevent their being equally common in the Oldham and other beds, in which all the plants retain their internal structure, if they existed as an independent type. But the moment we find a Calamitean plant with organisation it proves to be a Calamodendron. Even M. Grand' Eury is compelled to admit "il est au moins surprenant que l'on n'ait pas mis la main sur un Calamite avec la structure conservée." Very surprising, indeed, considering that we have obtained such numbers of these plants with structure from Oldham, Halifax, and Autun, as well as, though less abundantly, from Burntisland. The conclusion to be drawn is too obvious to need reiteration.

Imbued with these ideas respecting Calamites and Calamodendra, it was inevitable that M. Grand' Eury should fall into error respecting Asterophyllites. These plants are regarded by his school as the branches and leaves of Calamites. Hence he could not recognise as Asterophyllites any plant which had not a Calamitean axis. But I have shown that Asterophyllites has *not* such a structure, but one identical with the very different one of Sphenophyllum. M. Grand' Eury escapes the difficulty by contending that my plants are *not* Asterophyllites, but Sphenophylla. This is certainly not the case. Brongniart has clearly defined the latter genus a possessing 6–8 or 10 *truncate cuneiform* leaves; and after referring to the fructification of Sphenophyllum, he correctly says:—"Ce mode de fructification, malgré l'obscurité qui environne encore sa vraie structure, est trop analogue à celui des Astérophyllites pour qu'on puisse douter de l'affinité de ces deux genres." This conclusion is precisely identical with mine. Instead of 6–8 or 10 leaves in each verticil, my plants have 18 or 20. These leaves are linear, not cuneiform; and as my next memoir will demonstrate even more clearly than I have yet done, each leaf had a single central vascular bundle instead of the two or more invariably seen in Sphenophyllum.

In his views respecting the relations of Sigillaria and Lepidodendron, M. Grand' Eury also clings to the old Brongniartian ideas promulgated in bygone years. M. Brongniart and M. Renault have described the organisation of two Sigillarian fragments, *S. elegans* and *S.*

spinulosa, and have concluded that whilst their Diploxyloid organisation differs from that of the Lepidodendra, it justifies the conclusion that Sigillariæ were not lycopodiaceous but gymnospermous plants. But I have already shown that several indisputable Lepidodendra have precisely the same organisation. Hence I contend that Brongniart's reasons for separating these plants have no existence, and consequently his conclusions must be abandoned; M. Grand' Eury, forgetting this part of my work, and only remembering that I have also described the bark of a true Syringodendroid Sigillaria, and shown that it is identical in every feature with the corresponding tissue in Lepidodendra, says that I have arrived at my conclusion "par des faits isolés d'après l'analogue de l'écorce, et non par des exemples complets réunissant les caractères extérieurs aux caractères intérieurs." How, in the face of my published memoirs, my friend could make so erroneous a statement, I am at a loss to conceive.

I should have felt it necessary to have subjected the volumes under consideration to an incisive criticism on these and some similar points, were it not that he kindly allows me to quote from some letters which I have received from him. In these communications he says:—"Les points sur lesquels nous différons sont précisément ceux que je n'ai pas étudiés." Referring to facts which I have observed, he adds: "Comme je n'avais pas ces faits pour me guider, j'ai conclu d'après ce que je connaissais bien, et je ne suis pas fain de conclure que je me suis trompé; dans ce cas nous aurions dans les Sigillaires et les Lepidodendrons, des cryptogames excessivement elevées en organisation; si elevées qu'ils formaient, en quelque façon, une classe intermédiare entre ces plantes et les Gymnospermes." "L'Association presque constante des macrospores avec le débris des Sigillaires est en faveur de vos conclusions." Quite in accordance with the above remarks are the following observations which the author makes in his volumes: "Il est au moins curieux que, à part le corps vasculaire, les autres parties des Sigillaires soient semblables aux parties correspondantes des Lepidodendrons." This is perfectly true with the exception that the vascular portions are less exceptional than M. Grand' Eury's remarks imply. The Sigillarian stem is merely that of Lepidodendron Harcourtii, *with an additional* exogenous vascular zone interposed between that of the Lepidodendron and its investing cortex; *and which I find in other true Lepidodendra.* If all the plants of the coal-measures which possess a similar exogenous zone are to be transferred from the cryptogamic to the phanerogamic group, there will be few cryptogams left in the carboniferous rocks beyond Lepidodendron Harcourtii and the ferns. M. Grand' Eury concludes his notice of the Sigillariæ by a remark which I fully endorse: "Seulement je crains d'avoir tiré des conséquences trop complètes de ces indices insuffisants, dont je n'aurais peut-être alors même dû parler que pour éveiller l'attention des observateurs sur une solution possible du plus important problème de la paléontologie végétale."

Having thus indicated some very important points respecting which I am compelled to differ from M. Grand' Eury, I can with the sincerest truth again express my sense of the value of this new contribution to the study of the carboniferous flora, and of the praiseworthy perseverance with which the author has laboured for many years in collecting his materials. The most prominent fact which the work reveals is the remarkable abundance of the Cordaites in the coal-measures of Central France, compared with what we see in England. In some districts, as M. Grand' Eury informs us, the coal is almost entirely composed of their *débris.* I have met with nothing like this in Great Britain, but it is in strict accordance with what we know of the distribution of living plants, that whilst similar types may be expected to be met with over wide geographical areas, some forms will predominate in one region, whilst in other localities different types will prevail; hence the materials out of which coal has been found must have been widely different at these various spots.

The plates with which the above work is illustrated are extremely beautiful, as is usually the case with the productions of the French lithographers.

W. C. WILLIAMSON

OUR BOOK SHELF

Annæs do Observatorio do Infante D. Luiz. Magnetismo Terrestre. Lisboa, 1876.

THIS part of the *Annals* of the Lisbon Observatory is a continuation of those noticed in NATURE, vol. xiii. p. 301. The results for the magnetic declination are carried forward from 1867 to 1871, while some include the means from 1858 to 1875. This is the case for the secular change and annual variation. Mr. Capello found previously that the north end of the declination magnet approached the north at the rate of 5′·91 yearly (1858-1868). The results he now divides into two series, 1858 to 1866, with a rate of 5′·46, and 1866 to 1875, with a rate of 7′·64 yearly.

The yearly means are deduced from observations at 8 A.M. and 2 P.M. Mr. Capello has also shown that the diurnal law of disturbance appears to be different at Lisbon in different years of the decennial period.[1] In this case, even if two observations daily were otherwise sufficient to give accurate means, or means strictly comparable from year to year, the varying effect of the disturbance on the observations at the two hours mentioned would of itself interfere with this comparability. It is probably for these reasons that the yearly means at Lisbon do not appear to show the small decennial inequality in the secular movement first indicated by me in 1857, and afterwards discovered by Hansteen and Lloyd.

Mr. Capello has repeated discussions for the magnetic disturbances with the increased materials in his possession. He had observed in a preceding number of the *Annals*, that many observations which were considered disturbed (that is to say, which differed from the means for the hours by 2′·26 or more) really belonged to diurnal variations which were regular, only larger than usual; and it was pointed out in NATURE (in the notice cited above) that one cause of these excessive deviations would be found in the superposed lunar actions. Mr. Capello now finds that a great majority of these quasi-solar disturbances are rather to be considered due to the moon. This conclusion induces me to believe that if Mr. Capello had the necessary aid to perform the calculations for the lunar diurnal variations for each month, and for different positions of the moon, as well as for other investigations, the Lisbon observations could not fail to add many important scientific results to those already published.

JOHN ALLAN BROUN

Incidents in the Biography of Dust. By H. P. Malet. (London: Trübner and Co.)

THE first impression one gets of this book is that of a kind of nightmare. It begins by personifying dust and makes "us dusts" utter a great deal of incoherent talk which changes somehow into the voice of the writer himself, who by and by fades into Prof. Tyndall, then into "a weekly paper, *Punch*," then through Hugh Miller and the Holy Scriptures into the familiar tones of Mr. Henry Woodward, F.R.S., who gives way to the dusts again, and so on. The first impression, too, deepens upon further perusal. One never can be quite sure who is speaking; whether the "we" is the editorial pronoun or marks the utterances of the personified dust-motes. Sometimes, indeed, by a kind of feeble and perhaps, unconscious pun, it means both the author and "us dusts;" as where a sentence begins (p. 107), "Of all the authorities we have ever rested on, Sir Charles Lyell has described mountain formation most accurately." Or again: "Mrs. Somerville is a favourite authoress; we seldom find a protracted rest upon her volumes." The writer seems to have made a very hearty meal on all kinds of miscellaneous geological and other scientific and literary food. The variety and amount of the viands have been too much for him. Hence the wild speculations, the grotesque theories, the pell-mell rush of changing subject through the 272 pages of this curious but dreary volume. So completely has the nightmare taken possession of the author that in his frenzy he forgets the composition of the very air he breathes, and sententiously announces that while "the earth consists of air, water, and dust," the "air is composed chiefly of oxygen, hydrogen, and carbonic-acid gases." We would venture to suggest a good application of oxygen and hydrogen in the form of a shower-bath as a corrective. The book closes most appropriately with a spiritualistic *séance*, at which the *dramatis personæ* are a Medium, Spirit of Socrates, and Dust. If the author would discard all this "plain language," as he is facetiously pleased to call it, and tell us in simple straightforward English what it is all about, we should be prepared calmly to listen to him, but no more such "Biographies of Dust!"

Chemical Physics. By N. N. Lubavin. First fascicule. St. Petersburg, 1876, 346 pp., in 8vo. (Russian.)

THE author has given in a handbook a description of the various physical phenomena which, without belonging to the true domain of chemistry, are nevertheless involved in all chemical processes, and which can adequately be described as physico-chemical. These phenomena, of the highest importance for the student of chemistry who is interested in the philosophy of his science, are dealt with at length by the author in a very lucid and plain style. Without discussing advanced theories, M. Lubavin, in this first fascicule (the second being in the press) gives us only facts, and in a condensed form much useful information. He has carefully read what has been published in this department in France and Germany, but is not very familiar with our English works, except through German or French translations.

Enumeracion de los Vertebrados Fósiles de España. Por Don Salvador Calderon. (Madrid: T. Fortanet, 1877.)

THIS is a reprint from the *Anal. de la Soc. Españ. de Hist. Nat.*, tom. v., of Señor Calderon's valuable catalogue of the vertebrate fossils hitherto discovered in Spain, with an introduction and accompanying remarks. As the catalogue and an abstract of the introduction to it have been published in the *Quarterly Journal* of the Geological Society of London during the present year, it will not be necessary for us to do more than to call attention to the appearance of the work in its more complete form. Some interesting questions are opened up by the author concerning the distribution of several interesting Miocene forms such as Sivatherium, Hyænarctos, and Hipparion.

¹ See also Proc. Roy. Soc. (March, 1876.) Vol. xxiv. p. 273.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Museum Reform

EVERY one who puts faith in museums as educational engines must be grateful to Prof. Boyd Dawkins for the article on this subject in the number of NATURE for May 31. That reform is pressingly needed in most of our provincial museums is a proposition almost beyond question; but how such reform can be best effected is a subject open to any amount of discussion. The primary difficulty in organising a museum is usually a difficulty of finance. Money, which measures all things, measures the curator's power of procuring glass cases and suitable specimens. Where, then, the resources of a museum are very limited, the greatest amount of good will probably be effected by confining attention to the formation of local collections. Such work, being restricted within a narrow sphere, may be done thoroughly, even in the poorest museum. Yet it is work which will be valued by every true student of science. Prof. Blackie, in his "Self Culture," gives excellent advice when he says: "In order to assist in forming habits of observation in this age of locomotion I should advise young men never to omit visiting the local museums of any district, as often as they may have an opportunity; and when there to confine their attention generally to that one thing which is the most characteristic of the locality." Now it often happens that the things most characteristic of the locality are hardly thought worth exhibiting, and are precisely the things that we do not find in a provincial museum. Only last week I had occasion to visit a museum of thoroughly old-fashioned type, and to my surprise I found that the mineral industries of the neighbourhood, though of great importance, were absolutely unrepresented, whilst unlabelled curiosities collected from every quarter of the globe were heaped together in defiance of all principles of classification. It is true there is great temptation for a curator to display a little of everything, and a specimen from the Antipodes is no doubt regarded as a greater curiosity than a specimen from the neighbouring hills. But if a small museum is to have any educational value worth naming, its aims should be restricted, at least in the early stages of its development. Many museums undoubtedly teach too little by attempting to teach too much.

Perhaps the chief cause of unsatisfactory arrangement in so many museums is to be found in the difficulty of curatorship. Most museums naturally take their complexion from those who have charge of them; if the curator, for example, is a good entomologist, the collection of insects will be good; and so on. A general museum, indeed, needs a curator just a trifle less than omniscient. Even where each department is under charge of some honorary specialist, it by no means follows that the greatest educational value is got out of the collections. It seems to me that it would be an advantage, wherever practicable, to establish some kind of connection between the museum and the nearest college or other educational centre; assuming, of course, that it is a centre of liberal education where science asserts its proper position. Just as lectures teach principally through the ear, so museums teach through the medium of the eye; and those who have had most experience in oral teaching will probably be best qualified to assist in the oversight of an educational museum.

Another direction in which most museums imperatively need reform is in the simple matter of labelling. Too often the visitor leaves without carrying away much information, simply because he is unable to interpret what he has seen. A curator can therefore hardly be too free in the use of descriptive labels. Large labels, no doubt, occupy a good deal of space, and this can be ill spared in a crowded collection. Nevertheless, I believe it is far better to exhibit only half the number of specimens, fully telling their own tales, than to cram the cases with specimens unnamed or only meagrely described. If a museum is to be of real value educationally, it must be made as far as possible its own interpreter. F. W. RUDLER

Scientific Club, Savile Row

I HOPE ventilation of this subject in the columns of NATURE will direct attention to the necessity of more systematic arrangement, and that governors will seek to redeem these institutions from the mere curiosity shop style into which too many have developed, and to render them valuable educational instruments.

Interested in geology, I have been pleased, in occasional visits with pupils to our local museums, to note the gain to accurate knowledge as the diagrammatic illustration of the text-book is exchanged for the fuller teaching of fossil and specimen, and where, to chronological and stratigraphical plan, the characteristic fossils are indicated by special labels, and the time range shown by variously coloured mounts, the advantage is considerable. I would further suggest the desirability of numbering important objects, as in a picture gallery, and furnishing the visitor with an attractive catalogue. Where several museums exist in the same town could not the authorities, by mutual agreement, economise space and effort by division of labour, each one becoming to some extent exhaustive in a special direction?

In one of our best arranged museums I recently found, for pure want of room, Cambrian trilobites associated with basic rocks, and a fossil neatly stowed away in a case of Vesuvian products.

Bright, convenient, and well-keyed, our museums ought to increasingly attract students and gather in recruits from time to time from the inquiring public. A good supply should in this, as in some other educational difficulties, create demand, and stimulate public sentiment until our museums become so commodious and well-appointed as to bear comparison with the excellent models Prof. Dawkins refers to as established by our Continental neighbours; and the natural sciences gain in dignity amongst us until they enter into healthy rivalry with the elder and established studies of numbers and letters.

Manchester, June 2 WILLIAM GEE

I SEE with pleasure that Prof. Boyd Dawkins has again raised his voice urging the importance of museums as a means of education, but as there is one point regarding their management to which it may be useful to call attention, I shall be glad if you will allow me to do so through your pages.

Undoubtedly English museums compare most unfavourably with foreign ones, and this partly arises from the idea which is so prevalent that one man ought to be able to arrange and determine anything from New Zealand birds, plants, or fossils to a collection of Egyptian idols. The consequence is that we see such incongruities as were pointed out by Prof. Dawkins, to which I should like to add another, from one of the leading technical institutions of London; there a few years ago (and I suppose there are still), among building materials, some large Nummulites (a genus of fossil foraminifera), marked portions of brick made by the Israelites for the Egyptians when they were allowed no straw.

In a middle-sized foreign town in any of the other civilised countries of Europe there is a museum in charge of men who have given their attention to various branches of science; even in Italy, which is much behind in this matter of museums, we find in such towns as Turin a well-arranged museum with a considerable staff of curators, with the minerals in the hands of one man, the fossils in another, the vertebrates have, I believe, two or three of the staff to work at them, while the invertebrates are in the hands of another, and in the same way the historical and technical portions are no doubt under adequate management.

When we turn back to England we find such a humiliating thing as a town like Manchester with no museum worthy of fourth-rate town.

It will no doubt be some time before their importance is fully recognised and therefore as museums are likely to be for a long time insufficiently manned, might it not be a great advantage if a number of local museums joined together to employ specialists to determine different groups? Such work might no doubt be done very cheaply, for such men would often be glad of the opportunity of so much material passing through their hands.

A naturalist who was making any group, such as corals or crustacea, his subject, might visit the museums and would in a very short time be able to determine and arrange the greater part of the local collection, and might have those which required further research sent up to London for investigation at leisure upon the completion of his tour. Alderley Edge

The Antiquity of Man

HAVING carefully perused the proceedings that took place at the recent "Conference" on the subject of the antiquity of man at the Anthropological Institute, I confess to a feeling of disappointment. I had looked, if not for new geological facts, at least for something novel in the treatment of what was already known, instead of which the geological speakers seem, for the most part, to have merely reiterated opinions with which their names have been for some time identified. Thus my able opponent, Prof. Boyd Dawkins, does no more than restate views and conclusions which have already been controverted more than once, and to which, therefore, I need not reply here, as in so doing I should be only summarising what has been stated at length elsewhere. Mr. Dawkins's "case" and my own are now so fully before our fellow-hammerers that we may be well content to leave them for judgment to the future—a future which is probably not far off. Prof. Prestwich, again, while quite open to conviction that man may have lived in England in pre-glacial times, is yet strongly of opinion that all the human relics hitherto obtained in the south of England are of *post-glacial* age, because they occur in deposits that overlie "the boulder-clay." Now this conclusion would certainly follow if it could be shown that the "chalky boulder-clay" of East Anglia represents, as Prof. Prestwich thinks it does, the glacial period. Unfortunately it only represents one phase of that period. There is an *older* boulder-clay than that "chalky till," and there are two separate boulder-clays which are *younger*, as Mr. S. V. Wood has demonstrated. The East Anglian chalky boulder-clay was laid down, as I believe, during the climax of glacial cold, and is consequently much older than the upper boulder-clays that occupy the surface of Scotland and the North of England. For the evidence which has weighed with me in coming to this conclusion I must refer Prof. Prestwich to the account of the English glacial deposits, which is given in the second edition of my work on the Ice Age. The proofs and argument are too long to recapitulate here. That the East Anglian chalky till belongs to a much more ancient date than the upper boulder clays of Yorkshire and the North, must strike any one who will take the trouble to compare them. The East Anglian deposit has been subjected to long-continued and powerful erosion, and everywhere bears the impress of extreme antiquity, while the younger tills of the North have a comparatively recent appearance. Nor is this by any means all, for between the accumulation of the chalky till and the formation of the most recent boulder-clay or till of the North there certainly intervened one mild inter-glacial period. (There were in reality, as I believe, two such periods.) Now during the "last inter-glacial period"—that, namely, which preceded the deposition of the youngest boulder-clay of Yorkshire and the North—there certainly existed a land-surface in England over which the pleistocene mammalia roamed. The proofs of this are found in certain fresh-water and estuarine deposits which are met with near Hull and elsewhere, and which have yielded mammalian remains. and thousands of *Cyrena fluminalis* and other shells. Prof. Prestwich has himself described these beds and classified them as *post-glacial*, partly because they repose upon boulder-clay and partly on account of their fossil contents. But since the date of Prof. Prestwich's visit to the locality in question, the section (near Burstwick) has been much better opened up, and now one may see *resting upon these so-called post-glacial deposits a thick mass of tumultuous boulder-clay*. This boulder-clay is in my opinion as truly the product of glacier-ice as any ground-moraine or till in Scotland, Norway, or Switzerland, and points to a time when all Scotland and the northern districts of England, down as far as the valley of the Humber, were shrouded in snow and ice.

With reference to the recent discoveries by Mr. Skertchly near Brandon, which Mr. Evans and Prof. Hughes have convinced themselves lend no support to the view that man is other than post-glacial, I would ask geologists to suspend their judgment until they have had an opportunity of hearing the other side. Let them exercise a little of that "caution" which Mr. Evans desiderates, and not too readily acquiesce in his and Prof. Hughes' ruling. Mr. Skertchly, who has mapped the ground about Brandon and Thetford, and whom we may suppose, therefore, to be more intimately acquainted with the geology of that district than either of his opponents, has no doubt that certain implement-bearing brick-earths are covered by boulder-clay *in situ*. I have also carefully examined the sections in question and feel quite sure that Mr. Skertchly is right, and that the overlying accumulation is a true glacial deposit, and an integral portion of the so-called chalky boulder-clay. Prof. Ramsay, who has likewise recently visited Brandon, is, I believe, of the same opinion. But the occurrence of flint implements underneath the chalky till of East Anglia is, after all, no proof that these relics are pre-glacial. The most one can say about them is simply this, that the folk who used them lived in England before the climax of glacial cold. When human relics are got in beds of older date than those at Cromer, we shall then have a demonstration of the pre-glacial age of man in Britain. At the same time the presumption is (as many geologists will admit) that some portion of our ancient river-drifts and cave-deposits with flint implements do really belong to pre-glacial times. In short, after carefully reading the proceedings at the recent Conference, I find nothing to shake me in my present belief that none of the palæolithic deposits belongs to post-glacial times, but that all must be relegated to inter-glacial, and probably pre-glacial ages, and consequently that the palæolithic is separated from the neolithic age by the intervention of the last cold period of the glacial epoch. My opinion, therefore, is still as strong as ever that "until we clearly understand what was the succession of changes during the ice age, it is premature to speculate upon the geological age of those deposits which yield the earliest traces of man in Britain." In concluding, may I be allowed to suggest to the anonymous writer whose communication on the subject of the Antiquity of Man appears in the number of this journal for June 7, that before he again essays to criticise my views he might do well to become better acquainted with them. JAMES GEIKIE

Perth, June 15

BEFORE your readers accept the statements of Messrs. Evans and Hughes respecting my discovery of flint tools beneath the great chalky boulder-clay, as announced in NATURE last year, may I ask them to remember that as yet I have not published the evidence upon which I founded my statement? The delay has arisen from official and other causes; and although my paper is now written, it is, I have just learned, too late for reading during the present session at the Geological Society. Neither of the two gentlemen named is aware of the extent of my evidence, for I have not, as yet, told any one about it, except the two geologists mentioned below. As I shall show, there are now known to me about forty localities in which the brick-earths in question occur, and in most of them their relation to the boulder-clay is very clear; and even in the two or three spots in which that rock is not seen in the actual section, it overlies the implement beds near by on the same outcrop. The brick-earths have naturally suffered much denudation by the boulder-clay, and I have a splendid series of sections showing every phase from almost undisturbed material beneath the boulder-clay to small fragments (boulders, in fact) in that deposit. I wish, also, to state, that instead of four implements from two localities, as originally announced, I know at present nearly 150 from six different spots. The evidence is so clear and overwhelming when seen *en masse*, that it must be convincing to all who carefully weigh it. The boulder-clay which overlies the brick-earths in question is part and parcel of the great mass of the chalky boulder-clay, a formation which I have spent eight years in examining in the field almost daily, of which I have mapped about 2,000 square miles, and upon which I feel quite competent to form an opinion.

Prof. Prestwich is perfectly correct in ascribing the well-known palæolithic implements found in the gravel to a time subsequent to the formation of the chalky boulder-clay; *but that only proves those tools to be newer than the last glaciation of this particular area.* Now inasmuch as Mr. Searles V. Wood, jun., long ago proved, and as everybody who examines the ground must admit, that the "purple" and "hessle" boulder-clays are newer than the one we are dealing with, and as Dr. J. Geikie has shown that gravels bearing the same character and possessing the same peculiar fauna as the well-known palæolithic gravels (overlying, moreover, the chalky boulder-clay), pass under these newer beds, it is, to say the least, a misnomer to call these gravels *post*-glacial. They are post-glacial to this East Anglian area, but not to northern England; and the distribution of surface-beds containing palæolithic implements throughout Europe shows that they are confined exclusively to that area which was free from the erosive action of the newer and less intense ice-sheets of the latter part of the "Great Ice Age." Much of the misapprehension in this matter has arisen from the unfortunate name of "upper" given to the chalky boulder-clay. It *is* "upper" in East Anglia, but it is "lower" in Yorkshire.

My discovery does *not* prove man to have been pre-glacial; it merely shows that he was "pre-chalky-boulder-clay," and I last week obtained evidence to show that the brick-earths in question belong to the "middle glacial" of Mr. Searles V. Wood, jun.; that is to say, they are newer than the Cromer till, but older than the chalky boulder-clay.

Mr. Belt is mistaken respecting the quartzite implements near Brandon. They are found in gravel which is unquestionably above the boulder-clay, as can be seen in hundreds of sections, and the only conceivable source of that material is the boulder-clay. We have, in fact, two horizons of palæolithic implements, one above and one below the boulder-clay, and I am in hopes that the former will be found capable of subdivision, for many facts crop up in the course of my daily work which seem to point in that direction.

Prof. Ramsay and Dr. J. Geikie, who are eminently capable of judging of glacial phenomena, have gone over the area with me, and are perfectly convinced of the accuracy of my determinations. SYDNEY B. J. SKERTCHLY

Brandon

Nicephore Niepce

THERE is an error in one of your "Notes" of last week which you may be glad to have corrected. It is not to Niepce de St. Victor that the citizens of Chalons-sur-Saône (a town, by the way, not to be mistaken for Chalons in the Champagne country) are about to erect a statue, but to his uncle, Joseph Nicephore Niepce, who might well be designated as the first photographer, since he it was who succeeded first of all in fixing an image in the camera. In a "Life of Nicephore Niepce,"[1] recently published by Victor Fouqué, appear letters which leave little doubt that in May, 1816 Niepce had accomplished the feat of fixing shadows in the camera, for in a communication of that date to his brother he incloses four photographs, of which he says: "The pigeon-house is reversed on the pictures, the barn, or rather the roof of the barn, being to the left, instead of the right. The white mass which you perceive to the right of the pigeon-house, and which appears somewhat confused, is the reflection upon the paper of the pear-tree, and the black spot near the summit is an opening between the branches of the trees. The shadow on the right indicates the roof of the bake-house." This, then, is a description of the first camera-picture ever taken, and it was by reason of Niepce's inability to prevent his impressions from fading after a lapse of time that he turned his attention to the bitumen of Judea process, with which he produced photographs as early as 1824, one or two specimens being still among the science treasures of the British Museum.

The name of Nicephore Niepce is little known in England. And yet this should not be. As is well known he came to this country in 1827, and resided at Kew in the hope to receive aid and encouragement, and shortly afterwards, on his return to France, entered into partnership with Daguerre to work out together a more practical process. When Daguerre made known his discovery in 1839, his partner had been dead two years, and no mention was made of Niepce at the time Arago made his famous speech announcing the discovery of Daguerreotype. Specimens of the wonderful process were not long in reaching this country and the first picture was placed in Faraday's hands with the remark that he had never seen anything like it before. But Faraday said he had. A Frenchman, he remembered, had brought him a picture of Kew Church a dozen years ago, with the quaint remark, that "the sun had done it." Faraday was so certain of this that inquiries were at once instituted into the matter, and in the end, a communication was addressed by the Secretary of the Royal Society, Mr. Bauer, to the *Academie* at Paris, a communication which helped materially to substantiate the claim of the Niepce family, and to obtain for the son Isidore, a pension in acknowledgment of the father's services. The deed of partnership between Niepce and Daguerre is still extant, but how much of the latter's published results were due to his dead partner the world will never know. H. BADEN PRITCHARD

June 16

Japanese Mirrors

THERE is still something to be solved about the Japanese mirrors, which show the figures that appear in relief on the back in the disk of light reflected from the face. Not only does it seem impossible (without some indication which I have not yet met with) to tell which mirrors in a series will perform the feat, but it is equally difficult to say why one bunch of leaves will, and another in the same casting, will not appear in the spectrum.

In reference to Mr. Highley's quotation of Mr. Prinseps' conjecture (p. 132), "that the thinnest parts, from being the hardest,

[1] "La Verité sur l'Invention de la Photographie."

should give the strongest reflection, owing to a difference in density produced by stamping," and to the brassworker's solution, not only are the mirrors not stamped, but cast; but it is the thicker parts, those which stand out on the back in highest relief, which reflect the most light. I have one on the back of which there are two large characters as it were laid upon a background of trees. These letters have been carefully ground flat and polished like the front. Their figures not only appear more distinctly than those of other less highly raised adornments, but actually, in the sun, throw off a brilliant white light, which contrasts very markedly with the comparatively subdued spectrum from the rest of the plate.

Is it possible that there may be some difference in molecular arrangement during the consolidation of the melted metal in the thicker (relieved) and other parts of the plate? And yet, the thick rim of the mirror does not reflect a rim of light.

One of my specimens has suffered a little oxidisation, and I observe that this appears on the face to follow certain of the larger masses of relief on the back. This mirror does not "show the pattern through," but there is a curious bright rim reflected from the edge of each scar of injured surface.

Manchester R. D. DARBISHIRE

Colour-Sense in Birds

As the fact of the preference of sparrows for *yellow* crocuses still excites interest and requires explanation, perhaps you will allow me to call attention to the following remarks of Gilbert White in his "Observations on Nature":—

"Birds are much influenced in their choice of food by colour, for though white currants are a much sweeter fruit than red, yet they seldom touch the former till they have devoured every bunch of the latter."

The obvious criticism that the craving for sweets which distinguishes the human biped is not equally predominant among his feathered friends, and consequently, that their selection of the less sweet but more highly coloured fruit may be due to some taste other than the æsthetic, does not detract from the importance of White's generalisation that birds are much influenced in their choice of food by colour—a generalisation which, there is no reason to doubt, was based upon his own keen and repeated observation. PAUL HENRY STOKOE

Beddington Park

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—The following are Greenwich mean times of visible geocentric minima of Algol, for July, August, and September, according to the elements adopted by Prof. Schönfeld:—

	h. m.			h. m.			h. m.
July 11	11 51	...	Aug. 20	15 11	...	Sept. 12	13 39
,, 31	13 31	...	,, 23	11 59	...	,, 15	10 28
Aug. 3	10 20	...	Sept. 9	16 51	...	,, 18	7 16

Minima of S Cancri occur on September 8 at 15h. 1m., and September 27 at 14h. 14m:

A minimum of Mira Ceti will fall on July 23, according to Argelander's formula of sines, the same perturbations being applied as in the case of the maximum of the year, which is computed to occur November 9·7.

Mr. John Tebbutt, writing from Windsor, N.S. Wales, on April 13, states that in consequence of remarks on the probable variability of μ Doradûs, in NATURE, vol. xv. pp. 14 and 281, he examined the star on February 26, and March 14, and found it of the 8th magnitude. There is a star, estimated 9th magnitude, about thirty seconds of time west, and twelve seconds north of it. With such an instrument as was employed by Lacaille at the Cape of Good Hope in 1751, μ Doradûs, with its present brightness, would hardly have been visible. Lacaille calls it a fifth magnitude.

MINOR PLANETS AND COMETS OF SHORT PERIOD.—Dr. von Asten, in the course of his recent researches on the motion of Encke's comet, found that, although in the interval 1819-68 the comet had experienced in each period of revolution an almost exactly equal amount of acceleration, and that this might be attributed to the existence of a resisting medium, yet in order to connect the last two appearances in 1871 and 1875 with the previous ones, it is necessary to have recourse to the hypothesis of an extraordinary perturbation which, in the period 1868-71, counteracted the influence of a resisting medium. For certain reasons Dr. von Asten is led to conjecture that about the middle of the year 1869, when the comet was in the region occupied by the numerous group of small planets (the radius-vector being about 3·2), it made so close an approach to one of these bodies, as yet undiscovered, that a sensible effect on the comet's mean motion was the result.

In connection with this hypothesis it may be interesting to note that the late Prof. Hubbard, whose masterly investigations on the motion of Biela's comet appeared in Gould's *Astronomical Journal*, came to the conclusion that the separation of the comet into two distinct bodies, by whatever cause effected, took place in all probability in a heliocentric position corresponding to about longitude 318°·6, latitude + 12°·0, with radius-vector 4·36, which position the comet occupied in November, 1844 (*Ast. Journ.*, No. 140). It is stated in some works that the comet in 1846 separated under the very eyes of astronomers; nevertheless it is upon record that the companion was first recognised on December 29 by Herrick and Bradley at New Haven, but was not again seen until Maury refound it on January 13; and its not having been remarked when the comet was first glimpsed in the Northumberland and other powerful telescopes may well have been owing to distance and faintness.

A radius vector of 4·36 would, until quite recently, have been considered as placing the comet rather outside the probable superior limit of distance of the minor-planet group, but the discovery of Hilda by M. Palisa in November, 1875, considerably extended the limit, this body in aphelion being distant from the sun 4·6. Although the separation of Biela's comet, if it really took place at the epoch assigned by Prof. Hubbard, could not have been owing to an encounter with this particular planet, yet the position indicated for the occurrence is clearly a possible one for a meeting with an unknown member of the group. In saying this much we are of course aware that the separation may have been owing to a very different cause, indeed it might be supposed that such a *rencontre* would have left a more sensible effect upon the mean motion of the comet.

METEORIC FIRE-BALLS IN AMERICA.—Prof. Daniel Kirkwood in a communication to the American Philosophical Society, on March 16, gives some particulars of meteoric fire-balls which appeared in unusual number in the United States in the latter part of 1876 and beginning of the present year. The circumstances attending the appearance of eight conspicuous meteors are included: the dates were 1876, July 8 (two fire-balls), December 16 and 21, January 3, 20, and 23, and February 8. The train of the larger meteor of July 8 was visible at least forty minutes, the mass having been apparently dissolved or dissipated in the latter part of its track; the motion about the sun was retrograde, but sufficient materials were not forthcoming for determining the orbital velocity or the nature of the orbit. The fire-ball of December 16 had been visible but a few seconds near San Francisco when it apparently plunged into the Pacific at no great distance from the shore, the fall being followed by a loud detonation. The meteor of December 21 was remarkable for the length of its track, between 1,000 and 1,100 miles, one of the longest upon record, and, moreover, the track would appear to have been somewhat curved. When crossing Indiana the principal fire-ball was followed by a train of smaller meteors, many of which exceeded Venus and Jupiter in apparent magnitude; the breadth of the cluster, as seen from Bloomington, was 3°, and the length at least 20°, from which Prof. Kirkwood concludes that the true diameter was five miles; and the length about forty miles; several explosions occurred during the passage of the meteorite over Indiana and

Ohio, and a fragment weighing about twelve ounces, fell upon a farm near Rochester, Indiana, a part of it being secured by Prof. Kirkwood. The body is described as "peculiar in its structure; being pisolitic and remarkably friable." It is inferred that no part of the mass could have escaped out of the atmosphere. The aerolite of January 23, or rather a portion of it, after the final explosion, reached the earth in Kentucky, and is now in the collection of Dr. J. Lawrence Smith, of Louisville. The report is stated to have resembled discharges of heavy ordnance, in such close succession, that the different discharges were barely distinguishable; height at first appearance about seventy miles.

THE TRANSIT OF VENUS, 1882.—In *Astron. Nach.*, Nos. 2133-4. we have another calculation of the elements of this transit from M. Leverrier's Tables; it is by Dr. Deichmüller, of the Observatory at Bonn, who has followed Prof Oppölzer's method for the necessary data for reduction of the observations which are interpolated down to short intervals in Paris time. There are special calculations for certain principal stations.

THE LAND OF HISSAR AND KOLAB

THE eastern part of the dominions of the Emir of Bokhara is the belt of land between 37° 30′ and 39° N.L., and 67° and 71° E.L., bordered on the north by the now Russian province of Samarkand and the Karategin, and on the south by Afghanistan (the Balkh, Kunduz, and the Badakshan districts). It has hitherto been all but totally unknown. M. Maïeff, after having, together with Lieut. Vishnevsky and M. F. Schwarz, thoroughly explored it in 1875, gives us a description of the land of Hissar and partly that of Kolab (*Isvestia* of the Russ. Geog. Soc., 1876, 4th fasc.), with an elaborate map, based on numerous determinations of latitudes and longitudes, surveys, and barometrical measurements of heights.

Two great rivers running east and west, the upper Zerafshan on the north, and the Pandsh, or Upper Oxus, on the south, are the natural boundaries of the country. A third river, the Shehrsebz, running in the same direction under 39° N.L., borders its north-western corner, and a mass of high table-lands, the Pamir, rises to the east of the Kolab district. The whole land is filled with mountains belonging to the Tian Shan system. Two main ridges, which both run north-east to south-west, and are divided by the broad valley of the Surhan,[1] form the backbones of this hilly tract. Secondary ridges, either parallel to the main ones, or spreading out of them, fill the country. But at their western extremities, the mountain ridges are far lower than we know them to be in the east. Thus, the ridge between the Shehrsebz and the Surhan, now called the Hissar Ridge,[2] rising above the snow-line in its eastern parts, is far lower in the western; and its highest pass, Ak-rabat, is but 4,590 feet high, whilst other passes are as low as from 2,200 to 3,600 feet above the sea-level. The second main ridge, lying to the east of the broad Surhan valley and running between it and that of the Vaksh, seems to be higher, but yet far below the highlands of Kokand or of Eastern Turkestan. Besides, the highlands are deeply cut into by large and broad valleys which have in their lower parts a prevailing direction south by west, running thus to the Oxus. The north-western slope of the Hissar ridge is drained by only one river, the Guzar-daria, an affluent of the Shehrsebz; but, instead of being an insignificant stream, as on our present maps, it appears as a mighty river fed by the perpetual snows of the Sengri-dag, and its upper shores are occupied by a numerous population. East of the Hissar ridge we see a series of broad well-peopled valleys. First, that of the Shir-abad, from about 2,500 to 900 feet high, with the towns Derbent, Baisun, and Shir-abad. Next, the valley of the Surhan river which, as well as the Guzar and the Shir-abad, rises in the snow-covered ridge Meshai-Kentely, and receives many affluents. Some time before its annexation to Bokhara, this valley was a centre of the political life of the country, and, going back in its history, we come to a time when—a local tradition says—the population was so dense that a cat could travel upon the roofs of the dwellings from Denau to the Amu. Now, the population is concentrated in the upper, better watered parts of the valley, where we find the towns Kara-tag, Sary-djui, Yourchi, and Denau. Further east we have the valley of the Kafirnagan (the Ramid of Ibis-Dast), the source of which is about Paldorak, this river being second in size to the Surhan. An enlargement in the upper parts of its valley, running east and west, is well peopled, and contains the towns Hissar, Fyzabad, Kafirnagan, and Doshambe. Then, below Hissar, the river enters a deep ravine, Pavi-Duldul (the foot of the Duldul, the mythic horse of Ali), at the issue of which is the town Kahadian (460 feet high), close to the Amu-daria.

Further east, beyond the second main ridge alluded to above (its local names are—By-katyn, Mazi-melek, Avan-tau, &c.), we have the basins of the Upper Oxus, *i.e.*, of the Vaksh (or Surhab) and the Pandsh, which both, M. Maïeff observes, must be considered as the sources of the Oxus. The former rises in the glaciers of the Alai-ridge and runs, under the name of Kyzyl-soo, on the Pamir table-land. After having received a great affluent, the Muk-soo, the river bears the name of Surhab and enters the Bokhara dominions through an impracticable deep ravine, at the well-known bridge Pooli-sengui. After a short course among mountains it soon emerges on a plain some 500 feet high. Divided into many branches, the main one about 180 yards broad, it runs to its junction with the Pandj near Kurgan-tube. Only one of the affluents of the Pandj, the Kchi-Surhab (little Surhab), was explored by M. Maïeff; it is formed by two rivers, the Baldshoan and Kolab, the valley of the latter being well peopled and cultivated, notwithstanding the extensive marshes which have given their name to the town, Kolab.

The population of the country consists of Usbecks and Tadjicks, the former occupying mostly the lower and better parts of the valleys, having driven the Tadjicks back to the upper parts. The banks of the Amu-daria, and especially the western parts of the country, are mostly peopled with Kungrad-Usbecks, the Tadjicks appearing more numerous to the east. The towns contain, as usual, a very mixed population. The lower parts of the Vaksh and the Kolab valley are mostly peopled by Usbecks of the Katagan tribe. Some Kirgises have begun to found settlements in the lower parts of the Vaksh and Pandsh valleys; and some miserable Turkomans are strewn among the Usbecks on the shores of the Amu. Jews, Hindoos, and Afghans form a very small percentage of the population.

As to the climate of the country, it is easy to perceive that it must be comparatively mild. In the higher parts of the Kafirnagan valley there are occasionally falls of snow about two feet deep, but the lower parts of the valleys have a mild, rainy winter. Figs grow at Shir-abad unsheltered during the winter. All kinds of corn and fruits common to Central Asia are produced in abundance. Cotton, however, is cultivated only in Shir-abad, owing to facility of export to Karshi (on the Shehrsebz). Rock-salt is worked in the neighbourhoods of Guzar and on the Upper Vaksh, but it must be found also elsewhere, the salt springs being numerous. Two gold mines are known on the shores of the Vaksh, and richer ones are reported to exist in the Darvaz.

The country is under the dominion of the Emir of Bokhara, being administered by nine *becks*, vassals to the emir, seven in the Hissar district, and two in that of Kolab.

[1] Tupalik on Mr. Arrowsmith's map in the *Journ. Roy. Geog. Soc.*, 1872. Tupalan is the name of one of the upper affluents of the Surhan.

[2] Its local names are Bash-hurd, Baisun-tau, Meshai-kentely, &c.

HOW TO DRAW A STRAIGHT LINE[1]

IV.

I NOW come to the second of the parallel motions I said I would show you. If I take a kite and pivot the blunt end to the fixed base and make the sharp end move up and down in a straight line, passing through the fixed pivot, the short links will rotate about the fixed pivot with equal velocities in opposite directions; and, conversely, if the links rotate with equal velocity in opposite directions, the path of the sharp end will be a straight line, and the same will hold good if instead of the short links being pivoted to the same point they are pivoted to different ones.

To find a linkwork which should make two links rotate with equal velocities in opposite directions was one of the first problems I set myself to solve. There was no difficulty in making two links rotate with equal velocities in the same direction—the ordinary parallelogrammatic linkwork employed in locomotive engines, composed of the engine, the two cranks, and the connecting rod, furnished that; and there was none in making two links rotate in opposite directions with *varying* velocity; the contraparallelogram gave that; but the required linkwork had to be discovered. After some trouble I succeeded in obtaining it by a combination of a large and small contraparallelogram put together just as the two kites were in the linkage of Fig. 18. One contraparallelogram is made twice as large as the other, and the long links of each are twice as long as the short.

The linkworks in Figs. 30 and 31 will, by considering the thin line drawn through the fixed pivots in each as a link, be seen to be formed by fixing different links of the same six-link linkage composed of two contra-parallelograms as just stated. The pointed links rotate with equal velocity in opposite directions, and thus, as shown in Fig. 28, at once give parallel motions. They can of course, however, be usefully employed for the mere purpose of reversing angular velocity.

An extension of the linkage employed in these two last figures gives us an apparatus of considerable interest. If I take another linkage contra-parallelogram of half the size of the smaller one and fit it to the smaller exactly as I fitted the smaller to the larger, I get the eight-linkage of Fig. 32. It has, you see, four pointed links radiating from a centre at equal angles; if I open out the two extreme ones to any desired angle, you will see that the two intermediate ones will exactly *trisect the angle*. Thus the power we have had to call into operation in order to effect Euclid's first postulate—linkages—enables us to solve a problem which has no "geometrical" solution. I could of course go on extending my linkage and get others which would divide an angle into any number of equal parts. It is obvious that these same linkages can also be employed as linkworks for doubling, trebling, &c, angular velocity.

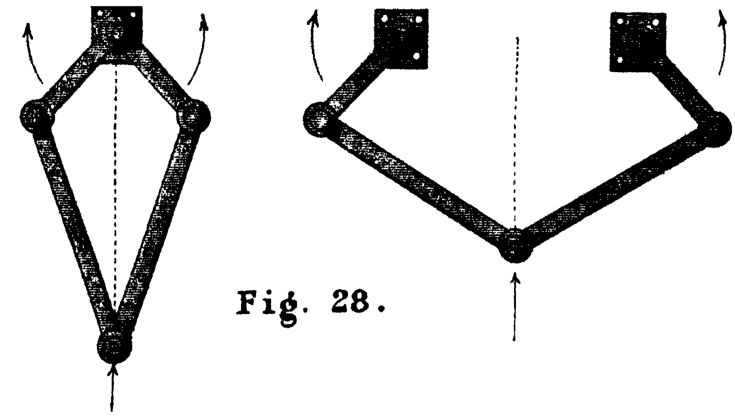

Fig. 28.

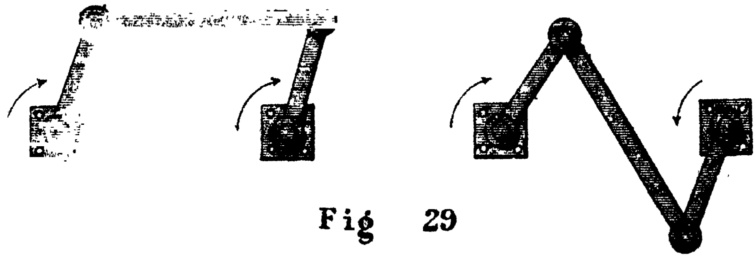

Fig 29

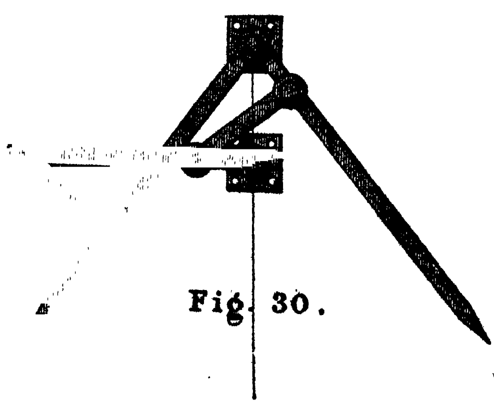

Fig. 30.

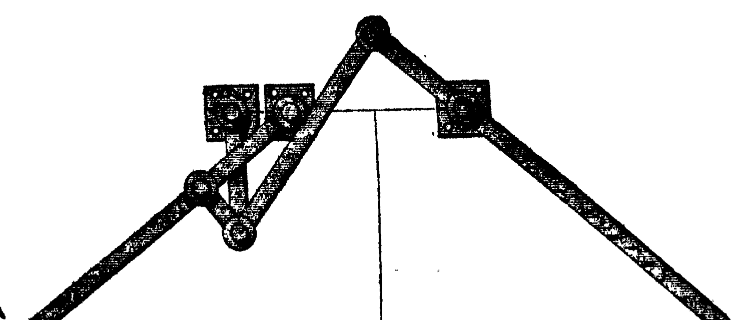

Fig. 31.

Another form of "Isoklinostat," for so the apparatus is termed by Prof. Sylvester, was discovered by him. The construction is apparent from Fig. 33. It has the great advantage of being composed of links having only two pivot distances bearing any proportion to each other, but it has a larger number of links than the other, and as the opening out of the links is limited, it cannot be employed for multiplying angular motion.

Subsequently to the publication of the paper which contained an account of these linkworks of mine of which I have been speaking, I pointed out in a paper read before the Royal Society, that the parallel motions given

[1] Lecture at South Kensington in connection with the Loan Collection of Scientific Apparatus, by A. B. Kempe, B.A. Concluded from p. 127.

there were, as well as those of M. Peaucellier and Mr. Hart, all particular cases of linkworks of a very general character, all of which depended on the employment of a linkage composed of two similar figures. I have not sufficient time, and I think the subject would not be sufficiently inviting on account of its mathematical character, to dwell on it here, so I will leave those in whom an interest in the question has been excited to consider the original paper.

At this point the problem of the production of straight-line motion now stands, and I think you will be of opinion that we hardly, for practical purposes, want to go much farther into the theoretical part of the question. The results that have been obtained must now be left to the mechanician to be dealt with, if they are of any practical value. I have, as far as what I have undertaken to bring before you to-day is concerned, come to the end of my tether. I have shown you that we *can* describe a straight line, and *how* we can, and the consideration of the problem has led us to investigate some important pieces of apparatus.

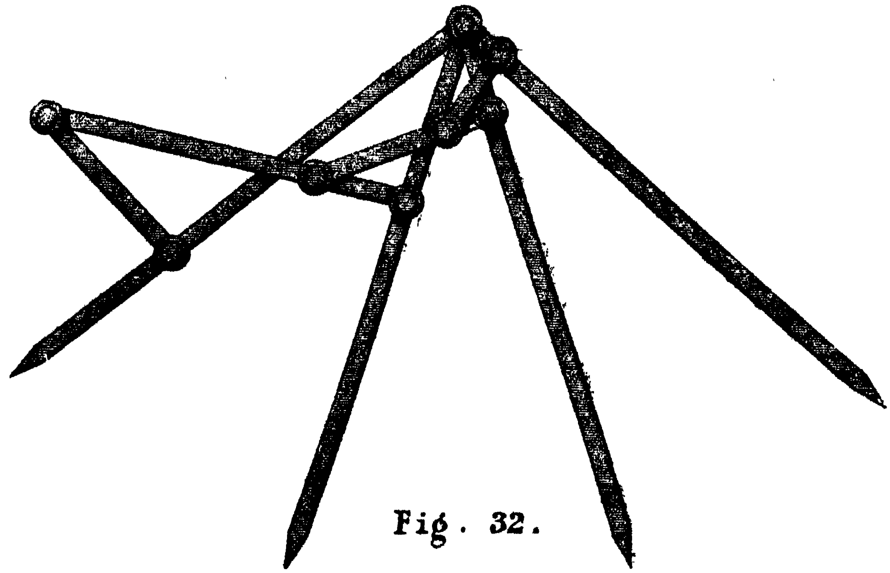

Fig. 32.

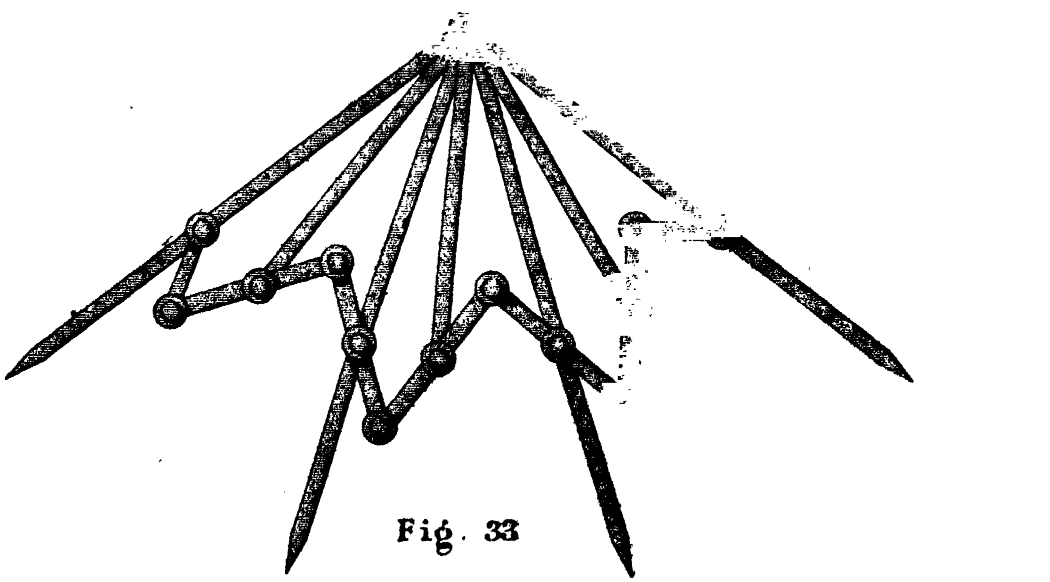

Fig. 33

But I hope that this is not all. I hope that I have shown you (and your attention makes that hope a belief) that this new field of investigation is one possessing great interest and importance. Mathematicians have no doubt done much more than I have been able to show you to day, but the unexplored fields are still vast, and the earnest investigator can hardly fail to make new discoveries. I hope therefore that you whose duty it is to extend the domain of science will not let the subject drop with the close of my lecture.

BIOLOGICAL NOTES

THE TICHORHINE RHINOCEROS.—A number of the *Memoirs* of the Imperial Academy of Sciences of St. Petersburg just issued contains an elaborate article on the Tichorhine Rhinoceroses by the veteran naturalist, Dr. J. F. Brandt. Dr. Brandt treats of two extinct species under this category, which he calls *R. antiquitatis* (i.e., *R. tichorhinus*, auctt.) and *R. merkii*. With the latter he proposes to unite *R. etruscus* of Falconer. Remarks are added upon *R. leptorhinus* of Cuvier and other allied species. When we consider the number of valuable contributions to science recently made by Brandt, Middendorf, Kowalewski, Radde, von Schrenck, and other distinguished names of the Academy of St. Petersburg, it becomes somewhat ridiculous to a naturalist to hear the oft-repeated assertion of the British patriot "that the Russians are as great barbarians as the Turks!"

Oscar Hertwig on the Phenomena of Fertilisation.—The last number (Vol. iii., Part 1) of the *Morphologisches Jahrbuch*, contains the second part of Oscar Hertwig's very important researches on the phenomena immediately preceding the cleavage of ova in the Echinoid *Toxopneustes*, in two genera of leeches, and in the amphibia. He has watched most carefully the process of fertilisation and the ova before fertilisation, and has examined them after the action of various reagents. His accounts are accompanied by very valuable figures. From his own observations, and a comparative study of other recorded facts, he appears to have made generalisations worthy of the attention of all biologists. The following is a brief summary of his conclusions. The unripe ovum is characterised by the possession of a germinal vesicle, distinguished from all cell-nuclei by its great relative size, by its definite membrane, its more or less fluid contents, and its possession of one or several nucleoli. The germinal vesicle in this signification does not become the nucleus of the first cleavage-sphere; in many animals it disappears long before fertilisation, in other cases during that process or during the ripening of the ovum. At any rate the germinal vesicle loses all its distinctive characters. The active nuclear substance, or a part of it, remains and forms a new nucleus of much smaller size, lacking a distinct membrane and true nucleoli. From a highly differentiated form is produced a primitive nucleus; instead of a germinal vesicle we have an ovinucleus. In Toxopneustes the retrogression of the germinal vesicle is accompanied by its movement to the outer surface of the yolk, where it disappears, with the exception of the germinal spot; the latter again reaches the centre of the yolk and becomes the nucleus of the ripe ovum. In Hirudineæ there is an accessory prelude to fertilisation, the budding-off of "directive bodies" immediately after oviposition. After this arises a spindle-shaped ovinucleus really derived from the breaking up of the germinal spot. In amphibia the exceedingly large germinal vesicle gets to the surface and disappears. Only a small portion, one or more nucleoli, passes over into the inconsiderable ovinucleus. The parts of the germinal vesicle not contributed to the ovinucleus seem no longer serviceable, and get transformed into the so-called excretory bodies and sphere. In Amphibia a mass of this kind appears as a yellowish covering over the dark pole of the egg. Like Toxopneustes appear to be Medusæ, Siphonophora, Ascidians, some Vermes, Arthropods, &c., possessing in the ripe and unfertilised ova a small homogeneous, membraneless nucleus in the middle of the yolk or on its periphery. The Hirudineæ resemble Gasteropods, Heteropods, Pteropods, and some Vermes. Here the ripe egg has mostly on its periphery a small spindle-shaped nucleus. In fishes and reptiles, as in the frog, there is a germinal vesicle with many nucleoli, some of which form the ovinucleus. After this stage Hirudineæ twice exhibit a budding from the surface of the ovum forming the so-called directive bodies, the ovinucleus contributing to them. The actual occurrences of fertilisation correspond very closely not only in animals but in plants. In Toxopneustes a single spermatozoon reaches the ripe ovum and is transformed into a small corpuscle, the sperm-nucleus, surrounded by a protoplasmic rayed figure. It travels in from ten to fifteen minutes to the central ovinucleus and is fused with it. In *Rana temporaria* the spermatozoon enters at the side of the excretory body and becomes like that of Toxopneustes, travelling to the ovinucleus and fusing with it. In Hirudineæ the spermatozoon enters subsequently to the budding of the first directive body, and after transformation gets to the centre of the ovum and there remains till the budding of the second body. Then the ovinucleus travels to the centre and is apposed to and fuses with the sperm-nucleus, which has swollen considerably. Thus in these cases the cleavage-nucleus is formed by the union of the two sexually-differentiated nuclei.

Individual Variations in Animals.—At the last meeting of the St. Petersburg Society of Naturalists, Prof. Wagner made a communication "On the Individual Variations in Animals, their Causes, and Results." Pointing out that the appearance of new races, varieties, and species is rendered possible by the appearance, at all stages, of the development of life of individual variations, which variations give rise afterwards to more or less constant new forms, the Professor sketched the causes of these individual variations, exterior and interior, insisting especially on the importance of these latter. The causes of variability, he said, are not only the physico-chemical influences of the medium inhabited by the individuals, *i.e.*, the exterior causes, but also, to a very important degree, the interior causes, *i.e.* those subjective physiological, and therefore also psychological, individualities which characterise each individual, and which modify to a considerable extent the influence of exterior influences on each separate representative of the species.

A New Cheetah.—At the meeting of the Zoological Society on Tuesday last, Mr. Sclater described a new species of cheetah, from South Africa, differing from *Felis jubata* in the fact that the whole body is covered with spots of a dark yellow instead of black, and at the same time is considerably more thickly covered with hair. Mr. Sclater proposed the name *Felis lanea* for this apparently new species.

North American Lepidoptera.—Mr. William H. Edwards has published a catalogue of the diurnal lepidoptera of North America and Northern Mexico, supplementing the well-known work by Dr. Morris, printed some years ago by the Smithsonian Institution. He enumerates no less than 506 species. This is about equal to that of the previous catalogues, the additional new species being balanced by canceling names which were synonyms or not legitimately entitled to introduction in the North American list. The special object of Mr. Edwards is to bring about what he considers a satisfactory nomenclature, dissenting from the radical changes which he insists Mr. Scudder has made in his recent divisions and lists, in few of which he concurs.

A New Shell.—Mr. C. R. Thatcher, the experienced conchological collector, has just returned to this country after a five years' collecting journey through China, Japan, Philippine Islands, and Australia. He has procured several new species of Murex, Cancellaria, and one wonderful specimen of an entirely new genus. This specimen was described at the meeting of the Zoological Society on Tuesday, June 5, by Mr. George French Angas, by whom it is proposed to give the name Thatcheria, in honour of its discoverer. It was the traveller's particular aim to procure specimens of the rare *Cypræa thatcheri* and *Voluta thatcheri*, both of which he found a few years ago, for which purpose he travelled many hundreds of miles into the interior of Japan, often at the risk of his life.

GEOLOGICAL NOTES

Rare Minerals in the North of Scotland.—The accidental use of a mass of granite for building purposes near Tongue, in Sutherlandshire, has led to the detection of several rare minerals, and of quite a remarkable number of species and varieties associated in the same mass of rock. From among the fragments of the boulder pieces of a bright green stone were sent to the museum of the Duke of Sutherland by Dr. Joass, of Golspie. These were afterwards analysed by Prof. Heddle, of St. Andrews, and found to be the variety of orthoclase felspar, termed amazonstone. For the purpose of more careful examination as to the mode of occurrence of this uncommon substance, Prof. Heddle has recently visited the locality, which is the side of the ridge rising to the east of the village of Tongue. He found the granite mass to be merely a large boulder, and had it thoroughly broken up. It has yielded the following remarkable assemblage of minerals:—amazonstone in simple and twin crystals, radiated cleavlandite, lepidomelane, pinite, fluorite, sphene, zircon, magnetite, ilmenite, allanite, smoky quartz with peculiar faces, and a mineral which a carefully instituted comparison shows to be thorite passing into orangite. The specimens of amazonstone obtained from the boulder are of unparalleled magnificence. One which has been sent to the museum of the Duke of Sutherland exhibited a surface of some three square feet, about a dozen large crystals, of which eight were unbroken and perfect. One crystal, unavoidedly broken in the extraction, showed the following extraordinary dimensions:—viz., a length of 15½ inches, with a breadth and thickness of ten and eight inches respectively. The minute structure of these crystals is peculiar, and has been fully described in a recent paper by Dr. Heddle on Scottish felspars in the *Transactions* of the Royal Society of Edinburgh. The exceedingly rare thorite was found in only a small quantity. From an examination of the granite of this and other boulders on the same hill, it appears that they have probably come from the huge mass of Ben Laoghal, which lies a few miles inland to the south-west. Should this be their origin, we may expect yet to find new sources of amazonstone, and perhaps other rare minerals among the numerous corries and crags of that picturesque mountain.

TERTIARY LEAF-BEDS OF COLORADO.—Mr. E. L. Berthoud, of the Territorial School of Mines, Golden City, Colorado, sends notes of a section near that place which presents some considerable resemblance to the sections in Antrim and Mull, where the miocene leaf-beds and lignites are associated with sheets of basalt and tuff. The order of succession is as follows:—

Basalt	120	feet
Lignite and leaf-bed	2½	
Hard mud ly clay and sandstone	13	
Second leaf-bed	3	
Clay, sandstone, conglomerate	40	
Third small leaf-bed in clay	2	
Sandstone and clay, &c.	30	"
Basalt	25	"

The resemblance is further borne out by Mr. Berthoud's list of plants, which includes *Platanus aceroides*, *Filicites hebridica*, *Populus arctica*, *Corylus McQuarii*, *Fagus macrophylla*, *Quercus chlorophylla*, *Sequoia*, sp. (?), *Gymnogramma Haydeni*, *Cinnamomum*, n. sp., *Ficus*, 2 sp. nov., *Magnolia*, 2 sp, *Juglans*, 2 sp., *Sabal Campbellii*, *S. Grayana*, and *S. goldianus*, *Myrica*, &c.

INFLUENCE OF ANCHOR-ICE UPON FISHING-GROUNDS.—Prof. Hind, to whose late researches in Labrador we recently called attention, has published some remarks on the effects of the formation of ground-ice in retarding the decomposition of fish-offal, and thereby in seriously damaging the value of the Labrador fishing-grounds. He shows that the ice formed on the sea-bottom freezes the offal, and protects it from being devoured by sea-scavengers and from decomposition; that every rise in temperature which prevents the formation of anchor-ice promotes the decomposition of the offal; that when this takes place, as it does every year under a covering of surface-ice, the water, not being aërated, becomes foul with gases and from the removal of its oxygen, and that the result is fatal to the young cod and other fry which then seek the coasts in search of food. He states that vast multitudes of the young fish are, from this cause, destroyed every summer and autumn in the bays and fjords, and he accounts for changes which have taken place in the migratory movements of seals by this wholesale destruction of the food which they used formerly to find in the coast-waters. He recommends the utilisation of the offal, which would not only eventually prove remunerative as a source of artificial manure, but would remove the poisonous gases which are set free on the melting of the anchor-ice at a time when they cannot fail to prove highly destructive.

ORIGIN OF THE TREES AND SHRUBS IN THE SOUTH OF FRANCE.—In a recent memoir presented to the Academy of Sciences of Montpellier, the veteran professor Charles Martins discusses the history of those trees and shrubs in the south of France which suffer from severe cold, such as the carob-tree, oleander, European palm, myrtle, sweet-bay, pomegranate, olive, fig, laurustinus, ilex, vine, and others. He shows that most of these occur among the tertiary and quaternary deposits, that some of them, indeed, like the oleander (*Nerium oleander*), go back even into eocene times. He points to the fact that their remains occur in the geological formations, not only of the countries where the plants are still living, but even of tracts considerably further to the north, both in France and in Switzerland, where their living descendants or analogues could not endure the severity of winter now. The tender trees and shrubs of the Mediterranean seaboard thus serve to prove the former warmer climate of France and its subsequent refrigeration. They are merely the surviving relics of a tertiary vegetation preserved by the exceptional mildness of the climate in which they grow. A single winter of exceptional rigour, or even a single night of extreme cold, like that of January 13, 1826, when the thermometer fell to 9°·7 below zero (Cent.), would suffice to destroy them. It may be presumed, however, that during at least the height of the glacial period these tender plants were driven southwards beyond their present northern limits, and that they have subsequently crept north again.

U.S. NATIONAL ACADEMY OF SCIENCES

ACCORDING to the terms of its charter from Congress, the National Academy of Sciences must hold its annual meeting in April, at Washington. It holds also a semi-annual meeting in the autumn. Its membership has been very slowly increasing, till now it numbers nearly, if not quite, 100. At the last meeting, April 17-20, Prof. Henry presided. The Academy resolved to present a memorial to Congress, in favour of the establishment and maintenance of an International Bureau of Weights and Measures with the object of promoting permanence, precision, and uniformity in the standards, by the joint action of the leading powers of the world, according to the convention submitted to the Senate.

Five new members were elected:—Prof. John W. Draper and Dr. Henry Draper of New York, Dr. Elliot Coues of Washington, Dr. S. H. Scudder of Cambridge, Mass., and Mr. Charles S. Peirce of the U.S. Coast Survey.

The annual report of the president, Prof. Henry, recounts briefly the year's work of the Academy. The Academy reports progress in the work of preparing and publishing the scientific results saved from the wreck of the *Polaris* and in general contributed by the expedition in which that vessel was [illegible]. This work is in the hands of Dr. Emil Bessels, the scientific director of the expedition, and will be finished in three quarto volumes. The first volume is already published; it is a quarto of 960 pages relating to astronomy, pendulum experiments, winds, solar radiation, and meteorology in general. It is illustrated by fourteen plates, two maps, and forty woodcuts; only 500 copies of this volume were printed. The second and third volumes relate to geology, palæontology, mineralogy, botany, zoology, and ethnology. They will include a monograph on the Eskimo, illustrated by 100 plates and 200 woodcuts. The Academy has divided the income from the Bache fund, so as to cover several distinct researches, as follows :—(1) On sun-spots and chromosphere, conducted by the late Prof. Winlock; the results are published, with plates, in the transactions of the Harvard Observatory. (2) Magnetic survey of the United States, in charge of Prof. J. E. Hilgard; during the year twenty-five new stations in New England and Lower Canada have been occupied; at all the stations the dip, declination, and horizontal intensity are observed. (3) Comparisons of sensations of light; in charge of Mr. Charles S. Peirce. The object is especially to ascertain the mathematical formula connecting the capacity of the eye for light sensations with the physical variations of radiation; two sensations are compared, the one fixed, the other variable; part of the results have been published. (4) Researches on the distribution of heat on the solar surface, the laws of its radiation and absorption, and effects on terrestrial climate; conducted by Prof. S. P. Langley. (5) Researches on the laws of sound and the duration of vibrations of tuning-forks; conducted by Prof. A. M. Mayer. The work of utilising the observations made on the transit of Venus is under direction of a committee of which the president of the Academy is a member; progress has been made in this work, but it is scarcely yet ready for report. The endeavour to obtain an appropriation for a permanent building to display the scientific and other material contributed by the Government of the United States and other nations during the Centennial Exhibition, failed to obtain a two-thirds vote in the House of Representatives after passing the Senate without dissent. The effort will be renewed at the next session of Congress. The collections are large, valuable, and instructive, including the costly gifts of other nations, and the entire exhibit that was in the "Government Building" at Philadelphia.

During the meeting the members of the Academy were formally invited to visit the President of the United States at the White House. They were duly presented, and President Hayes expressed himself in a brief speech as fully appreciating the value of scientific pursuits, and willing and desirous to advance the interests of science. The reception was notably pleasant and cordial.

We give abstracts of the more important communications :—

Prof. Alexander Agassiz gave a brief notice of researches on the young stages of some osseous fishes. The history of previous researches on these points, since those of von Baer at the beginning of this century, was reviewed. Prof. Agassiz concludes that with few exceptions the tail begins to be formed below the dorsal cord. If embryos and very young animals are examined, a lobe is found much developed in some and common to all. The tail fin and the anal fin are probably modifications of the same organ. There is a general uniformity in the plan of construction of the tails of fishes whether osseous or otherwise.

Under the title of "Some Results of Deep-sea Dredging," Prof. Agassiz stated views partly founded upon his general knowledge and study of the products and observations made during the *Challenger* expedition, and partly upon information obtained in conversations with Prof. Sir C. Wyville Thomson and other members of the expedition. The fact of a point of zero temperature being in all oceans but varying in depth with latitudes, had been indicated by previous expeditions and was fully established by the *Challenger* observations. At the equator a depth of 500 fathoms is needed to reach this zero line; as we approach the poles the depth of this line decreases till at last it is at the surface. Sometimes the temperature of the lower water is 2° or 3° below zero, but the conditions are, in general, uniform. Equally uniform is the fauna below this line. Above it, the arctic, temperate, and tropical faunas are clearly distinguishable from each other. There is a remarkable uniformity among the animals of the tropical fauna, such as may have resulted if in a previous era the isthmuses of Darien and Suez were absent, the Sahara was covered by the sea, and an equatorial current swept freely around the world. The deep-sea fauna is so singularly like the cretaceous that its forms would have been at once assigned to that epoch by most palæontologists if they had been fossil. The similarity if not identity of these forms indicates that there has been scarcely any change since that era. This is true of echinoderms, worms, and even of some fishes. It is equally true of some shore animals found both off our coasts and in the chalk. These have been subjected to the most varied conditions of existence as compared with their ancestors, and yet have not altered. There is evidence that natural selection, even under conditions where its forces are extreme, may not bring about any change. The present continents are probably much older than has been supposed. There is an entire want of evidence that great continents existed where oceans now are. The shore mud from our continents is washed down comparatively only a few miles from shore; the depths are not reached by this mud. Other well-known theories need to be modified. At a depth of 2,500 feet crustacea are found having good eyes. These organs have undergone no change during innumerable centuries. There are similar facts established as to starfish. There is no very great number of blind animals in the ocean depths. Those that are blind need not be classed as retrogressions from ancestors that had eyes. Both as to blind animals in the sea and those found in caves, it seems most probable that they were the descendants of eyeless ancestors. In the discussion which followed this communication, Prof. Agassiz said that he had long doubted the theory of geologists respecting an immense miocene continent.

Prof. Joseph Le Conte, of Oakland, California, furnished a paper on critical periods in the history of the earth and their relation to evolution; and on the quaternary as such a period. This paper instanced and enlarged upon the breaks in the geological and palæontological records, and argued that a more rapid rate of evolution had been operative during the intervals, which he designated as "critical periods." The quaternary era he regarded as one of these critical periods during which rapid changes had taken place, but it differed from most of such periods in the fact of its records being preserved.

Prof. G. K. Gilbert described the characteristics and mode of formation of the Henry Mountains.

Dr. F. V. Hayden described the results of boring artesian wells in a locality near Rawlins Springs in Wyoming Territory on the line of the Union Pacific Railroad. The district is on the dividing line of the watershed of the continent, some of the streams on the sides of the district flowing to the Atlantic, and some to the Pacific oceans. The rainfall of the district is very small—not over six to ten inches per year. The wells were bored to depths varying from 300 to over 1,000 feet. The water obtained was from 1,000 to 2,000 gallons per hour; it was lifted by pumps driven by windmills. The result showed the feasibility of thus irrigating very arid regions. The wells were bored under Dr. Hayden's direction, in a sinclinal basin which he regarded as of tertiary formation, probably eocene; but palæontologists who had examined its fossils had pronounced them cretaceous. Dr. Hayden regarded this as an instance where the chasm between the cretaceous and tertiary rocks was bridged over; he stated that the rocks were consecutive from cretaceous to middle tertiary. This opinion was not fully shared by the other geologists present, and the discussion which followed became exceedingly animated, as it brought up questions long at issue between the respective students of the rocks and of the fossils of that region.

Major J. W. Powell presented some remarkable facts respecting the public domain of the United States. Dividing the United States into two portions, the humid, where the rainfall is sufficient for agriculture, and the arid, where it is not, the latter is found nearly to equal the former.

Prof. Elias Loomis, of Yale College, contributed his seventh paper of a series entitled "Contributions to Meteorology," this paper continuing the investigation of rain areas which was begun in the last. Prof. Loomis selected all the cases in the United States during fifteen months—September 1872, to November 1873—in which the reported rainfall amounted to at least eight inches in eight hours. For each of these cases the curves of equal rainfall were drawn on the map and compared. The form of these curves, though occasionally irregular, in general approximates an ellipse, of which the major axis is not quite double the minor. In these cases the area of one-inch rainfall exceeded in length 500 miles; in six cases of one-half-inch rainfall 750 miles; frequently the entire area is an oval of more than 1,000 miles length and exceeding 500 miles breadth. In general the rain area centre is east of the low pressure centre, but in several instances the reverse was the fact, and in some cases the rainfall appeared to have had decided influence on the storm's progress, as to its direction. It was concluded that rainfall is not essential to low barometer areas, nor the chief cause of their formation or progressive motion. Such areas result from a general atmospheric movement toward a central area, and may be caused by unequal barometric pressure, unequal temperature, or unequal amounts of aqueous vapour. The two last-named causes are not comparable to the first of the three in cogency, and only deflect the winds slightly. The progress of areas of low barometer in all latitudes is mainly determined by the same causes as those which determine the general atmospheric circulation; their normal direction is changed by whatever causes may change the direction of the winds.

Prof. William Ferrel, of Washington, delivered a communication on the progressive movements of storms; the object being to show that the movement of great storms is determined by the currents—especially the upper currents—of the atmosphere.

Prof. Pickering presented the results of an investigation made in connection with Prof. W. A. Rogers on systematic errors in star declination. A comparison with the mean both of the earlier and later catalogues rendered probable the existence of systematic errors in the Gesellschaft catalogue.

Prof. Simon Newcomb presented a communication on the secular acceleration of the moon and its increasing deviation from uniformity through many years. He reviewed the existing theory on the subject; the calculation of Laplace according with Halley's estimate of the acceleration as about 10½ seconds of time, to be multiplied by the square of the centuries for a given period; also the Adams theory, which reduces the explanation of Laplace to about 6 seconds, leaving more than 4 seconds to be otherwise accounted for. In ascribing the surplus acceleration to diminished rotation of the earth, we are dealing with a subject where the evidence should be carefully weighed. Much dependence seemed to be placed on the records of ancient eclipses. Prof. Newcomb considered these eclipses separately. The most promising of the Greek solar eclipses was that of Agathocles, tyrant of Syracuse, occurring at the commencement of his voyage to attack Carthage. But we do not know on which side of Sicily he sailed; according to whether he was on one or the other side of the coast, the difference of time for that eclipse may be calculated as justifying the 10 seconds or the 6 seconds acceleration of the moon. The eclipse known as that of Thales has a record open still more to criticism, because it came to its historian by hearsay, and probably through two or three generations after the lapse of a hundred years. It seems curious that if Thales predicted the year (by an estimate of lunar periods) he did not also predict the day. Each of the ancient solar eclipses yielded similar elements of doubt on careful examination. From the records of lunar eclipses if all uncertain features be weeded out, the old estimate of acceleration will be reduced one half. The Arabian records of lunar eclipses were published at Leyden in the early part of this century. The work is very rare. Altitudes of sun and moon are constantly given in it. Calculations from these eclipses give the smaller estimate of acceleration. From all the data he has been able to study Prof. Newcomb concludes that the whole amount of acceleration is about 8·4 seconds. He hopes to make further estimates from modern records, having had the good fortune to pick up in Paris carefully compiled data of occultations going back to 1680.

In introducing his communication on "a Proposed New Method in Spectrum Analysis," Prof. S. P. Langley, of Allegheny Observatory, said that in giving this title to his description of his method, he believed, and, so far as he could ascertain, was justified in believing, that the method in this special application of it, was quite new. The process consists not only in placing in juxtaposition, simultaneously, the spectra of light from two opposite edges of the sun's disc (which had been done before), but also in determining that when these spectra are taken respectively from east and west edges, the atmospheric spectrum lines still coincide, while the solar lines of the two spectra do not coincide. Prof. Langley was anxious to disclaim any intention to abate one jot of the praise due to Prof. C. A. Young for conclusively demonstrating that the difference of wave-lengths from the east and west edges of the sun can be measured and its rotation thereby be proved. The history of this line of discovery was briefly given. Zöllner, Secchi, and Hastings thought they had perceived a change in the refrangibility of the light, and Vogel, using Zöllner's reversion spectroscope, obtained a displacement of from ·08 to 0·15 of one of Angström's units. Finally, Prof. Young, using a Rutherfurd grating, showed a velocity of the sun's equator of 1m. 42s.; and also that independent measurements of solar and atmospheric lines gave different results for these two classes. Prof. Langley's new method has the advantage of great security against instrumental errors, since the two classes of lines under like instrumental conditions, betray their diverse origin. In 1875, while studying the selective absorption of the solar atmosphere, Prof. Langley constructed an apparatus for comparing homogeneous light from different parts of the solar disc; use being made of two pairs of prisms of total reflection, connected with a spectroscope so as to give spectra from different parts of disc side by side. A photometric apparatus was attached to compare the relative intensities of light in different parts of these spectra. The whole apparatus was not intended at first for the comparison of individual lines of the spectrum, a purpose for which somewhat similar arrangements had been used by Lockyer, Hastings, and perhaps others; but Prof. Young's success suggested to Prof. Langley another and cognate method of using the principle of Doppler, to which this apparatus is well adapted. For six months Prof. Langley has been engaged in overcoming the instrumental difficulties of this conception. Only within a few days has he been able to produce complete results. When the apparatus is pointed so as to receive the light from the north and south poles of the sun, the lines are continuous in the two spectra; but when the instrument is rotated so as to take light from the east and west sides, all the solar lines are found discontinuous at the junction of the spectra, while the atmospheric lines remain continuous. If the instrument is rotated 180° the solar lines again appear discontinuous, but the spectrum whose solar lines were before shifted to the right as compared with the other, will after such rotation show them shifted to the left. In order to keep clear of any bias of judgment, Prof. Langley was careful not to know beforehand which way the instrument was pointed; but the displacement in every observation tallied with the theory. Essential aid was given in the construction of the instrument by the use of the choicest of glass gratings, ruled 8,600 to 17,200 lines to the inch, which Mr. Rutherfurd, of New York, sent for the purpose of this investigation. In the higher spectra of these admirable gratings thirty-one lines are discriminated in the E group where Angström and Kirchhoff have a dozen. On actual comparison for the fine lines of that group more have been counted with the grating than with the most powerful spectroscopes consisting of trains of twelve or more prisms. The method of analysis by Prof. Langley's instrument seems less adapted to quantitative work than Prof. Young's, but in this respect it is hoped also to make it useful by employing the micrometer upon the double displacement obtainable in right and left hand spectra of the same order presented simultaneously and in combination. By the observed displacement or fixity of any line we can now discriminate certainly as to its solar or telluric origin. It is hoped that a ready means of mapping atmospheric lines will thus be afforded, since indeed they are already mapped by this process before the eye of the observer.

Gen. J. G. Barnard, U.S.A., contributed a mathematical essay, also in part historical, on the internal structure of the earth as affecting the phenomena of precession and nutation, supplementary to an article under this head in vol. xix. of the "Smithsonian Contributions to Science," being the third of the "Problems of Rotary Motion." The paper shows that Gen. Barnard has coincided in Sir William Thomson's change of view. The formation of a diurnal tide in the fluid earth is called in doubt by this paper. In general it presents work of the kind that Sir William Thomson was longing for in his Glasgow address—a solution, coherently worked out, of the problem above indicated.

Prof. O. N. Rood, of Columbia College, New York, contributed two papers giving details of his researches concerning colours. Prof. Rood used a set of brilliantly coloured circular discs representing the chief spectrum colours, and also purple. By combining in successive proportions with these colours, a white disc, and giving the combined discs rapid rotation, the following results were attained: the lighter shades of vermilion became purplish; of orange, more red; of yellow, more orange; of greenish yellow, unchanged; of yellowish green, more green; of green, blue; of cyanogen blue, less greenish and more bluish; of cobalt blue, a more violet blue; of ultramarine, violet; of violet, unchanged; of purple, less red and more violet. Exactly similar effects were produced when violet instead of white was used to reduce the colours. Hence the mixture with white is the same as if the colours were moved towards the violet end of the spectrum. Prof. Rood thinks his results tend to indicate violet as one of the primary colours, which cannot be said of Maxwell's third fundamental colour, an artificial ultramarine, or Bezold's, a blue violet, careful tests of those colours having been fully carried out. The foregoing results were laid before Mr. Charles S. Peirce. He has reported at considerable length on the mathematical principles involved. He regards the results as in accordance with Fechner's law, that the sensation is proportional to the logarithm of the excitation. When the objective brilliancy of any light is varied, the specific subjective brightness is not changed in the least; but the only effect on the sensation is to add to, or subtract from it a variable amount of a certain constant sensation, which Mr. Peirce designates as the "colour of brightness." This ceases to be true when negative logarithms are involved. The yellow of the spectrum comes very near the colour of brightness. From these considerations a diagram has been constructed showing the colorific effects of mixing white with any part of the spectrum. The results of theory as shown by the diagram, closely accord with those of experiment upon the sensation of colour.

Prof. Rood also presented a paper on Newton's use of the term "Indigo" as a prismatic colour. It was intended to indicate the range of the spectrum between the blue and the blue-violet regions. The order of refrangibility is thus stated: prussian-blue and indigo; cobalt blue; genuine ultramarine blue; artificial ultramarine blue.

Prof. Joseph Le Conte, of California, sent a communication on the structure of the crystalline lens and its relations to periscopism. The discovery of Dr. Hermann, and his deductions therefrom, were first considered. These are that the crystalline lens, by its structure, is endowed with the property of forming distinct images of objects though lying on the extreme margins of the field of view, of forming perfect images on the retinal screen, even to the extreme anterior margins. Thus the eye has an enormous field of view compared with optical instruments. The purpose of the structure is to give periscopism to the eye. Prof. Le Conte believes, however, that as far as periscopism is concerned this structure is of little if any value in man for want of a corresponding suitable retinal structure. The indistinctness of the retinal image is different from the indistinctness of an imperfect perception of the image, the former being due to the properties of the lens, the latter to the organisation of the retina. In proportion as we go upward in the scale of animal life we find the powers of the central spot of the optical apparatus more thoroughly developed for the purposes of binocular vision.

Prof. A. Mayer, of Stevens Institute, presented four communications. He described a "Vernier microscope," which he believes to be new. The object is to substitute an accurate and permanent scale cut on glass for the varying errors of a micrometer screw. The instrument is of small cost and its errors are not varying. On a glass plate a series of lines is cut in tenths of millimetres; the central millimetre is divided into ten parts. This scale slides in carefully wrought guides in front of the objective of a firmly fixed microscope. In the focus is another scale so adjusted that ten of its parts accurately subtend the image of $\frac{9}{100}$ths of the millimetre scale. Thus a Vernier is formed which reads down to the $\frac{1}{1000}$th of a millimetre. The glass slide is so shaped that its rounded conical end abuts against the object to be measured. Readings to the full capacity of the instrument can be quickly obtained.

Prof. Mayer described his apparatus for measuring the expansion of metals and alloys under differences of temperature. It is believed that the coefficients of expansion, now inaccurately known, will be more correctly ascertained by this research.

The vibrations of tuning-forks received further investigation by Prof. Mayer; the cost of inquiry was defrayed by the Bache fund. The probable error in these determinations is the $\frac{1}{100}$ of one vibration, *i.e.*, with 256 vibrations to a second the probable error is $\frac{1}{25600}$ of a second. Differences in amplitude of vibration make no difference in the vibratory period of the fork; pressure applied to the fork also has no effect on the vibratory period, though it shortens the continuance of the note.

Prof. Mayer also described his investigations into the distribution of magnetism in long bar magnets. Some of these bars which were tested were five feet in length. Various methods have been tried for ascertaining the facts of magnetic distribution; Prof. Mayer gave due credit to other workers in this field, and described their experiments.

The Academy will hold its semi-annual meeting next autumn at New York.

NOTES

The following is a list of the officers of the forty-seventh annual meeting of the British Association which will, as we have intimated, commence at Plymouth on Wednesday, August 15:—President Elect—Prof. Allen Thomson, M.D., LL.D., F.R.S., F.R.S.E. Vice-Presidents Elect—The Right Hon. the Earl of Mount-Edgcumbe, D.C.L., the Right Hon. Lord Blachford, K.C.M.G., Dr. William Spottiswoode, F.R.S., Dr. William Froude, C.E., F.R.S., Mr. Charles Spence Bate, F.R.S. General Secretaries—Capt. Douglas Galton, C.B., F.R.S., Dr. Philip Lutley Sclater, F.R.S. Assistant General Secretary—George Griffith, M.A., F.C.S. General Treasurer—Prof. A. W. Williamson, F.R.S. Local Secretaries—Messrs. William Adams, William Square, F.R.C.S., Hamilton Whiteford. Local Treasurer—Mr. Francis Hicks. The Presidents of the Sections are as follow:—Section A: Mathematical and Physical Science—President, Prof. G. C. Foster, F.R.S. Section B: Chemical Science—President, F. A. Abel, F.R.S. Section C: Geology—President, W. Pengelly, F.R.S. Section D: Biology—President, J. Gwyn Jeffreys, F.R.S., F.L.S. Department of Zoology and Botany, J. Gwyn Jeffreys, F.R.S., F.L.S. (President), will preside. Department of Anatomy and Physiology, Prof. Macalister, M.D. (Vice-President), will preside. Department of Anthropology, Sir Walter Elliot, K.C.S.I., F.L.S. (Vice-President), will preside. Section E: Geography—President, Admiral Ommanney, F.R.S., F.R.G.S. Section F: Economic Science and Statistics—President, the Right Hon. the Earl of Fortescue. Section G: Mechanical Science—President, Edward Woods, C.E. The reception room will be opened on Monday, August 13, at 1 P.M., and on the following days at 8 A.M., for the issue of tickets to members, associates, and ladies, and for supplying information. No tickets will be issued after 6 P.M. The first general meeting will be held on Wednesday, August 15, at 8 P.M., when Prof. Andrews, F.R.S., will resign the chair, and Prof. Allen Thomson, F.R.S., President Elect, will assume the Presidency, and deliver an Address. On Thursday evening, August 16, at 8 A.M., a *soirée*; on Friday evening, August 17, at 8.30 P.M., a Discourse by Prof. Warington Smyth, M.A., F.R.S., on the Physical Phenomena connected with the Mines of Cornwall and Devon; on Monday evening, August 20, at 8.30 P.M., a Discourse, but by whom not yet arranged; on Tuesday evening, August 21, at 8 P.M., a *soirée*; on Wednesday, August 22, the Concluding General Meeting will be held at 2.30 P.M. The local arrangements for the Plymouth meeting are not yet matured, but we believe they will include an exhibition of paintings chiefly by artists of Devon and Cornwall, including magnificent examples of Reynolds, Opie, Eastlake, Northcote, Cooke, Prout, &c. There will be excursions to Torquay or Kent's Hole, &c., and the Dart; up the Tamar or Cotehole; to the Moss Clayworks and over Dartmoor; to the Eddystone Breakwater and Government establishments; to the Caradoc mines; and to Penzance, the Lizard, the Land's End, &c.

A RECEPTION was held by the President of the Royal Society and Lady Hooker at Burlington House, on Wednesday evening June 13, which was largely attended. The invitations included ladies as well as men of science. The rooms were decorated with plants, and there was a collection of instruments and objects of scientific interest. Among the novelties were new spectroscopic instruments exhibited by Mr. Browning and Mr. Hilger; and Messrs. Tisley and Spiller's harmonograph curves, drawn on smoked glass.

A CONGRESS on Domestic Economy, organised by the Society of Arts, is to be held in Birmingham on July 18 and 19. Section A is to include (1) Needlework; (2) Cleanliness; (3) Food and Cookery; (4) Household Expenditure; (5) Thrift. Section B (6), Health; (7) Sickness; (8) The Dwelling; (9) Warming and Ventilation. Section C (10), Teaching the Subjects in Elementary Schools; (11) Text-books; (12) Inspection and Government Grants; (13) Importance of Female Inspectors; (14) Examinations. A number of papers are already promised, among them being papers by Mrs. W. E. Gladstone and Prof. Huxley. The Local Committee includes the Lords-Lieutenant of Staffordshire, Warwickshire, and Worcestershire, the Bishop of Worcester, several noblemen, clergymen, the Mayor of Birmingham, &c.

THE Helvetic Society of Natural Sciences meets this year at Bex, in Canton Vaud, from August 19 to 27. Several interesting excursions have already been arranged for. Prof. Louis Dufour, of Lausanne, will be president. English naturalists will be heartily welcomed.

THE death is announced of Lieut.-Gen. Sir Henry James, director of the Ordnance Survey of Great Britain from 1854, until his appointment to the command of a battalion of Royal Engineers in 1874, since which he has lived in Southampton in failing health. He was seventy-four years old, and from 1844, when he was director of the Geological Survey in Ireland, had written on various scientific subjects.

SOME bones of *Lithornis emuinus*, an enormous bird of the eocene period, have just been discovered in the London clay at Sheppy by Mr. W. H. Shrubsole, of Sheerness-on-Sea. Casts of these fossils will be taken for the British Museum.

THE well-known traveller, Dr. Schweinfurth, has recently returned to Egypt from a two months' journey through the Arabian desert, richly laden with scientific collections. He proceeds to Berlin to complete the arrangement of the large quantities of botanical specimens collected by him in his late expeditions.

No. 4 of the *Quarterly Bulletin* of the Cairo Society of Geography contains a valuable account, by Dr. Nachtigal, of his visit to Wadai, as the country between Darfur and Bagirmi is called, and notes on the country of Harrar, by Mohammed Maktar. The same Society has published separately an obituary notice of the late Marquis de Compiègne, by M. C. Guillemine.

A VALUABLE and somewhat elaborate geographical sketch of Loango and the Loango Coast, by Dr. Pechuel Lösche, has been published in a separate form from the *Mittheilungen* of the Leipzig Geographical Society.

THE Annual Report for 1876-7, of the West London Scientific Association, speaks favourably of the progress of that Association, which now numbers 186 members.

IN the Buenos Ayres *Standard* of May 13 D. Francisco Moreno describes a journey he made up the Santa Cruz river, in Southern Patagonia, in about the 50th deg. of S. lat. Notwithstanding the great rapidity of the current, he succeeded, with three sailors, in ascending the river, taking thirty days to it. The Santa Cruz issues from a fine lake thirty miles long and ten broad, in S. lat. 50° 14' 22" and 71° 59' W. long. D. Moreno was the first to sail along this lake, which he explored and sketched pretty thoroughly, making considerable geological collections in the neighbourhood both of this and of other lakes in the same region. Amongst these was Lake Biedma, in the neighbourhood of the still active volcano, Chalten. A river more than 200 yards wide connects Lake Biedma with Lake Santa Cruz.

MR. G. BROWN GOODE, assistant curator of the National Museum at Washington, has been engaged during the past winter in investigating the natural history of the Bermudas, and has recently returned with a large collection, filling twelve barrels and forty-three boxes, and including over 1,000 bottles of invertebratas in alcohol. His collections embrace the entire marine fauna of the coast—fishes, molluscs, worms, &c., many of which are believed to be entirely new to science.

MR. ROBERT LOWE, M.P., presided on Wednesday, last week, at a meeting of the committee formed for the purpose of organising a testimonial to Mr. John Simon, F.R.S., late medical officer to the Privy Council and Local Government Board, in recognition of the long and valuable labours he has rendered to the State, and of his eminent services to sanitary science. It is proposed that the testimonial shall assume the form of a bust in marble of Mr. Simon for presentation to the Royal College of Surgeons, agreeably to the wishes of the Council of that body. The cost, together with the expenses, will probably amount to 500*l*. We are sure that not only members of the medical profession, but all who are interested in sanitary science, will willingly contribute to a monument to one who has done so much for that science.

A SPECIAL direction of science and arts has been added to the French Ministry of Public Instruction. M. Walteville has been appointed to the new office, and it is supposed that having nothing to do with politics, he may continue in office irrespective of any change in the Ministry. It would be well to insure a continuity of action and professional independence to the head of so useful an administration.

A NEW photographic department has been established in France for the reproduction of scientific or artistic objects. The laboratory will be kept up exclusively by Government. The State photograpers will be required to employ the most advanced methods and to work for the improvement of the art.

ON Friday night a series of interesting experiments with the Jablochkoff electric light took place at the West India Docks, under the direction of M. Denayrouze. The apparatus used for the occasion consisted merely of an electro-magnetic machine worked by a small steam-engine, some insulated wires, and the electric candles, which are the invention of M. Jablochkoff, and composed, as we have already described, of two carbons placed side by side with a slip of insulating substance between them, which burns away with the carbon exactly in the same way as the wax of a wax candle is consumed with the wick. The first experiment in order to show the suitableness of the invention for dock purposes consisted in the lighting of four of the "candles" in a large yard. The light thus obtained, which was shaded by ground glass, brilliantly illuminated the inclosure, it being possible to read small print at a considerable distance from the lights, while at the same time the eyes were not affected by the glare, as is the case with the ordinary electric light. The second experiment was confined to the illumination of the top story of one of the large warehouses, and this, like its predecessor, was equally successful. A large vessel at the quay side was also lighted up, as also was a portion of the quay. The whole of the experiments were very successful, and it was stated that each "candle" gave a light equal to 100 gas lights. The light is said to be much less expensive than gas.

THE Leicester Literary and Philosophical Society have commenced the publication of its *Transactions* from its foundation in 1835, as far as material for these can now be obtained. We have received the first two parts of this publication, extending from 1835 to 1841; they contain much likely to interest not only the members of the Leicester Society, but all who take an interest in the progress of local societies, now becoming so widespread and efficient.

SOME experimental researches on the light refraction of a number of gases are described by M. Mascart in the *Annales Scientifiques*. A beam of light was sent through a collimator to two plates of plate-glass connected together at right angles; the halves of the beam were bent right and left by refraction through the glass. They then went parallel through two copper tubes containing the gases, and after refraction by a second system of glass plates placed in reverse directions, the halves were united again, and the beam passed through a slit to a system of prisms, then to a telescope. If the pressure in one copper tube were as varied, the phases of the two parts of the beam were unlike, and from the number of fringes, the refraction of the gas could be determined. The influence of pressure was examined, then the refractive power for different wave-lengths, then the influence of temperature; and the absolute refractive power deduced from the various factors obtained. The numbers for the latter range from 0·1387 (hydrogen), and 0·2706 (oxygen) to 0·7036 (sulphurous acid), and 0·8216 (cyanogen). The refraction of a gas mixture is equal to the sum of the refractions of the mixed gases. But the refraction of a compound is in general greater than that of a mixture of the simple gases composing it.

As determinations of longitude increase an ever-increasing number of control determinations are obtained. The number of the latter in Germany and Austria is now such that M. Albrecht has considered an attempt at equalisation of the system might prove advantageous, as at least an opinion might be formed regarding the degree of accuracy of the differences of longitude directly measured, and attention would be called to the weak parts of the system. He has accordingly, with M. Sadebeck, attempted an equalisation of the system of longitude determinations between the following stations:—Strassburg, Paris, Mannheim, Bonn, Leiden, Göttingen, Brocken, Leipzic, Berlin, Vienna, Munich, and Bregenz. An account of the investigation appears in *Astronomische Nachrichten*, No. 2,132. A numerical value is assigned to the various determinations, which extend over the last fifteen years; and this was necessarily, of course, somewhat arbitrary in character. In a table M. Albrecht gives for each pair of places the difference of longitude as calculated and the difference observed, and then the difference between the two. The greatest improvements are obtained in the determinations for Leipzig-Vienna and Berlin-Vienna (the difference for the former being + 0·136s., and for the latter 0·102s.) In the former case, there was some uncertainty as to the personal equation, and in the latter two weak currents had been operated with. The improvements are, of course, only approximate, and the certainty of the individual improvements obtained is considerable only when numerous control-determinations are to hand. The result sufficiently shows that a very large number of control-determinations, and an extensive establishment of the system is necessary to remove all doubt with regard to the relative position of the various stations.

As an illustration of the rapid growth of the now celebrated *Eucalyptus globulus*, we may mention that in the more elevated parts of Jamaica trees now exist about sixty feet high, the trunks of which measure a foot in diameter near the ground. These trees have been raised from seed introduced to the island about six years ago. It is proved that in the lowland districts the tree does not thrive, thus upsetting its suitability for regions in which it was at one time specially advocated.

THE new *Journal of Forestry*, the first number of which appeared on May 1, seems to have made a good start, judging from the contents of the two numbers that have now been issued. The contents are sufficiently varied to make the journal welcome to all in any way interested in forests or forest produce, both practically and scientifically, for we find not only articles on forest work for the month, but also a brief *résumé* of Mr. Thiselton Dyer's recent address on "Plant Growth" at the London Institution.

THE additions to the Zoological Society's Gardens during the past week include two Condor Vultures (*Sarcorhamphus gryphus*), a Chilian Sea Eagle (*Geranoaëtus melanoleucus*) from South America, presented by Mr. John T. North; two Chaus Cats (*Felis chaus*) from North Africa, presented by Capt. W. Renney; a Crested Guan (*Penelope cristata*) from South America, presented by Mr. Daniel Miron; a Green-winged Trumpeter (*Psophia viridis*) from Brazil, a Common Trumpeter (*Psophia crepitans*), a Demeraran Cock of the Rock (*Rupicola crocea*) from Demerara, a Black-necked Stilt (*Himantopus nigricollis*), a Sun Bittern (*Eurypyga helias*), two Orinoco Geese (*Chenalopex jubata*), a Capybara (*Hydrochærus capybara*) from South America, a Moor Monkey (*Semnopithecus maurus*) from Java, purchased; six Chilian Pintails (*Dafila spinicauda*), seven Summer Ducks (*Aix sponsa*), bred in the Gardens.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—An examination will begin on October 2 for the purpose of electing to a Physical Science Postmastership at Merton College. The postmastership is of the annual value of 80*l*. for five years, to be raised after two years, at the recommendation of the tutors, to 100*l*. The subjects of examination will be chemistry and physics; there will be a practical examination in chemistry, and candidates will have opportunities of giving evidence of a knowledge of biology. Further information from the tutor in physical science.

There will be an examination on October 11 for electing to a Natural Science Scholarship at Exeter College. The scholarship is of the annual value of 80*l*. for four years, without any limit of age. The examination will be in biology, chemistry, and physics, and candidates will be expected to show proficiency in at least two of these subjects. The examination will be to a large extent practical, but special weight will be given to a knowledge of general principles. Further information may be obtained from the Natural Science Lecturer, Prof. E. Ray Lankester.

Mr. M. J. Jackson, of University College, London, has been elected to the vacant (Holmes) Scholarship in Natural Sciences at St. John's College. The scholarship is of the annual value of 100*l*. for five years.

MANCHESTER.—Prof. Boyd Dawkins, F.R.S., has just completed his course of Field Lectures on Geology, at Owens College. Upwards of forty students—the large majority of whom were other than regular students of the College—availed themselves this year of the opportunity offered for acquiring some practical knowledge of geology. Excursions were made to the mountain limestone of Derbyshire, the coal measures near Oldham, the Permian rocks of Alderley Edge, where the copper veins disseminated throughout the sandstone were studied, and where traces of prehistoric man, in the shape of a few flint implements, were discovered. During Whit week Oxford was visited, and the Oolitic beds of the neighbourhood were explored.

During the session which has just closed, 100 students have worked in the chemical laboratories of Owens College, while the number of students attending the various courses of chemical lectures has amounted to about 200. Over a dozen original communications have proceeded from the chemical department during the session.

TAUNTON COLLEGE SCHOOL.—An address of sympathy with, and confidence in, the Rev. W. Tuckwell, head-master of the Taunton College School, is published in the local and educational papers, with the signatures of nearly all the parents. It appears that the school is heavily in debt, and that the numbers, chiefly through an attack of fever, have fallen below the paying point. The panic-stricken officials have selected the head-master as a scapegoat, attribute the loss in numbers to his "unpopularity," and are endeavouring to drive him to resign, a movement against which the parents protest in very animated terms. The part taken by this school and its head-master in working out and popularising the systematic teaching of science in company with the old-fashioned classical curriculum impels us to record these facts, and to look with interest for the result of this latest struggle between Philistinism and culture.

UNIVERSITY COLLEGE OF WALES.—A Welsh gentleman engaged in business in London, in addition to sums of 250*l*., 2,500*l*., and 1,100*l*. (the last sum in conjunction with his brother) previously subscribed, has just placed in the hands of the Council of the University College of Wales, a sum of money to be used in promoting scientific agriculture in Wales. According to a circular just issued, "one of the means proposed to be adopted in furtherance of this object is the delivery of courses of lectures free of charge to persons engaged in tuition in Wales, whereby they may be qualified for giving elementary instruction in the principles of agriculture in their several schools." Prof. Henry Tanner, M.R.A.C., examiner for the section under the Government Department of Science will, on August 7 next, begin a course of twenty lectures, to be continued from day to day, at the College in Aberystwith.

THE UNIVERSITIES' BILL was read a third time in the House of Commons and passed on Monday, and a first time in the Upper House on Tuesday.

ADELAIDE.—We have received a copy of the *Calendar* of Adelaide University for 1877. This University has at present only four professors, who represent very fairly the main branches of literature and science. There is only one professor for Mathematics and Natural Philosophy, and the professor of Natural Science gives instruction in Chemistry, Geology, and Botany. We hope the University will soon be able to carry the principle of sub-division of labour into these two professorships, and thus promote efficient teaching, and at the same time relieve these two professors of a burden they ought not to be made to bear in this advanced age. There are some points in which our home universities might advantageously imitate that of Adelaide. Judging from the programme of the B.A. examination, the Adelaide graduates must be possessed of a more varied amount of knowledge than the ordinary graduates of our universities. Some knowledge of physical science (physics and chemistry), must be possessed by every graduate, and a choice of subjects is given in the second and third stages, whereby a candidate can take his degree either through literature or science. The University possesses a few valuable scholarships, one, of the value of 200*l*. per annum for three years, being awarded after examination in mathematics and natural science, the holder being required to proceed to England, take a degree in science at the London University, and undergo a training in engineering. We cannot but admire the lines on which education is conducted at Adelaide, and we trust the University may soon be able to extend its staff of teaching.

BERLIN.—The report of the Berlin University for the present year shows an attendance of 2,237 students, a decrease of 253 on the past year. The lectures are also attended by 2,080 other persons not connected with the University. The students are divided among the faculties as follows:—Theology, 135; law, 792; medicine, 297; philosophy (philology, history, &c.), 644; mathematics and natural sciences, 369. 194 students are from foreign countries, including nine English and thirty-nine Americans. The professors and privat-docenten number 200—fourteen in the theological, eighteen in the legal, seventy-four in the medical, and ninety-four in the philosophical faculties. The University library contains but 60,000 volumes, the royal library of 700,000 volumes being chiefly used.

UPSALA.—The *Abo Underrattelser* states that the Imperial Academy of Sciences of St. Petersburg will be represented by MM. Gadoline and Grote at the celebration of the 400th anniversary of the foundation of the University of Upsala.

SCIENTIFIC SERIALS

American Journal of Science and Arts, June.—An account of the discoveries in Vermont geology of the Rev. Augustus Wing (continued), by James D. Dana.—On barite crystals from the Last Chance Mines, Morgan County, Missouri, and on Göthite from Adair County, Missouri, by G. C. Broadhead.—Estimation of chromium and aluminium in steel and iron, by Andrew A. Blair.—On the chemical composition of triphylite from Grafton, New Hampshire, by S. L. Penfield.—On a new mode of manipulating hydric sulphide, by Josiah P. Cooke, jun.—On a base derived from a waste product in the aniline manufacture, by C. Loving Jackson.—On an association of gold with Scheelite in Idaho, by B. Silliman.

Verhandlungen der k. k. zoologisch-botanischen Gesellschaft in Wien, vol. xxvi. (Parts I. and II.), 1876.—The following are the principal papers in this volume:—Synopsis Cecidomydarum, by J. v. Bergenstamm and P. Löw.—On the structure and habits of lichens, by Dr. Arthur Minks.—On the ornithological fauna of the Austrio-Hungarian Empire, by A. Pelzeln (fourth paper).—Biology and characteristics of Psyllodæ, with description of two new species of the genus *Psylla*, by Dr. F. Löw.—On the flora of fungi in Hungary, by Fr. Hazslinsky.—On the butterfly fauna of Surinam, by H. B. Möschler.—Mycological researches, by Schulzer von Müggenburg.—On the lichen-flora of New Zealand, by Dr. A. von Krempelhuber.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. x., fasc. viii.—On the encystment of the Proteus of Quanzati (*Amphileptus moniliger*, Ehr.), by M. Maggi.—Theory of reticular woodwork combined with an articulated system in modern American suspension bridges, by M. Clericetti.—The silk of the *Bombyx mylitta*, by M. Gabba.

THE *Jahrbuch der k.k. geologischen Reichsanstalt* (1876, vol. xxvi., Oct.-Dec.) contains the following papers:—On the ore deposits of the southern Bukowina, by B. Walter.—On the soda and Szek-soil in the Hungarian Lowlands, by E. von Kvassay.—On some green slate of the Saxon Erzgebirge, by Dr. E. Geinitz.—On the petrographical condition of the tuft-stones occurring in the Devonic formation at Graz, by Joh. Terglav.—On some rocks from the neighbourhood of Rosignano and Castellina Maritima to the south of Pisa, by Dr. Friedrich Berwerth.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 14.—"On the Minute Structure and Relationships of the Lymphatics of the Mammalian Skin, and on the Ultimate Distribution of Nerves to the Epidermis and Subepidermic Lymphatics," by George Hoggan, M.B., and Frances Elizabeth Hoggan, M.D. Communicated by Dr William Farr, F.R.S.

"Refractive Indices of Glass," by J. Hopkinson, D.Sc., M.A. Communicated by Prof. G. G. Stokes, Sec. R.S.

"Electrostatic Capacity of Glass," by J. Hopkinson, D.Sc., M.A. Communicated by Prof. Sir William Thomson, F.R.S.

"On the Difference of Potential produced by the Contact of different Substances," by Prof. R. B. Clifton, F.R.S.

Linnean Society, June 7.—Prof. Allman, F.R.S., president, in the chair.—Dr. Maxwell Masters read an interesting paper on the "Morphology of Primroses." Hitherto much discussion has arisen with reference to the superposition of the stamens to the petals, the free central placenta, and the nature of the ovules in the Primulaceæ. From a lengthened study and comparison of the development of the flower, minute structures, and phenomena of monstrosities, the author arrives at conclusions differing somewhat from those hitherto held. Cultivation is not the reason of the frequent structural variation, for deformed Primulaceæ in the wild state are far from uncommon; indeed the wild primrose itself is very much subject to such changes. Certain genera and species are more frequently found deformed than are others; for instance, the cowslip is less subject to change than is the primrose. Entering into all the more important variations observed by the author and recorded by others, in various parts of the flower, he sums up: (1) That the petals of most Primulaceæ are late outgrowths from the receptacular tube. (2) That the placenta is a direct prolongation of the receptacle or axis, and without apex or side connection with the carpels. (3) The placenta occasionally in monstrous flowers arises from the margin or centre of carpel, but sometimes is detached, the detached placentæ cohering like a solid column. (4) Staminal and carpellary leaves may occasionally be divided or lobed. (5) The ovular coat is essentially foliar, representing blade or undivided leaf, and is not a direct production from the axis. (6) Processes of carpellary leaf may be infolded, thus forming secondary carpels.—The Rev. G. Henslow followed by a "Note on the causes of numerical increase of parts of plants." In this he classified the various methods and causes of the increase of parts of leaves and floral whorls, more especially with the view of limiting each of the various kinds to its proper cause respectively.—The secretary briefly indicated the contents of a paper by Mr. Marcus Hartog, "On the floral development and symmetry in the order Sapotaceæ." From the extracts read of this communication it appears the author, from observation of growing plants in Ceylon has independently arrived at and here brought forward further evidence tending to the same results propounded by the two foregoing home botanists.—"On the nymph stage of the Embidæ, with notes on the habits of the family, &c.," was next read by the author, Mr. R. McLachlan. He stated that in 1837 Prof. Westwood (in *Trans.* Linn. Soc.) instituted the characters of *Embia*, a genus of insects allied to the white ant. Lately (therefore forty years after) Mr. Michael, of Highgate, discovered some orchids partially destroyed by an insect found to belong to the Embidæ, and subsequently the nymph form obtained fills a gap in the insect's history. Mr. McLachlan, in allusion to the habits, recorded by Mr. Lucas and others, mentioned its being carnivorous and spinning a silken web like that of a spider, which, however, Mr. McLachlan believes to be far protection from its enemies, while he doubts its carnivorous propensities, regarding it as probably a vegetable feeder. He then entered into the subject of systematic position, structure, distribution, number of species, concluding with a detailed description and zoological remarks on those forms of the Embidæ now known. He observed that the larvæ of a species of *Embia* has been noticed in fossil amber. The living forms inhabit both hemispheres at spots wide apart. None are known from Australia.—Mr. G. Busk verbally explained the more important points in the succeeding paper, viz., "Observations on British Polyzoa," by the worthy field naturalist, Mr. Charles Peach. The latter has faithfully described and delineated a number of forms of this marine family, some of which he regards as new to science, and of other known genera and species he adds much information regarding their habits and history. For instance, *Scrupocellaria scruposa* he shows has tubulous wool-fibre-like roots armed with spines, and by which it attaches itself to certain sponges, &c., a fact previously unknown.—A notice of the Lichens of the *Challenger* expedition, by the Rev. J. M. Crombie, and on Crustacea inhabiting certain hollow sponges, by Mr. Edward J. Miers, were two papers read in brief extract.

Zoological Society, June 5.—Prof. W. H. Flower, F.R.S., vice-president, in the chair.—A communication was read from Dr. A. B. Meyer, inclosing a paper by the late Dr. Bowerbank, describing five new species of sponges, discovered by Dr. Meyer at the Philippine Islands and New Guinea during his recent travels in the Eastern Archipelago.—A communication was read from Mr. E. L. Layard, F.Z.S., containing some remarks on the exact localities of certain species of Birds of the Islands of the South Pacific.—A second communication from Mr. Layard contained remarks on a paper by Mr. R. B. Sharpe on the Cuculidæ of the Ethiopian Region.—A communication was read from Mr. Arthur G. Butler containing an account of a collection of Lepidoptera, made at Cape York and on the south-east coast of New Guinea by the Rev. J. S. MacFarlane. Of these five butterflies and four moths were described as new to science.—Dr. A. Günther, F.R.S., read a report on a collection of fishes made during the late Arctic Expedition by Mr. Hart, Naturalist on board H.M.S. *Discovery*. Among them was a new species of Charr, from a lake near the winter-quarters of the *Discovery*, which was proposed to be called *Salmo naresi*.—A communication was read from Mr. D. G. Elliot, F.Z.S., containing a review of the genera and species of Ibidinæ or sub-family of Ibises.—A communication was read from Mr. Martin Jacoby, containing the descriptions of some new species of Phytophagous Coleoptera from various parts of the world.—Messrs. P. L. Sclater and O. Salvin read descriptions of six apparently new species of birds from collections lately received from Ecuador and Peru. Amongst these was a remarkable new duck of the genus *Fuligula* from the vicinity of Lima, Peru, proposed to be called *Fuligula nationi* after Prof. Nation, its discoverer.—Mr. A. H. Garrod read the third part of his series of papers on the anatomy of Passerine birds, and treated specially of some modifications of the Tracheophonine larynx which he had lately ascertained to occur in the genera *Pteroptochus* and *Grallaria*.—Mr. George French Angas communicated notes on a collection of land and fresh-water shells from South-west Madagascar; amongst these Mr. Angas pointed out three new species of *Helix*, one of *Bulimus*, and one of *Physa* which he proposed to call *Helix watersi*, *H. balstoni*, *H. ekongoensis*, *Bulimus balstoni*, and *Physa madagascariensis*.—A second communication from Mr. Angas contained the description of a remarkable shell from Japan, which he named *Thatchera mirabilis*, also the description of a new species of *Leiodomus* from Kurrachi, Scinde, proposed to be called *L. kurrachensis*.

Entomological Society, June 6.—J. W. Dunning, vice-president, in the chair.—Mons. René Oberthür, Rennes, France, was elected a foreign member.—Mr. J. W. Douglas exhibited sixteen species of *Psyllidæ* (four of them being new to Britain), which he had taken during the latter half of 1876. Mr. Douglas took the opportunity of calling the attention of entomologists to the wide field for investigation offered by these insects, the economy of many of the species being still quite unknown.—Mr. F. Grut exhibited a white downy nest from Jamaica supposed to be the work of some insect.—Mr. H. Goss exhibited a dark variety of *Cleora glabraria*.—Mr. C. O. Waterhouse exhibited a magnificent dragon-fly from Borneo. This insect, which is new to science, he has proposed to name *Gynacantha plagiata*. The specimen, a female, measured more than six inches in expanse. —The Secretary read a circular from Dr. Buchanan White, of Perth, soliciting specimens of *Hemiptera* (especially exotic) from entomologists, as he was engaged in working out that order of insects.—Dr. Sharp communicated a note on some species of Rhyncophorous beetles from New Zealand, which had been sent to Dr. Leconte for examination.—Mr. Pascoe made some remarks upon the foregoing note.—Mr. J. W. Slater communicated a paper on the food of gaily-coloured caterpillars, in which he attempted to show that brightly-coloured larvæ generally fed upon poisonous plants.—A discussion ensued, in which Messrs. Dunning, McLachlan, Waterhouse, and Meldola took part. Mr. Meldola called the attention of the Society to the explanation of the subject given by Wallace in 1867, and exhibited some butterflies which were the sole survivors of an old Indian collection, the greater part of which had been demolished by mites. The surviving specimens all belonged to protected genera (*Euplœa*, *Danais*, and *Papilio*), proving that the quality which rendered these insects distasteful was, to a certain extent, retained after death.

Anthropological Institute, June 12.—Col. A. Lane Fox, F.R.S., vice-president, in the chair.—Mr. W. J. Knowles, of Ballycully, read a paper on some recent discoveries of flint implements, worked bones, and other objects in a kitchen midden at Ballintoy, co. Antrim.—The director then read some notes on customs of the Caledonia women of Stuart's Lake and Fraser Lake Indians, and two legends of the Langley Fort Indians, by Mr. Gavin Hamilton, of the Hudson Bay Company (communicated by Dr. John Rae, F.R.G.S.)—Staff-Surgeon Messer, R.N., M.D., then made some interesting observations on the subject of poisoned arrows, as used by the South Sea Islanders, and the effects, moral and physical, of them on Europeans and blacks.—Mr. G. M. Atkinson exhibited for the Rev. J. C. Roger, Rubbings from a Runic inscription found on a stone in Cunningsburgh churchyard, Shetland Isles, and of a stone with Oghams, found five feet below the surface at Lunnasting, Shetland Isles.

Victoria (Philosophical) Institute.—The Rev. Isaac Taylor read a paper on the history of alphabets. De Rouge's great discovery has proved that the alphabet is the oldest existing monument of human civilisation—older than the pyramids. There were three stages in its invention:—1. Ideograms—pictures of things. 2. Phonograms—symbols of words and syllables. 3. The letters of the alphabet. After giving a brief account of the syllabic writing which was developed by the Japanese out of the Chinese, and by the Cypriotes out of the Cuneiform, he went on to explain De Rouge's discovery of the mode in which the Semites had selected twenty-two letters out of the 400 Egyptian hieroglyphics, and thus formed that first alphabet which had been the parent of all alphabets in the world. He showed how all the alphabets of the world were to be traced, by means of the Moabite stone, to their source in the Egyptian hieroglyphics. He went on to explain the causes of alphabetic change:—1. Those due to nature of writing materials—clay, stone, papyrus, parchment, palm-leaves. 2. Indolence in the writing. 3. Need of legibility.

CAMBRIDGE

Philosophical Society, May 21.—Mr. Pearson read a paper on one passage in Hesiod and three in Ovid's Fasti, which he said he considered might be properly tested and illustrated from modern astronomy. Admitting, as is often averred, that many allusions of this nature in the classical authors are inaccurate or wrong, some he thought might be still found to have the stamp of truth about them. Hesiod says (Op. et Di. 564 67) that sixty days after the winter solstice Arcturus rose during twilight in the evening. Arcturus's position for January 1, 1875, is given in the *Nautical Almanac* as R.A 14h. 9m. 55s., Dec. 19° 50′ 22½″ N. If we convert these data into latitude and longitude, reduce the star's longitude by about 36° 10′, which, at the annual rate of 50″·1 for *precession* will bring us to about 730 B.C., and reconvert the star's new *longitude* and *latitude* into R.A. and Dec., we shall find that the position of the star in the early part of the eighth century B.C., which may be fairly taken to represent the era of Hesiod, was something about 12h. 6m. R.A. and 33° 30′ north dec. On Feb. 20, at that time, in lat. 38¼° N., about the situation of Ascra and Helicon, the sun would set about 5.40 P.M., while Arcturus would rise above the horizon about 5.53 P.M., a relative position of the two luminaries which fairly answers to the words of the poet. And while investigating the position of the star, Mr. Pearson said he found he had unintentionally explained, as he believed, the epithet "late-setting," applied to Arcturus in Hom. Od. E′ 272. Arcturus at that epoch would first have been visible at the time of its morning setting about May 24, and would set June 1 at 3.30 A.M., July 1 at 1.32 A.M., Aug. 1 at 11.30 P.M. During the early summer, therefore, when the Greek seaman or agriculturist was often spending the nights out of doors, the late time at which this brilliant star would set must have been quite unmistakable, and Ulysses is naturally described as keeping his eye fixed on it while sailing eastwards, as carefully as he kept the Bear on his left. Again in the "Fasti" of Ovid, i. 654, ii. 76, we are told that Lyra, or *Vega*, was last visible when setting in the evening, about February 1. "Ubi est hodie, quae Lyra fulsit heri?" Employing again the method of calculation indicated above, we find on that day at Rome the sun would set about 5.10 P.M., and Lyra about 5.44. As the days at that time of the year are rapidly lengthening, while the star would set earlier every day, it is obvious that the date assigned for the last appearance of the latter is nearly exact. Ovid's references to Arcturus are not at first sight so satisfactory. May 26th and June 6th ("Fasti v. 733, vi. 235) are both assigned as the first days on which he is visible, probably by a mistaken reference to two different modes of calculating the time of a star's rising. On May 26 the star would rise at 4.25 A.M., on June 6 at 3.43 A.M. The sun on the former day rises at Rome about 4.35, and on the latter at 4.30 A.M. If we consider Ovid to have consulted two different authorities, one of which gave the true and the other the visible heliacal rising of the star, no reasonable exception can be taken to the value of his statements. He makes, however, a remark about Capella which seems really erroneous. He says ("Fasti" v. 113) that she rises on May 1st, *i.e.*, is then first visible in the morning. But at the time when Ovid lived she would, according to the mode of computation used in the previous examples, have risen about 3.0 A.M., while the sun would not have risen until after 5.0. We have a similar apparent mistake in Pliny and Columella, nearly contemporaries, who fix Arcturus' rising for the 23rd or 21st of February. On that day the sun would set at Rome about 5.35 P.M., whereas the star would not pass the horizon before 6.30 P.M. They seem to have copied from Hesiod without any thought. The late Mr. F. Baily, in his edition of "Ancient Star Catalogues," published in vol. xiii. of the *Memoirs* of the Royal Astronomical Society, does not seem to have actually compared the positions there given to any of the principal stars with those which in the present day we must suppose them to have then occupied. As, however, the present rate of change in the obliquity of the ecliptic would have made it in the time of Eratosthenes (230 B.C.) about 23° 43′, whereas that astronomer fixes it roughly at 23° 51′, it is to be hoped that, making allowance for inaccuracies in the MSS., such a process of verification may be attempted with some prospect of success; and possibly some explanation found of Ptolemy's idea that in his time (A.D. 140) the amount of annual *precession* was only 36″.—Mr. J. W. L. Glaisher communicated to the society a ten-figure table of the values of e^x and e^{-x}, with their logarithms from $x = 1$ to $x = 500$ at unit intervals. The table was intended to accompany Prof. F. W. Newman's table of e^{-x}, and will appear with it in the *Transactions* of the Society.

PARIS

Academy of Sciences, June 11.—M. Peligot in the chair.—The following papers were read:—On the densities of vapour; reply to M. H. Sainte-Claire Deville, by M. Wurtz.—On the atomic notation; reply to M. Berthelot, by M. Wurtz.—Second note on the *Nouvelle Navigation* of M. Villarceau, *apropos* of the interior sea of the Algerian Sahara, by M. Naudin. He urges that the result would very probably be an immense pestilential focus. The slope would be slight, and the depth of water in the border of the lake small. A large portion of land would thus be alternately covered with water in the rainy season, and left dry in the summer; and with the mixture of salt and fresh water, bright solar light, and tropical heat during two-thirds of the year, there would be active generation of organisms, the putrefaction of which must corrupt the air all round.—Theory for finding the number of co-variants and contra-variants of order and degree, given, linearly independent of any system of simultaneous forms containing any number of variables, by Mr. Sylvester.—On the rotatory polarisation of quartz, by MM. Soret and Sarasin. They have extended their researches to the ultra-violet radiations, using the light had from induction sparks between cadmium points and applying the spectroscope with fluorescent eye-piece.—Observations on the ovigerous tubes of the Phylloxera, by M. Boiteau.—Results obtained at Cognac since 1875, by the use of alkaline sulpho-carbonates, by M. Monillefert.—On the use of sulpho-carbonates, by M. De Georges.—On a new electric lamp with oblique circular rheophores, by M. Regnier. He was led to this arrangement from having observed that with rheophores meeting angularly the most of the light was emitted at the summit of the angle. The occultations—hitherto inseparable from carbon discs—are suppressed. Each rheophore has its own clockwork movement, and the motors, pivoted, can oscillate with their respective rheophores. One is manœuvred by the operator, who puts the carbons in position; the other, commanded by a solenoid in the circuit, oscillates automatically, bringing the carbons in contact, or separating or approximating them at the proper time.—M. Cance presented a new system of electro-magnets with multiple cores, in which M. Camacho's tubular cores are replaced by small soft iron rods juxtaposed, and enveloping, two by two, the different layers of spiral; this gives certain advantages.—M. Trouvé presented an improved sound for wounds caused by fire-arms.—On the infinitely small displacement of a dihedron of invariable size, by M. Mannheim.—Historical remarks on the theory of motion of one or several bodies, of constant or variable forms, in an incompressible fluid (continued), by M. Bjerknes.—On certain functions, similar to circular functions, by M. Appell.—Comparative study of observations by day and by night; second note, by M. Perrier. He finds that azimuthal observations by night have a degree of precision at least equal, if not superior to that of observations by day, and thinks they should forthwith be introduced into the practice of geodesy.—On the determination of the zenith of a ship or point observed at sea by means of straight lines of height; insufficiency of the zenith or place of the ship called *the most probable*; determination of a point nearest the true zenith, by M. Bertot.—Researches on the use of magneto-electric machines with continuous currents, by M. Gramme. With baths coupled in tension, M. Wohlhill, of Hamburg, got a deposit corresponding to 43 kilogr. of silver per hour, while expending 15-horse power on the machine. M. Gramme describes several experiments by himself of this nature.—Influence of a mechanical action on the production of various hydrates in supersaturated saline solutions, by M. Gernez.—On the new general method of synthesis of hydrocarbides, acetones, &c., by MM. Friedel and Crafts.—Researches on normal propylene, by MM. Reboult and Bourgoin.—Composition of a substance formed on an iron rod altered by a Siemens gas furnace, by M. Terreil. Under the simultaneous action of the oxidising and reducing gases of the furnace, the iron was transformed almost wholly into anhydrous protoxide of iron. M. Daubrée made some remarks on this.—On the asparagine of amygdalene; hypothesis on its physiological *rôle* by M. Portes.

THURSDAY, JUNE 28, 1877

SOLDIERS' RATIONS

THAT Soldiers' Rations are not without influence upon a campaign no one will dispute. It is not enough to have murderous weapons and big battalions to insure conquest nowadays, and in the last two little wars in which this country engaged these were indeed of secondary importance. The Abyssinian campaign, when our troops marched nearly four hundred miles across a rugged and unknown country, has been justly termed a victory of engineering, while the Gold Coast expedition, by reason of the efficient sanitary arrangements which reduced to a minimum the deadly effects of a terrible climate, may be fitly called a doctor's war. No doubt in the case of European struggles, far more depends upon the purely military element; but if the Prussian needle-gun contributed in a great measure to the defeat of the Austrians at Sadowa, it is none the less true that the famous *Erbswurst*, or pea-sausage, of the Germans had much to do with their maintaining the siege of Paris during the long cold winter months of that capital's investment.

It is a little difficult to institute comparison between the nutritive qualities of the rations served out to soldiers in various countries. A soldier in the field, whether marching or fighting, must put forth more muscular energy than in times of peace, and according to Dr. Parkes and other authorities, it is the nitrogen in his food, more than anything else, that is necessary to the activity of the muscle, and this is required in greater quantity in proportion to the increase of work. That hard labour can be performed for some time without any increase of nitrogenous diet is true no doubt, but in this case it is at the expense of the nitrogenous constituents of other parts of the body, in the neighbourhood of the muscle, and it would be impossible for a man to continue such labour for any length of time. Whether the nitrogenous matter he assimilates is contained in meat or bread seems to be a matter of little import. An English soldier who gets a three quarters of a pound ration of meat daily is said to be no better off, as regards the nutritive character of his diet, than a German soldier, whose staple food is rye bread, and this one can well believe, looking at the constituents of the two food-stuffs. Meat from a lean animal, contains but 12·8 per cent. of nitrogenous matter, whereas samples of rye which have been analysed, have been found to contain as much actually as 15·8 of the same body. Moreover, the amount of water in a pound of meat and a pound of bread is a matter that must not be overlooked, for while in the former it amounts to 57 per cent., in the latter case it is only about 40. As, too, a loaf of bread constitutes of itself a very perfect diet, the starch and fat it contains supplying the calorifiant or heat-producing matter necessary in animal food, we may assume that troops fed upon good bread are as well off as those supplied with more costly rations. At the same time it cannot be denied that different climates and different conditions have a vast influence upon dietary, and while British soldiers require a goodly allowance of meat to sustain their energy, the Turk rarely tastes such food from one week to another. In fact, in the Moslem soldier we have the most easily satisfied of beings, so far as the commissariat is concerned. He does not even require bread, but will fight for weeks and months together upon rations of meal or bruised Indian corn, which serves him indifferently for breakfast, dinner, and supper. The Russian has rather better food, although from our point of view his fare may appear frugal enough. Two pounds of black bread and a quarter of a pound of fresh meat, or bacon in lieu thereof, with garlic, salt, and plenty of tea, seem to be the daily rations of the Czar's soldiers, though a coarse sweet bean, known in this country as the locust bean (Johannisbrod), is occasionally, also employed as food. There is no knowing what the composition of Russian bread is, but assuming it to be for the most part of rye or Indian corn, there should be little difference between the nutritive qualities of the rations of the Turks and Russians, supposing, that is, the soldiers in both cases receive pretty well as much as they can eat. There is enough nitrogenous matter to make muscle and bone, as well as sugar and starch, or non-nitrogenous bodies to supply animal heat and to support the respiratory organs. Taking milk as the most perfect food we have for our standard, which may be said to be made up of nitrogenous matter, oil, and sugar, we find that the proportion of nutritive, to heat-producing, or calorifiant, matter, is as one to two. Beans and peas come next in order to milk, the proportion here being as one to three, while in oatmeal it is as one to five, and in rye, wheat, Indian corn, &c., as one to seven or eight. Thus the Turk and the Russian being fed mainly upon rye and Indian corn derive equal benefit from their rations, although the Muscovite soldier gets additional energy, no doubt, from the small ration of meat allowed him.

The highly nutritive character of pea-flour at once points to the *raison d'être* of the pea-sausage of the scientific German soldier. This newly-invented food-stuff consists, as our readers probably know, of peamea and bacon fat, suitably seasoned, and pressed into skins and boiled. The ordinary daily ration of a German soldier is 2 lb. of rye bread and a dinner of soup, which sometimes has a piece of meat floating in it, but generally does not; this, together with a scanty stipend, which barely suffices to buy him a cup of coffee in the morning and a herring, or salted cucumber, to eke out his bread with, constitutes the whole of his allowances. In the last European war, these comestibles were replaced during some portion of the campaign by the *Erbswurst*, and there cannot be a doubt that the health of the Teuton army was improved by a regular and sufficient supply of this suitable food, while at the same time it greatly simplified the commissariat service of the invaders. Butchers, bakers, army ovens, and cooking pontoons were for a while dispensed with, and thus it was possible for corps and regiments to move, when necessary, without a great deal of impedimenta. Moreover, as we have seen, the pea-flour gave that extra nutrition which troops subject to unusual exertion, coupled with exposure to cold and frost required. To the English palate the pea-sausage had an unmistakable taste of tallow, and there is no doubt that all kinds of fat and grease were employed in its production when the supplies of bacon run short. Animal fat of some kind was, however, absolutely necessary to supply the system with heat, and combining the former in this way with pea-flour was a most happy idea. The pea-sausage might either be eaten cold in the condition in which it was issued to the soldier, or made into a sort of soup with boiling water.

And here we may mention a circumstance of especial interest to scientific men, in connection with the manufacture of this new food. The *Erbswurst* was produced in such huge quantities, that it was found to be absolutely impossible to procure a sufficient number of skins and bladders to contain the preparation. All sorts of substitutes were tried. Oiled fabric and vegetable parchment, as well as other waterproof materials were essayed in vain, for an envelope was required which was elastic and unaffected by boiling water. At last a chemist stepped in and solved the problem. He proposed the use of gelatine mixed with bichromate of potash, or in other words the process employed by photographers now-a-days in producing what are termed carbon-prints. It is well known that if a solution of gelatine and bichromate of potash is spread upon paper and exposed to light, the gelatine becomes insoluble in a very short time, and will effectually resist the action of cold or hot water to dissolve it, this principle being in fact that upon which photographic prints are produced, the portions of a surface which refuse to wash away, constituting a picture. This same mixture was used for treating the sausages. The food was pressed into proper shapes and then dipped into the bichromated gelatine solution, after which it was exposed to daylight for a couple of hours, when the gelatine formed a tough skin around it, capable of being boiled with impunity.

Turning to the British soldier we find in him the most daintily fed of all warriors, unless it was the Servian in last year's war. If we are to believe special correspondents, the rations of the Servian soldiers were almost unlimited, and furnished a striking contrast to the fare of the frugal Turks. An oka, or 2½ lbs. of brown bread, half an oka of fresh meat, together with a modicum of rice, meal, and paprika was the daily ration, the last-named comestible being employed for making soup; the *pot-au-feu*, so we were assured, was to be found simmering in camp from early morn till noon, and then only came off to make room for the coffee kettle. The Servian soldiery, too, usually had a ration of spirits called slivovitch, or plum brandy, allowed them, and yet withal they had no such powers of endurance as the maize-fed Turks. In this country a soldier's ration is three quarters of a pound of meat and one pound of bread, which is supplemented in war time by a quarter of a pound of cheese, together with cocoa or tea, sugar, &c. In the Crimea there was a standing order that hot tea should always be kept ready when practicable, so that the men might partake of it at any time, and in the Abyssinian and Ashantee campaigns the camps were never broken up of a morning before the troops had been supplied with a cup of warm coffee for breakfast. Tea and coffee exercise the same effect upon the system as wine and spirits, but their stimulative action is less marked, and our commanding officers are enjoined never to issue a ration of spirit except under extraordinary circumstances, as in the case of distressing marches, or when troops are engaged in the trenches or up at the front. And yet, as we have said, with this apparently liberal feeding, our men do not receive so much actual nourishment or nitrogenous matter as the German soldier, whose mainstay is the 2lb. loaf of black bread he receives daily. The meat, bread, sugar, &c., received by our soldiers in the Crimea yielded, we are told by the Royal Commissioners, but 23·52 oz. of nutritive principle, while Germany gives her soldiers 32·96 oz., which is still further increased when the latter are fed on such highly nitrogenous diet as the pea-sausage. The Turks, poor as their food may seem to us, probably derive as much nutriment from it as English troops from their bread, meat, and cocoa, for weight for weight, the Turkish rations contain more nitrogenous matter. If, too, their meal is what is termed "whole flour" it will, since it includes the husk, contain more nitrogen still, and, like oatmeal, be one of the most generous foods known. Our Scotch troops, we fancy, would be little the worse if fed solely on porridge for a time. The reader may remember Lord Elibank's retort on Dr. Johnson's definition of oats as the food of horses in England and of men in Scotland: "Yes," said he, "and where else will you find such horses and such men?" A growing soldier, hard at work all day at gun-drill, or other laborious work, does not buy extra meat when he is hungry, but foregoes his beer at the canteen for another pound loaf, thus approaching his diet very nearly to that of the German warrior, whom we have shown lives almost entirely on bread and enjoys the most nutritive fare. At the same time it is necessary to bear in mind that the conditions under which a man lives must guide the nature of his food. A man inhabiting a cold climate such as ours, requires more animal food than would be the case if he lived in a country nearer the equator, and British troops, we fear, would loose much of their energy if fed altogether on farinaceous food. But as we have striven to show, it is not always a so-called liberal diet which affords the soldier the greatest quantity of nutriment. H. BADEN PRITCHARD

GEIKIE'S "PHYSICAL GEOGRAPHY"

Elementary Lessons in Physical Geography. By Archibald Geikie, LL.D., F.R.S., Murchison Professor of Geology and Mineralogy in the University of Edinburgh, and Director of the Geological Survey of Scotland. (London: Macmillan and Co., 1877.)

AS our knowledge of natural phenomena widens and our insight into the character and mode of operation of the forces which give rise to these phenomena becomes more profound, we are called upon from time to time to take a new survey of the fields of inquiry and to reconsider the principles on which the useful, but necessarily more or less arbitrary, classification of the natural history sciences is made to depend. To instance a notable example, the time-honoured division of the "three kingdoms in nature" has now, by almost universal consent, been abandoned in favour of a more logical grouping of the objects of natural history science depending on the presence or absence in them of the principle of life, and hence has arisen the term biology to include botany and zoology, while mineralogy, released from an unnatural bond, seeks and finds new alliances with those branches of knowledge, crystallography, chemistry, and petrography, with which it has so many and such intimate relations. Etymological purists have indeed cavilled at the term "biology," and the opponents of change have disputed its *raison d'être*, but it is impossible to deny that its invention was the natural consequence of the growth of juster views concerning the relations of living beings to one another, or that, on account of its fitness, it bids fair to survive all hostile criticism.

Now in the same way that the development of our knowledge of the lowest forms of life has led to the breaking down of the unnatural barriers between the animal and vegetable kingdoms, and the union of all the anatomical, physiological, systematic, and ætiological branches of our knowledge of living beings into the federal republic of biology, so the growth and establishment of a juster geological philosophy has greatly modified, and indeed almost revolutionised, our conception and treatment of certain branches of geographical science.

For more than half a century the principle which demands that the geologist shall interpret the past history of the globe by means of a constant reference to the operations now going on upon its surface, has been steadily gaining ground; and this postulate may now be said to have taken its place as the very cornerstone in all geological reasoning. But if geology has thus to own her dependence on geographical knowledge, she has more than requited her obligations by the new vitality which she has infused into her sister science. It is not too much to assert that the growing conviction of the necessity for a more systematic, a more searching, and a more accurate investigation of the phenomena of the globe and of the forces by which they are produced—a conviction which has prompted the despatch of expeditions for carrying out carefully organised researches both on sea and land—has been to a very great extent created and fostered by the revelations of glaring imperfections in our knowledge of the earth's existing economy which are continually being made by geology.

The work before us is an example of the treatment of geographical questions from the point of view of a geologist, and we are not surprised to find that its author is evidently strongly actuated by the conviction of the necessity for a broader and more vivid presentation of the action and reaction upon one another of the various forces operating upon the surface of the globe, than is usually found in works on physical geography, in order to convey a just idea of the character and significance of the features which it presents. Thus, in the introductory chapter, after referring to that complex interplay of agencies by which the fluid envelopes of the globe are maintained in constant circulation, and the elements of its solid crust made to pass through ever-varying cycles of change—a series of phenomena which has suggested to the profounder thinkers of all ages an analogy between our planet and a living being—the author goes on to say:—

"Now this life of the earth is the central thought which runs through all that branch of science termed physical geography. The word geography, as ordinarily used, means a description of the surface of the earth, including its natural subdivisions, such as continents and oceans, together with its artificial or political sub-divisions, such as countries and kingdoms. But physical geography is not a mere description of the parts of the earth. It takes little heed of the political boundaries except in so far as they mark the limits of different races of men. Nor does it confine itself to a mere enumeration of the different features of the surface. It tries to gather together what is known regarding the earth as a heavenly body, its constitution, and probable history. In describing the parts of the earth—air, land, and sea—it ever seeks to place them before our minds as to make us realise not only what they are in themselves, but how they affect each other, and what part each plays in the general system of our globe. Thus physical geography endeavours to present a vivid picture of the mechanism of that wonderfully complex and harmonious world in which we live."

In that easy and graceful style, of which he possesses so perfect a mastery, the author proceeds in subsequent chapters to give a sketch of those vast fields of knowledge which are opened up to us by this method of looking at the phenomena of the globe. The book is exactly what it professes to be—a series of elementary lessons; but, while it may be read with profit and delight by any fairly-taught schoolboy, it will not be found wanting in instruction and suggestiveness for more advanced students. On some questions, as for example that of the nature and causes of the great movements of the atmosphere, the author has been particularly successful in embodying within a very small compass a mass of information which the student could otherwise gain only by the perusal of a number of special treatises To teachers of elementary science who desire a model on which to frame their lessons for beginners, so as to secure their attention and interest and to arouse the enthusiasm of such among them as are capable of that sentiment, we very heartily commend this admirable little book.

The author points out in a note that the subject of physical geography, as here treated of, is conterminous with that division of science for which the name of physiography has been suggested. The advances made in recent years in the study of physical astronomy and the relations which have been established between celestial and terrestrial objects by the development of spectrum analysis and the study of meteorites, taken in connection with that strongly-felt necessity for a deeper insight into the mode of operation of the forces operating upon the surface of the globe, both from within and without, which geological research has awakened, have independently suggested to many thinkers the desirability of permitting certain portions of natural knowledge to crystallise around a new centre. The importance of this new science thus growing up on the confines of geography, geology, astronomy, and biology, and linking them all together, a science the study of which would form the most fitting preparation for the detailed pursuit of all and each of the natural sciences, was long ago pointed out by Prof. Huxley; and in a course of lectures delivered in 1870 he sought to illustrate the objects and methods of this latest-born member of the family of the natural sciences. In that most excellent of geological text-books, Prof. Dana's "Manual of Geology," the term "physiography" is also employed, in the same sense as advocated by Prof. Huxley. Nor is the use of the term confined to English writers, for in several of the best German manuals of geology, such as Dr. Hermann Credner's "Elemente der Geologie" and Dr. F. von Hochstetter's "Die Erde nach ihrer Zusammensetzung, ihrem Bau, und ihrer Bildung," the necessity of this term physiography is admitted and its use justified. Like the term "biology," that of "physiography" may not improbably meet with some opposition on its first introduction, but as the importance and connection of the branches of knowledge which it embraces become more widely appreciated, the necessity and convenience of the name will doubtless make themselves very generally felt. In conclusion, we cannot part from the little book which has prompted these remarks without taking the opportunity of congratulating the author on his success in presenting to the public, in a form at once compendious and popular, the outlines of this very important branch of science. J. W. J.

THE LABORATORY GUIDE

A Manual of Practical Chemistry for Colleges and Schools. Specially Arranged for Agricultural Students. By Arthur Herbert Church, M.A., Professor of Chemistry in the Agricultural College, Cirencester. Fourth Edition, revised. (London: John Van Voorst, 1877.)

THE fact that Prof. Church's "Laboratory Guide" has reached a fourth edition is a proof that the work has been found useful by that class of students for whom it is specially arranged. Notwithstanding this fact we cannot regard the book as occupying other than a second-rate position in the literature of applied chemistry. The aim of the "Guide" is (1) to place before the student a series of lessons in chemical manipulation in working through which he shall obtain a practical knowledge of "some of the chief truths learnt during the course of lectures on inorganic or mineral chemistry;" (2) to instruct the student in qualitative analysis with especial reference to the analysis of agricultural products; (3) to lay before the more advanced student a number of processes for the quantitative analysis of agricultural substances, food stuffs, manures, &c. The first part of the work comprises a number of fairly well chosen examples in chemical manipulation, preparation of gases, and examination of solid substances. What we should most object to in this portion of the "Guide" is want of method. A few blowpipe experiments are introduced here and there, followed, perhaps, by a short description of one or two rough experiments illustrative of the manufacture of superphosphates; these are succeeded by desultory tests for sugar in milk, by casual semi-quantitative experiments on bread, and so on. To a student without any knowledge of chemistry such a course as that sketched in the first part of the "Guide" may be of use, although we think more care would require to be shown in the selection of experiments; but the book assumes that the student accompanies his practical work by attendance on lectures; surely then the practical course ought, from its very commencement, to be systematic and progressive. The directions given in each lesson are, as a rule, too meagre; without the constant superintendence of a teacher we doubt whether the beginner in practical work could make much progress. In some cases the directions are so vague and inexact as to be positively misleading: witness the method for detecting alum in bread (p. 43). Part II. treating of qualitative analysis has the same failings as Part I.; it is not exact and definite. The author, in his introduction, especially announces that the work is limited in its aim, so that we cannot find fault with him for not including tests for all the metals; but so far as it goes the information given, and the system of teaching pursued, should have been definite, condensed, and such as would train the student in habits of accuracy. No doubt the reactions detailed are true so far as they go; the schemes of analysis are tolerably good, yet there is about it all a slipshod appearance which stamps the work with unsatisfactory character.

The processes of quantitative analysis are chiefly such as are required in the examination of agricultural products, and substances used in manufacturing manures, of a few leading food stuffs, of soils, and of waters. As the author has not wished to produce a large work, he has limited himself to a description of methods of analysis "intended only for the particular case mentioned;" these processes "may fail if . . . . other substances be present than those here supposed." We cannot help thinking that this is exactly what he ought not to have done; if the book is to be a guide to the student, if it does not pretend to the place of an encyclopædic reference book, then processes of *general* applicability, should have been selected, processes which would illustrate the application of the general principles of analysis, not processes which the student is to learn by rote, and which he will therefore come to regard in much the same light as that in which the cook views her book of receipts. Many of the processes, regarded simply as prescriptions, are faulty or very meagre. Who would apply the volumetric Uranium method for determining phosphates in the manner described on pp. 157, 158? Aided only by the description of the volumetric method for determining chlorine given on pp. 159, 160, who could ever hope to perform an exact estimation of that element? From what is said on p. 150 one would suppose that "reduced phosphates" can be readily determined with something like accuracy. Th report of the British Association Committee has shown that no method for even approximately determining these phosphates has as yet been introduced.

The processes for the analysis of milk, cheese, and butter are extremely meagre. Now that we are possessed of really good and reliable methods for analysing these food stuffs, the introduction into a manual of vague and sketchy methods is almost worse than the omission of all methods, whether good or bad.

One point there is in which Prof. Church deserves all praise, namely, the employment of a systematic nomenclature. The system adopted is that first employed in the works of Roscoe, and of Harcourt and Madan, and now adopted in the *Journal* of the Chemical Society, in Watts's *Dictionary*, and in most of the modern treatises. This system, although not slavishly bound down by rule—although it allows one to say *sulphate of zinc* as well as *zincic sulphate*—is founded on certain definite ideas, and has, at the same time, shown itself capable of expansion with the needs of an increasing science.

The system is, moreover, nearly identical with that employed by the German chemists. Prof. Church has done well in making use of it.

OUR BOOK SHELF

Researches on the Glacial Period. By P. Kropotkin. First fascicule. 827 pages in 8vo. With Maps and Woodcuts in a separate brochure. (*Memoirs* of the Russian Geographical Society, vol. vii., 1876.)

THE book consists of two parts. The first is a detailed account of a journey in Finland and a short visit to Sweden, both made in 1871 under the auspices of the Russian Geographical Society, for the special purpose of studying the glacial formations and the *ösar* (eskers or kames). The second part is an inquiry into the meaning and value of various evidences of the glacial period—the striation of rocks, the forms of rocks and mountains, the boulders, the loose deposits, and the moraines and *ösar*. Out of the seven chapters into which this part is divided only the three first (sketch of the development of the glacial theory, striation, and forms of mountains) appear in this fascicule, and the two last (loose deposits and their classification, moraines, and *ösar*) are summarised at length in an Appendix.

The first fascicule is illustrated by a hypsometric map of Finland (southern half) with all known *ösar* shown upon it; by a map of the most interesting, esker Pungaharju, five miles long; by some other maps and sections of less importance; by a section on a large scale of the loose deposits along the Tavastehus-Helsingfors Railway, and by ninety woodcuts, a large part of which are sections of *ösar*.

The main conclusions as to the glaciation of Finland are in accordance with those arrived at by Messrs. Erdmann, Wiik, Helmersen, and Schmidt, viz., that this low table-land, continuous along its north-western and southern borders with two low and flat border-ridges, was covered with an immense ice-sheet which, creeping from Scandinavia, crossed the Gulf of Bothnia, traversed Southern Finland in a direction south by east, crossed the Gulf of Finland and crept further on in the Baltic provinces. The numberless striæ, the positions and directions of which exclude any suspicion of their having been traced by floating ice, the striation on the islands of the shallow gulfs, together with that of the Onega basin, the Neva valley, and the Baltic provinces, the uninterrupted sheet of till, *i.e.*, of a true unstratified and unwashed morainic deposit covering Finland, the numberless moraines parallel to the glacial striæ, and hundreds of other evidences, settle the existence of such an ice-sheet beyond any doubt. As to traces of marine formations, there are none above a level of about 100 to 120 feet; only local lacustrine deposits cover the till above this level.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Indian Rainfall and Sun-spots

I HAVE observed no notice in NATURE[1] of an important discussion which took place a month ago at one of the Royal Society's meetings on Dr. W. W. Hunter's report on the cycle of rainfall in India, and its coincidence with the periods of eleven years disclosed by sun-spot observations. As one interested in solar research I have carefully considered that report, and I think the author has made out a case within the limits which he assigns to himself. The application of the mathematical law of errors has not altered this opinion in my mind, and from a consideration of the whole subject I have been led to the following conclusions:—In the first place I would remark that in certain meteorological elements, of which the rainfall throughout the world is probably one, and the barometer *in these latitudes* is another, oscillations which we regard as non-periodic, are very large compared with periodic variations. The consequence will be that in dealing with a series of barometric observations in these latitudes, the mean difference of individual observations from the mean of the whole series, or in other words, the mean irregularity, will not be materially modified by the introduction of the comparatively small semi-diurnal variation. But this is no argument against the existence of such a variation, nor is the fact that at Madras the mean rainfall irregularity is not *greatly* reduced by the introduction of an eleven-yearly cycle any argument against the existence of such a cycle. As a matter of fact, this mean irregularity *is reduced, although perhaps not very markedly*, by the introduction of this cycle. The true test of a physical cycle is its repetition, and, since in the present important aspect of this question we cannot, perhaps, calmly wait for other sixty-four years' observations before venturing a conclusion, let us now endeavour to break these sixty-four years up into periods, and see whether we obtain any traces of physical persistence from this method. Grouping, as Dr. Hunter has done, the sixty-four years' Madras rainfall into series of eleven years, beginning with the first in 1813, we obtain the following table:—

Years employed.	Year of Series.										
	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.
A. 1813–23	45·11	32·41	56·00	41·16	63·56	76·25	36·33	70·01	47·13	59·61	26·62
B. 1824–34	33·72	56·05	60·73	88·41	37·89	36·87	32·43	44·35	18·45	37·11	39·00
C. 1835–45	41·47	44·76	49·26	52·33	53·07	58·65	58·32	36·48	50·28	65·36	38·05
D. 1846–56 ...	79·81	80·99	54·76	39·81	36·88	64·32	72·69	35·82	43·20	32·32	46·99
E. 1857–67 ...	52·95	48·50	55·14	27·64	37·19	38·18	54·61	47·23	41·64	51·39	24·37
F. 1868, end.	41·43	32·31	74·10	56·35	73·67	51·83	62·90	37·12	21·49		
Whole period.	49·1	49·2	58·3	50·9	50·4	54·4	52·9	45·2	37·0	49·2	35·0

In this table 3, 4, 5, 6, 7 embrace the maximum rainfall group, and 8, 9, 10, 11 the minimum rainfall group, and the sun-spot maximum occurs generally about the beginning of 3, and the sun-spot minimum a little before 11.

We have, therefore, taking the means of the five maximum rainfall years a result = 53·4 for the whole six series, and also, taking the means of the four minimum rainfall years, a result of 41·6 for the whole six series.

But we can obtain similar results for each individual series as under:—

		Max. Group.		Min. Group.
Series A	...	54·7	...	50·8
B	...	51·3	...	34·7
C	...	54·3	...	47·5
D	...	53·7	...	39·6
E	...	42·6	...	41·2
F	...	63·8	...	29·3 (incomplete.)

We have thus considerable evidence of repetition. In connection with this it will be interesting to see if there is any other physical difference indicated between years of maximum and minimum spots besides mere difference of rainfall. Now a very interesting additional peculiarity has been indicated by General Strachey, who has observed that the conception of a cycle of eleven years introduces a decidedly diminished mean cyclical deviation for the minimum period. General Strachey has, no doubt, likewise remarked that this is not chiefly due to those particular years that are nearest the sun-spot minimum. I do not, however, see that we have any right in tracing a connection between solar epochs and rainfall values to insist that the minimum of the one shall correspond absolutely with the minimum of the other, and the maximum of the one with the maximum of the other. In conclusion, the fact that the introduction of a solar cycle diminishes considerably the deviation for minimum years is one of very great interest, since it is these very years that have become so practically important. I trust, therefore, that further attention will be devoted to this very interesting inquiry.

BALFOUR STEWART

[1] See abstract of Gen. Strachey's paper on another page.

Natural History Museums

I AM sure that many readers of NATURE will heartily thank Prof. Boyd Dawkins for his valuable articles just published in your journal on the need of establishing natural history museums in the principal towns of our country. The ideas set forth cannot fail to be reciprocated by a largely increasing number of students who, like myself, are suffering under the disadvantages of not having local museums for reference and in which to compare specimens and examine the various natural history objects which I wish to study. In addition to a museum, I think such buildings should contain lecture-rooms specially fitted up for scientific lectures, as the value of able discourses is frequently lost for want of clearness in illustration.

The professor cannot over-estimate the value of museums, as every lover of natural history cannot be a collector; but every one in full possession of his faculties can observe so far as he has the power of seeing, and if he cannot examine the wide field of nature for facts he will at least examine the proofs of them in the museums, if at hand.

A few personal observations may serve to show the difficulties under which the so-called working classes have to labour in the pursuit of knowledge.

Some years ago I began to study the works of Sir C. Lyell and other authors on geology, and while so engaged I many times travelled eighteen miles after a hard day's work to compare specimens in the old museum, St. Peter's Street, Manchester. I had tabular views of the characteristic British fossils at hand, but as perfect specimens only are figured, I experienced a doubt and uncertainty pretty nearly in everything I wanted to compare, while in the museum I could find the actual specimen sought after with which to correlate those of my own. The flash of satisfaction experienced by a collector on comparing his objects with those in a well-arranged museum is indeed very great, and there are few things more likely to stir him up to renewed efforts. But the interest of museums is not confined to the collectors of natural history objects; it extends to every man who reads and cares to master the objects about which he reads. In this way his knowledge of things becomes real and he expresses himself with confidence, and in many cases has decided while others are thinking. To show further the need of museums I may state a fact perhaps not generally known, that in one place in the north of England a large number of science students have formed themselves into an itinerant society moving from place to place to suit the convenience of the various members who reside apart. The meetings are generally held at a respectable inn on Sunday evenings, at which papers are read by the more ambitious members, and any interesting objects named, which some of the party never fail to bring up, and their habitat declared.

If the corporate bodies or the educational department of the State would only undertake to provide museums in the principal towns of our country I feel sure that the cry of continental superiority would soon vanish. At home we have the materials out of which the philosopher and the artisan can spin the fibre of future greatness by rightly directing the forces of nature, but the isolated fragments want collecting and receptacles providing in which to store them. Many lives like that of the Banff naturalist could be written if only known, and Prof. Dawkins could not have fixed on a centre of operation more favourable from which to begin than that of Oldham. Men more selfishly removed above praise, working for science for its own sake, he cannot find, and it is a pity that they have not a common repository in which to store their invaluable collections beyond their own full cabinets. I hope the professor's articles will be a means of calling attention to the desirability of establishing museums for the better diffusion of scientific knowledge.

I write from the point of view obtained by my own experience as a working man who has done his best to educate himself.

WM. WATTS

Corporation Waterworks, Oldham, June 16

Koenig's Tuning Forks

ON vient d'attaquer en Angleterre l'exactitude du diapason officiel français. Mr. Alexander J. Ellis ayant trouvé que les notes d'un tonomètre, composé de 65 anches d'harmonium et construit par Mr. Appunn, ne s'accordaient pas avec ce diapason, a cru devoir déclarer dans un mémoire publié par le *Journal of the Society of Arts* (25 Mai, 1877), et dans votre journal (31 Mai, 1877), que le La_3 normal français donnait non pas 870 vibrations simples, comme on l'avait cru jusqu'à présent, mais bien 878 vibrations simples.

Mr. Ellis ayant constaté de plus que les diapasons de ma construction s'accordaient parfaitement avec le La_3 français, n'a pas hésité à affirmer que tous ces diapasons, y compris ceux de mon grand tonomètre, qu'il n'a probablement jamais vus, et en tout cas jamais pu examiner, étaient nécessairement inexacts. N'ayant pas à ma disposition l'instrument dont s'est servi Mr. Ellis, j'avoue que je me serais trouvé assez embarrassé pour dire immédiatement, par où péche cet instrument au point d'avoir donné entre les mains de Mr. Ellis des résultats si extraordinaires; heureusement je me suis rappelé une lettre de M. Helmholtz à Mr. Appunn et publiée par ce dernier lui-même dans une brochure sur les théories acoustiques de M. Helmholtz; cette lettre concerne justement un instrument de même nature du même constructeur et explique suffisamment les surprenantes découvertes de Mr. Ellis. "J'ai examiné à plusieurs reprises votre tonomètre," écrit M. Helmholtz à Mr. Appunn, "et je suis étonné de la constance de ses indications. Je n'aurais pas cru que les anches pussent donner des sons aussi constants que ceux que donne l'appareil, grace à votre méthode pour régler le vent. L'instrument varie un peu, il est vrai, avec la température, comme feraient aussi des diapasons; on ne peut donc s'en servir pour la détermination des nombres absolus de vibrations que lorsqu'on peut travailler dans une pièce qui n'est pas chauffée par un poêle. J'ai compté les battements à l'aide d'un chronomètre astronomique, et je crois que votre pendule à secondes a été légèrement inexact, car, si les nombres de battements s'accordent très bien entre eux, le nombre absolu en a été non pas de 240, mais de 237 à la minute. La température, qui était assez basse pendant mes expériences, a pu y être pour quelque chose, mais on peut éliminer cette influence en comptant jusqu'au bout les battements d'une tierce majeure, ce qui m'a pris un quart d'heure. J'ai trouvé ainsi pour mon diapason de Paris 435·01 vibrations, ce qui l'accorde à $\frac{1}{40,000}$ pris avec le nombre officiel de 435·00 vibrations."

Cette lettre prouve que le nombre entier des battements de l'octave du tonomètre essayé par M. Helmholtz était de $\frac{237}{60} \cdot 64 = 252 \cdot 8$, et sa note fondamentale de 505·6 vibrations simples au lieu de 512 vibrations simples. En comparant cette note de 505·6 vibrations simples avec un diapason donnant réellement 512 vibrations simples, Mr. Ellis eût trouvé ce dernier de 6·4 vibrations simples plus aigu, et l'eût sans doute considéré comme donnant 518·4 vibrations simples. Or il a trouvé 516·7 seulement pour mes diapasons de 512 vibrations simples avec le tonomètre dont il s'est servi; on voit donc que la note fondamentale de ce dernier était déjà plus exacte que celle du tonomètre examiné par M. Helmholtz puisqu'elle donnait 507·3 vibrations simples mais qu'elle restait encore assez loin de la véritable valeur.

Le fait que M. Helmholtz a pu trouver le nombre de vibrations exact du diapason officiel français avec un instrument de cette nature (et même encore moins parfait que celui dont s'est servi Mr. Ellis), en déterminant d'abord la correction de cet instrument, montre à l'evidence que Mr. Ellis a négligé de déterminer la correction du sien; il s'est donc beaucoup trop hâté de déclarer que ces petits tonomètres à anches d'harmonium sont les plus parfaits et les plus exacts qui existent, et de contester si légèrement les résultats obtenus par les Lissajous, les Despretz, les Helmholtz, les Mayer, etc., etc.

RUDOLPH KOENIG

Paris, le 5 Juin

Antiquity of Man

MR. SKERTCHLY is absolute that I am mistaken; to me it appears that he has missed the point of my letter, and misinterpreted my views. His important discoveries of flint implements in early glacial beds are, I think, strongly corroborative of the opinions I expressed in my paper on the "Drift of Devon and Cornwall" (*Quar. Journ. Geol. Soc.*, vol. xxii. p. 88), and in that on the "Geological Age of the Deposits containing Flint Implements at Hoxne" (*Quar. Journ. Science*, July, 1876); but I willingly admit that in the present stage of the inquiry Mr. James Geikie has as much right to claim that they support his theory, and I agree with the latter that it is premature to discuss the relation of man to the glacial period, before we have settled what was the succession of events that occurred at the time.

Mr. Geikie contends that there were two or more glacial periods with inter-glacial warm or mild ones; I, that there was only one glacial period and that the disappearance of palæolithic man from Northern Europe was principally due to the submersion of the greater part of the land beneath the water of an immense freshwater lake or sea, at or a little before the culmination of the ice age. If Mr. Geikie's views should be ultimately accepted, the term "inter-glacial" will be most appropriate; but should, as I hope and believe, mine be proved to be nearer the truth, I should prefer to use the term "pre-diluvial" instead of "pre-glacial," as heretofore, to express the age of palæolithic man.

THOMAS BELT

The Cedars, Ealing, June 22

WILL you kindly allow me to correct an apparent breach of official etiquette and act of discourtesy in my last week's letter? I should have said that only two geologists prominently interested in the question at issue had seen my evidence; for, of course, Mr. H. W. Bristow, F.R.S., Director of the Geological Survey of England and Wales, has been kept fully *en rapport* with my work, and has several times visited me at Brandon. I am anxious that no statement of mine should appear to slight so eminent a geologist and so considerate a friend.

Brandon SYDNEY B. J. SKERTCHLY

Colour-Sense in Birds—Blue and Yellow Crocuses

UNLESS your readers are quite tired of the subject, may I add a fact which will be subversive of a good deal that has been written about yellow crocuses and sparrows. I dislike yellow crocuses, and four seasons since planted some hundreds of blue and white in the garden underneath my windows. For two seasons they flowered in beautiful profusion. In 1876 the sparrows for the first time destroyed these flowers completely. I allowed the roots to remain for another year—viz., 1877—but they suffered the same usage, hardly a single flower being left uninjured. So complete was their destruction that I have had the roots dug up.

I regard the proceeding as an imitative one; blue and white crocuses, not being common in the vicinity, were new to the sparrows, and until one more experimental than the rest attacked them they were safe.

A similar result will occur with domestic pigeons; if reared exclusively with small grain, as wheat and barley, they will starve before eating beans. But where they are thus hungry, put a bean-eating pigeon amongst them, and the habit is immediately propagated.

I have seen fowls refuse maize at first, but on seeing others eat it, they follow suit, and become excessively fond of it.

W. B. TEGETMEIER

Purple Verbenas

HAVING now read for the first time the letters in NATURE regarding the preference that sparrows show for the yellow crocus, it might perhaps help to elucidate the problem were it known that the choice of colour is not only confined to birds, as a few years ago our garden was infested by rabbits and there was a row of eight beds planted in turn, with white, red, and purple verbenas. The flowers of the red and white were eaten close off, whilst those of the purple were never touched. This happened three years running, since which, the garden, being protected by wire netting, has remained undamaged.

A. M. DARBY

Japanese Mirrors

YOUR correspondents, Messrs. Atkinson, Highley, and Darbishire, have referred to several conjectures and experiments respecting the curious Japanese mirrors and the patterns they reflect. None of these gentlemen have, however, referred to the suggestion offered by Sir David Brewster in the *Philosophical Magazine* for December, 1832. In this paper Sir David drew attention to some similar phenomena in the light reflected from the surfaces of burnished buttons of metal, arguing that in the mirrors (of which at that time he apparently had seen no actual specimen) there were slight actual inequalities of surface, artificially produced, but concealed from observation by their slightness of depth and by the brightness of the polish. This, of course, may be independent of the particular figures raised in relief on the back, as in the case cited by Mr. Darbishire; and so thought Sir David, for he added:—

"Like all other conjurers, the artist has contrived to make the observer deceive himself. The stamped figures on the back are used for this purpose. The spectrum in the luminous area *is not an image of the figures on the back.* The figures are a copy of the picture which the artist *has drawn on the face of the mirror*, and so concealed by polishing that it is invisible in ordinary lights, and can be brought out only in the sun's rays."

I trust Mr. Atkinson may be able to learn in Japan the real process of manufacture of these curious toys. Meanwhile are there not specimens in many of our museums that would repay examination? Were there not some amongst last year's exhibits at the Loan Collection of Scientific Apparatus?

NOTE ON THE ELECTRICAL DISTURBANCE WHICH ACCOMPANIES THE EXCITATION OF THE STIGMA OF MIMULUS LUTEUS

MANY years ago my attention was drawn to the excito-contractility exhibited by the lipped stigma of *Mimulus luteus*, the structure of which I then gave an account of in the *Proceedings* of the Edinburgh Botanical Society. In connection with my recent investigation of the excitatory variation in *Dionæa* I have, during the last few weeks, in co-operation with Mr. Page, made experiments for the purpose of ascertaining whether in this organ, as in the leaf of *Dionæa*, the change of form provoked by mechanical stimulation is accompanied by a similar electrical disturbance.

Mimulus luteus is a favourite window plant on account of its showy flowers and the facility with which it can be cultivated. The mechanism of the contraction of the stigma can be best studied in the inferior of the two lobes, of similar size and form, of which the organ consists. In the unexcited state, when the flower is in full bloom, this lobe is curled outwards. The curling outwards is due, as I long ago observed, to the turgidity of the layer of loosely connected conducting cells, ending in papillæ, which constitute the stigmatic surface. So long as this tissue is turgid the elastic lamina by which it is backed is prevented from straightening itself, so that the whole lobe forms a scroll of which the axis is transverse. The effect of touching any part of the lobe, and particularly the papillary surface, is to diminish the turgidity of the tissue, as the result of which the organ slowly expands so as to face and ultimately meet its fellow.

The excitatory change of form which I have described is, as in the case of *Dionæa*, associated with an electrical disturbance of which the following are the most important features:—(1) The sign of the variation is the same as in *Dionæa*, the excited structure becomes negative to the rest of the plant. (2) The extent of variation is somewhat less than in *Dionæa*, the electromotive force developed between the stigma and style being usually about 25-thousandths of a Daniell, whereas in *Dionæa* the variation may amount to from 40- to 50-thousandths. (3) The variation is of relatively long duration; it reaches its maximum at the ordinary temperature of summer, about five seconds after excitation. It subsides at first rapidly, then very gradually, so that the effect may not have entirely passed off until two or three minutes have elapsed.

As in *Dionæa*, the period of electrical disturbance is shortened by increase of temperature. Thus in five stigmas in which the period was measured at 20° C. (68° Fahr.) and at 37° C. (98° Fahr.), the mean duration of the interval of time between the commencement of the electrical disturbance and the moment at which it began to subside was 6·2 sec. at the higher temperature, and 3 sec. at the lower.

In general, the stigma, when in the unexcited state, is positive to the style. As, however, it can be shown that other factors, not concerned in the excitatory process, are operative in the production of this result, not much importance is to be attached to it.

I send this short note in order that physiologists interested in the subject may be able to repeat the observations during the present season.

University College, June 27 J. BURDON-SANDERSON

TAUNTON COLLEGE SCHOOL

THE circumstances alluded to last week, under which the Taunton College School is threatening to collapse, and is in immediate danger of losing the head-master who has made it what it is, are interesting on public grounds to the advocates of scientific instruction, as well as to the general educationalist. In a pamphlet published in 1865, and containing letters from Dr. Daubeny, Prof. Phillips, and Dr. Acland, Mr. Tuckwell was, we believe, the first English schoolmaster to assert publicly the claims of science to an honoured place in the curriculum of all first-class schools; and his evidence before Lord Taunton's Commission, his papers read to the British Association in 1869 and 1871, and his communications to the Royal Science Commission, show how diligently he has for twelve years past been working out in his school at Taunton the many practical problems which beset the introduction of a new subject into an ancient, established, jealous system. The school has thriven in his hands, risen rapidly in numbers, and gained the highest public distinctions at the Universities, the India Civil Service, Cooper's Hill, and Woolwich; and though the short-sighted economy of his governing body left him for years without a science master or a laboratory, and refused him a museum, botanical garden, and science class-rooms, he has overcome all these difficulties by patience, by the munificence of friends, and by pecuniary sacrifices; and at this moment many distinguished scientific visitors are glad to testify to the completeness of a system which passes the whole school through a course of physics and chemistry, and includes physical geography, botany, and meteorology in its more special training. In 1875 the number of boys had risen to 120, but the thrift of the governing body kept down the number of the masters. The typical proportion of assistant-masters to boys in modern schools of this size is one in sixteen; the Taunton masters were only one in twenty-seven. The school could not continue to succeed under this policy; the masters were unequal to the work; the number of boys fell off until a visitation of fever brought them below the paying point, and the school, already heavily in debt, was on the point of being closed. The panic-stricken officials laid the blame upon the head-master; his theology and politics were pronounced suspect; his unpopularity had caused the falling numbers; and when his friends came forward liberally with money and promises of money the governing body took the money, but upon condition that the head-master should leave at Christmas. Against this parents and old pupils are indignantly remonstrating; both have sent to Mr. Tuckwell public addresses of sympathy and confidence; the parents forwarding also a strong protest to the president of the governing body, and in many cases threatening to remove their sons if Mr. Tuckwell goes. So far, however, the custodians of the school's interests show no sign of yielding; it seems certain that the head-master will be turned out, and more than probable that the school may, after all, collapse.

There are two points in this struggle between philistinism and culture on which we should like to dwell, in the interests both of general and of scientific education. The first is the mischief being worked in the less important first-class schools by the constitution and habits of their governing bodies. These were the pet institutions of the Endowed Schools' Commission. They were to include the educated gentleman of the county and the representative tradesman of the town: the first, rich in recollections of Eton and of Christ Church, was to initiate, develop, control; to support and instruct the head-master; and to keep his *bourgeois* brother straight; while that second-rate but docile coadjutor was to back the enlightenment of his superior, and to reconcile while he typified the democratic feeling so essential, it was thought, to the local popularity of a school. Charming in theory, it was in fact the weak point in the Commissioners' scheme. The feet on which their image had to stand were of iron mixed with miry clay; the two refused to coalesce, and the clay came uppermost. The gentlemen make admirable governors, but they are in London, in Scotland, on the Continent, at Quarter Sessions; and the local men, who are always on the spot, become virtually the governing body. They too frequently know nothing of education. They cannot understand a head-master's ideas and aims; they in too many cases govern the school as if it were a workhouse, and treat the head-master as they habitually treat the master of their union. The world has not forgotten Felsted Grammar School; and the committee of head-masters could tell us of many other cases, less notorious, but not less galling and mischievous. No first-class school can thrive unless its governing body is composed of gentlemen, who understand, as Mr. Walter said the other day at Wellington College, that their first duty is not to interfere with the head-master.

The second point is one which we have often urged before: the opposition offered by many of the clergy to the *Culturkampf*. Of course there are notable exceptions to this incrimination; but the *Viri Obscuri* of Revellius, and the clerical bigots who combined to oppose the new learning of Colet, Erasmus, and More, would recognise their legitimate posterity in those of the present day, who, themselves uneducated even according to the narrow standard of the past, join in denouncing science and unsectarianism as the irremissible sins of a head-master. Bishop Fox, the founder of the ancient school at Taunton, was rattened by the Oxford clergy for forcing the new study of Greek upon his college of Corpus Christi; his representative in Taunton shares his fate to-day, driven from the school which he has refounded for forcing on it the new study of science.

We write in no hope of assisting the head-master, or of educating his opponents into large-mindedness. Mr. Tuckwell will see his schemes collapse, and be parted from the profession in which all eagerly attest his success, and to which he has given the best years of his life. The school will either break up under the irritation of the parents, or its distinctive features will perish with the ruler who called them forth. The order of the old teaching, the assertion of the old theology, will resume their way in Taunton School. Chemistry, and physics, and botany; Shakspeare, and Milton, and Macaulay, and Guizot, will give way to gerund-grinding and Latin verse. Where Wesleyans, Independents, Quakers, Catholics, and Unitarians worshipped in the same chapel and attended the same scripture-classes, sectarian exclusiveness will re-enter its swept and garnished home. We can only chronicle the facts as indicating the obstacles to be met and reckoned with by the pioneers of modern educational progress. We can only express sympathy with the head-master, who will yet find some compensation for his worries in the unusual warmth of testimony contained in the address which first brought these circumstances to our knowledge, and in the consciousness that, having advanced a noble cause, his work will not in the end be thrown away.

ON DROPS

AMONG the many ways in which electricity is called in to give assistance in various physical investigations, one of the most elegant and interesting is the application of the electric spark to render momentarily visible a body that is rapidly moving or changing its form. The duration of the electric spark is so short—probably not more than $\frac{1}{24000}$ of a second—that a body, such as a rotating wheel or oscillating rod, moving in a dark room with extreme rapidity, will, if illumined by an electric spark, seem stationary, since the wheel or rod has not time to change its position appreciably during the short instant for which it is visible. If the spark be bright, the impression is left on the eye long enough for the attention to be directed to it, and for a clear idea to be formed of what has been seen.

The writer of this article has recently applied this method to watching the changes of form in drops of various liquids falling vertically on a horizontal plate. As usually seen, a drop of water falling from a height of ten or twelve inches on a smooth solid substance, such as glass or wood, seems to make an indiscriminate splash. The whole splash takes place so quickly that the eye cannot follow the changes of form; the impression made by the last part of the splash succeeding that of the first part so quickly as to confuse it.

A little careful observation, however, shows that the drop passes through very definite symmetrical forms, and that a splash is by no means an irregular hap-hazard phenomenon.

Let the reader let fall a few drops of milk, about $\frac{1}{4}$ inch in diameter, on a smooth dark surface of wood or paper, from a height of, say, six inches (milk is better than water, as it is easier to see, especially on a dark ground); he will observe that the liquid makes a blot with a more or less regular undulated edge, but the splash is too quick to follow with the eye.

Let him now substitute a drop of mercury for the milk. By watching the splash very intently he will be able to catch a glimpse of the mercury spread out in the symmetrical star-like form of Fig. 11*a* of Set 2. After the drop has been thus spread out it recovers its globular form, since the mercury does not wet the plate. On increasing the height of fall a few inches, it will be noticed that small drops split off in a more or less complete circle, and are left lying on the plate, while the rest of the drop gathers itself together in the middle of the circle.

The chief reason why these appearances could not be seen with milk is that the milk wets the glass or wood and sticks to it, while the mercury does not. But by smoking a slip of glass or card tolerably thickly in the flame of a candle we get a finely-divided surface of lamp-black to which the milk does not adhere any more than the mercury, and by very careful watching we may notice that the same radial star is formed by the milk, but it is much more difficult to catch sight of than the mercury star. But if the mark on the lamp-black be examined after the drop of milk or mercury has rolled away it will be found to consist of delicate concentric rings with numberless fine radial striæ where the smoke has been swept away. These may be seen very well by holding the glass plate up to the light if it has not been too thickly smoked.

The marks thus made are very beautiful and symmetrical, and it will be found, if the glass be uniformly smoked, that the same-sized drops of the same liquid falling from the same height will produce almost exactly similar marks: while if the height be changed the mark on the lamp-black will be somewhat changed; and it is a fair inference, if each drop makes almost exactly the same complicated, symmetrical mark, that the splash of each drop takes place in almost exactly the same way.

The glimpse that may be caught of the drop in the way described is obtained when the drop is really almost stationary, having flattened itself out on the plate and being on the point of contracting again to its original form.

That a drop if so flattened out will recover itself is seen on pressing down a drop of mercury with the finger or a drop of water with a piece of black-lead or other substance to which it does not adhere. On removing the pressure the drop springs back to its old form; the force which causes this being exerted by the curved surface of the liquid at the edge of the flattened drop, on the liquid within. The flatter the drop becomes the greater is the curvature of the edge and the greater the corresponding pressure tending to restore it to its original globular form. The extent to which a drop that has fallen on a plate will spread out depends on the velocity with which it strikes the plate, *i.e.*, on the height of fall; so that as long as the drop returns to the globular form the whole phenomenon of the splash may be regarded as an oscillation similar to that of a pendulum; the velocity of the liquid outwards being checked, overcome, and finally reversed by the ever-increasing pressure of the curved edge, just as a pendulum has its velocity checked, overcome, and finally reversed by the action of gravity.

It is only when the height of fall is very great that the liquid flies off in all directions and the splash ceases to be an oscillation; this case corresponds to that of a simple pendulum started with a blow so violent as to break the string.

But the liquid star and the complicated pattern on the smoked glass show that the splash is not a simple spreading out of the drop equally in all directions to return again.

In order to observe the form of the drop at any given instant during the splash, it is necessary to make use of the electric spark and to take advantage of the fact that drops of the same size falling from the same height will all behave in the same way.

It will be necessary to let a drop, say of mercury, fall on a plate in comparative darkness, and to produce a strong spark at the instant the bottom of the drop comes in contact with the plate, and so illumine it; the observer will then see the drop in the form it has at that instant.

A second drop must be let fall in the same way, and be illumined by the spark not at the first moment of contact, but a shade later, say $\frac{1}{100}$ second later, when the drop will have spread itself out slightly on the plate, and similarly we must illuminate a third drop a shade later than the second, and so on. The observer can, after a little practice draw from memory on each occasion the drop in the form in which he has seen it. It will be seen that the process consists in isolating consecutive phases of the splash from those that precede and follow, and which take place in darkness and so do not confuse what has been seen as they would do in continuous daylight.

The device adopted by the writer for so timing the appearance of the spark as to illumine the drop at any desired phase of the splash consisted essentially in breaking the current of an electro-magnet at the instant the drop began to fall; the magnet thus ceasing to act, releases a spring which immediately begins to pull the terminal wire of a strong electric current out of the other terminal, which is a cup of mercury, and the strength of the spring and the depth of immersion of the wire in the mercury are so adjusted that the wire leaves the surface of the mercury, and the required spark is produced at the instant the drop reaches the plate.

For the next drop the spark is made to appear a shade later, either by slackening the spring or increasing the depth to which the terminal wire is immersed in the mercury.

The following figures have been drawn in the way described, and show the behaviour of a drop of mercury about $\frac{1}{7}$ in. in diameter, falling from a height of about three inches on to a glass plate. Each figure represents a rather later stage of the splash than the preceding.

Set 2 was drawn from the final stages of a milk drop, ¼ in. in diameter, falling 4 in. on to smoked glass; but the forms are almost identical with those of mercury. Of this set I*a* and II*a*′ are vertical central sections of the middle part of the drop, while II*a* and III*a* are alternative forms of II and III.

From the ends of the rays of Fig. 4, usually twenty-four in number, small drops often split off. These are not

shown in the figure. One of the most curious features of the phenomenon is the transition from twenty-four rays to twelve arms, shown in Fig. 5. The beauty of many of the forms, especially of the ridged shell-like form shown in Fig. 4, when composed of shining quicksilver apparently rigidly fixed, is very striking. Very similar forms are obtained with milk, but whether with milk or mercury are liable to occasional variations. For a more detailed account the reader is referred to the *Proceedings* of the Royal Society, Nos. 174 and 177, 1876-77.

A. M. WORTHINGTON

CHEMICAL NOTES

On Errors in the Determination of the Densities of Mixed Vapours.—In the *Compt. Rend.*, lxxxiii., Messrs. Troost and Hautefeuille record some experiments made by them to discover the error which occurs in determining the vapour-density of substances by the application of the law of Dalton on the tension of mixed gases, and Boyle and Gay-Lussac's laws, as applied to a mixture of the vapour examined, either with air or with some other vapour. They examined a mixture of carbon and silicium chlorides, using a modified form of Gay-Lussac's vapour-density apparatus. On increasing the amount of carbon chloride, the tension of the silicium chloride diminished. The vapour-density of silicium chloride alone varied only from 5·94 to 6·0, but in presence of carbon chloride was found to increase 6·27 to 8·2.

On the Properties of Ruthenium.—In the same journal an account is given by Messrs. St. Claire-Deville and H. Debray, on the physical and chemical properties of the above metal. They find that the metal forms an oxide RuO_3, thus differing from osmium. By fusing the pure metal with potash and saltpetre, then saturating the ruthenicate thus formed with chlorine, and distilling in a current of the gas at about 80° C., they obtain the tetraoxide RuO_4 in yellow crystals, which, when reduced, yields the pure metal. The metal they obtained by purification from its alloy with zinc, was found to have a density of 12·261 at 0°. They also obtained a compound, $Ru_2K_2O_8$, in black crystals, on saturating the ruthenicate of potash with chlorine. For the analysis of ruthenium ores, the process they employ is based on the foregoing remarks. After the fusion of the ore with saltpetre and potash, the whole mass is distilled with chlorine, the excess of gas, together with the RuO_4, being absorbed by solution of potash. The potash solution is then treated with alcohol which precipitates the ruthenium as oxide, and this is finally reduced to the metallic state with hydrogen.

Aconitic Acid in Cane Juice and Raw Sugar.—In a late number of the *American Chemist* an account is given by Dr. Arno Behr of some experiments he has conducted on the above subject. For examining the properties of this acid he has found the so-called melado a proper material, this substance being merely cane juice boiled down to a concentration such as allows the sugar to crystallise out, the mother liquor being then drawn off and used for the production of the acid. The author has analysed an acid substance formed by decomposing its ammonia compound with sulphuric acid and extracting with ether, and assigns to it the composition $C_6H_6O_6$. He has also prepared silver, calcium, and ammonium salts of the acid body, the per centage composition of these salts agreeing closely with the theoretical composition of the silver, calcium, and ammonium aconitates. Although from the results of his analyses he has no doubt of the substance in question being aconitic acid, yet the melting point, 172·173° C., which he found was not in accordance with that generally given, viz., 140° C.*; the author therefore prepared some pure acid which had a melting point of 168-169° C. The acid formed from aconitine fused at 165° C. It is difficult, however, to determine the melting point as the acid is decomposed in the process of melting. The author has found the melado to contain 0·149 per cent. of aconitic acid. The sweet waters from charcoal filters used in refining raw sugar contain it in an appreciable quantity, and some molasses sugars give a peculiarly opaque solution from which a sandy sediment is deposited, appearing under the microscope to consist of small rhombohedral crystals, and which, on analysis, proved to be calcium aconite. The author thinks aconitic acid to be a normal constituent of sugar, and that it is worthy of remark that the two plants yielding the most sugar—the beet-root and sugar-cane—also produce two acids standing so chemically near each other as citric and aconitic acids, and which contain in their molecules the same number of carbon atoms as fruit sugar.

Minerals containing Columbium from New Localities in the United States.—Mr. J. L. Smith, of Louisville, has examined several species of minerals containing columbium, and claims the restoration of this name for the metal instead of that of niobium, generally given to it in England and on the Continent. His reason for making this reclamation is that the name niobic acid was incorrectly given by H. Rose to one of the acids found by him in his researches on the columbite of Bodemais, and subsequently proved by him to be identical with the columbic acid originally discovered by Hatchett in 1801. The name niobic acid, however, given by Rose, has never been altered, and Mr. Smith thinks the original columbic acid should have been retained. In remarks on the chemical constitution of the minerals described by him, Mr. Smith thinks that the composition of the columbates, although appearing at first sight complex and irregular, becomes much simpler when due allowance is made for the intermixture of the different varieties with each other. Columbite, the best known of the minerals, can be well recognised as a simple columbate of iron and manganese; microlite appears to be a columbate of lime; pyrochlore, a columbate of the cerium oxides and lime, but whether or not a neutral columbate remains to be investigated. Hatchetolite he considers as a neutral columbate of uranium and lime, and samarskite a basic columbate of iron, uranium, and yttrium oxides. Yttrotantalite and euxenite are basic columbates of yttrium and uranium, the first being anhydrous when pure, the second containing water. Fergusonite is a hydrated basic columbate of yttria, and Rogersite, a columbate still more basic. In arranging a general view of these minerals Mr. Smith does not take into account the constituents which exist in small quantities only.

Coefficient of Capillarity for Certain Liquids.—M. Gueront, in the *Comptes Rendus* (lxxxiii. 1291) describes experiments in which he finds that in any series of organic compounds the coefficient of capillarity decreases as the amount of carbon in the substance increases. He has examined three series of bodies, the fatty acids, the acid ethers of ethylic alcohol, and the ethers formed by the union of acetic acid with the different fatty alcohols. In the series of fatty acids those members above propionic acid agree with the above statement, but the two lowest members, acetic and propionic acids, are exceptions; this he thinks probably due to impurities; the two series of ethers, however, agree perfectly with the law. From his observations it becomes evident that the coefficient of capillarity of the ethers is higher than that of the alcohols or the acids from which they are formed, showing that the introduction of an organic radical into the alcohol molecule renders the body more fluid. On comparing the two series of ethers it was found that the isomeric ethers have nearly the same coefficient, but the acids isomeric with them are much lower. Thus valeric acid, which is isomeric with ethyl propionate and propyl acetate, has a coefficient only about one quarter that of these latter. The reason suggested for this difference is that in the two isomeric ethers atoms are grouped in a similar way, while in the isomeric acids the grouping is different.

METEOROLOGICAL NOTES

Sun-Spot Periods and Auroras from 1773 to 1827.—We have received a communication from Mr. Buchan inclosing the following table, showing the number of auroras observed by Mr. James Hoy at, or in the vicinity of, Edinburgh, each year from 1773 to 1781, and at Gordon Castle, Banffshire, from 1781 to 1827:—

Year.	Sun-spots.	Auroras.	Year.	Sun-spots.	Auroras.
1773	40	5	1801	39	2
1774	48	5	1802	58	2
1775	28	1	1803	65	6
1776	35	3	1804	75	5
1777	63	0	1805	50	2
1778	95	6	1806	25	2
1779	90	11	1807	15	1
1780	73	6	1808	7	1
1781	68	2	1809	3	1
1782	33	3	1810	0	0
1783	22	2	1811	1	0
1784	5	0	1812	5	0
	21	0	1813	14	0
17	89	10	1814	20	1
1787	105	12	1815	35	1
1788	108	9	1816	45	1
1789	111	22	1817	44	3
1790	84	4	1818	34	1
1791	53	6	1819	22	5
1792	47	1	1820	9	3
1793	40	2	1821	4	1
1794	34	1	1822	3	0
1795	22	1	1123	1	1
1796		3	1824	7	2
1797		1	1825	17	0
1798	4	0	1826	29	0
1799	10	1	1827	40	1
1800	18	0			

This table is of peculiar value with regard to the many questions at present under discussion in connection with sun-spots.

Sun-Spots and the Prediction of the Weather of the Coming Season at Mauritius.—In the *Monthly Notices*, new series, No. 1, of the Meteorological Society of Mauritius (December 21, 1876), Mr. Meldrum gives a clear and interesting summary of his researches into the relations of sun-spots to several atmospheric phenomena. A valuable table appears on p. 14 setting forth the number of cyclones which have occurred in the Indian Ocean between the equator and 34° lat. S. each year from 1856 to 1875, the total distances traversed by these cyclones, the sums of their radii and areas, their duration in days, the sums of their total areas, and their relative areas. The well-known thoroughness with which the Meteorological Society of Mauritius has worked at the storms of the Indian Ocean ensures that the subject has been exhaustively treated. The period embraces two complete, or all but complete, sun-spot periods, the former beginning with 1856 and ending 1867, and the latter extending from 1867 to about the present time. The broad result is that the number of cyclones, the length and duration of their courses, and the extent of the earth's surface covered by them all reach the maximum in each sun-spot period during the years of maximum maculation, and fall to the minimum during the years of minimum maculation. The peculiar value of these results lies in the fact that the portion of the earth's surface over which this investigation extends is, from its geographical position and what may be termed its meteorological homogeneity, singularly well fitted to bring out prominently any connection that may exist between the condition of the sun's surface and atmospheric phenomena. A drought commenced in Mauritius early in November, 1876, and when the paper was read on December 21, Mr. Meldrum ventured to express publicly his opinion that probably the drought would not break up till towards the end of January, and that it might last till the middle of February, adding that up to these dates the rainfall of the island would probably not exceed 50 per cent. of the mean fall. This opinion was an inference grounded on past observations, which show that former droughts have lasted from about three to three and a half months, and that these droughts have occurred in the years of minimum sun-spots, or at all events in years when the spots were far below the average, such as 1842, 1843, 1855, 1856, 1864, 1866, and 1867, and that now we are near the minimum epoch of sun-spots. It was further stated that the probability of rains being brought earlier by a cyclone was but slight, seeing that the season for cyclones is not till February or March, and that no cyclone whatever visited Mauritius during 1853–56 and 1864–67, the years of minimum sun-spots. From the immense practical importance of this application of the connection between sun-spots and weather to the prediction of the character of the weather of the coming season, we shall look forward with the liveliest interest to a detailed statement of the weather which actually occurred in that part of the Indian Ocean from November to March last.

Meteorology in South Australia.—The publication of the meteorological observations made in this colony, which required to be discontinued in 1870 owing to the heavy pressure of official duties devolving on Mr. Charles Todd in connection with the construction and organisation of the Overland Telegraph, was resumed in an extended form in January, 1876, and we have now before us the first nine monthly issues, which bring the publication down to the end of September last. The reports detail, with some care, the conditions under which the observations are taken, the three or six daily observations made, and full *résumés* of the monthly results. An extremely valuable part of the reports is the monthly table of the rainfall at upwards of eighty stations, as observed by the officers of the postal and telegraph departments, and a number of volunteer observers who have co-operated with Mr. Todd in observing the rainfall for many years. The stations are arranged in geographical order from north to south, commencing with Port Darwin on the north coast, and along with the monthly amounts there are also given the averages of the month at all those places at which at least seven years' observations have been made. Among the many points of interest offered by these tables are the torrential rains of the north coast in the first three months of the year, frequently rising to from ten to sixteen inches in the month, their rapid diminution on advancing inland to Barrow's Creek or Alice Springs, and the great diminution in April, and the rainless, or all but rainless character of the northern region from June to September, when the prevailing winds of Australia become decidedly continental, or blow from the interior seawards. Since it would be impossible to over-estimate the importance of barometrical and thermometrical observations from this extended network of stations in South Australia, we very earnestly hope that the Colony will soon take steps to obtain these observations and publish them in the interest of meteorology.

Rainfall Observations in the East of France from 1763 to 1870.—In the *Bulletin Hebdomadaire* of the Scientific Association of France, of the 10th instant, Prof. Raulin gives an interesting historical account of all the rainfall observations made during these 108 years anywhere in that section of France which is marked off by lines joining Givet on the Meuse, Lauterbourg on the Rhine, Belley near the Rhon, and Decize on the Loire, and which thus comprehends seven well-marked regions, viz., the plain of Alsace, the chain of the Vosges, the plateaux of Lorraine and Bourgogne, the plains of Champagne and Bresse, and finally the chain of the Jura mountains. During the past three years Prof. Raulin has been engaged collecting all available materials for a monograph on the rainfall of this part of Europe, which, judging from his great monographs of the rainfall of other sections of France and of the rainfall of Algeria, will doubtless take its place as a permanent contribution of very high value to meteorological science.

IOWA WEATHER REPORT.—We observe from a circular issued by Prof. Gustavus Henrichs to the volunteer observers of Iowa (U.S.), that his report of the observations made at the meteorological stations of that State during 1876 is to be published as an Appendix to the *Report of the Iowa State Agricultural Society*, and that as the monthly reports are published in fully twenty of the newspapers, the *Weather Review* will be discontinued. The *Weather Report* about to be published will embrace an account of the meteorological system now in full operation over the State, and discussions of the rainfall, storms, and other phenomena, the normals which have been ascertained for different localities, and the detailed observations made at the Central Weather Station.

OUR ASTRONOMICAL COLUMN

THE SATURNIAN SATELLITE, HYPERION. — Prof. Asaph Hall, in *Astron. Nach.*, No. 2,137, publishes an ephemeris of this faint object about the approaching opposition of Saturn, with the view to facilitate observations, especially near the conjunctions. He remarks that although the satellite was discovered (by Bond and Lassell) nearly thirty years since, the difficulty of observing it has been so great that no satisfactory determination of its orbit has been practicable; most of the observations being made near the elongations, the position of the plane of the orbit is not accurately deducible therefrom, though it probably does not coincide with the plane of the ring, but appears to lie between those of Titan and Japetus. With the view to assist observation in the present year Prof. A. Hall has calculated elements from his observations in 1875, which may be stated as follows :—Perisaturnium passage, 1875, August 24·0036 mean time at Washington ; distance of perisaturnium from the node 40° 0′, eccentricity 0·125, semi-axis major 214″·22, period of revolution 21·3113 mean solar days. For the reason stated above it is supposed for this approximate orbit that its plane coincides with that of the ring, the node of which on the earth's equator is assumed to be in 126° 9′·1, and its inclination thereto 7° 3′·8. From these data auxiliary quantities and an ephemeris for Washington midnight, August 1–September 15, are added, and it is suggested that with the aid of the former comprising the interval June 1–December 28 a more accurate calculation may be made by Mr. Marth's formulæ.

Taking the solar parallax at 8″·86 Prof. A. Hall's elements would give for the mean distance of Hyperion from the centre of Saturn 914,000 miles, distance in perisaturnium 800,000, in aposaturnium 1,028,000 miles.

The first computation of the orbit of this satellite was by the late Prof. G. P. Bond, of Cambridge, U.S., from his distances observed between 1848, September 19, and January 12 following; his period of revolution is 21·18 days, mean distance 214″, eccentricity 0·115; the elements will be found in the *Proceedings* of the American Academy of Arts and Sciences.

THE TRIPLE-STAR 7 CAMELOPARDI.—The third component of this triple star was detected by Baron Dembowski on September 28, 1864, having been overlooked by Struve at Dorpat, who measured A and B in 1831, his mean result being 1831·57, pos. 238·32°, dist. 25″·647″. The Galarate epoch for the new companion is (A C) 1865·33 pos. 308°·83, dist. 1″·245. Baron Dembowski says the object was one of great difficulty for his refractor principally on account of the sombre hue of the star C, which did not appear always of the same intensity; referring to his observations at the epoch 1865·25, he remarks, "Elle avait alors une couleur de cendre mouillée ; je n'ai jamais vue d'étoile aussi sombre.' His magnitudes of C in 1864-5 vary from 7·0 to 9·0, while in the middle of November, 1865, he could not perceive the least trace of the star. Mr. Crossley measured A B at the end of December, 1873, but has no reference to the third star. The object will be worth watching on the score of variability and the unusual duskiness noted by the Galarate observer.

THE CAPE ASTRONOMICAL RESULTS FOR 1874.—Mr. Stone has just circulated his volume of observations made at the Royal Observatory, Cape of Good Hope, in 1874, being the thirteenth separate publication which has emanated from this important and active astronomical establishment since the year 1871, when Mr. Stone undertook its direction. We believe there is not a refinement in observing or computing which is not introduced into the Cape work, and the results have consequently a very high value, comparable with the best work of the kind published by the great European and American observatories, where attention is given to stellar astronomy. The volume for 1874 contains the mean positions of 1,246 stars, including all Lacaille's stars of the *Cœlum Australe Stelliferum*, which now fall between 155° and 165° of north polar distance, and some additional ones in the same zone. Lacaille's stars between N.P.D. 145° and 155° were similarly observed in the course of the year 1875, and those between N.P.D. 135° and 145° in 1876, the reductions to mean places for the former zone having been completed at the beginning of the present year. A complete determination of the accurate places of all Lacaille's stars, founded on the Cape observations, is therefore in a very forward state.

As an appendix to this volume of Cape Observations, Mr. Stone presents tables intended to facilitate the computation of star-constants, which appear likely to prove of very great service to the practical astronomer. By a slight modification of Bessel's form for star-corrections he has been able to tabulate the quantities in a very convenient and compendious manner, so that the whole computation occupies but a short time. Mr. Stone hopes that the use of these tables may render it unnecessary to give star-constants for every star contained in future catalogues, the labour of forming which, and of insuring their accuracy is very great. It is probable, as he observes, that the use of star-constants in various catalogues has been in many cases extended beyond the time when they could be introduced with a due regard to the precision required in modern stellar astronomy, which will be obviated by the use of the tables in question. It is understood that Mr. Stone liberally offers to supply a copy of these tables to anyone who would find them of real service, and who will make application for them. A few remarks on the *modus operandi* with the tables are reserved for a future column.

THE BRITISH ASSOCIATION AT PLYMOUTH

FEW towns in the United Kingdom have so much to interest alike the scientific and the general visitor as Plymouth ; and the meeting there of the members of the British Association in August next should prove alike pleasant and profitable. For the general visitor it will perhaps be enough that the Plymouth Hoe is one of the finest promenades in England, and that the landscapes of the neighbourhood are at once most varied and most attractive. The man of science will be able to enjoy all this and a good deal more. The zoologist may if he pleases revel in dredging expeditions in and off the Sound, which are sure to yield an ample reward. For the mechanician there are three of the most no able works of modern engineering skill to inspect—the Eddystone Lighthouse, the Plymouth Breakwater, and the Royal Albert Bridge, while the Government dockyards and factories at Devonport and Keyham, and the war vessels which stud the Hamoaze, will have a general as well as a special interest. One of the most enjoyable excursions of the Exeter meeting was that to the Three Towns, on which occasion the Government establishments were visited and gunnery and torpedo practice, with all the latest electrical arrangements, witnessed on board the *Cambridge*. The science of war has by no means stood still since then. The botany of the locality presents some peculiar features, and the algology is very rich.

In the domain of natural science special interest however attaches to the local geology. Plymouth rivals Torquay in its development of the great Devon limestone, which lines the northern borders of the twin estuaries of the Tamar and the Plym, along which the Three Towns are built, and trending southward and eastward, occupies the northern shores of Cattewater, and after a break reappears in mass at Yealmpton. The Hoe is limestone—a natural esplanade, an ancient plateau of denudation, with occasional alluvial deposits of sand and clay in pockets and fissures, remains of raised beaches, and a few ossiferous cavities. The limestone abounds in fossils, coralline in the more massive portions as a rule, but with areas crowded with molluscs of the ordinary Devonian type. Its chief palæontological interest lies, however, in its bone caves. The ossiferous caverns of Oreston, a little village on the southern bank of Cattewater, which were discovered originally in the course of quarrying the stone for the breakwater, whilst other members of the series have been opened from time to time since, are well known by description at least to geologists. Those of Yealmpton have hardly attracted so much attention. The fauna differs in both series in some important particulars from that of Kent's Cavern, though including in each case the ordinary cavern carnivora. The whole literature of the Oreston and Yealmpton caverns will be found in the *Transactions* of the Devonshire Association, compiled by Mr. Pengelly. And if the palæontologist should then feel special interest in a locality which has yielded so much to his branch of science, the stratigraphical geologist will find some notable materials for the study of the "still-vexed Devonian question" in the sections along the eastern shore of the Sound and elsewhere. The cliff section from Mount Batten, by Staddon Heights and Bovisand to the mouth of the Yealm has been described by Sedgwick, Murchison, de la Beche, Phillips, Holl, Pengelly, Jukes, and other eminent geologists, and interpreted very diversely, though the balance of opinion still remains that its shales and sandstones overlie the limestone. The contortions and plications are, however, in some parts very remarkable, and should be studied *in situ*.

There is nothing very noteworthy in the immediate mineralogy of Plymouth, but the mining districts of Cornwall and Devon, within easy reach, are the richest mineralogical field in the kingdom, and in the barrows circles, cromlechs, pounds, dolmens, and menhirion, still scattered in profusion over the wild flanks of Dartmoor, and along many a Cornish moorland, the anthropologist will find plenty to delight him. Upon the importance of the contributions of Kent's Cavern to the early history of man we need not dilate. The results of the explorations there, with the literature of the cavern, prepared by the indefatigable pen of Mr. Pengelly, will be found in the Devonshire Association *Transactions*.

The Plymouth Institution, with which is amalgamated the Devon and Cornwall Natural History Society, and which fittingly took the initiative in proposing the invitation of the Association, is the centre of the scientific life and work of the neighbourhood. It is a society of some standing, for it was founded so far back as the year 1812, and its members have done much to elucidate science in its connections with the district, and to cultivate literature and the fine arts. The natural history section of its museum is rich in local ichthyology, and fair in some other departments of its fauna. There are some very valuable antiquities; and the mineralogical and geological collections, though far from complete, are by no means wanting in interest. Bones from the ossiferous fissures on the Hoe, the caverns at Oreston and Yealmpton, and from Kent's Hole, form a prominent feature of its palæontology; and there are a few specimens which have a special value in having been presented by the Rev. Richard Hennah, who first established the fossiliferous character of the Plymouth limestone. The Institution issues *Transactions*, and has published some valuable papers bearing alike on science and upon local history, topography, and literature, from the "Law of Electrical Accumulations," by Sir W. Snow Harris, F.R.S.; to a paper "On the Letter R," by R. F. Weymouth, D.Lit. It will be evident, therefore, that the institution has been doing good work.

But now for some particulars concerning the local arrangements. These are in the hands of a large and influential executive committee, with sub-committees for the chief departments—finance, reception, sectional, excursion, fine art, &c. The mayor is the chairman of the executive; the secretaries being Messrs. W. Adams, W. Square, and H. Whiteford, while Mr. F. Hicks is the treasurer.

In one respect, and that a most important one, Plymouth will distance almost every town the Association has visited. We allude to the convenience of its sectional accommodation. The great hall of the Plymouth Guildhall, with its royal statues and magnificent historic windows, is the noblest hall in the whole south and west of England. Here the president will deliver his address and the evening meetings be held. In the law courts adjoining, and the spacious rooms of the municipal offices, some of the sections will be accommodated. Others will meet at the Mechanics' Institute, the Athenæum, and the Royal Hotel, the whole of which are within less than five minutes' walk of the Guildhall and each other. Since one or two of the other section rooms were decided on, it has been suggested that the sections to which they were appropriated may also be accommodated within the limits first indicated; but whether that be so or not, in the most remote case the most distantly located sections will only be six or seven minutes' walk apart. The members of the Association will know how to appreciate this.

Close by the Guildhall is St. Andrew's Hall, a large building recently erected as a skating rink. This will be utilised in connection with the Association for an exhibition of the fine arts. Plymouth is the artistic centre of Devon and Cornwall, which have given birth to many famous painters, and the exhibition is intended to be specially representative of western art. The Queen is among the contributors, and leading residents throughout the two counties. Living artists will be well represented; but the staple of the exhibition will consist of examples of Reynolds, Opie, Eastlake, Prout, with Haydon, Northcote, and other artists of note. With the exception of Opie, who was a Cornishman, and Reynolds, who was born at Plympton, four miles off, the artists here named are Plymothians.

Every effort is being made to get up an enjoyable and scientifically interesting series of excursions. It is perhaps rather a disadvantage in one way that the neighbourhood of Plymouth should be so beautiful, for therein lies a strong temptation to let fine scenery get the better of hard science. However, it so happens that there is very little difficulty in combining both. In 1841 there was but one excursion—to Tavistock and Wheal Friendship. This year there are six proposed—three for the Saturday and three for the Thursday following, in addition to which the Earl of Mount-Edgcumbe has most kindly consented to open his magnificent park on the Saturday to the members. The botanists will need no excuse for visiting Mount-Edgcumbe; if the geologists do they may find it in the interesting intrusive rocks at Cawsand, referred to in De la Beche's Report. One of the excursions proposed for Saturday is by steamer to the breakwater, and Smeaton's famous work, the Eddystone Lighthouse, winding up with a trip round the harbour, with its men-of-war, dockyards, forts, and factories. The Government establishments are always open to English folk. Our foreign friends who may desire to go over them, will have to provide themselves with a special order. There will be also a trip to Liskeard, for the Caradoc and Phœnix mines, and the famous Cheesewing. As mining is the special industry of Cornwall, and to a great extent of South Devon, it has been thought desirable to have two mining excursions—one on each day. South Caradoc is one of the richest copper mines in Cornwall; Phœnix is a tin mine; and both are admirably managed and excellently adapted to illustrate mining operations. The mineralogy of this district has some peculiar features. Phœnix has lately yielded the rare minerals chalcosiderite, andrewsite, and the beautiful turquoise-hued henwoodite. The third excursion will be to the Lee Moor China clay works. These are situated on the skirts of Dartmoor, not far from Plympton, are of immense size, and afford probably the best illustration of this great industry, which Cornwall and Devon owe to the researches and ingenuity of Cookworthy, chemist and potter, manufacturer in the Plymouth china of the first true English (hard) porcelain. It is likely that this excursion will be taken up by the Plymouth Institution, and so arranged as to embrace a visit to Princetown, and its convict prison, and some of the fine prehistoric antiquities of Dartmoor; if not there will probably be an extra excursion with this object given by the institution.

Thursday will be a long day, and wholly given up to excursion pleasures. The mining excursion will be up the lovely river Tamar to Devon Great Consols, which communicates by a railway of its own to shipping quays at Morwellham, in the close vicinity of the most picturesque scenery of the Tamar valley. On the way, by the kindness of the Countess Dowager and the Earl of Mount-Edgcumbe, the party will have an opportunity of inspecting Cotehele, one of the most perfect examples of a mediæval mansion now extant. At Devon Consols—not long since the largest and richest copper mine in the land, which gave in dividends considerably over a million—not only are mining operations conducted on the most extensive scale, but there are enormous arsenic works, huge water-wheels, and many other objects of interest. The other excursions arranged for the day are to Torquay and Penzance. The good people of Torquay intend to follow the capital precedent set in 1869, and to invite and entertain a number of guests. *En route* from Plymouth a steamer trip may be made down the lovely river Dart; and at Torquay there are plenty of objects of interest. The Torquay Natural History Society has a well-stored museum; Kent's Cavern is of course a museum in itself, with a very Cerberus of a curator in Mr. Pengelly; and then there are the works of Mr. Froude, F.R.S., at Chelson Cross, where he conducts those delicate experiments for the Admiralty on the forms of ships and their properties of stability, and to which he intends to invite members of the Association who are specially interested in this branch of mechanical science. Steps are, we believe, being taken at Penzance to give the excursionists thither a hearty welcome. The museums of the Penzance Natural History Society and of the Royal Geological Society of Cornwall, the latter of which contains the best public mineralogical collection in the West of England will be thrown open to them, and excursions in all probability organised to the chief attractions of the neighbourhood. It is hoped to provide special railway facilities for those who may wish to visit other parts of the country—such as Tintagel or the Lizard, or the western mining district. At Truro is the excellent museum of the Royal Institution of Cornwall, which will be open to visitors.

The former meeting at Plymouth, of the Association, was in 1841, with Dr. Whewell, as president, and was a very successful gathering. Six-and-thirty years are a long time, and it is remarkable that so many who took a prominent part on that occasion are yet with us. One of the vice-presidents still survives—the Earl of St. Germans; two of the local secretaries, Mr. R. W. Fox, F.R.S., and Mr. R. Taylor, F.G.S.; a vice-president of the statistical section, the Earl Fortescue, then Viscount Ebrington; Dr. Owen, F.R.S., vice-president for Zoology and Botany; and Mr. Robert Hunt, F.R.S., then secretary of the section of Chemistry and Mineralogy, are still with us. There will not be wanting opportunity, therefore, of comparing personal experiences in 1841 and 1877.

INDIAN RAINFALL AND SUN-SPOTS

On May 24 Gen. Strachey read a paper before the Royal Society entitled "On the alleged Correspondence of the Rainfall at Madras with the Sun-Spot Period, and on the True Criterion of Periodicity in a Series of Variable Quantities."

He stated that a paper had recently been printed by Dr. Hunter, the Director-General of Statistics to the Government of India, having for its object to show that the records of the rainfall at Madras, for a period extending over sixty-four years, establish a cycle of rainfall at that place which has a marked coincidence with a corresponding cycle of sun-spots—the rainfall and sun-spots attaining a minimum in the eleventh, first, and second years, and a maximum in the fifth year.

The Madras register extends over sixty-four years, beginning with 1813. The mean rainfall for the whole period is 48·5 inches. The deviations from the mean vary from 30·1 inches in defect to 39·9 inches in excess. The arithmetical mean of these deviations (disregarding the signs) is 12·4 inches.

Dr. Hunter divides the sixty-four years' observations into six cycles of eleven years, and calculates the arithmetical mean of the successive years of the whole series of cycles. The results are as follows:—

Years of cycles of eleven years.

	1st.	2nd.	3rd.	4th.	5th.	6th	7th.	8th.	9th.	10th.	11th.
Average difference from the mean of 64 years.	in. +0·6	in. +0·7	+9·8	+2·4	+1·9	+5·8	+4·4	−3·4	−11·5	+0·7	−13·5

In the above calculation the first year of the cycle of eleven is 1813, so that the average period of maximum sun-spots will be about the third or fourth year of the cycle, and the period of minimum will be about the tenth or eleventh of the cycle. This table apparently indicates a period of maximum between the third and the seventh years, and of minimum between the eighth and the second years.

But as the only signification of the arithmetical mean value of a series of observed quantities is that it is one above and below which there is an equal amount of deviation in the individual observations, the question whether or not the mean values thus obtained can be accepted as showing a definite law of variation from year to year in the cycle must be determined by examining the differences between those means and the individual observations on which they are based.

Treating the observations in this manner, it appears that the mean difference of the individual observations from the means shown in the table amounts to 11·2 inches, and differs but little from the mean difference of the individual observations from the arithmetical mean of the whole series. In other words, the supposed law of variation obtained from the means of the six eleven-year cycles hardly gives a closer approximation to the actual observations than is got by taking the simple arithmetical mean as the most probable value for any year.

In order to obtain a practical test of the probable physical reality of the cycle of eleven years, the author calculated a series of mean values corresponding to those given in the table for a series of cycles of five, six, seven, eight, nine, ten, twelve, and fourteen years. The mean differences between these means and the observed quantities are all within a very small fraction of one another, and of the mean obtained from the eleven-year cycle—

in short, one cycle is in this respect almost as good or as bad as another.

Now, if in any series of quantities, such as the rainfall observations at Madras, there be a law of periodicity, each observed quantity may be supposed to be compounded of a periodical and a non-periodical element. If we take the sum of a large number of cycles, each of which coincides with the cycle of periodicity, the non-periodical elements will tend to be eliminated, and the means for the successive years of the cycle will indicate the periodical elements for the successive intervals. At the same time the differences of these means from the several original quantities from which they were obtained will be the several non-periodical elements.

In proportion as the periodical elements are small or large in relation to the corresponding non-periodical elements, so the differences (obtained as above) will be inversely less or more different from the differences between the individual observations and the mean of the whole of them; and if there be no periodicity, the two sets of differences would, in a sufficiently long series, be identical.

Hence it may be inferred that when the differences (taken as before) closely approximate in magnitude to the mean difference of the original observations from the arithmetical mean of all of them, the periodical elements in those observations must be correspondingly small; and this applies manifestly to the eleven year-cycle and to the whole of the arbitrary cycles for which the differences were calculated.

Further to test the reality of the periodicity, the author rearranged the series of sixty-four years' observations, in a purely arbitrary manner, in cycles of eleven years, by drawing the actual observations at random one after another, and setting them down in succession till the whole were exhausted. From three arbitrary cycles thus prepared, the differences averaged 10·9, 11·2, and 11·6—results which again indicate that the actual sequence of the observed quantities of rain has no material effect on the mean differences, or any such tendency to a diminution in their numerical value, which is the necessary accompaniment of a true periodical element.

Moreover, the mere circumstance of any series of cyclical means showing a single maximum and single minimum gives no real indication of such a result being a truly periodical feature. It is obviously to argue in a circle, first to assume a cycle on which to work, which shall give a single maximum and minimum, and then to infer that there is true periodicity because of the single maximum and minimum. The test of the periodicity is in truth to be sought altogether outside of the particular values of the successive elements of the cyclical means.

It is manifest that a complication of periodical elements may so mask one another as to prevent positive results being obtained by the examination of the means and differences in the case before us. But the whole scope of the present argument is negative, and it leads to the conclusion that there is no proof of greater tendency to periodicity in the eleven-year means than in the original isolated observations.

As the sun-spot period is not exactly a cycle of eleven years, the author examined the results obtained by a comparison of the observations corresponding to the known periods of maximum and minimum sun-spots, without reference to any special length of cycle. These results he also considered to be negative.

A further test of the character of the conclusions was sought from the rainfall observations at Bombay and Calcutta, which have been made for the greater part of the period over which those at Madras extend. It is hardly conceivable that there should be a coincidence with the sun-spot period, such as is supposed to have been found at Madras, based on any physical cause, which should not in some way be discernible in the rainfall at Bombay and Calcutta.

The results thus got are also held to be entirely negative, and to indicate no concordance among the means of the several years of the cycle at the different places. The Bombay and Calcutta observations, treated as those of Madras were, to ascertain the deviations of individual observations from the successive means of the cycle, give quite similar results.

Although the special object of the communication was to deal with the alleged correspondence between the Madras rainfall and the sun-spot periods, the author had also turned his attention to Mr. Meldrum's speculations of a similar character, and had tested some of them in the manner explained.

Among these were the Greenwich observations for fifty-five years, which will be found at p. 307 of vol. xxi. of the *Proceedings* of the Royal Society, and the results got from them were quite analogous to that obtained from the Indian observations.

Further, to illustrate the argument on which the paper was based, the case was considered, in which a well-ascertained periodicity exists, as that of the diurnal barometric oscillation. The figures used were taken at random from an old Madras register, the intervals being made two-hourly, and the entries and the differences of the observed barometric heights from the daily means in thousandths of an inch, so as to reduce the calculations.

The figures being merely illustrative, the circumstance of their not exactly representing any physical phenomenon was a matter of no significance.

The treatment of these figures led to results very different from those got from the rainfall observations. The mean difference of all the supposed observations from the mean of all of them being thirty, the mean of the differences between the two-hourly means and the original figures was reduced to seven, indicating the distinct presence of a periodicity.

Re-arranging the figures in an arbitrary cycle of ten periods instead of twelve, the mean of the differences which before was seven was increased to thirty, showing that with the total destruction of the periodicity the mean difference of the two-hourly means and the original figures was the same as the mean difference with the arithmetical mean of all of them.

In conclusion, the author specially explained that he did not call in question the possible or actual occurrence of terrestrial phenomena corresponding to the sun-spot period, but only desired to point out that in the case of the rainfall observations under review the evidence was not sufficient to establish either any periodicity or such a correspondence.

In some remarks made subsequently the author pointed out how the comparison of the successive combination of the observations, beginning with one cycle and then combining two, and so on, till the whole were united, supplied another way of treating the figures which showed that the successive means of the differences between the mean rainfall for the combined cycles and the mean for the several years of the cycle when combined, followed the law that would hold good if there were no appreciable periodicity, that is to say, that this mean should gradually diminish in a ratio inverse to the square root of the number of cycles combined.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Prof. Humphry has been appointed to represent the University at the 400th anniversary of the University of Upsala in September next.

Prof. Adams' report to the observatory syndicate for the year from May, 1876, to May, 1877, does not contain anything of unusual interest. The year has been exceptionally favourable for astronomical observations, and 3,618 observations were made with the Transit circle. All the publications of the observatory are well forward, and the general work has been carried on smoothly and efficiently.

The following awards have been made for proficiency in natural science at St. John's College:—To F. T. S. Houghton, a foundation scholarship, the Wright's Prize, and augmentation of exhibition to 100*l.* for the past year. To Marr, Slater, F. J. Allen, Stewart, augmentations of exhibitions.

LONDON.—A public meeting in support of the London School of Medicine for Women was held the other day at St. George's Hall, the especial object being to raise 5,000*l.*, with a view of enabling the Executive Council to carry out an arrangement with the authorities of the Royal Free Hospital, under which students from the school were to receive clinical instruction. Mr. Cowper-Temple, M.P., Mrs. Garrett-Anderson, and Mrs. Westlake were amongst the speakers. 2,600*l.* have already been subscribed.

The Senate of the London University have decided by a majority of five not to postpone giving medical degrees to women till all the other faculties were open to them.

MANCHESTER.—On Friday last the scholarships and prizes gained during the session by students in the Faculties of Arts, Science, and Law were distributed at the Owens College. The Dalton Senior Mathematical Scholarship was gained by J. P. Whitney; the Dalton Junior Mathematical Scholarship by J. D. Pennington; the Dalton Chemical Scholarship by J. K. Crow; the Platt Physiological Scholarship by L. Larmuth. Mr. Crow presented a research upon the "Hypovanadous Compounds," and Mr. Larmuth a research upon the "Physiological Action of certain Vanadium Compounds." The number of students in the various departments of the College during the session just closed has been—Arts, Science, and Law, 415; Medicine, 175; Evening Classes, 900; making a total—allowing for double entries—of 1,450, being an increase of seventy on the number registered during the session of 1875-76.

LEEDS.—On Saturday the prizes and certificates awarded to the students at the termination of the third session of the Yorkshire College of Science were distributed by Lord Frederick C. Cavendish, the President of the College. Thoroughly gratifying reports of progress were made by all the professors. Not only has a site been obtained for the erection of permanent buildings, but an architect has been appointed to prepare plans and superintend the erection of the buildings. The first step has been taken to provide what we have all along advocated, a complete curriculum in literature as well as in science, by the appointment of Mr. Marshall as classical professor, and it is hoped that in a very short time a professor of modern literature will also be added to the staff. Liberal contributions have already been made towards the great expenses required to start the institution, and the University Extension Committee have handed over the whole of the funds of which they had been made administrators in connection with Leeds. Still to attain anything like efficiency the sum already obtained must be doubled. It is the people of Yorkshire who will mainly benefit by this new institution, and we hope it will not be difficult to convince them that it is both their interest and their duty to provide the greater portion of the funds required.

DURHAM.—At a recent Convocation the following degrees and licences were conferred in connection with the University:—B.Sc.: John Thomas Dunn, Mather Scholar. Associates in Physical Science: Edwin Cooke, John Richard Hutchinson Williamson.

PARIS.—The reconstruction of Charlemagne College, one of the most celebrated national colleges in Paris, has just been finished. The fitting-up of the buildings has begun, and they will be ready by October next. This college was established after the Revolution in the Hotel d'Anville, rue St. Antoine, which had been purchased from Anne de Montmorency by the Cardinal of Bourbon, and bequeathed by him to the Jesuits, then in hostility with the University.

A large number of houses having been pulled down in the Quartier Latin to make room for the Boulevard St. Germain, the works for the enlargement of the School of Medicine have been begun, and will be completed before the Exhibition. The expense will be 2,838,000 fr.

NOTES

THE varied and cultured tastes of the Emperor of Brazil are unusual even among private individuals, and probably without a parallel among his own limited class; his activity and eagerness for knowledge are astonishing. While in Paris, as we stated at the time, he was present at almost every scientific meeting of any importance, and in London this interest in science manifests itself quite as strongly. He has attended every meeting of the Royal Society since his arrival, was present at Mr. A. R. Wallace's lecture, carefully inspected the Science School at South Kensington, called the other day on Mr. Crookes, visited Dr. Siemens on Tuesday and Mr. Spottiswoode on Wednesday, and indeed has conversed with almost every man of science in London who has been doing any original work during the past few years. These visits are not mere formalities, for the Emperor is not satisfied until he masters whatever new research is submitted to him. On Tuesday he was made an honorary member of the Anthropological Institute and of the Royal Historical Society. Were the Emperor to stay here for some time we believe his presence would have a distinct influence on the public recognition of science; and if there were any one in this country in a similar station who took an equally real interest in science, we believe it would be all the better.

UNDER the auspices of the Sanitary Institute, Dr. Richardson, F.R.S., will deliver a lecture at the Royal Institution, Albemarle Street, on Thursday next, at 4 P.M., "On the Future of Sanitary Science in relation to Political, Medical, and Social Progress." We hope to give a verbatim report of this lecture in next week's number.

THE last meeting of the Royal Society previous to the recess was held last Thursday.

WE regret to see that Poggendorff's name has been entirely suppressed in the title-page of the new volume of the *Annalen*. The journal now edited by Borchardt still bears Crelle's name, and our *Philosophical Magazine* still keeps the names of Tilloch, Nicholson, and Thomson on its title-page. A similar allusion to the man who has made the *Annalen* what they are, would have been a better tribute to his memory than the short account of his life which closes what we must now call the last volume of *Poggendorff's Annalen*.

THE twenty-sixth meeting of the American Association for the Advancement of Science will be held at Nashville, Tennessee, commencing August 29, 1877. The president at this meeting will be Prof. Simon Newcomb; the permanent secretary is Prof. F. W. Putnam.

THE Geologists' Association have arranged for an excursion into Derbyshire on Monday, July 23 and five following days, under the direction of the Rev. J. M. Mello, Prof. Boyd Dawkins, and Mr. Rooke Pennington.

THE Select Committee to which the Ancient Monuments' Bill was referred met on Monday, when Sir John Lubbock was chosen chairman. The Committee meets again on Monday next, when evidence will be taken.

AT the meeting of the Royal Geographical Society on Monday, the last of the three lectures on scientific geography arranged for this session was given by Mr. A. R. Wallace, "On the Comparative Antiquity of the Continents." The object of the lecture was to establish the comparative antiquity of continents by an examination of the living and extinct animals found in each, and the lecturer came to the general conclusion that the main divisions of the earth had been nearly the same from the earliest period. The Emperor of Brazil was present during the lecture.

IN our report of the Anniversary Meeting of the Geographical Society it was stated that the Society contemplated organising an African Exploration Fund. The Society, it is known, has taken no share in the International African Association founded by the King of the Belgians; while doing everything to forward the views of that association, it seems to be of opinion that England ought to carry out African exploration independently. The Prince of Wales has become patron of the African Fund, and a special committee has been appointed, with the president of the society as chairman, the society having given a special donation of 500*l*. A map accompanying the programme of the scheme shows how large an area has been explored by British travellers, and several routes in Eastern Africa are suggested for exploration or careful examination. A comparison has been made of the length of each journey in Africa in a few recent instances, with the cost of making it. It appears that the total expense of despatching a well-equipped exploratory expedition from England may be roughly reckoned at the rate of 1*l*. 10*s*. for each geographical mile of country travelled over in Africa, supposing the expedition to return to the place whence it set out. In through journeys the rate is in many cases nearly twice as great. The aggregate length of the seven specified routes is about 7,700 geographical miles; consequently, the total cost of the proposed explorations, at the above rate, would amount to about 11,550*l*. No doubt many besides fellows of the society will be willing to help forward this new scheme. In connection with this we may here state that the International African Commission has concluded its labours. It has decided that the organisation of stations in Africa belongs to the Executive Committee. The principal object of these stations will be the suppression of the slave trade. It has also been decided that an expedition shall leave Zanzibar in the direction of Lake Tanganyika. The King of the Belgians has been re-elected president of the Commission.

Trübner, of Strassburg, publishes this month the first number of a new *Zeitschrift für physiologische Chemie*, edited by Prof. Hoppe-Seyler, of Strassburg and other eminent German chemists. The purpose of the journal is to keep together such original papers in physiological chemistry as are now scattered over various chemical, physiological, and medical journals. The new *Zeitschrift* will be published every two months.

It is stated that in a field near Cologne the Colorado potato beetle has been found in every stage of development.

In connection with the agitation in favour of planting the streets and squares of Manchester with trees, and protecting the suburban vegetation, which is being carried on by the Field Naturalists and Archæologists' Society of that city, a paper by Mr. R. H. Alcock, F.L.S., containing some curious information, was read at the last meeting of the Society. Mr. Alcock has experimented for the last twenty-five years in planting trees in the vicinity of his mill, situated in Bury, a smoky manufacturing town, a few miles from Manchester. He finds that the plane (*Platanus orientalis*), which is so successful in London, will not grow at all in Lancashire smoke even with careful culture. But on the other hand he has been very successful with the beech, sycamore, birch, wych elm, and Turkey oak. The lime, however, is the tree chiefly recommended: indeed, Mr. Alcock says of it that he is absolutely certain it will grow well in the Manchester thoroughfares if properly planted. If the Manchester people are enabled to walk *unter den Linden*, they will have reason to thank the Society which is making such commendable efforts to solve the problem in question.

It is just 140 years since the National Library of Paris was made public. The area of the building has been enlarged more than twenty times since that, and a scheme is now being planned for isolating the building from every other house.

An important French work has just appeared at Geneva—"Le Massif du Mont Blanc. Étude sur sa Constitution géodésique et géologique, sur ses Transformations et sur l'état ancien et moderne de ses Glaciers," by E. Viollet Le Duc, with 112 illustrations, and a map on the scale of 1 : 40,000. The work is the result of seven years' exploration, during which the author has set himself to map and describe with all possible accuracy, the characters of the rocks and of the soil, the successive beds of glaciers, the positions of moraines, the forms of the *cônes de déjection*, as well as the general aspect of this great upheaval. The map, based on the former maps of Capt. Mieulet, on the well-known relief of Mont Blanc constructed by Bardin, on the surveys of Forbes, on the work of Alph. Favre, and on careful surveys by the author himself, is indeed a remarkable work, scientifically and artistically. After many attempts the author has given up the idea of representing the relief by level curves, and has returned to the old graphic system under a light corresponding to that of the sun about 10 o'clock on a summer morning. In this way the relief of the locality is so perfectly represented on the map as really to deceive the eye. The geological description deserves the attention of all geologists.

Mr. E. G. Ravenstein, F.R.G.S., read an elaborate paper at the Statistical Society on Tuesday evening last week, on the populations of Russia and Turkey. The former of these Empires has 84,584,482 inhabitants, the latter only 25,986,868, or, including Egypt, Tripoli, and Tunis, 43,408,900. The population of Roumania is 4,850,000, of Servia 1,352,500. The population of Russia increases at the rate of 1·1 per cent. per annum, the increase amongst the Jews being at least double what it is amongst the Christians. With respect to Turkey there exist no data for calculating the increase, though it is most probable that the dominant race does not increase at all, a fact accounted for by vicious practices, and by the sacrifices demanded from it for the defence of the empire. Some curious facts were commented with respect to the proportions between males and females. Throughout Asiatic Russia and in a considerable portion of European Russia the male sex preponderates. The same fact has been noted in Roumania, in Greece, and in other parts of Europe. The author thus summed up the results of his investigations:—In the Russian Empire there are 100 Russians to every 50 members of other nationalities, and 100 Christians to every 16 Mohammedans and Pagans. In Turkey, on the other hand, 100 Turks have opposed to them 197 members of other nations and 100 Mohammedans, 47 Christians.

Mr. Stanford has just published sheet No. 1 of a large-scale map of the seat of war in Europe. It exhibits with great minuteness the region on both sides of the Danube where operations are being at present carried on, and extends southwards as far as the latitude of Philipopolis. It is admirably executed, and will enable a reader to follow the movements of the belligerents with complete satisfaction. Mr. Stanford also publishes a bird's-eye view, by Maclure and Macdonald, of the seat of war in Asia and Europe from Kurdistan, much better executed than the generality of similar maps.

Further details appear in the American papers of the recent destructive earthquake and wave on the west coast of South America. A Lima correspondent states that at about 8·30 on the night of May 9, a severe earthquake shock, lasting from four to five minutes, moved the entire southern coast, even reaching down as far as Antofagasta. The first shock was succeeded by several others of less intensity, and the sea, receding from the shore, seemed to concentrate its strength for the fearful and repeated attacks it made upon the land. It left Callao and proceeded southward. At Mollendo the railway was torn up by the sea for a distance of 300 feet, since repaired; and a violent hurricane afterwards set in from the south, preventing the approach of all vessels, and unroofing the houses of the town. At Arica the shocks were very numerous, and caused immense damage in the town, the people flying to the Morro for safety. The sea was suddenly perceived to recede from the beach, and a wave from ten feet to fifteen feet in height rolled in upon the shore, carrying before it all that it met. Eight times was repeated this assault of the ocean. Iquique is in ruins. The movement was experienced there at the same time, and with the same force. Its duration was exactly four minutes and twenty seconds. It proceeded from the south-east, directly from the direction of the Ilaga. The town of Tarapatt, twenty-five leagues inland, and the villages of Rica, Matella, and Canchones were more or less damaged. The shock of earthquake was especially severe at Chanavaya. In some spots the earth opened in crevices of fifteen metres in depth, and the whole surface of the ground was changed. At least 200 persons were killed. At Antofagasta the atmosphere was illuminated by a red glare, supposed to proceed from the volcano of San Pedro de Atacama, a few leagues in the interior. The sea completely swept the business portion of the town during four hours. At Huanillion the wave which succeeded the earthquake was nearly sixty feet in height. Mexillones was visited by a tidal-wave sixty-five feet in height. Two-thirds of the town were completely obliterated. In connection with the so-called "Tidal Wave" of the Pacific, Mr. Manley Hopkins writes to yesterday's *Times*:—About the 1st of May last the great crater of Kilauea, on the flank of Mauna-Loa, had become active. On the 4th rather severe shocks of earthquake were felt at the Volcano House. At 3 P.M. that day a jet of lava was thrown up to the height of about 100 feet, and afterwards other jets, to the number of fifty, perhaps, were in operation. Subsequently jets of steam issued along the line formed by a fissure four miles in length, down the mountain side. On the 5th, an observing party finding the disturbance lessened, descended into the vast crater. On the plain which forms the floor of the crater a mamelon had been thrown up 1,400 feet in diameter and 700 feet in height. Fire and scoria spouted up in various places. Pele's hair, vitreous filaments formed in the volcano, abounded. Things returned to a quiescent state. Between 4 and 5 A.M. of the 10th an oscillation of the sea was observed at Hilo, on the east coast of the great southern island of Hawaii. At a quarter before 5 the great "earthquake wave" struck the village. The greatest difference between the crest and the trough of the wave was here, and it measured 36 feet. On the opposite side of the island, in Kealakekua Bay, where Cook died, the measurement was 30 feet. In other localities the difference varied down to 3 feet. The regurgitations of the sea were violent and complex, and continued through the day. The great wave seems to have struck all the islands at the same time without reference to position. The height of the waves was nowhere so great as at Hilo. In 1868 a great earthquake wave destroyed Arequipa and Arica; 30,000 lives were lost at that time. Allowing five hours for the difference of longitude between those ill-fated towns and Honolulu, and supposing that the centre of the seismic action was rightly placed, the wave on that occasion, 1868, was calculated to have travelled the 5,000 miles between Arica and Honolulu in twelve hours, or at the rate of 446 miles an hour.

THE shock of an earthquake visited the district between Aix-la-Chapelle and Cologne at about 9 A.M. on Sunday. The movement was from south-west to north-east, and lasted from three to fifteen seconds. The vibration resembled that caused by a heavy goods train. The *Cologne Gazette* remarks that the last earthquake in the Rhine district occurred on November 17, 1868, two days after a considerable eruption from Vesuvius had commenced

AT a recent meeting of the Christchurch (N.Z.) Philosophical Institution, Dr. Haast gave an account of the discovery of remarkable ancient rock paintings in the Weka Pass Ranges. Some of them are fifteen feet long; they represent animals of foreign countries, weapons and dresses of semi-civilised people; underneath are characters like those of the Tamil language, and those on the ancient hill found in the North Island.

THE great Moscow Polytechnic Museum was opened on June 12 by an extraordinary meeting of the Society of Friends of Natural Science.

THE Irkutsk newspaper *Siberia* announces that on April 28, at 9.30 A.M., an earthquake was felt at Irkutsk. The shock was very short and rather strong.

THE second fascicule of the sixth volume of the *Memoirs* the Kazan Society of Naturalists contains the annual report of the Society. The most important work done by the Society was a geological exploration of the permian and carboniferous deposits along the banks of the Volga, between Stavropol and Syzran, by M. Stuckenberg, and of the banks of the Kama the Vyatka government, by M. Zaytseff.

THE additions to the Zoological Society's Gardens during the ist week include a Patas Monkey (*Cercopithecus ruber*) from West Africa, presented by Mr. Edward Poulson; a Yellow Baboon (*Cynocephalus babouin*) from West Africa, presented by Mr. H. E. Walters; a Purple Kaleege (*Euplocamus horsfieldi*) from the North-west Himalayas, presented by Mr. John Ditmas; an Imperial Eagle (*Aquila imperialis*), European, a Barrabands Parrakeet (*Polytelis barrabandi*) from New South Wales, deposited; seven Spotted-billed Ducks (*Anas pœcilorhyncha*), seven Chilian Pintails (*Dafila spinicauda*), eight Summer Ducks (*Aix sponsa*), two Bronze-winged Pigeons (*Phaps chalcoptera*), a Geoffroy's Dove (*Peristera geoffroii*), bred in the Gardens; a Hippopotamus (*Hippopotamus amphibius*), born in Holland, purchased.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 31.—"The Physical Properties of Homologues and Isomers," by Frederick D. Brown, B.Sc.

When we attempt to compare the physical properties of a series of compounds presenting very similar chemical properties, we find, that although our knowledge regarding one or two members of the series is tolerably complete, it is very restricted concerning the others.

Among the alcohols of the $C_nH_{2n+1}OH$ series, for example, there are two—methyl and ethyl alcohols—with whose physical properties we are well acquainted, but when we pass to the other members of this series we find, that with the exception of numerous determinations of density and boiling-point, experiments have been limited to the measurements of expansion which have been carried out by Kopp, Pierre and Puchot, and others.

In order to supply this want, I have undertaken a series of experiments, the first of which are here noticed.

The density, expansion, and vapour-tension of propyl and isopropyl iodides have been measured with the greatest care; the chief difficulty to be overcome being the impurity of the liquids themselves, more than a kilogramme of each was specially prepared and dried by means of phosphoric anhydride; it was then submitted to fractional distillation, about 500 grammes of perfectly pure iodide being thus obtained; this was again distilled and collected in about four portions, each of which formed the subject of a series of experiments. The results obtained with all these portions agreed most satisfactorily, showing that when the substance is prepared with care, the error due to impurity is well nigh obviated.

The following table gives the results in such a form as to show that when the tensions of the saturated vapours of both iodides are equal, the densities and consequently the molecular volumes are unequal.

Vapour tension millims.	...ling-point ...mal propyl iodide.	...ling-point ...sopropyl ...odide.	D... ...sity of ...mal propyl iodide.	Density of isopropyl iodide	...iff...rence between ...lensities
200	62°·37	50°·50	1·66704	1·64590	0·02114
300	73·51	61·33	1·64493	1·62359	0·02134
400	81·95	69·70	1·62808	1·60646	0·02162
500	88·84	76·44	1·61446	1·59246	0·02200
600	94·70	82·11	1·60250	1·58068	0·02182
700	99·83	87·13	1·59221	1·57035	0·02186
760	102·63	89·86	1·58670	1·56497	0·02196

It will be seen that this is in contradiction to Kopp's law, but that it is in accordance with the modern dynamical hypotheses on the constitution of matter, since the instability of the secondary iodide may be due to the greater *vis viva* of its molecules, which in turn would cause an increase of the mean distance between the molecules.

I may here mention that I have made a very complete series of experiments on the vapour-tension of normal propyl alcohol. The curve representing these observations intersects that which expresses the tensions of normal propyl iodide, so that whereas at 760 millims. the iodide boils at 102°·5 and the alcohol at 97°·3, at 370 millims. they boil at the same temperature, viz., 79°·5, and at 120 millims. the boiling-point of the iodide is only 49°·5, whilst that of the alcohol is 56°.

This fact, which probably arises from the much greater latent heat of propyl alcohol, obviously renders useless all attempts to derive the boiling-points from the constitution of chemical compounds, so long as the boiling-points at the ordinary pressure of the atmosphere alone are taken into account.

Mathematical Society, June 14.—Lord Rayleigh, F.R.S., president, in the chair.—Prof. Crofton, F.R.S., proved some geometrical theorems relating to mean values. These theorems were chiefly interesting as examples of the employment of the theory of probability to establish mathematical results; they were of a kindred nature with theorems given in the *Phil. Trans.*, 1868, p. 185, and in Williamson's "Integral Calculus," second edition, p. 329. Mr. Merrifield made a few remarks on the communication.—Prof. Clifford, F.R.S., read a paper on the canonical form and dissection of a Riemann's surface. The object of the paper is to assist students of the theory of complex functions by proving the chief propositions about Riemann's surfaces in a concise and elementary manner. To this end certain results of Puiseux's were assumed at the outset. Prof. Smith in making remarks on the paper expressed his indebtedness to the author in having cleared up a difficulty which presents itself in Lüroth's paper on the subject.—Prof. H. J. S. Smith, F.R.S., gave a short account of a further communication upon Eisenstein's theorem.—Mr. Tucker communicated a paper by Mr. J. C. Malet entitled, "Proof that every Algebraic Equation has a Root."—The Society's next meeting will be held on the second Thursday in November.

Royal Astronomical Society, June 8.—Dr. Huggins, F.R.S., in the chair.—Some tables for facilitating the computation of star constants were presented by Mr. Stone.—Mr. Marth explained diagrams referring to conjunctions of Saturn and Mars between July and November next—being a triple conjunction.—Dr. Royston Pigott described a method of collimating reversible instruments by which the error could easily be determined within 2". Mr. Dunkin intimated that he would be greatly disappointed to find his collimation 0"·25 out.—Mr. Gill recounted some of the troubles that beset people who go after parallax, and described some methods of getting rid of systematic errors.—The president in the name of the meeting said "Good-bye" to Mr. Gill on the eve of his departure for the Island of Ascension.—At 9 P.M. the proceedings were stopped by the president to leave time for the special meeting called to consider a proposed alteration in the bye-laws.

PARIS

Academy of Sciences, June 18.—M. Peligot in the chair.—The following papers were read:—On the notation of Berzelius, by M. Berthelot.—Some observations on the mechanism of chemical reactions, by M. Berthelot. The new facts observed relate to direct oxidation of haloid salts, and of sulphurous and arsenious acids.—On the order of appearance of the first vessels in the aërial organs of some Primula, by M. Trécul.—On the crystalline form and the optical properties of proto-iodide of mercury, by M. Des Cloizeaux. The crystals generally occur in the form of thin, flexible, weakly dichroic plates, of the quadratic system, but liable to be mistaken for a clinorhombic combination. Across the planes of cleavage they give strong double refraction, with positive axis. The salt is completely isomorphous with calomel (or the protochloride); and it is imperfectly so with red bi-iodide of mercury, which, however, has a *negative* axis. M. Berthelot, in view of such facts, remarked on the uncertainty they throw on the employment of isomorphism as a method for determining the number of atoms contained in a compound, and consequently the absolute value of the atomic weights.—Reply to the observations of M. Mouchez, by M. Villarceau.—On M. Villarceau's *Nouveau Navigation*, by M. Mouchez.—On the interior sea of the Algerian Sahara, by M. Favé. The slope at the borders of the lake, he points out, would be very pronounced.—Theory for finding the number of variants and contravariants of given order and degree linearly independent of any system of simultaneous forms containing any number of variables (continued), by Mr. Sylvester.—On the present state of the solar atmosphere; letter from P. Secchi. In presenting a *résumé* of the spots and protuberances of 1876, he gives his reasons for thinking the sun in a state of *relative* (not *absolute*) calm. M. Janssen's view that there is rather a tendency to speedy dissolution of spots than a state of (even relative) calm, implies, he thinks, the false idea that spots can be maintained for long without the continuance of eruption. Their short duration indicates a short time of eruption, therefore weak solar activity. Spots continue because the dissolved matter is replaced by freshly erupted matter. We have no proof, either, that dissolution is more rapid at the periods of minimum. There are now signs of re-awakening activity.—On electro-magnets with rundles of iron, by M. Du Moncel. He is led to study these again by experiments of M. Fridblatt and M. Jablochkoff. The lateral action of the magnetising currents on the rundles is limited, he thinks, to a simple dynamical reaction between parallel currents, which may, with very strong currents, make plates of iron adhere strongly to the cheeks of the spiral, but which does not develop *exteriorly* on these plates well-marked magnetic polarities. This latter only occurs where the plates are so small that the spirals act on them by enveloping them like a core.—On the use of sulpho-carbonates and sulphide of carbon in treatment of the vine, by M. Marés.—On a temporary affection of sight, by M. Pierre. Reading, one day, after having had brain fever, a glazed volume, he found the characters apparently more distant than the paper (about 4 mm.); and the exercise was very fatiguing. In the next eight or ten days the characters seemed gradually to come nearer to the surface.—Historical remarks on the theory of motion of one or several constant or variable forms in an incompressible fluid, &c. (continued), by M. Bjerknes.—Determination of groups formed of a finite number of linear substitutions, by M. Jordan.—On the metallic solar eruptions observed at Palermo from 1871 till April, 1877, by M. Tacchini. In 1871 the zone of eruptions was confined between + 70° and − 40°; in 1876 it extended only between zero and − 21°; and in the first four months of 1877 there has only been one very small eruption.—On a new general method of synthesis of hydrocarbons, acetones, &c., by MM. Friedel and Crafts.—Reducing action of phosphorus on sulphate of copper; phosphides of copper, by M. Sidot.—Chemical researches on crystallised carbonate of lead formed on objects found at Pompeii, by M. de Luca.—Observations on some xanthates; separation of cobalt and nickel, by M. Phipson.—Researches on tetrachloride of carbon and its employment as an anæsthetic, by M. Morel. He was led to this application of it by the similarity of its formula (C_2Cl_4) to that of chloroform (C_2HCl_3). It is found a perfect anæsthetic and more powerful than chloroform, but quite capable of being regulated. The periods of insensibility and collapse are identical with those of chloroform; that of excitation is more pronounced. A mode of preparing the substance is described.—Observation of a bolide at Clermont-Ferrand on June 14, 1877, by M. Grerey. The head was about five to six minutes apparent diameter; the light was bright and flashing, with slight reddish and bluish gleams. No sound was perceived.—On a solar halo, by M. Vinot.

THURSDAY, JULY 5, 1877

THE CAXTON EXHIBITION

THE exhibition just opened at South Kensington to commemorate the 400th anniversary of the first authentic publication issued from an English press, is one that must appeal to all who can read, and possesses an interest for the man of science from various points of view. We need not repeat the many platitudes that have been uttered and are now likely to be reiterated on the vast importance of the invention of printing by means of movable types. It was a gift to the people of Europe of a pair of intellectual seven-leagued boots wherewith to tread the path of culture; progress during the last 400 years has been beyond all proportion more rapid than during any previous period, and while no doubt other causes have been at work, the strongest impulse has been received from the invention so interestingly illustrated at South Kensington. Mr. Gladstone, in his speech on Saturday, stated that he did not think the invention of movable types in itself anything very extraordinary, and wondered that it had not been blundered on long before the time of Gutenberg and Fust. But the same might be said of most inventions in their first rude forms; we who are accustomed to locomotive engines and ocean-going steamers, for example, are apt to wonder how the world was so long in hitting on these applications of steam. But the truth is that in art as in nature no stage is reached by a leap; it requires a collocation of many little circumstances before any new form is ripe for development. And probably, if we could minutely trace the precedents of the invention of printing, we might find that it was the most natural thing possible that it should have taken place just when it did and not before. Probably all the material conditions or "environment" may have reached the proper stage a century before the actual invention, but then there was no Gutenberg or Fust (or whoever the genius was, for this is no place to discuss the much-discussed question) with the requisite discernment to perceive this, and the practical skill to proceed in the direction indicated by the conditions. It is curious that all the extant remains of the work of the earliest known printers are really wonderful in beauty of execution, which makes one doubtful if we have any of the very earliest specimens, and whether the date of invention should not be pushed further back than the accepted one.

The exact date of the invention, however, has not been satisfactorily ascertained. That it was complete by the year 1450 there seems no doubt, and by the year 1500 printing-presses had been set up in 220 places in Europe, and many books, mainly editions of the classical writers, and religious books, were in circulation by their means. Mainz was the city in which the new art reached its first full development, spreading thence to Haarlem and Strassburg, from Haarlem to Rome, 1466, by Sweynheym and Pannartz, who are said to have been the first to make use of Roman types, to Paris in 1469, to England about 1474, and to Spain in 1475.

The exact date of the introduction of printing into England is not certain; it may have been 1471, it was not later than 1477, the date of the publication of Caxton's "The Dictes and Sayings of the Philosophers," the first book certainly printed and published in England, at the Almonry at Westminster Abbey, where Caxton set up his press; it is to commemorate this event that this year has been chosen for the Caxton celebration. There is a story that a press was set up at Oxford a few years before Caxton's at Westminster; but the evidence for this statement is quite untrustworthy. The first English book printed was by Caxton at Bruges, probably in the year 1474, "The Recuyell of the Histories of Troye." It was at Bruges, where Caxton lived in his capacity of mercer, a man of great importance, and in the retinue of the Duchess of Burgundy, that he learned the new art of printing from Colard Mansion; when he brought the invention to England he was probably about fifty years of age, having been born in the Weald of Kent somewhere about 1420: nearly all dates connected with Caxton are very uncertain.

According to Oldys, the first book in which Caxton had any hand is one which may very fairly be considered as connected with natural science. Its title was "Bartholomeu de Proprietatibus Rerum," said to have been printed while Caxton was at Bruges in the retinue of the Duchess of Burgundy. The work is a kind of natural history, by Bartholomew Glanvill, a Franciscan friar, who flourished about 1360, explaining more especially the nature and properties of the beasts, birds, fishes, stones, &c., mentioned in Scripture. The work had already been translated into English in 1398 by John de Trevisa, and the translation was printed in England, probably on the first paper made in this country, by Wynkyn de Worde, after Caxton's death. It is only right to state, however that according to Mr. Blades, the great authority on all connected with Caxton, no impression of the edition in which Caxton is said to have had a hand, has ever been found.

Caxton, who died in 1491, although he published from his press at Westminster a wonderfully large and varied collection of works, does not appear to have been attracted to any bearing on science, strictly so called. Probably Mr. Gladstone hit on the reason in his estimate of Caxton's character when he spoke of him as a thoroughly practical Englishman who went in only for what would pay. The "Image or Mirror of the World," one of the popular books Caxton translated from the French, treats, however, of a vast variety of subjects after the imperfect natural philosophy of the day. We have an account of the seven liberal arts; of nature, how she worketh; and how the earth holdeth him right in the middle of the world. We have also much geographical information, amongst which the wonders of the Inde occupy a considerable space. Meteorology and astronomy take up another large portion. The work concludes with an account of the celestial paradise. There are twenty-seven diagrams explanatory of some scientific principles laid down in this book; and eleven other cuts illustrative of other subjects treated in the work. The work was translated by Caxton in 1481, but the first edition has no printer's name, place, or date. The history of the "Mirror of the World" may be summed up thus:—Before the middle of the thirteenth century an unknown author wrote in Latin "Speculum vel Imago Mundi." In

1245 this was turned into French metre by the Duc de Berry; in 1464 this was turned into French prose, and from this text Caxton took his translation.

Even abroad the proportion of scientific to other classes of works issued from the early printing presses was comparatively small; but this may be satisfactorily enough accounted for by the fact that there were then comparatively few really scientific works in existence. From the Italian presses a very large number of arithmetical and geometrical works were issued at the end of the fifteenth and beginning of the sixteenth century. The Alphonsine tables were printed at Venice in 1483; but one of the earliest works in any way connected with science must have been a folio sheet, "Conjunctiones et opposiciones solis et lunæ," dated 1457; the place of publication we have been unable to ascertain. There is a "Gerardis Cremonensis Theoria Planetarum," quarto, dated 1472, and an Albertus Magnus "Opus de Animalibus," printed at Rome in 1478. Other early printed works which, considering the time, may be classed as scientific, are "Questiones Johannis Cunonici super octo libros Physicorum Aristotelis" (Padua, 1475); "Garetani de Thienis in Meteor. libros Aristotelis Expostio" (Padua, 1476); "Prognosticon," a meteorological work published at Venice in 1485. But when we come into the next century the number of strictly scientific works published in England and other European countries increased with amazing rapidity, and we may say has gone on increasing in ever enlarging proportion ever since. The first English translation of Euclid by Billingsby is said to have been published in 1570.

It is a small thing that books of science are all but unrepresented in the Caxton Exhibition; these could no doubt have been obtained had they been sought for; but the object of the exhibition is simply to illustrate the origin and growth of the art of printing, which has been an inestimable boon to science as it has been to every other form of human activity, and the man of science owes as much gratitude to its inventors, and to Caxton its ntroducer into England, as does the worker in any other department of culture. Happily, as we hope to show, science has been able to some extent to repay her debt by importing improvements into the art which would not have been possible but for her researches.

THE DEVELOPMENT OF THE OVUM

Bütschli on the Earliest Developmental Processes of the Ovum, and on the Conjugation of Infusoria.

Studien über die ersten Entwicklungsvorgänge der Eizelle, die Zelltheilung und die Conjugation der Infusorien. Von O. Bütschli. (Frankfurt, 1876.)

FEW subjects can be more important in their bearing on biology than the more prominent of those considered in this volume. It now rests on a morphological basis which will never be shaken, that there has been a procession of the most complex animal forms from simpler and still simpler ones, until we reach eventually the ultimate of organised simplicity. There may be difficulties n the way, but they are as nothing to the overwhelming evidence which morphology provides in its support; doubt, indeed, is no longer possible; and every year diminishes the circumscribed area of difficulty. But our knowledge hitherto of the developmental processes which take place in the earlier states of the simplest elementary organisms is wholly incompetent. Much labour has been expended, and doubtless good work has been done; but as it at present stands, it is conflicting, crude, and essentially wanting in coincidence and correlation. The work before us is the result of an attempt on the part of its author to penetrate farther into the matter than his predecessors, and by completer knowledge to harmonise or explain away conflicting evidence and doubtful interpretation, and if possible to give a sequence to the morphological processes in the simplest ova, and in the least apparently organised of animal forms.

From the smallness of the space at our disposal all consideration of the second subject discussed in this volume must be passed over. It deals with cell and nucleus fission generally; but as it is chiefly theoretical, we may the more readily omit it, merely remarking that the author concludes that there is a fundamental harmony in the method of fission in the cells of both animals and plants; a conclusion which it may be fair generally to admit; but in the minute detail, only discoverable by prolonged research, there will be found palpable differences.

That which gives distinction, and to some extent importance to the book, is (1) its minute and practical investigation into the earliest changes effected by development in the ova of some of the more lowly organised animal forms; and (2) the abundance of data which it appears to provide for the support of a new theory of propagation amongst the infusoria, which Bütschli propounds and advocates.

The embryological researches under the first head were conducted principally upon the ova of the Nematoid worms and the Rotifers. To a limited extent the living egg was studied; but the greater part of the results are derived from investigations of the ova treated with acetic acid. This is greatly to be regretted. The difficulties which present themselves in the minute examination of such ova in the living condition, are doubtless great, indeed complete results could scarcely be obtained from this alone. But undoubtedly the continuous examination of a set of living ova in process of development should be carried on simultaneously with every method of treatment which will reveal structure and change in ova of the same form in the dead condition. Only in this way can every possible mutation be traced, and its correlation and sequence be established.

It is extremely difficult to distinguish even striking discoveries in this direction from the manifold claims put forward by the many observers. We must state generally the facts as they at present appear, and seek to indicate the points specially claimed as new by Bütschli. It is now well known that the ovum is not suddenly formed, and then stimulated into new activity by fertilisation. It evidently, in its very lowliest condition, goes through a process of internal growth and development; after which apparently it perishes unless fecundated. In 1864 Balbiani endeavoured to prove that besides the *germinal vesicle*, there existed one still more important, which he called the embryogenic cell or vesicle in the ovarian ovum; and it was held by leading embryologists that it was round this cell that the true embryo was constituted; but in what manner, each observer appears to have determined for himself. The disappearance of what was accepted as the germinal vesicle was generally agreed to; but whether before or after impregnation was never fully determined. That it merely retrograded to the centre and determined segmentation as the result of fecundation, was held by many; while the embryogenic vesicle was said to persist, and from it were derived the now celebrated "globules polaires," or "Richtungsblaschen," which had been variously called by different writers from Carus downwards "white vesicles," "round vesicles," "clear globules," and so forth, and which are now thought to enter directly into the genital organs of the future being; Balbiani considering them of much importance in the evolution, inasmuch as they are found just in the region of the ventral layer of the blastoderm where the genital organs appear.

We have only space for a consideration of one of the instances adduced by Bütschli of earliest ovum development; but that may suffice to indicate the distinctive nature of his work. We select the eggs of *Nephelis vulgaris.* In their youngest state, the yolk is retracted from the delicate membrane, and there is, resting on the yolk, a minute mound of spermatozoa. At a little distance from this spermatozoal eminence there is an eccentrically placed spindle-shaped body, composed of fine longitudinal fibres, which at the equator of the spindle are swollen to a thick shining granular zone. The yolk mass is depressed at one point, and the spindle has its long axis directed to that of the flattened yolk. At the ends of this body there are clear homogeneous spots, from which rays go forth in all directions through the yolk. This spindle-shaped body Bütschli affirms to be the true *germinal vesicle;* and it is this which is carried upward to the surface of the yolk, by the elevation of the upper set of rays proceeding from the homogeneous spot over its upper apex, until eventually this spindle is pushed out of the yolk in three segments. In the part first protruded fine granules appear, and these retain their connection with the fibres in the part still inclosed in the yolk, by fine filaments, which also terminate in a zone of granules. This protruded vesicle is the "Richtungsbläschen;" the real place and relation of which, in the subsequent development of the egg, is nowhere determined by these researches. In the stage of partial protrusion of this vesicle, at about a quadrant from the point of its exit, another clear space arises sending out its radial rays; this enlarges, moves to the centre, and the germinal vesicle—now the "Richtungsbläschen"—is at this time quite protruded. At a point in the yolk determined by the point of exit of the "Richtungsbläschen," two minute nuclei appear, one in the upper margin of the clear space, and the other between that and the point of exit of the said vesicle. They are at first entirely disconnected, and both, by treatment with acetic acid, prove to be true nuclei. But they soon unite in the clear spot or space, and, at its expense, rapidly grow. They become a perfect nucleus with a distinct envelope and fluid contents, and distributed within the latter are dark granules. While these processes have been taking place two of the three segments of the "Richtungsbläschen" have again united, and at the same time the transformation of the nucleus begins. At two points on opposite sides of the nucleus, and in the direction of the long axis of the yolk, there arise clear spots and their accompanying rays. Between these, the nucleus differentiates itself into long fibres, and becomes a spindle-shaped body exactly like the germinal vesicle. An equatorial zone arises in it which is called a nuclear-band (kernplatte), which now divides; and each half recedes to the opposite ends of the spindle-like body. These ends now lose their points and become rounded, and in the mean time occurs the furrowing or constriction of the yolk. Another equatorial band arises in the nucleus or spindle, and when the constriction of the yolk is half accomplished the formation of nuclei of the second generation takes place from the ends of the spindle, these being nuclei in the completest sense. These fuse together and grow at the expense of the clear space—the growth of the nuclei and the diminution of these homogeneous spaces being in all cases correlative. When these nuclei are developed both hemispheres of the yolk collapse, and an almost spherical shape is again resumed.

What became of the fibres of the spindle was never discovered, but about this time the remaining segments of the "Richtungsbläschen" reunite, and in it a system of fibres appears. The following fission processes are but repetitions of this.

It becomes from the above apparent that Bütschli takes it for granted, first, that the eggs studied had been subject to no earlier developmental changes than those with which he starts. Next, that there can be no question as to the identity of his "spindle-formed body" and the germinal vesicle. He further at first claimed the extrusion of this germinal vesicle as the "Richtungsbläschen," as a sole result of the stimulus of impregnation; and ventures to consider that the process of nucleus formation described is widely diffused in the animal world, and that it is probably universal in impregnated eggs.

But (1) there is not the remotest evidence to show that processes of considerable import may not have preceded the condition with which these investigations started; complex processes are still known to occur in the unimpregnated ovum. We have only indeed to turn to the next example given by Bütschli himself to prove all this. In *Cuculanus elegans* the ovum leaves the ovarium without an envelope; and within the yolk is seen the "large *round* germinal vesicle and the germinal spot." The latter vanishes after impregnation, and the germinal vesicle becomes eccentric—and the next thing we are told is that "the germinal vesicle was no longer in the yolk, but *instead of it* there was a spindle-shaped something like that seen in Nephelis." How was the change effected? What were the steps? The transition is all-important, but how it happened is not worked out; and it would be, in so important a question, a matter of the greatest interest to know *how* the perfect spindle-formed body, with which these observations begin, arose. Nothing final can issue in this inquiry until, from first to last, every process and every step therein has been consecutively made out.

(2) The identity of this body with what is known as the germinal vesicle is certainly probable, but by no means certain, at present. It is certainly true that this supposition derives considerable support from the fact that Ratzel

found that in the ripe ova of *Tubifex*, prior to laying, the spherical germinal vesicle lost its spherical shape, elongated, became spindle-shaped with a meridional striation, and so forth, closely resembling the nuclear spindle of *Nephelis*. But as the process is described by Bütschli this would involve the necessity that the *whole* of the germinal vesicle was extruded as the "Richtungsbläschen" in every case. Against this, however, there are irresistible facts; and in an appendix to the volume the author is bound some sense to admit that there are cases where "a part of the germinal vesicle may remain." If this be so evidently there is missing a link in the chain of observation. Difficulties of an equally complex character present themselves in the collation of these researches with those of other distinguished embryologists which it would be hopeless even to attempt to consider here.

3. That the expulsion of the "Richtungsbläschen" is a result of impregnation must also be abandoned. In the text of this treatise the author earnestly contends for this point nevertheless; and endeavours to dispel the force of the very definite results of Œllacher, Bischoff, Flemming, and Beneden. But these are points that may be settled with comparative ease, and it certainly is true that the expulsion of the "Richtungsbläschen" may show itself as one of the earliest phenomena of development in the unfertilised egg. This is now admitted, and in the appendix is allowed by Bütschli.

4. The universal application of the method of development seen in *Nephelis*, although strongly contended for, and carried by analogy into the interpretation of the theory advanced in the third part of the volume to account for the propagation of Infusoria, can only be admitted with the utmost caution. The evidence given by the author is by no means perfect. In *Cucullanus elegans*, for example, he admits that the transition of the nucleus spindle into the "Richtungsbläschen" cannot be made out as in *Nephelis*, but contends that it *ought not to be doubted*. And precisely the same difficulty attaches to the transformations of the nucleus, of which "nothing could be certainly found;" yet the same doctrine is carried over, as though precisely the same phenomena had been witnessed as in *Nephelis*. So in relation to other Nematoids, it is rather inference than evidence that the protruded vesicle is the germinal vesicle, as in *Nephelis*. So in *Limnæus auricularis*, essential points in the origin and subsequent evolution of the spindle and nuclei are presented, not as the result of observation, but of inference, and a leap across a chasm between two preparations of the ovum which show no continuity of evolution, is taken with an assurance that "doubtless," although the intermediate process was not made out, we might be guided by the analogy of *Nephelis*.

These facts are pointed out, not in the slightest degree to detract from the value of the author's observations, but simply to separate them, as such, from the inferences he draws from them. There can be little doubt that great value belongs to the discovery of the nucleus spindle and its behaviour in evolution; and there can also be little question that it is largely original research; but its relation to anterior and subsequent processes is not so definitely discovered. It is nevertheless a source of great interest to find that Balbiani has given such complete and recent confirmation to the main characteristics of the spindle-nucleus.[1] It is true that he does not confirm the division of the equatorial band in the nucleus, and claims to have shown the existence of the clear spaces and rayings accompanying the nucleus-transformations in the eggs of spiders four years before. But evidently a step is gained by these observations on the earliest development of the ovum; although, from the careful work of M. Fol, it is clear that not only the interpretation, but the detail, may be open to question.[2]

J. DRYSDALE

(*To be continued.*)

THE ALKALI TRADE

The History, Products, and Processes of the Alkali Trade, including the most Recent Improvements. By Charles Thomas Kingzett. (London: Longmans, Green, and Co., 1877.)

TOWARDS the middle of last century the price of oil of vitriol was 130*l*. per ton; the same substance now sells at 5*l*. per ton. In the first years of the present century soda crystals sold at about 60*l*. per ton; their present price is about 4*l*. 15*s*. per ton.

In 1861 the Lancashire district produced 8,800 tons of soda crystals, 4,600 tons of caustic soda, and 11,700 tons of bicarbonate of soda. The same district consumed, in that year, 161,000 tons of sulphuric acid and 135,000 tons of salt. Five years later (1866) 194,000 tons of salt were consumed in the same district, while the out-put amounted to 25,000 tons of soda crystals, 11,000 tons of caustic, and 6,500 tons of bicarbonate, together with 87,000 tons of soda ash and refined alkali, and large quantities of bleaching liquor, bleaching powder, &c. The following numbers, obtained from the Alkali Association, show the increase in the alkali trade of the United Kingdom between the years 1862 and 1876:—

	1862.	1876.
Annual value of finished products	£2,500,000	£6,500,000
Weight of dry products ...	280,000 tons.	845,000 tons.
Raw materials used:—		
Salt	254,600 ,,	538,600
Coals	961,000 ,,	1,890,000
Limestone and chalk ...	280,500 ,,	588,000
Lime	—	139,000
Pyrites	264,000 ,,	376,000
Nitrate of soda	8,300 ,,	12,200
Manganese	33,000 ,,	18,200
Total	1,801,400 tons.	3,562,000 tons.
Capital employed in the business	£2,000,000	£7,000,000
Hands employed	10,600	22,000
Wages paid them annually..	£549,500	£1,405,000
Weight of soda exported ...	104,762 tons.	270,856 tons.
Value of exported soda ...	£885,245	£2,209,284

These facts enable us to form some idea of the enormous growth of the alkali trade within recent years. This growth has been in a large measure coincident with

[1] Sur les Phénomènes de la Division du Noyau Cellulaire, *Comptes Rendus*, Oct. 30, 1876.

[2] Sur les Phénomènes Intimes de la Division Cellulaire, *Comptes Rendus*, Oct. 2, 1876.

the growth of scientific knowledge. The facts discovered in the laboratory have been turned to account in the alkali work, and the theories of the chemist have not unfrequently received confirmation at the hands of the manufacturer. Conversely, the wants of the manufacturer have hastened the discovery of fresh facts, and the success or failure in the application of these facts on the large scale has reacted beneficially upon the advance of chemical theory. In 1750 sulphuric acid was manufactured by distilling sulphate of iron in earthen vessels luted to glass receivers. The destruction of plant obliged the manufacturer to adopt a better method. The chemist supplied him with the facts: Nitre and sulphur when burnt together produced sulphuric acid. The manufacturer supplied the mechanical means for realising this process on the (comparatively) large scale. Soon after this time Scheele discovered chlorine; the manufacturer, acting on the experiments of the chemist, turned to account the fact that chlorine readily combines with hydrogen. But the impulse thus given to the bleaching trade necessitated a corresponding advance in the manufacture of sulphuric acid. The chambers in which the nitre and sulphur were burnt were enlarged, improvements were adopted, and the price of the acid decreased while the consumption increased.

In more modern times we see the need of a cheaper method for manufacturing chlorine, giving rise to the successful process of Weldon, a process based upon strictly experimental laboratory data, and to the hitherto not so successful process of Deacon. We see the failure of the latter process inducing its discoverer to extend his researches, and as a consequence chemical science is enriched with a valuable paper which throws considerable light upon the general principles of chemical dynamics.

While the history of the alkali trade illustrates the benefits conferred upon manufactures by science, and the requital made to science by manufactures, it also forcibly illustrates the uses which to-morrow may bring for the waste products of to-day.

The monopoly granted by the King of Sicily to one firm in the exportation of sulphur obliged the manufacturers of oil of vitriol to have recourse to some other source of sulphur. The introduction of pyrites led to the accumulation of burnt ore, and this again to Henderson's method for extracting copper, a method which, whether considered chemically or commercially, has proved most successful. The hydrochloric acid sent out from the chimney of the alkali works has, since 1863, been almost wholly condensed, and from this once wasted acid immense quantities of bleaching powder are now manufactured. The acid liquors from the manganese still, although rich in manganese, were formerly sent into the nearest stream, thus causing at once a loss to the manfacturer and a nuisance to the neighbourhood. Now, however, these liquors are turned to use, the nuisance is abated and the manufacturer is enriched.

But if one is to acquire a just idea of the immense dimensions, and of the importance of the alkali trade from a commercial, chemical, or general point of view, one must learn in detail the history of the manufacture, the development of the processes which gather round the alkali trade as their centre, and the connections which subsist between the practical carrying out of the manufacture and the general principles of chemical science. Such a knowledge may be obtained from the work before us. Mr. Kingzett gives a clear and succinct account of the rise of the alkali trade and of the present state of the manufacture. Notices, sufficiently detailed for the purposes of the general reader, of all the recent improvements are introduced. The allied trades, especially the bleaching powder and soap manufactures, are described.

The book necessitates a general knowledge of chemistry on the part of the reader, inasmuch as processes are everywhere referred to their fundamental chemical principles. He who wishes for a rule of thumb acquaintance with the alkali manufacture will certainly find the information given in this work beyond his scope. On the other hand, the man who, having a general knowledge of chemistry, really wishes to learn how chemical facts are turned to account in manufactures, and also how mechanical difficulties are overcome, cannot do better than study—not read only—the work before us.

The chemical manufacturer also may gain from this work a more extended knowledge of his trade, and he may receive many hints, which, if he be of an inventive turn of mind, he may some day turn to account. The author has evidently endeavoured to treat the subject from the standpoint of the scientific manufacturer, and we think he has very fairly succeeded.

Full details of the more modern improvements of Hargreaves, Mactear, and others in the manufacture of alkali are given. The Weldon process for manufacturing bleach is described minutely, the improvement suggested by Mr. Weldon, whereby loss of calcium chloride would be avoided, is mentioned, and its utility is pointed out.

Of course there are parts of the book which it appears to us admit of improvement. The introduction of an index would add to the value of the work. Might we suggest to Mr. Kingzett that it would be well to re-write the preface, and generally those portions of the work in which he indulges in philosophising? The book begins with a platitude: "The wealth of a nation may be said to be indicated by the magnitude of its commerce." It closes (the last chapter is purely statistical) with a poor simile: "Life may be compared to a spectrum with its bright and dark lines."

M. M. PATTISON MUIR

OUR BOOK SHELF

River Terraces. By Col. George Greenwood. (London: Longmans and Co.)

FOR somewhere about fifteen years no name occurred more frequently in the geological correspondence of our magazines and newspapers than that of "George Greenwood, Colonel," and no letters carried with them a more marked individuality than those to which that name was appended. They never betrayed any doubt or hesitation, but made merry over the doubts and difficulties of other and more experienced observers; they showed in vigorous language that in so far as a correspondent agreed with their author, he was right, that in so far as he differed he was wrong. Fathers in science like Lyell and Darwin, as well as striplings, not yet emancipated from geological long-clothes—one and all needed instruction and correction at the hands of the enthusiastic Colonel. He spoke of the geologists of the country as schoolboys, whom he had to drill in the beggarly elements, and divided them into classes according to their acquirements or their aptitude to receive his lessons. He began by enforcing his views as those of Hutton and Playfair, and gradually so identified himself with them that he regarded them and the very words expressive of them as his own property, which no one should claim or touch except in the way he chose to sanction. Peace be with his memory! He did a good work in his time. Men gladly overlooked his personal failings for that sound sense so often underlying his self-asserting remarks about geological forces which had not been adequately understood in this country when he began his crusade of "Rain and Rivers." The present volume is a reprint of his letters on all manner of subjects, written at different times from 1859 to 1875. But surely its publication was not needed for the scientific reputation of the author. The letters are given as they originally appeared, full of references to passing incidents, and to letters by other writers, which of course are not inserted, but without which Col. Greenwood's diatribes are often unintelligible. There is no attempt at editing. The title of the book also is misleading. Instead of a treatise on river terraces, it is a medley of clippings from the columns of various periodicals relating to such varied subjects as Spelling, the Possessive Augment, Source of the Nile, Glen Roy, a Horse-Chestnut Tree, Rain and Rivers, Sirloin, Pronunciation of Latin, Lakes with Two Outfalls, a Beech pierced by a Thorn Plant, Origin of the Chesil Bank, &c., &c

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Tait on Force

In Prof. Tait's lecture on "force," which its writer seems to have intended as a model of perspicuity and accuracy, we are told that "we must measure a force by the rate at which it produces change of momentum." Nothing could be clearer or more satisfactory than this statement. Then Prof. Tait proceeds to tell us what force "is," and we read—"Force is the rate of change of momentum"—giving to this word "is" the meaning which the so-called metaphysicians give to it; and it seems to me that we might jangle over it for ever, without ever knowing whether this latter statement be true or not; for although we may all agree as to the proper *measure* of a force, it seems to be more difficult to tell what force "is." Possibly we might roughly measure the hunger of a man under different circumstances, by determining the number of pounds of beef he would consume, but it would be hardly warranted to say that hunger "is" a certain number of pounds of beef.

Perhaps it may be advantageous to apply the name force to the thing which we have heretofore called rate of change of momentum due to force, but I cannot imagine how any one can think that a certain "rate of change of momentum" can produce a unit of momentum in a unit of time. Until this shadowy "phantom" called force can be brought a little more sharply into focus, it seems to me that considerations as to what it "is" may profitably be left to those who appear to delight in the obscurity of obscure things—the metaphysicians.

St. Louis, June 4 FRANCIS E. NIPHER

P.S.—On showing this note to a friend, my attention was drawn to a note by Robert Napier in *Engineering*, which makes the present one seem almost superfluous. Remembering, however, the difficulty which I had in understanding these very points on account of the loose way in which they are put in many text-books, I feel that too much cannot be done to prevent such things from going into text-books in the future.—F. E. N.

[Prof. Nipher's censure does not apply to my lecture, simply because he fails to remark that I had two objects in view, (1) to point out the sense in which the word *force* must be used if we desire to avoid confusion; (2) to point out that, in all probability, there is no such *thing* as force. Under the first head I of course referred to Newton's "Laws," and in them language is used which at least suggests the objective reality of force as the *cause* of change of motion. We must take Newton as we find him. But there is no inconsistency in afterwards proceeding to give reasons which appear conclusive against the objective reality of force.

With some of Prof. Nipher's other remarks I can cordially agree. Since my lecture was published I have been in almost daily receipt of passages containing errors amounting often to the wildest absurdities, due to misuse of the term force. The latest to which my attention has thus been called is in the *Cornhill Magazine* for June. Here the non-scientific public is gravely told that "*what mathematicians call the moving force exerted by the earth on the moon is eighty-one times greater than the corresponding force exerted by the moon on the earth.*"—P. G. T.]

On Time

If I understand V. A. Julius's letter in NATURE, vol. xiv. p. 122, on the measurement of time, it may be thus summarised:—

As equal times, unlike equal linear magnitudes, cannot be brought alongside of each other, their equality can be ascertained only by means of velocities. (This will not be disputed.) We define those times as equal during which the same space is traversed by equal velocities; but the postulate that a velocity, *e.g.* that of the earth's rotation, continues unchanged, is arbitrary, incapable of proof, and justified only by practical convenience.

It seems to me, on the contrary, that the postulate is not necessarily arbitrary, but may be absolutely justified by facts. The best case to put is that of the pendulum, which, according to Sir William Thomson, is probably capable of measuring time with greater accuracy than the motion of the earth itself. If we assert that equal forces acting through equal spaces produce equal velocities (and this is rather a definition than an axiom), then the assumption of the equal velocity of all the pendulum's strokes postulates nothing except that the force of gravitation continues unchanged. I admit that I see no way of proving this, but it may be safely assumed in the absence of any known or probable cause of change. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, June 19

The Antiquity of Man

I HAVE no desire to enter into the controversy respecting the age of the palæolithic implements found in brick earth near Brandon, by Mr. Skertchly. I had the great pleasure of going over some part of the ground with him and Mr. Belt in November last. But what I saw then was not sufficient for me to make up my mind upon the question. Of course Mr. Skertchly, with his immense experience, has far more evidence in his repertorium than a cursory visit could afford to me.

My object in writing this letter is to point out that, if it should eventually be proved that *a* glaciation of the surface has occurred in East Anglia subsequent to its human occupation, but one which is not identical with, but posterior to, that glaciation (whether land or marine) which deposited the great chalky boulder-clay, then this is no more than I put forward many years ago in my papers on the "warp" (*Geol. Journal*, 1866); and on the "glacial origin of denudation" (*Geol. Mag.*, 1866); and on the "denudations of Norfolk" (*Geol. Mag.*, 1868).

I think this is the direction to which the course of opinion appears to be tending, and I ask you kindly to bring under the notice of the younger generation of geologists the speculations of an elder brother.

I call the product of this supposed glaciation "trail." The more orthodox, I believe, consider it to be "rain wash," and I had hoped that some competent writer would have thought me worth confuting. But none has done so. I have reason to think that one of your correspondents did actually put down as boulder clay this very deposit, at one of the most important sections which I saw near Brandon. Harlton, Cambridge, June 28

Museum Reform

NO one acquainted with the condition of the greater proportion of our provincial museums can do otherwise than confess with sorrow that much of what is alleged against them in the paper of Mr. Boyd Dawkins is too true. While fully concurring in all he says as to the actual state of matters in these amorphous receptacles of curiosities and conceits, and as to the crying need for reform, you will perhaps allow me to make a few comments as to the causes which contribute to keep museum collections in their present disreputable condition, and the means by which they may be worthily organised, and raised to their high and proper position among the educational agencies of the country.

It is necessary in the first place to accept Mr. Boyd Dawkins's glorification of the collecting instinct with some modification or rather amplification of its scope. A man is indeed "poor and much to be pitied" who is not a collector in some sense; but it does not require demonstration that many of the best and greatest benefactors of mankind are not collectors in a way that contributes to the building up of museums. Statesmen, soldiers, poets, philosophers, and orators are not of necessity poor and much to be pitied because they may not devote their leisure to the collection of coleoptera nor find solace in the beauties of Lucca della Robbia. In nine cases out of ten, indeed, the collector is a person of one idea, and that idea is that the gathering, labelling, and arranging of the objects of his fancy is the beginning, end, and sum of science. He is generally an estimable person; but as regards scientific culture he is quite as well employed in collecting spoiled postage stamps as he would be in gathering together the species of any of the great divisions of the animal kingdom. When we come to the tenth man—the intellectual collector—we find a really scientific worker, but one necessarily confining himself to a limited field. He is in short a man with a hobby, or, to put it more courteously, a specialist. Put a man of this select class in charge of a provincial museum, and while probably he is too wise to speak slightingly of any department of human knowledge, he will inevitably develop his own special subject at the expense of all others. A geologist draws towards him rocks and fossils, an entomologist collects in the particular group of insects to which he has given attention, and an archæologist looks only or mainly for antiquities. If the man is a simple collector of the ordinary type he knows nothing or despises everything beyond his region, and hence in part the jumble of ethnology, art, and science which Mr. Boyd Dawkins so graphically describes.

A specialist, though an indispensable cultivator of science, is a very bad museum curator. A curator should be like a newspaper editor, a man of general knowledge and culture. Unlike an editor, he should belong to no party, but be possessed of catholic sympathies in science and art; ready to accept and use the assistance of specialists, in a way that will subordinate all departments to one harmonious general plan. Further, he should possess an experimental knowledge of the routine duties of a museum, such as can only be obtained by a training or apprenticeship in a well-organised museum.

No provision, I need hardly say, exists at the present time for training young men to museum work, and there is no pecuniary inducement held out for lads to seek curatorial qualifications. The training obtained in the great metropolitan museums is special; and in the government service there is no hiving off of apprentices. Municipal and free library authorities have not yet learnt that a well-equipped museum is an expensive institution, and though many corporation dignitaries may spend annually 1,000*l*. and upwards on purchases for their private collections, it does not occur to them that it is necessary to do more than open the doors of a public museum or art gallery, and allow collections to accumulate, arrange, classify, catalogue, and conserve very much of their own accord. And so we obtain the dusty, misleading, higgeldy-piggeldies which do duty in provincial towns as "museums."

Before these institutions can rise from their present dismal estate it is essential that much more money be devoted to them. Of course it does not matter whence the funds come—from public rates or private benefaction—provided it comes honestly; but there is, as the law now stands, hardly in any town sufficient rating power to build and maintain a museum adequate to the population and wants of the locality. Free library boards with their penny rating limit have in many instances committed themselves to very ambitious mistakes by instituting numerous district libraries, and throwing in a public museum to the bargain, under the delusion either that their penny is like the wizard's inexhaustible bottle, or that these institutions will live and flourish "without visible means of support." The result is, that while libraries have been crippled and half starved, ratepayers have been justly disgusted with the very name of museum.

The provincial public mind, both official and extra-official, stands sorely in need of enlightenment as to the nature and functions of a museum. The education of opinion on these points is the first step required for the elevation of local museums. With that effected, enlarged rating power, a demand for competent men, and adequate support to institutions on a broad educational basis would soon follow. Local museums, ceasing to be mere curiosity-shops, receptacles of "relics from Sedan," "water from the Jordan," with six-legged cats and similar monstrosities, would become storehouses of well-selected information and material for the use of teachers and investigators, as well as instructive and elevating resorts of the general public.

No class of institutions existing could be made mutually more helpful than museums. Duplicates innumerable go to wreck and destruction in the stores and cellars of almost every museum, while certainly many kindred institutions stand in need of what is simply an encumbrance to some. Similarly with labels and stores of information, each institution at present stands apart, working painfully, and perhaps erringly, at tasks which might well be spared, seeing that it is and has been done over and over again in other institutions. Again, one locality possesses rare and unusual facilities for obtaining particular classes of objects, and that advantage can, by a system of exchange, be made properly beneficial to its own museum by drawing what it needs from others. Further, in these days of comparative infancy, the experience of the officers of the older museums would be of unspeakable value to those struggling amid difficulties of which they barely recognise the nature; and to all, the countenance of the great institutions—which should be prepared to stand more *in loco parentis* than they at present do—and the advice and help of their specialists would be of much advantage. In these days of conferences, associations, and unions, it is manifest that there is room for a conference of museum keepers, and no one can doubt that vast good would result from drawing the officers of museums of all kinds into closer relationship with each other. Will the energetic officers of South Kensington not display once more their organising talent by bringing together such a conference, which, it may be hoped, would result in a permanent union among museum officers.

J. P.

Taunton College School

MAY I ask the insertion of the following brief remarks:—

The writer of the article in your paper of the 28th on Taunton College School is under some strange misapprehension, which perhaps may account for his unfavourable criticism of the schemes of the Endowed Schools' Commission. He clearly implies, though he does not positively state, that the present disturbance at Taunton (of which I know nothing) and the scandal at Felsted two or three years ago are in some way attributable to the wrong constitution of the governing body, under schemes of the Endowed Schools' Commission.

Taunton College School is not under a scheme of the Endowed Schools' Commission, and no scheme was ever proposed for it by that body. A scheme for Felsted Grammar School was proposed by the Endowed Schools' Commission, with the hearty goodwill of the late master, but was rejected by the House of Lords on the motion of the Bishop of Rochester (now of St. Alban's). The trustees who dismissed Dr. Grignon were the very body whose constitution our scheme proposed largely to modify, and who were in consequence not a little annoyed.

Your writer will, I hope, excuse my saying that he will serve the cause of science and of schools much better if he does not weaken his attacks on the guilty by hitting, or making feints of hitting, at the innocent.

HENRY J. ROBY,
Late one of the Endowed Schools' Commissioners

Manchester, June 29

Hog Wallows

I HAVE been watching with some interest the progress of the discussion on the "Hog Wallows" of California, which has been in progress in your paper during nearly all of this year. When a member of the California Geological Survey Corps, I had numerous opportunities of studying the phenomena in that and the adjoining states of Oregon and Nevada; more especially in the southern parts of the desert. There they are developed on the largest scale, and there their origin is obvious.

Prof. Le Conte's account of them wants but a single word to have settled the question. I attributed them, then, exclusively to the action of the wind, and after reading what others have to say about them, see no reason for changing that opinion. The Professor says, "I attribute them to surface erosion." Had he inserted *aërial*, nothing more would have been wanted; although, since he speaks of weeds and shrubs taking possession of them, subsequent to their formation, he does not seem to have exactly hit on the *rationale* of the process.

One case may serve as an illustration. In the southern end of the Reese River Valley, Nevada, is a broad, perfectly level plain without a water-course; only a few shallow dry gutters show where the rain water runs to scattered spots, where it sinks or evaporates. The region is almost rainless. The plain is covered for many square miles with these mounds, varying up to four or five feet high, and up to twenty, thirty, and even perhaps forty feet in diameter. In every case they are made up of only the finer particles of the soil, the coarser grains and gravel being visible in the interspaces. The dust and sand has in all cases been heaped up in and around a clump of sage bush which continues to grow out of the top of the mound. Little vegetation grows on the flanks of the mounds, and when it does, it forms the nucleus of a subsidiary hillock. The mounds are thus formed by building up, and only the intervening spaces are caused by an erosion, taking place to day, and not caused by water, much less by ice. WM. M. GABB

Puerto Plata, Sto. Domingo, June 5

Fertilisation of Salix repens

DURING May I was watching the movements of the insects on a plant of *Salix repens*, when I noticed some facts which may prove interesting to some of your readers. It was mainly visited by the common hive-bee (*Apis mellifica* ☿) and the humble-bee (*Bombus terrestris* ♀). The former of these flew gaily about from catkin to catkin merely taking one bite at each; but the latter went far more systematically to work; it never flew at all, but crawled in a ludicrously feeble way from catkin to catkin, and once on a catkin it cleared it thoroughly, thrusting its proboscis between every pair of florets. I do not know whether this greater thoroughness is at all times characteristic of the humble-bee as compared with the hive-bee and should much like to be informed. And another thing which I do not understand is, that one of these humble-bees appeared to have two kinds of pollen on its legs, one that of *Salix repens*, the other of a much darker and more-orange colour, though when examined under the microscope the grains proved to be of the same shape. Wellington College, Wokingham, June 30

THE FUTURE OF SANITARY SCIENCE—POLITICAL, MEDICAL, SOCIAL[1]

I COULD have wished it had been in my power on the present occasion to produce one of those essays which appeal to the imagination while they prepare the mind for the reception of sanitary principles and practice. Such essays are tempting and, in their place, instructive. To-day I am bound on a voyage less pleasant, yet I hope not less useful.

There has recently been called into existence a new society under whose summons we now meet. The society has assumed to itself the expressive name of the Sanitary Institute of Great Britain. It starts as a voluntary effort by men and women who are willing and anxious to give effect to those teachings of sanitary science which the past half-century has revealed. It invites all who are concerned to utilise the knowledge that has been acquired in that time. It wishes to encourage new research. But it has for its most anxious care to render useful to mankind at large the accumulated store of knowledge which at this moment lies ready for so many grand purposes relating to health. It accepts as its object, work for health, health of all the human family.

Shall some one say the object is ambitious? Yea, we reply, it is confessedly ambitious. Shall some one say the means at command for the work to be attempted are weak? Even so. Life is short, art long. Yet the short yields the long, and but for the short the long could not be. It is out of these littlenesses of human effort that the greatnesses follow. Or, as Benjamin Rush very forcibly puts it, and simply as forcibly: "There are mites in science as well as in charity, and the ultimate results of each are often alike important and beneficial."

It is my fortune, good or bad, to have to preside over the council of this new society. Of the ability of those who form the council, and of their experience, I need not speak in detail, for their names are familiar to the world. They represent, I may say, sanitary science in all its branches, and from them, working harmoniously together, good results must be expected.

It seems fitting therefore as we enter on our work to look forward to the future. It is a part at least of our duty to look towards the future with the view of seeing in what directions we may best proceed; what assistances we may have to call upon; and chiefly what great powers we may have to consult and propitiate.

The three great powers with which our society will have to treat are the political, the medical, the social. From each of these we shall expect constant assistance. To one or other of these, whatever we do, our work will be transmitted or transferred. They will bring it into practical form and effect, or they will reduce it to nothingness. We can suggest and set forth initiatives, and with that our functions are complete in each particular branch to which we address ourselves.

It is our special duty to keep this special fact steadily in view and to limit our labours by it. It too often happens that young societies like young men are apt to believe that they can conduct national processes as easily as they can conceive them, and under this belief fail most signally with the best of attempts. I remember in my early career getting a lesson from one of our late well-known statesmen on this very point. I was explaining to him the efforts I had made in 1855 and the succeeding three years to establish a registration of the diseases of this kingdom, and I bewailed the hard experience which proved that the greater the scientific success of the effort the more impossible it became to carry it out. In fact, said I, in a pitiful strain, the success almost ruined me in mind, body, and estate. "Served you right," was the immediate reply, "Served you right. If individual men could carry out national projects where would be the nation?" The reply was hard as it was unanswerable, and from that time to this I have given up all thoughts of doing more than sowing seed in the field of literature and leaving it to the chance of fructification on that extensive soil; or in showing some mere model of experiment which, perchance, may grow into working form. And this, I think, is the whole natural scope of our Institute,—to sow the

[1] An address delivered before the Sanitary Institute of Great Britain at the Royal Institution, on July 5, 1877, by Benjamin W. Richardson, M.D., LL.D., F.R.S.

seed of sanitation; to think out plans of projects for working methods; to lend its many minds, as if they made up the mind of one man, for devising from the past the best for the present, and respectfully to declare our conclusions.

The directions in which we shall have to move, the lines on which we shall have to move, are, I repeat, chiefly three—the political, the medical, the social. The powers on these lines must be approached in every work of ours, however simple, however complicate it may be. I shall try, as the title of my discourse explains, to indicate certain points in which we are most likely to come in contact with these powers and the changes we may expect to work in and through them.

The Political Part.

In this country political action has been varied in relation to sanitary improvements. Sometimes political necessity has crossed sanitary progress, as, for example, in the imposition of a tax on sunlight, on foods that are essential to life, and in the granting of licences for the sale of pernicious drinks. At other times, and by fits and starts, political action has been in aid of sanitary work. So far back as the reign of Edward the Third, 1361, a royal proclamation was made through Parliament for preventing the slaughter of cattle in the streets of London because of the pollution of the streets and the drains which arose from that cause. From that time under great emergencies other similar acts came into force. They rarely lasted very long. As the urgent necessity for their existence passed away, they were allowed to fall into abeyance, and no permanent machinery was kept in order for insuring their continued and effective action.

Let me not, however, in saying this, be understood as conveying any special charge of neglect against English legislation. It is just to state, as an historical fact most creditable to our national history, that our legislators have by a long precedence taken the lead in sanitary affairs over those of other nations. In 1802 the great sanitary act for regulating the labour of children in factories set the example from which much useful legislation has followed at home and abroad. In 1838 that great original sanitary scheme for the registration of the births and deaths of the kingdom was inaugurated, to become a collection of facts relating to life, and disease, and death, of which there is elsewhere no parallel. And, since the era of the Crimean campaign, so much legislation has been attempted bearing on health, I dare not attempt even to enumerate the titles of the different measures that have been introduced. At this moment there can be no doubt as to the sincerity of our governments, of whatever party they may be composed, for dealing with every subject relating to the public health in an efficient manner, and in as rapid a progression as the slow and sure mode of parliamentary procedure will permit. The subject indeed presses at this moment with so much force on the governing mind, that if there be any danger ahead it is the danger of too miraculous a draught of small enactments, to the exclusion of comprehensive measures which all who run may read.

In saying this it is necessary to guard myself against error of expression. By comparison with all the nations of the world beside, we have obtained legislative measures which are splendidly comprehensive. No other country in the world can present an approach to the Public Health Act of 1875. That Act, as far as it goes, is admirably constructed. Its constitution of sanitary authorities throughout the kingdom; the power it vests in those authorities to appoint learned medical officers of health; the provisions it makes for securing to each locality better sewerage, freedom from nuisances, improved water supply, regulation of cellar dwellings, governance over offensive trades, and removal of unsound foods; the provisions for prevention of spread of infection and for the erection of hospitals and mortuaries; and the provisions for the regulation of streets and highways, lighting of streets, establishment of pleasure grounds, and regulation of slaughter houses; these, as well as the general provisions for the carrying out of the Act, are most commendable as practical plans by the working of which the nation may be tempered into sanitary mould of thought and character.

In a word the Act of 1875 is an improvement of the first degree on all that has preceded it, and although much of it, by the necessities of the constitution of our country,—which recognises the domination of free will even in its age of ignorance,—of a permissive nature, the working of the Act must in a few years remove a great amount of disease from the land and prevent the invasion of diseases of an epidemic and spreading type.

Sanitation however admits of being studied from two distinct points of view, the legislative and the scientific. The legislator may say, and perhaps with justice, that the production of such a measure as the Act of which I now speak is as much as can be done. The man of science may say that this is childish talk, that much more requires to be done, and that after all that which has been done, though it be comparatively great, is practically imperfect and very little. Science in this respect is always in advance of legislation, and that is her true place,—the pioneer's place. I remember the time perfectly when every fragment of the Public Health Act of 1875 was in the hands of men of science solely, and was called a chimera, over which great lawgivers shook their wise heads and passed by.

At this moment the positions of science and legislation are relatively the same as they have ever been, and it is fair for us men of science now as in the past time to declare the way ahead for the law-maker. I shall proceed again, therefore, as I have often before, to indicate one or two new starts in sanitary legislation, not from the legislative but from the purely scientific point of view, uninfluenced by the many and vehement individual grievances and troubles which beset the path of the minister of state. In so doing I shall indicate also, by inference, what I think our society ought to support in the sanitary policy of the future.

In the first place, then, we ought to expect in the political progress of sanitation that there will be established in connection with the Government one central department in which every subject, directly and even indirectly, connected with the health of the people, will be considered. This department, it is to be hoped, will be under the control of a Cabinet Minister, and will supervise the sanitary work performed at present by the Local Government Board, the Registrar-General's department, the sanitary regulations of jails and reformatories, and all the duties now pertaining to the supervision of factories, in so far as the health of the employed is concerned: in fine, every sanitary work that can be weeded out of every other department of the state.

To such a central board or department a specific name is necessary. The name should be as distinct as that of the department for war, for the navy, for the exchequer, or for the post-office. The name, it is to be hoped, will be emphatically the Health Department, and the chief of it the Minister of Health.

It may be urged that substantially we are drifting into some such order as is here suggested. It may be urged that the Local Government Board is step by step assuming the duties assigned, as above, for the State Department of Health. To some extent this is true, and it might be advisable, for the sake of the connection which must always exist between such a central board and the various local boards, in the kingdom to add to the name of Health Department that of Local Government Board. But for the sanitary object the leading name must be Health, and Local Government must come in merely as indicative of the connections that exist between the State and the local centres—as the machinery.

In this question of progress there is involved an immense deal in a name. It is essential to the scientific sanitary teacher that every reasoning mind in the kingdom should become familiar with the two significant words, public health, or national health. It is equally necessary to let the people know fully that the Government has the health of the country under its general and wise supervision. But it is utterly impossible to make either of these facts understood by the masses so long as any sanitary authority, central or local, has a title which fails to convey the meaning of its functions. To speak to the masses who are listening to a lecture or discourse on health about a local government board is only to confuse them. They ask you afterwards what it all means, and they go away imbued with the impression that it means anything except what relates to the health of the people.

I am speaking very practically in suggesting that in the course of political sanitary progress it is an absolute necessity for success to give its proper and only name to the department of state which presides over the national health. I do not state too much in declaring that every public measure would carry more weight if it went forth as being under the supervision of the health department. It may appear a refinement of illustration, and yet it is a sound argument that vaccination would have met and would meet with far less opposition if it were enforced under the general supervision of a State department of health. As it is the people connect the carrying out of vaccination with something other than health, and even as distinct from the idea of conservation of health. It is looked upon as a legal tyranny, having no scientific setting forth of its intention, and as springing from no scientific authority. If you attempt to reason with its active opponents on the subject, and refer to the authority that exists, they dispute the competency of the authority in name and form; and, foolish as the objection may be, it is potent for obstruction.

In making this suggestion there is no necessity to offer a word against the continued action of local self-government. The work of the local centres in all parts of the kingdom instead of being in any degree curtailed and restrained, should be encouraged and maintained. In the sanitary local work the word health should, however, again come forward as the one prominent designating term to which all others should be subject.

Our Sanitary Institute could not turn its attention to any more suitable labour than that of inculcating the necessity for the institution of one state department exclusively devoted to the health of the people. In the success attending such an effort a double result would be achieved. The country would have secured for it the best and most direct guidance on its most vital interest, and scope would be given to the industry of men of science in a new direction. Men, whose lives have been devoted to the study of life and health, would be prepared by their devotion for the accepted service of their country in public form, and the Houses of Parliament would become, at last, congenial spheres for their labours. The Houses would be strengthened by such adhesions; the men would be more useful and honoured.

Another work in the political line which will be demanded in the future for the benefit of the sanitary cause is the preparation of such a digest of all our practical sanitary laws that every person of intelligence can read and understand what may be legally enforced for the maintenance of health. What may be done in this direction ought to be so simple and so plain as to be brought into a school-book. Not a line should be left for the subtlety of the legal brain to twist into contortioned illegibility. The laws by which the health of a man, and thereby of a nation, can be preserved to the utmost, are so simple in nature that nothing but the utmost simplicity can truly express them, and the whole labour of the future, if it is to be of any service whatever, must be directed to the discovery and establishment of such simplicity of exposition and direction. Up to the present time much that has been done has been provoked by that most untrustworthy of all human provocatives to action,—fear. Some great epidemic has occurred that has caused universal dismay; some great catastrophe has occurred, like that of the Crimean campaign, which has excited universal criticism on the failure of sanitary provisions by the authorities of the nation. Some such slip has been permitted in sanitary rule as that which recently let scurvy undermine the workers during a great enterprise of discovery. Straightway on the heels of such events there have been commissions of inquiry, and as a direct or indirect result there has often come forth some particular enactment. Or—and this is by no means rare—some individual of the House of Commons, impressed with the danger of a great national evil, has pressed for a national remedy, and, by steady persistence session after session, and by showing that he never knows when he is beaten, has forced the Government to take up his measure and to carry it through.

From these modes of legislating for health we have obtained many minor acts which fill and refill the national statute books. And still this process promises to go on, a process of labour in a circle with much loss of time and expenditure of force without ultimate progression.

It would be vain to find fault with the past for its doings. As vain to find fault with the State for meeting State disorders by empirical remedies as it would be to find fault with the physicians of a former day for the same mode of procedure. If the people demand a recipe they must have it, be it from the State or the family physician. The question that now comes forward is whether the time has not arrived for ceasing to treat the health of the nation by specific or supposed specific remedies for particular errors, and whether we may not find in the future a few very simple and natural guiding principles on which all acts of Parliament relating to the health of the people may be based?

Before this effort can be attempted the existing acts that touch on health,—public health acts, metropolitan health acts, contagious diseases acts, vaccination acts, factory acts, acts relating to the importation of cattle, adulteration acts, and others relating to prisons, workhouses, and the like, and which, if they even lie latent are not repealed,—these, one and all require to be considered together, with the view of determining whether an English or even a British act of settlement for the vital regeneration of the realm is not practicable on a simple natural basis of natural requirement.

I am fully aware that this suggestion carries with it the idea of a gigantic labour; but it will have to be done, and once fairly tackled I dare say the apparent difficulties will readily dissolve away. It is a mere question between doubting and attempting: and we all know and feel that—

> "Our doubts are traitors,
> And make us lose the good we oft might win
> By fearing to attempt."

Supposing the existence of an efficient central department of health acting under the direction of a minister of health, a grand new duty, as it seems to me, would be to determine what is the evil or what are the evils that have to be removed in order that the cleanest bills of health may be regularly presented to the nation. Without such preliminary knowledge all sanitary work is unsound to the last degree. It were as wise for me to write a prescription for a man without inquiring into his disease, his antecedents, and modes of life, as for the State physician to prescribe for national sickness without inquiry into the nature of the sickness, its antecedents, and the cause or causes that led up to it. The great work, therefore, and indeed the first sanitary work of the future, standing before all other sanitary legislations except the formation of the central authority, is the systematic enumeration, week by week, of the diseases of the kingdom, through the length and breadth of the kingdom. It is utterly hopeless to attempt any decisive measure for lessening the mortality, which is certainly more than double what it ought to be, until this State labour is faithfully carried out. It is vain, comparatively speaking, to know what totality disease hands over to death, unless we know also what health under one or other cause of disturbance yields over to disease. Physicians and statists strain their eyes to try to get at the extent of disease. Laborious geographers like Mr. Haviland spend years in constructing maps from the tables of mortality, in order to get a mere approximation of the distribution of disease in England: and meanwhile disease itself, constantly cheating the observers, is making its way without being under any systematised recorded observation.

For the omission of a registration of disease there is no conceivable excuse. The thing has only to be done. The organisation of the Registrar-General's department has fully opened the way to the collection and the utilisation of the facts relating to birth and death. These elements swing in the statist's balance readily, and are weighed by our consummate state weigher of life and death, Dr. Farr, as accurately as the Chancellor of the Exchequer balances the national ledger. With equal readiness Dr. Farr, if the data were collected for him, could tell from week to week the health as well as the mortality of the kingdom. In a short time, under such regular record, the whole nation would know the reigning health, the reigning disease, of every centre of life. And if, as might easily be done, the diseases of the lower animals and the diseases of the vegetable kingdom were included in the returns, all the facts of disease would be completely rendered.

I think I have already referred to an effort I made many years ago to carry out this design of registering the diseases of the kingdom. I refer to that effort again for a simple reason,—for the purpose of indicating that there is really no greater difficulty in getting the facts than there is in utilising them. I attempted no more than the registration of the epidemic diseases, and I could afford no more than the publication of a quarterly abstract of the data that were forwarded. But in a short time fifty medical observers were sending in returns from as many stations, extending from St. Mary's, Scilly, to Lerwick, in the Shetland Islands. These stations could easily have been increased to any extent, and the amount of information regularly communicated was indeed most valuable.

Two facts connected with this attempt are perhaps worthy of note, one as showing something determined, and the other as showing something suggested. In the returns sent from the district of Canterbury in the spring quarter of the year 1857 was included the first account of the invasion of this country, at least in any known time, by the disease since then so prevailing and fatal, diphtheria. This disease first appeared in the little village of Ash, and was called the Ash fever. The outbreak was observed and recognised by Mr. Reid, of Canterbury, and was reported to my register by Mr. Haffenden, who collected for me the facts of prevailing diseases from eight medical observers living near to him, of whom Mr. Reid was one. The first facts of a new disease in this country were thus recorded on the spot, which is something even as matter of history. How such a fact, reported at once to a central government authority, might be dealt with; how promptly a central authority so advised might act in arresting a fatal epidemic at its origin, and what national service might be rendered thereby, you, quite as well as I, can judge!

The fact of a suggestive nature springing from the working of the returns is not less interesting. The labour led me to refer to the returns of sickness sent every week by the medical officers of the Poor-Law districts to their boards of guardians. I found that these returns, over 3,000 in number, which, when they have served their local purpose, are practically worthless, could by the slightest modification be utilised as returns of the sickness of all the sick parochial population under official medical care, and I submitted a plan for such introduction to public approval and to the Government, but without effect. Yet if the plan had been adopted from those three thousand weekly returns, cast away and still cast away, I calculate that 156,000 tables of disease per year would have been submitted to scientific analysis which, since the time when the suggestion was first made, would have multiplied into 3,276,000 tables, including in each table a record of at least ten times as many particular examples of disease. To what important national uses such an array of facts systematically arranged and examined could have been applied you, as well as I, can judge! And still neither of us can judge effectively, because in dealing with data taken from nature there is always something important to be elicited which never was looked for, and often, too, that something unlooked for is better than that which was specially looked for.

Our Sanitary Institute will do well in continuing to press this scheme for the registration of disease on the Government, and it may greatly assist the work by lending its mind to the best means of collecting the facts on which the weekly reports of disease will have to be based. I might enlarge on this part of my subject, but I should prefer to remain silent until the views of the medical officers of health, now a large and influential class, have been correctly ascertained. My present purpose is served if I have sufficiently directed public attention to the principles of the design.

In the future of sanitary science the politician must come forward more determinately than he has yet done, in order to secure for those over whom he governs three pure requisites—pure water, pure food, pure air.

The Public Health Act of 1875 deals with the water question, and makes provisions for the local authorities to supply their respective districts, by means of a company, or by independent action. For my part I see no hope of any effective change for the better by these propositions. It is utterly hopeless to trust to companies in a matter of such vital moment. It is equally hopeless to trust to the undirected action of local authorities. If we trusted to such agencies for the collection and delivery of letters by post, does any one suppose that the results of our present postage system would be attained? Yet important as intercommunication by letter is, it is less important than the supply in due quantity and pure quality of that vital fluid which makes up three parts out of four of every human organism, and which is wanted as much by the millions who never receive a letter, as by the millions who do. In this political part of sanitation, the Government must do one of two things. It must either produce a process or processes for pure water supply, and insist on every local authority carrying out the proper method; or it must,—and this would be far better,—take the whole matter into its own hands, so that under its supreme direction every living centre should, without fail, receive the first necessity of healthy life in the condition fitted for the necessities of all who live.

By recent legislation we have some security for obtaining fresh animal food, and foods freed of foreign substances or adulterations. The penalties that may be inflicted on those who sell decomposing, diseased, or adulterated foods are beginning to have effect, and much good is resulting. Nevertheless, even here the legal rule falls short of completeness. The inspection of animal food is as yet most unsystematic and imperfect. With all our richness of means ready at command, we have not approached that admirable system for the inspection of animal foods which our Jewish brethren, through ages of ignorance and oppression, have managed so efficiently to carry out, and which has entirely saved them from many of the great calamities of disease that have fallen on less careful people. The complete inspection of animal foods, including milk, is a clear piece of sanitary law which, from day to day and hour to hour, must ultimately be enforced.

Imperfect as legislation may be in respect to supply of pure water and food, it is advanced in these directions when the steps it has taken for supplying pure air are brought under observation. There is no practical legislation of any kind on this requisite. The air of our large towns is charged with smoke and impurity. The air of our great factories is charged with dusts which destroy life with the precision of a deadly aim. Dr. Purdon, one of the certifying surgeons under the Factory Acts, reports that in the flax-working factories under his care the carders, who are all females, if they get a carding-machine at eighteen years, generally die at thirty years. Can any fact be more terrible than such a fact, that a girl of eighteen should have to live by an occupation that will bring her existence to an end in fourteen years, and to that end with all the prolonged wasting, sleeplessness, suffering, incident to the disease consumption of the lungs. If it were the fate of these doomed workers that at the close of fourteen years' work the majority of them were taken forth and shot dead in an instant, their fate were infinitely better than it is. The heart of the nation would thus be roused, and the law in all its majesty would be put in operation to arrest the progress of the crime and to punish the offenders. Yet, year after year as effective an offence goes on, and because the results of it is hidden in the sick-room there is no arrest of its progress, no punishment for its commission.

In the application of political science to preservation of health not one subject presses more earnestly than the question of the supply of a pure atmosphere to the millions of industrials of these islands. In an inquiry I recently undertook on this matter for the Society of Arts, Manufactures, and Commerce, the facts that came before me were as of a new world. You will find a compact mass of these facts in the lectures I had the honour to deliver before that learned society. Those lectures contain a tithe only of the things seen. I am quite sure that our leading politicians can have no adequate conception of the mental and physical condition of the great industrial classes, or of the need that exists for reconciling those classes to their fate. These truths are plain.

The catechism has failed to satisfy them. Bad air keeps up in them a depraved mental as well as physical state. Their poverty and not their will consents to their condition. In short, as a physician dealing with the physiological and psychological phenomena belonging to a class instead of an individual,—and this is all the difference there is between a politician and a physician,—my diagnosis is that a serious organic state febrile, fitful, fatal, exists in this part of the nation; that it demands the watchful consideration of all physicians, State and ordinary; and that the sooner the natural cure for it, pure air, and plenty of it, is let in the better for every class everywhere.

All political troubles have a physiological cause. To the Statesman not less than to the physician, physiology is the only true source of knowledge. A society such as ours, therefore, possessing as it does professed physiological skill, may render most important service by tracing out for the legislator the simplest scientific means for removing with atmospheric impurities and by preparing for that sanitary future when men universally shall breathe purity even with their freedom.

If any other incentive to action in this direction were required it would be the further fact that all diseases, mental and physical, national and individual, begotten of an impure atmosphere, are transmitted on. The consumption of body, the restlessness of mind are reproduced and gain intensity of development with each generation until practically they inaugurate a distinct racial type of human imperfectedness.

With this topic of legislating for pure air would come in naturally the question of homes for the people and the development of those recent acts which have been passed to meet the necessity. These efforts of the world political can scarcely be over-estimated; but there is one movement which stands before them and which has been singularly overlooked. It is essential that the home of the working man should in every case be cleared of the details of daily work. So long as he is compelled to work in the room in which he sleeps and takes his food, so long his home must be an unhealthy centre, and too often it will be the centre from which infected work will pass out, bearing infection into the homes of the wealthy. A modification of factory legislation by which a free and properly regulated work-room should be within the easy reach of every working man in every crowded centre is a necessity which all sanitary labourers should strive to get supplied. Our Institute has another urgent task before it in the effort to enforce this necessity on public attention.

In the future of sanitary science one more amongst many other reforms of a political character must needs claim important consideration. I refer to the political assistance that must be given to all of us who are engaged in the labour of quenching the drunkenness of our land. Our best sanitary efforts will fall far short of their deserts until this object shall be achieved. Over the future of sanitary science will be suspended a pall of sorrow until this object shall be achieved. Does any one desire to know how the mortality of the kingdom is modified by strong drink, let him read the knowledge in the State record book which tells that those who sell the destroyer die by it at the rate of one hundred and thirty-eight to the hundred of the whole population. Then, starting from this signal fact, let him trace the influence of the destroyer through all the courses of diseases which, under learnedly obscure names, spring from it and kill from it in all classes of society. Finally, let him reckon up the hereditary evils which are engendered by the same destroyer and the influence of that on the course of disease, and his lesson will be in some measure complete.

I do not think this the occasion to discuss the value of the different political sanitary measures that have been, or are at this time, in the public mind for the repression of the national evil now touched upon. Be it sufficient for me to state two impressions only. Firstly, that every day's experience of the question in various communities where as a teacher of abstaining temperance I am wont to labour, indicates to me that unless the State does come to the aid of the teacher the battle against intemperance must be indefinitely prolonged. Secondly, that if the State, itself doing nothing active in the way of repression, would but determine to cease to legalise the cause of the evil and to make revenue out of the transaction, the labours of the temperance reformer would have the most prosperous season of success presented to their view. Hitherto this has not been considered as a sanitary question. In the future no sanitary student will venture to exclude it from his studies.

The contemplation of the political sanitary future of this kingdom offers many other topics, all of which I must leave, in order to devote a few minutes to our subject in its relation to medical science.

The Medical Part.

The influence which sanitation will exert in the future over the science and art of medicine promises to be momentous. It promises nothing less than the development of a new era; nor is it at all wide of the mark to say that such new era has fairly commenced. The greatest of the world's philosophers, the philosopher whose thoughts cover the world of science as with a garment, I mean Lord Bacon, said of the medicine, of his day, that it stood for judgment on quite different merits than did other learned pursuits. "Other arts and sciences," he argued, "are judged of by the power and ability exhibited in the conduct of them by their professors, and not by success or by events. The lawyer is judged by the skill of his pleading, not by the issue of the trial; the pilot by his skill in directing the course of the ship, not by the fortune of the voyage. But the physician can perform no particular act by which his ability can be directly demonstrated, and therefore he is principally judged by the event, which is very unjust. For who shall decide, if a patient die or recover, whether the good or the evil is brought about by art or by accident? Whence," says he, "imposture is frequently extolled, and virtue decried. Nay the weakness and credulity of men is such, that they often prefer a mountebank or a cunning woman to a learned physician. So the ancients made Esculapius and Circe brother and sister, and both children of Apollo. Hence," he adds, "physicians say to themselves in the words of Solomon, 'If it befall to me as befalleth fools, why should I labour to become more wise?' And therefore one cannot wonder that they commonly study some other art or science more than their profession, because they find that mediocrity and excellency in their own art makes no difference in profit or reputation; for man's impatience of diseases, the solicitude of friends, the sweetness of life, and the inducements of hope, make them depend upon physicians with all their defects."

Had Bacon spoken these sayings in the present day, he had spoken, with one or two exceptional errors, as truthfully as he spoke in his own time. Had he been a physician, he might indeed have gone further than he did. He might have urged his too frequent inadequacy himself to decide whether his own success rested, in particular instances, on skill or on accident. He might further have added how oftentimes the cheek of the right-minded physician pales or burns with doubt as he hears his own praises declared for skill which he himself cannot for a moment take credit to his own heart. This has been the fate of medicine until our day. On such fate all the quackeries have flourished; on it all the "pathies" and dogmatic systems of medicine have flourished; on it the idea of cure has found too willing acceptance and belief.

At last a change has come over the science of medicine. With true nobleness of purpose, true medicine has been the first to strip herself of all mere pretences to cure, and has stood boldly forward to declare as a higher philosophy the prevention of disease. The doctrine of absolute faith in the principle of prevention indicates the existence of a high order of thought, of broad views on life and health, of diseases and their external origins, of death and its correct place in nature. The doctrine of absolute faith in curative medicine, of power vested in the hands of a distinct sect or class, and exercised by them as by regal right and without the assistance or interference of those upon whom it is exercised, indicates a low standard of knowledge; a too confiding spirit in the wisdom of a minority; a departure too wide from the safe law of self-preservation; and an ignorance of the avoidable causes of diseases; a blindness and therefore an unnecessary exposure to danger; an overweening and sudden fear of dangers of all kinds little and great, and a hasty and thoughtless pursuit after that mode of rescue from dangers of disease which claims for itself the greatest pretensions and boasts the greatest successes.

It shall remain as one of the glories of medicine that she herself has first seen these truths, and, willing to sacrifice her own interests to truth and light, has put them forward without fear, without reward. In the science of prevention medicine takes in fact all the world with her. The science becomes a political, a social, as well as a medical study. It appeals to every mind. When it once is so set forth it fills all men with its teachings. It models itself into household truths and commingles with the moral and even religious elements of life. Admitted for a season into the household, it steps forth again to find its way into the legislature. It becomes eventually a governing science—a law.

This scientific course commenced, must needs go on. But in its going it must needs also change greatly the old face of medicine, and remove in the change the Baconian reproach. I do not think there is much difficulty in foreseeing what in the main the change will be like.

I need not say that the "pathies" will go. The pathies of all kinds are as dead as door-nails, and wait only to be decently interred in a common grave. In time the word cure will go altogether. It is clear already that there is indeed no such thing. A man born to live through a given cycle lives through it free of disease, unless he be stricken from without. If he be stricken, and by the stroke the natural functions, by the exercise of which he lives, are not so disturbed but that they can swing back again in due order, he may recover; if he be stricken beyond this, he will die. Nature will pursue her course undisturbed by either event. She will make no special effort to kill, and assuredly she will put out no special hand to save. A man may intervene, and may, by knowledge, put the stricken body into such a condition that it may swing back into natural course whereby he will have put it into a condition in which it will not die. This is the very highest development of medical art resting on science. But it is not cure, in the common meaning of that term.

By the progress of sanitary science and by its influence on practical medicine we shall attain these perfect rules of management after the infliction of the stroke of disease; and I do not doubt that the art of placing the stricken under such conditions that they may not die will for ever afford scope for the inventive genius of man. The more immediate triumphs will, however, come in that part of the work which is purely preventive. Down from the skies comes the forked lightning and lays a man prostrate. It is a question for the ages who shall place that man in a condition under which he shall certainly swing back again into life. But the preventive art that puts up a metallic rod to divert the lightning from other men, that is the present triumph of human skill; skill which, carried to perfection, shall prevent the stroke and put out the second art by removing the necessity for its application.

With the progress of sanitary science we must expect to see preventive medicine taking the ascendancy. Cure will cease, prevention will grow. Humanly-made epidemics, like the great plague of London, which was planted and reared in the rush-covered floors of domiciles saturated with the organic refuse of years, or like the modern typhoid, which is fed by streams of drinking water uncleansed from human excreta, such self-made epidemics will be prevented by simple mechanical skill. Diseases imposed by indulgence in harmful pleasures and appetites, or by physical overwork and shock, will be removed by the effect of moral influences and knowledge of cause; and gradually, I believe, those persistent evils, which, like the lightning-stroke, come without human ordinance or fault, will be placed also under some protecting care, and, if not removed, reduced to a short calendar.

It is felt by some that the medical Sanitarian of the future will have his best efforts thwarted by the forcible excess of life beyond the means that can be found for the support of life, as if life were a mere secondary principle in the universal order. I see no such cause for fear. That in the progress of life on the earth the day will ever come when the earth will not supply food for its people is to my mind pessimism carried into an insane vulgarity. It is clear that man can always reduce to his wants the lives of all animals except man. The question rests therefore on the abnormal increase of man alone. Nature knows that and rules accordingly. Let man remain savage, and, however sensual he may be, he will die fast enough by war, plague, famine, or luxury. In that state he will never overstock the earth, but either grope in solitary places a neglected family, unprotected from all the killing vicissitudes, or will sink into luxurious barbaric decadence. Let man become exalted in life; exalted by communion with noble pursuits; with pursuits of science, art, letters, and cultivation of greatest happiness for the greatest number, and his sensual life will become too subject to the virtue to leave a chance for the danger which a low sensuality sets up as a terror and at the same time a temptation for the vulgar.

I think it my duty to deal plainly with a question which affects so closely the future of sanitation, and to express, from an experience which is confirmed, as I know, by some of the brightest ornaments of my learned profession, that nothing is wanted to correct the danger of over-population but improvement of mental process; nearer communion with the eternal mind in His works; purer artistic education, healthier homes, more rational amusements, and the ennobling influence of a holier life amongst those who assume to be the cynosures of the nation.

On the whole the prospects of medical learning and action will be greatly improved by sanitary advancement. It is possible that fortunes or reputations resting on faith in famous curers will dwindle slowly away, and that not for long will the skill of the physician be valued by the fallacious reckoning of mere results. But in exchange there will be opened to the physician a career in which skill of labour will be exhibited together with results, the results obvious as to their relation to the work, and both, if good, successful beyond praise.

The Social Part.

The future of sanitary science in relation to social life generally, its effect that is to say on all classes of the community, promises steady progress. No one who has been actively engaged for the past quarter of a century in sanitary work can doubt this statement. Throughout all sections of the community there is desire to know; and if the legislator will be content not to legislate until he sees that free-will guided by knowledge is in the same train with him—it doesn't matter in which class,—all will go well. The workers in our Sanitary Institute though they be not legislators can, nevertheless, greatly assist Parliament by bringing free-will into harmony with knowledge, and though the distinction does not at first sight stand out, in separating free-will from ignorance and from those automatic demonstrations of ignorance which are the outward and visible signs of unhealthy habits of life.

The social work that has to be carried out for the future of sanitary science is purely educational. Educational not merely by lectures and books and lessons from books, but by demonstrations of sanitary works, plans, buildings, mechanisms, results of all labours bestowed on the cause. Without venturing on details of this kind which would land me in another address, I may be content to touch on two points, both of vital moment for the future.

The first of these relates to modes of teaching so as to carry the sympathies of the learner and his more refined tastes along with his reason; to attract and charm his senses as well as his intellect. It is said of us sanitarians, and sometimes I fear with some truth, that we would make health hideous. We need not do so; and if the feat has ever been accomplished it is but the work of a "'prentice han," that ought to be forgiven. Health truly is beauty in the living evidences of it, and should be so in those inanimate evidences which the builder and the engineer construct for us. I would therefore urge that in all coming sanitary work, theoretical or practical, the sanitarian should call the artist also to his side, and that no design of a sanitary kind should ever be executed in which the hand of the artist does not play its beautifying part.

And if I might suggest so much to the imaginative scholars who live to make life sweeter to the many, I would ask them,—poets, painters, sculptors, players, musicians,—to believe that to render practical even their refined labour is to render that labour more acceptable, more diffusible, more durable.

The second topic relates to those who require first to be taught the sanitary lessons of the future. I want strongly to enforce that it is the section of the nation which Dr. Farr classes as the domestic, the six million of women of the nation, on whom full sanitary light requires first to fall. Health in the home is health everywhere. Elsewhere it has no abiding place.

I have been brought indeed by experience to the conclusion that the whole future progress of the sanitary movement rests for permanent and executive support on the women of the country. When as a physician I enter a house where there is a contagious disease, I am, of course, primarily impressed by the type of the disease and the age, strength, and condition of the sick person. From the observations made on these points I form a judgment of the possible course and termination of the disease, and at one time I should have thought such observations sufficient. Now I know them to be but partly sufficient. A glance at the appointments, and arrangements, and managements of the house is now necessary to make perfect the judgment. By this is shown what aid the physician may expect in keeping the sick in a condition most favourable for escape from death; and by this is also shown what are the chances that the affection will be confined to one sufferer or distributed to many. As a rule to which there are the rarest exceptions, the character of the judgment is hereupon dependent on the character of the presiding genius of the home,—on the woman who rules over that small domain. The men of the house come and go; know little of the ins and outs of anything domestic; are guided by what they are told, and are practically of no assistance whatever. The women are conversant with every nook of the dwelling, from basement to roof, and on their knowledge, wisdom, patience, and skill, the physician rests his hopes. How important, then, how vital that they shall learn as a part of their earliest duties, the choicest sanitary code. How correct the decision of the founders of the Sanitary Institute, that from the first they should include sanitarians of both sexes as working associates.

To women more than to men this work is new. To women more than to men this work is hard to realise. Naturally more conservative than men they are moved with less haste to tasks of reformation and reconstruction. More sensitive to criticism than men, they are given, at first, to resent, as if it were an insult to past customs and usages to which they are attached, the suggestion of innovation. But these passing difficulties removed, there is in the hearts of women such matchless generosity, such overpowering love for every device tending to promote the happiness of all things of life, that we sanitarians may indeed be content for the future of sanitary science in its social aspects, if we do no more than win them to our cause and entrust its details to their ministering spell.

PERU[1]

STUDYING in Mr. Squier's new work the records and ruins which attest the civilisation of Peru before the Spanish Conquest, one finds oneself repeating the often-asked question, Did these advanced arts and institutions arise out of native savagery, or were they at least developed under the guidance of ideas imported from the Old World? Mr. Squier holds that they were indigenous, and his opinion (which is that also of Mr. Markham) must have great weight, not only from the minute care with which he has examined the ruins during his two years' exploration, but from his familiarity with the Spanish literature on the subject. Some readers, however, like the present reviewer, while admitting that much of the Peruvian culture has such a stamp of peculiarity that it must be home-made, may not feel quite so certain of the whole being absolutely free from foreign influence. It is much to affirm of a bronze age people like the Peruvians (for particulars and drawings of their somewhat special types of bronze implements, see pp. 175, 579) that they invented this alloy independently. For an excellent case of mingled native originality and similarity to Old World types, attention may be called to the stone-circles of Sillustani, as exemplified by Fig. 1, reproduced from Mr. Squier (p. 384). He calls them "sun-circles," which, however, is begging the question of their as yet unproved purpose. At any rate there they stand, circles of erect unhewn stones like the cromlechs of Europe and Asia, but with a special feature in the surrounding pavement or "platform" of well-fitted hewn stones, with a gutter running all round the circle near the inner edge.

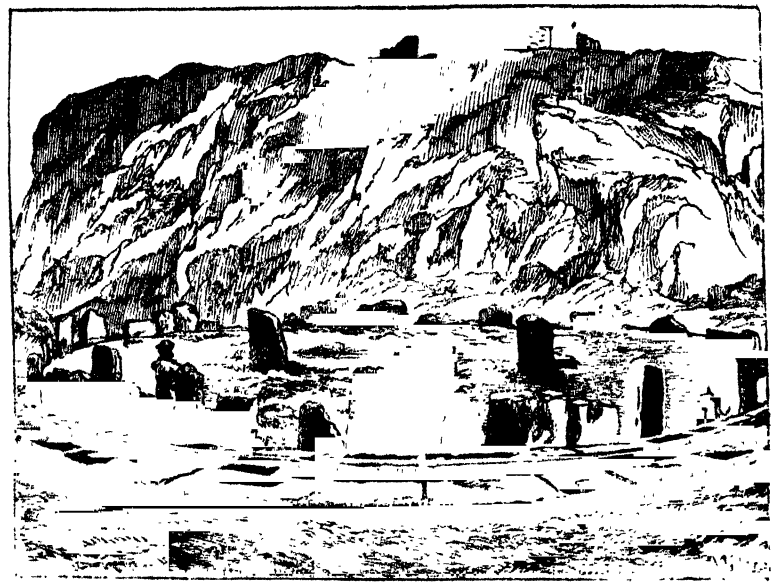

FIG. 1.—Sun-Circle, Sillustani.

On the hill above are seen the ruins of chulpas or burial-towers. Fig. 2 shows two of these, the left-hand one being a beautiful example of building in close-fitting blocks of hewn-stone, an art which had attained in Old Peru to a perfection hardly reached elsewhere in the world. This tower is thirty-nine feet high, and widens as it rises from sixteen feet at the base to nineteen feet at the spring of the dome top. In a still larger chulpa there are hewn trachyte blocks as large as twelve feet long on the curve of the face, by seven feet high, and five feet deep. The stones, fitting together face to face without mortar, are imbedded within in the mass of the structure, which is of rough stones laid in clay. Extraordinary skill in masons' work is shown by these blocks being not only cut in the sides and outside curvature to a radius from the centre of the monument, but in the gradual swell of the structure as it widens out, as well as the curve of the dome, being accurately taken in each block (p. 382). The blocks were not shaped after being put in position, as is proved by numbers of them lying on the ground, perfectly cut to conform to their places in towers that were never finished, so that they were hewn to plans in which every dimension of the structures had been previously fixed. Yet with all this skill there was not the mechanical knowledge to provide anything like pulleys or cranes to hoist the heavy blocks into their places. The inclined planes of earth and stones built up against the chulpas still remain, up which the stones were moved, probably with levers, and possibly with rollers also. Looking at the woodcut, one sees a low opening cut through a block at the base of the tower, just large enough to admit the body of a man; this leads into the circular burial chamber, vaulted with flat, over-lapping stones. This primitive arrangement of the "false arch," which reminds one of those which children make with their bricks, is usual in Peruvian as in Central American architecture. Yet, as if to complicate the problem of architectural history in America, there are exceptional cases where, as at Pachacamac, true arches of sun-dried bricks are still to be seen (p. 71).

FIG. 2.—Round Chulpas, Sillustani.

Of the more usual Peruvian masonry, where the blocks, accurately faced, are kept in position by their mere bearing on one another, without cement or mortar of any kind, Fig. 3 presents a specimen. It is interesting for other reasons, being one of the Ynti-huatana, or "sun-years," by which the solar year was determined. The following passage from Garcilaso de la Vega's "Royal Commentaries of the Yncas" seems to describe structures of this kind:—

[1] "Peru. Incidents of Travel and Exploration in the Land of the Incas." By E. George Squier. (London: Macmillan, 1877.)

"The Yncas were also acquainted with the equinoxes, and observed them with great solemnity. . . . To ascertain the time of the equinox they had a stone column, very richly carved, erected in the open spaces in front of the temples of the sun. When the priests thought that the equinox was approaching, they carefully watched the shadow thrown by the pillar every day. The pillar was erected in the centre of a large circle, occupying the

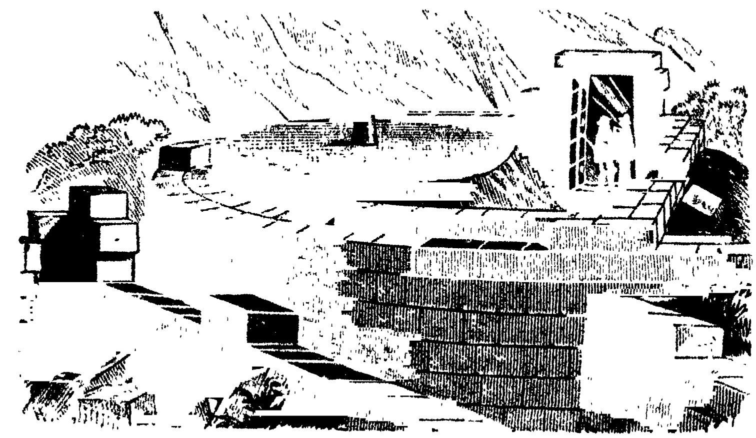

FIG. 3.—The Inti-Huatana of Pisac.

whole width of the courtyard. Across the circle a line was drawn from east to west, and long experience had shown them where the two points should be placed on the circumference. They saw, by the shadow thrown by the column in the direction of the line, that the time of the equinox was approaching; and when the shadow was exactly on the line from sunrise to sunset, and the light of the sun bathed the whole circumference of the

FIG. 4.—Ancient Vases and Modern Peruvian Heads.

column at noon, without any shadow being thrown at all, they knew that the equinox had arrived. Then they adorned the pillar with all the flowers and sweet herbs that could be gathered, and placed the chair of the sun upon it, saying that on that day the sun with all its light was seated upon the pillar" (Markham's translation, published by the Hakluyt Society, vol. i. p. 179).

It is true that a "stone column very richly carved" seems an inappropriate description of the plain truncated conical gnomon shown in the drawing. It is, however, as Mr. Squier says (p. 525), "sharply cut and perfectly symmetrical." Can this be all that Garcilaso meant by "columnas de piedra ríquisimamente labradas"? or were others of these structures furnished with more ornament? Garcilaso also describes towers near Cuzco erected for determining the solstices; but Mr. Squier considers that his account is confused, and that these so-called towers were only Ynti-huatanas. From this opinion Mr. Markham, writing in the *Academy* for May 19, quite dissents, and probably most readers who go through the whole of Garcilaso's chapter will consider that he had some idea of what he was writing about, and will take it on his (and other) evidence that the Peruvians had, in fact, solstice-towers as well as these equinox-cones. After all one must admit, with Mr. Squier, that the Peruvians had not advanced so far in astronomy and computation of time as the Mexicans and Central Americans.

No traveller before Mr. Squier had thoroughly explored the great lake of Titicaca with its sacred island, celebrated in tradition as the place whence Manco Capac and his sister-wife Mama Ocllo, children of the Sun, and first of the Yncas, came down to govern and civilise Peru. In this cold desolate region, twelve to thirteen thousand feet above the sea, ruins of palaces, convents, and the temples of the Sun and Moon still remain to attest its sanctity under the Ynca rule. Mr. Squier's estimate of the true value to be placed on the traditions of the Yncas is reasonable and moderate. To the warlike genius which enabled them to subjugate the vast land, to the political genius with which they organised the system of communication and social control, which is one of the most wonderful phenomena in the history of nations, he does full justice without countenancing the absurd idea that the whole development of Peruvian culture is to be attributed to this one conquering tribe. His researches, indeed, bring out more clearly than ever the distinctness of much of the native civilisation of Peru from that of the Yncas, whose rule had not been extended over the whole land till near the time of the Spanish Conquest.

The ruins of the temple of Pachacamac, and elsewhere near Lima, show us a people similar in origin and language to the Yncas, but who had their nationality and culture before the conquering tribe came down upon their coast from the high valleys of the Andes. The Chimus of the Truxillo district spoke a language still known in some villages, and said to be quite distinct from the Quichua of the Yncas. Yet these people had attained to peculiar skill in metal-work and pottery. Indeed from this district come the well-known Peruvian vessels with double spouts or double bodies often modelled in the form of an animal or a pair of animals, and with a kind of whistle uttering the creature's proper cry when the vessel is tilted so that the water in it forces air in and out through the hole. Not less curious are the well-modelled head-vases, which (Fig. 4) give us the means of comparing the features of the ancient and modern inhabitants. With reference to this and other drawings here reprinted from the hundreds contained in Mr. Squier's volume, he may be congratulated on the thoroughness with which he has enabled his readers to understand the book which suggested his exploration—Prescott's "History of Peru."

EDWARD B. TYLOR

THE METEOROLOGY OF THE FUTURE

A VISION

FREELY translated from the Japanese by one who is thankful that he does not live in Japan. The translator would remark that in importing our Western institutions it is of great consequence to appropriate likewise the spirit which pervades them. "Dead flies cause the ointment of the apothecary to send forth a stinking savour" (old Eastern proverb).

(*N.B.—This translation is dedicated to the Council of the Royal Society.*)

A QUIET people are the dead,
What stillness do they keep!
The battle rageth overhead,
But marreth not their sleep.

And yet that this is sometimes broke
Hath been revealed to me;
'Twas in eighteen hundred and eighty-one
At the bottom of the sea.

There lay poor Jack, his perils past,
No more to turn the quid,
Nor pipe his eye (since barnacles
Were feasting on the lid).

Long thin sea-ropes in tangled coils
Were round and round him curl'd,
Yea, scaly things above him swam,
Down in that green sea-world.

He could not weigh his anchor up,
He could not heave astern—
And thus in my bewildered ear
He spun his doleful yarn.

"*'Twas not the storm that brought me here*
"*In Davy Jones's grip,*
"*But 'twas because my mates and me*
"*Sailed in a rotten ship.*"

I answered him: But knowst thou not
That Plimsoll's noble band
Board every ship, and punch its ribs
Before it leaves the land.

No rotten beam but would be seen
By such a skilled detector—
The dead man groaned—"*Alas! dear mate,*
"*They jobbed the ship's inspector.*

"*Not two hours' sailing from the Nore*[1]
"*The wind began to veer,*
"*The storm was strong, the ship was weak,*
"*And we were driven here.*"

Belay! belay! thou man of Death,
Thy yarn won't hold together,
Dost thou not know we have a board
That telegraphs the weather?

A board that sits both night and day,
With facts and figures stored,
Why man alive!—The dead man groaned—
"*Alas they jobbed the board.*"

Why dost thou groan thou man of death?
Why so blaspheme and cuss?
Their chairman sure was not the smith
To forge thy fetters thus?

His was a mind of many sides,
Well filled with *a* and *b*,
And *x* and *y*, and likewise *z*—
"*But he didn't know the sea.*"

[1] Of course this word does not occur in the original—only its Japanese equivalent.

As thus he spake I forthwith said—
Well, even if this be true,
The captain makes not all the ship,
Now, what about the crew?

There's one I know—"Divine" doth best
Express his god-like presence;
"*He knew the sea but never dived*
Beneath its phosphorescence."

Then, I replied, there was a third,
In fame to none will yield,
He led the band who reaped renown
On India's famine field.

Was he the man to see thee die?
Thou wilt not tax him—come?
The dead man groaned—"*I met my death*
Through a sun-spot maximum."

One more—the rover of the crew—
Hath sailed o'er many seas;
Come now, be reasonable, he—
"*Was busy shelling peas.*"

I wakened up in sheer disgust,
And to myself I said,
The living man for prejudice
Is beaten by the dead.

THE SPECTRA OF CHEMICAL COMPOUNDS[1]

IN this paper Mr. Moser discusses the question, whether chemical compounds have a spectrum of their own or whether they only show the superposed spectra of their elements. To those who have worked at the subject the question can hardly be called an open one. Ever since the too much neglected work of Mitcherlich it was proved that each compound has its own characteristic spectrum, and whatever evidence subsequent workers have added to the question, the merit of having decided it belongs solely to Mitcherlich.

Nevertheless Mr. Moser's work is a valuable one and for several reasons. Other questions still at issue are intimately connected and cannot be discussed without once more referring to Mitcherlich's work. Most of these questions are not as yet amenable to strict proof but must be decided by the common sense of those who work at the subject. It is therefore of importance that as many as possible should take up the question, and though each worker may add little to the stock of knowledge, the consensus of opinion, thus established, will advance the subject materially. It is a pleasure to find that Mr. Moser has apparently arrived at the same theoretical views which have formed the leading string during the last years to the experimental work of Lockyer and others in this country. Mr. Moser mentions the suggestion of Prof. Helmholtz that the line-spectra are due to the vibrations of an atom while the band spectra are due to the more complex molecule. This is precisely the view first put forward by Lockyer, and it has thus received a striking confirmation from an independent quarter.

Mr. Moser experiments on the changes which certain absorption spectra undergo by a variation first of the thickness of the absorbing layer, and secondly of the temperature. With regard to the variation of thickness of the absorbing layer the conclusions seem simple enough. The bands get darker and wider. The influence of temperature is divided into two parts. On the great majority of bands the increase of temperature has apparently the same effect as an increase of mass; that is, it increases the absorption.

It is more than probable that this increased absorption is really due to an increase in the number of molecules giving the absorption spectrum in question. If a gas is

[1] By James Moser (*Pogg. Ann.*, vol. clx., p. 177.)

near the temperature at which it condenses, its molecules as a rule aggregate before they finally pass into the liquid state. Each molecular aggregation has its own spectrum, and thus a change of temperature producing a difference in the relative number of molecules in these different states will increase the absorption of one spectrum, while it weakens some other absorption spectrum. If the spectrum which gets weaker lies in the invisible part, the only visible effect of temperature is to increase the darkness of the whole observed spectrum. In many cases, however, we can follow out not only the increased absorption of one spectrum, but at the same time the gradual breaking up of another spectrum, and this affords a beautiful illustration of the gradual dissociation which we can now trace step by step.

In order to make my meaning clearer I shall trace in detail the effect of an increase of temperature on the absorption of sodium vapour. If we heat up sodium in an iron tube we observe at first a continuous spectrum stretching from the red and blue end of the spectrum towards the green. If the mass of sodium vapour is sufficiently great the two banks will join, and the whole spectrum will be absorbed. If we now raise the temperature the light will force its way through the bank in the green, and then, almost as suddenly as if a curtain was withdrawn, the spectrum will open from the green towards both sides. The continuous absorption now has entirely disappeared, but a series of finely-shaded bands are seen. The D-line will soon make its appearance, and if we now continue to increase the temperature it will increase in darkness, and we shall soon arrive at a point where the bands quickly fade away, and as we see them disappearing, we see the whole absorption thrown into the D-line, which gets thick and of an intense black colour.

No one who has ever actually observed this fact can for a moment doubt that we have here to do with a real breaking up of the band-molecule, as we may call it, into the simpler molecular state in which it gives the line absorption. Similarly at lower temperatures the band-molecules aggregate and give the continuous spectrum of which we have spoken.

The three vapours which Mr. Moser has examined are: Iodine, bromine, and the oxides of nitrogen. That the darkening of the absorption bands of iodine is due to a breaking up of a more complex molecule is shown by the fact, discovered by Lockyer, that there exists a molecule of iodine which gives a continuous absorption, and which is more complex than the band-molecule. There can be little doubt that this also is the explanation of the analogous phenomenon in bromine vapour. The brown vapour of the oxides of nitrogen are known to be a mixture, and it is, t erefore, not surprising that the relative quantity of the different oxides changes with the temperature.

It is, indeed, the second effect of temperature observed by Mr. Moser, that some of the bands disappear as the temperature is raised. There can be little doubt that in the case of the oxides of nitrogen, the three disappearing bands are due to a compound which is broken up as the temperature is raised.

A curious alteration is noticed in the case of iodine and bromine vapour. In each case one band was observed to disappear and to be replaced by a number of fine equidistant lines. I noticed some time ago a similar replacement of a fluted band by a number of fine lines approximately in the same place in the emission spectrum of carbonic oxide. The change requires a more careful study before any decided opinion can be given as to its cause. ARTHUR SCHUSTER

OUR ASTRONOMICAL COLUMN

THE LATE PROF. SANTINI.—Giovanni Santini, Professor of Astronomy and Director of the Observatory in the University of Padua, whose decease has been announced in the daily journals during the last week, had nearly completed his 91st year, having been born at Borgo S. Sepolcro, in Tuscany, on the 30th of June, 1786. Educated at the University of Pisa, he applied himself especially to the study of the exact sciences, and in 1814 was appointed successor to Vincenzo Cheminello at the Observatory of Padua. He subsequently became Rector of the University and Director of Mathematical Studies, to which position was attached the Professorship of Astronomy.

Santini was the last of a phalanx of distinguished practical astronomers among whom were Argelander, Bessel, Carlini, Encke, Mädler, Struve, and others, which will long live in the annals of the science. The work with which he has been more particularly associated and brought into prominence in the astronomical world, relates to the celebrated comet of Biela, the perturbations of which body were calculated by him upon a uniform system from 1826, when the comet's period of revolution was first determined, to 1859, for which year he prepared an ephemeris, though the track in the heavens was too unfavourable to permit any hope of observations. Santini's memoirs on Biela's comet appear partly in *Memorie dell' I. R. Istituto Veneto di Scienze, &c.*, earlier ones in the *Transactions* of the Academies of Padua and Modena. His colleague, Dr. Michez, took up his work for 1859 and continued the calculation of perturbations to 1866, in which year the comet was sought in vain, and we have no further computation of the effect of planetary attraction upon its motion.

Amongst the other astronomical works of Prof. Santini are several catalogues of stars in the neighbourhood of the equator, or from declination + 10° to − 12°, for the epoch 1840, in which the differences from the positions in Bessel's zones are exhibited. Also an investigation of the mass of the planet Jupiter, from observations of the elongations of the fourth satellite, made at Padua in the first four months of 1835, which gave a result confirming the value deduced by Sir George Airy by similar observations at Cambridge a short time previous, Airy's figure being $\frac{1}{1048 \cdot 69}$ and Santini's $\frac{1}{1049 \cdot 2}$. He was the author of a valuable work for the student, "Elementi di Astronomia," which contains a great amount of information relating to the practice of astronomy, that can hardly yet be said to have become antiquated, though the second and last edition appeared in 1830; the writer of these lines gladly acknowledges his indebtedness to this work, when a student of astronomical methods of observation and calculation, some thirty years since. Santini was elected a correspondent of the Institute of France (Academy of Sciences) in 1845.

THE DOUBLE-STAR 72 OPHIUCHI.—The close companion to this star was detected by M. Otto Struve, with the Pulkowa 15-inch refractor, in 1842. In a note to his catalogue of 1850, he remarks: "I have looked at this star very frequently, and have noted it many times as a single star. On three occasions, however, I have seen it double, always very nearly in the same direction, and at a distance of 1″·5. I do not know how to explain these discordances, except by supposing that the light of the satellite is very variable." In 1847 the angle was measured 166°·3, and the distance 1″·59. Dawes states he had examined the star with different telescopes, including Mr. Lassell's 20-feet reflector, but had never obtained a glimpse of the companion. Secchi thought he saw it double in July, 1857, but placed small reliance upon the observation; in August, 1859, he obtained undoubted evidence of duplicity; the angle was 3°·75, and the distance 0″·604 for 1859-61, magnitudes 4 and 7; he remarks on this occasion: "E certamente doppia, e ben separata." The suspicion of the discoverer is, therefore, likely to be confirmed when large instruments are brought to bear upon the object frequently.

A REPORTED OCCULTATION OF MARS BY VENUS, A.D. 368, JULY 30.—Amongst the observations extracted from the Chinese Annals by the Jesuit missionary Gaubil, and printed in the *Connaissance des Temps* for 1810, is one which is thus translated: "An 368 = 3e année Tai-ho, 6e lune, jour Kia-yn (30 juillet) Venus éclipsa Mars." It may be worth while to examine how far M. Leverrier's tables will represent this reported observation. Calculating for July 30 at 0h. and 8h. Paris mean time, we find the following quantities:—

SUN.

True longitude. ° ′ ″	Log. earth's radius-vector.
127 10 31·4	0·0045397
127 29 50·7	0·0045058

VENUS.

Geoc. longitude. ° ′ ″	Geoc. latitude. ° ′ ″	Log. radius vector.
166 25 48	+ 0 30 59	9·860940
166 49 12	+ 0 29 53	9·860966

Distance from the earth at noon, 1·1263.

MARS.

Geoc. longitude. ° ′ ″	Geoc. latitude. ° ′ ″	Log. radius vector.
166 35 25	+ 0 34 50	0·196730
166 48 17	+ 0 34 37	0·196623

Distance from the earth at noon, 2·2168.

Hence the conjunction in longitude would occur July 30 at 7h. 18·5m. Paris mean time, or July 30 at 15h. 4m. mean time at Nanking, where the Chinese Court was then established; Mars north of Venus 4′ 39″. Consequently, according to M. Leverrier's tables, there would be no occultation, but a very close approach, and considering the calculated time of conjunction, at an early hour in the morning, whereas the planets would be evening stars, it would appear that an occultation was only inferred from some previous or subsequent observations or both. The accuracy of the Chinese record, so far as regards a near appulse of the two planets about the time named, is however confirmed.

THE PREHISTORIC STEPPES OF CENTRAL EUROPE

IN a recent number of the *Magdeburgische Zeitung* is an interesting article by Dr. A. Nehring, upon the former extension of the steppes of Russia into Northern Germany. The country between Magdeburg and Halberstadt now belongs to one of the most fruitful and best cultivated districts in the Fatherland. Yet there are good grounds for believing that in former days this country was for a lengthened period a steppe—probably not an isolated steppe, but connected on the east with the great steppes of Russian Asia.

Northern Germany, including the country designated above, is generally regarded as having been in former times either overflowed by the sea and beset by icebergs, bringing down erratic blocks from the Scandinavian ice-mass, or, as Cæsar and Tacitus subsequently found it, covered with thick forests and extensive marshes. Both these views are correct—the one for what is usually called the Diluvial epoch—the other for the period immediately preceding historic times. Yet we may be allowed to ask what was the state of things in the intervening period? that is, after the sea had left the plains, and before the wood from the neighbouring heights had grown over it. It is probable that the former sea-bottom, which made its appearance as a sandy plain saturated with salt, in many parts of North Germany became a steppe. The same thing has happened in other parts of the world.

A steppe need not necessarily be quite flat. Within the range of the extensive plains of the present steppes and prairies there are not unfrequently hills and undulating or elevated surfaces, and rocks breaking the uniform level. The absence of wood is characteristic; the sandy surface is covered with grasses, dwarf herbs, and stunted bushes, which increase rapidly after the rainy season, but fade away altogether in the dry season, and present the appearance which we generally associate with the word "steppe." The soil is not altogether unfruitful, for the sandy loam is much appreciated by many kinds of plants. It is only where the former sea-bottom consists of pure sand that herbage is altogether deficient. We designate as deserts such tracts of land—especially when they occur in hot countries. The soil of the "steppe" proper is often very fruitful, but its defect is that it has no regular supply of water, being only here and there varied by streams, marshes, and lakes, the latter generally salt. In the neighbourhood of such water a continuous vegetation may be developed, but the greater part of the steppe is covered with herbage for only a few months after the rains, and this disappears as quickly as it grows. Heat and cold, drought and flood, luxuriance and want succeed one another very rapidly.

The fauna of the steppe is, in its most obvious features, quite peculiar. Such of its animals as live on the ground and cannot escape the bad season of the year by emigration, become so accommodated to the climate and soil that they are never met with in other places—that is in woody or marshy districts. Among these the steppe-rodents (such as Jerboas, Sousliks, and Voles) are most remarkable. They find sufficient sustenance in the twigs, leaves, and berries of the steppe-plants. The dry sandy soil is well adapted for their underground dwellings, which protect them from the severe winter and from the attacks of the beast of prey. Let us take, for example, the steppes which lie between the Lower Volga and the Upper Ob. The characteristic animals of this district are (1) the large Jerboa (*Alactaga jaculus*); (2) several species of Souslik (*Spermophilus altaicus*, &c.); (3) the Steppe-marmot (*Arctomys bobac*); (4) the little Piping-hare (*Lagomys pusillus*); (5) the Wild Ass (*Equus onager*); (6) the Saiga Antelope (*Saiga tartarica*). The remaining mammals met with, whether as residents or as temporary visitors, belong either to the fauna of Central Europe or to that of Northern Siberia.

Now this is exactly the same series of mammals which Dr. Nehring's continued researches in the stone quarries of Westeregeln (in the Circle of Manzleben) have brought to light. As regards the number of individuals the steppe-mammals show an undoubted predominance. The most numerous are the Jerboas and the Sousliks, which must formerly have inhabited the neighbourhood of Westeregeln in large numbers. Nearly quite as numerous must have been the wild asses, of which the teeth and bones occur in large masses. There are also many remains of Voles, mostly of such species as at the present time are only found in Eastern Europe and Western Asia. Of the marmot and piping-hare Dr. Nehring has at present only single examples, but expects to find more as his excavations continue.

Of the characteristic steppe-mammals mentioned above the Saiga is the only one not yet found at Westeregeln. But it is to be expected that it will yet be discovered there, because the whole facies of the extinct fauna indicates its former presence, and the Saiga has already been found fossil in several places further to the west. Perhaps also a specimen of a supposed large sheep (*Ovis*), which was obtained some years ago near Westeregeln, may really have belonged to the Saiga.

On the whole, if we put the Saiga aside, the Diluvial fauna of Westeregeln seems manifestly to have been a steppe-fauna, and brings us to the conclusion that the district in which these animals dwelt must have been a steppe of similar character to that which now extends between the Volga and the Ob, and perhaps have been even in direct connection with it. That the animals, the remains of which are found in the Diluvium of Westeregeln, actually lived on the plains under the Harz, Dr. Nehring has proved satisfactorily by his own researches. It follows that this country must have formed a steppe during a certain portion of the Diluvial period.

If the above conclusions are right it follows that in a former epoch those parts of Central Europe which were formerly covered by the sea generally became steppes before coming into their present condition. Perhaps the Magdeburg-Halberstadt steppe extended southwards over Aschersleben and Halle into the valley of the White Elster, for Prof. Liebe has found, near Gera, fossil remains of several specimens of the large Jerboa, as also of the Souslik and other animals which have been obtained at Westeregeln. Besides, remains of the same animals, as well as those of the Saiga antelope and wild ass, have been found at several other points to the west. It follows, therefore, that the steppe must have extended considerably in that direction.

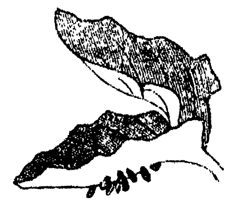
The result of these investigations is the more important as manifest traces seem to show that at the Steppe period man had already occupied the plains of middle Europe, and occasionally took up his abode even on the ancient steppe of Westeregeln.

The cause of the disappearance of the ancient steppes of Central Europe Dr. Nehring supposes to have been the gradual increase of the forests which advanced along with the change of climate. In the Steppe period England and Scandinavia were still joined to the continent of Europe, the North Sea and the East Sea did not exist in their present extent, the Gulf Stream had a more northern direction, and the climate was drier and more severe than it now is. As the climate softened and the forests advanced from the wooded hills, the steppe animals gradually withdrew themselves towards the east, and disappeared, leaving only fossil remains to attest their former abundance.

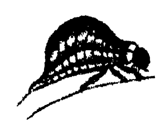
THE COLORADO BEETLE

WE have already several times referred to this destructive insect, and now that it has reached Europe we give an illustration of the creature in its various conditions, along with some notes which have been forwarded to us by Mr. Andrew Murray. The Board of Trade have reissued the circular, with a coloured illustration, referred to in our article on Our Insect Foes, vol. xv., p. 85.

The Colorado beetle belongs to that subdivision of vegetable-feeding species known as Phytophaga. It may help the general reader to an appreciation of their place and character if we mention the Turnip flea as a British species of this section, and still nearer to it those brilliant green little gems that are to be seen in quantity on the leaves of the white nettle (*Lamium album*) in summer, and which in Scotland bear the colloquial name of Virgin Maries, an appellation, however, which is also there sometimes indifferently given to the ladybird. The genus in this great section to which these little insects equally with the Colorado beetle belong is named Chrysomela. It is true that its first describer, Say, named it *Doryphora decemlineata*, and that at first that designation acquired such extensive currency that it was all but universally adopted; and many people from old habit or deference to general usage, even when they know it to be an error, still use it; but all entomologists know that it is not a Doryphora, but a portion of the great genus Chrysomela, without going into other details. The difference between them can be very easily pointed out by one single character. Doryphora is a massive Chrysomela with a strong spike projecting forwards from the middle (the mesosternum) of the under side, while Chrysomela has no such spike. The former is a genus peculiar to the South American region, including Central America, and contains the largest, finest, and most beautiful species of the family. Some of them are somewhat similarly marked to the Colorado beetle, which no doubt led to Say mistaking the genus. But although the Colorado species and its allies are clearly enough Chrysomelæ, systematists in arranging that genus have broken it up into several sub-genera or new genera, and the latest authority (Chapuis) has placed them in a genus named Leptinotarsa, but at the same time indicates his opinion that a further subdivision must take place, which will leave the Colorado beetle and its relations in a sub-genus by themselves, as was long ago (1837) proposed by M. Chevrolat, under the name of Polygramma. For the characters of these subdivisions we refer to M. Chapuis's genera, and for the specific characters of the species falling under Polygramma to Stahl's diagnosis and Mr. Riley's first

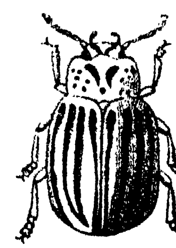


Potato leaf with eggs of Colorado Beetle on under side.



Larva of Colorado Beetle; natural size.—NOTE. The double row of black spots along the abdomen is not sufficiently distinct in this cut.

Pupa of Colorado Beetle: natural size. Colorado Beetle; natural size.



Magnified Sketch of Colorado Beetle.

Missouri Report (1869). These are, first, the true Polygramma (*Decemlineata*, Say) that has occasioned all this alarm, which is the most northerly species, its native home being the eastern base of the Rocky Mountains and the prairies extending eastward. Next a variety called *Multilineata* by Walsh and Stahl, but which is not specifically distinct. Then a good species, *Polygramma juncta*, which ranges through the Confederate States of North America, and is easily recognised by two of the dorsal black lines uniting to make one thicker one. Farther to the south, about Vera Cruz and Costa Rica, &c., there is another species very like the Colorado species, called *Polygramma undecemlineata*, Stahl, and which is found in enormous numbers in these parts of Mexico. Lastly Stahl records another, which we have not seen, from Mexico, under the name of *novemlineata*. All these feed on different plants, although probably plants all belonging to the same order, the Solanaceæ.

NOTES

THE Society of Arts has awarded its Albert Medal "for distinguished merit in promoting Arts, Manufactures, or Commerce, to Jean Baptiste Dumas, member of the Institute of France, the distinguished chemist, whose researches have exercised a very material influence on the advancement of the Industrial Arts." The Society's Medals for papers read during the session, have been awarded to Prof. Barff, M.A., for his paper on "The Treatment of Iron for the Prevention of Corrosion;" J. Meyerstein, for his paper on "Stenochromy, a Novel Method of Printing in Colours;" A. J. Ellis, F.R.S., for his paper on "The Measurement and Settlement of Musical Pitch;" B. St. John Ackers, for his paper entitled "Deaf not Dumb;" Commander Cameron, R.N., C.B., for his paper on "The Trade of Central Africa, Present and Future;" James Irvine, for his paper on "Our Commercial Relations with West Africa, and their Effects on Civilisation;" Sir Douglas Forsyth, C.B., K.C.S.I., for his paper on "The Progress of Trade in Central Asia;" W. Thomson, for his paper on "The Sizing of Cotton Goods."

A CIRCULAR has been issued by Messrs. Rowe and Groser, the hon. secretaries of the British Association Reception Committee at Plymouth, giving some interesting information about that town. Appended to this is a useful table of the tourist fares to Plymouth from some of the principal stations in the kingdom. Besides Mr. Warington Smyth, Prof. Odling and Mr. Preece have been named as lecturers. One of the excursions is likely to be to Exeter; at least the inhabitants of that interesting city are taking active steps to bring this about. Those of the members who were at the Exeter meeting of 1869 have no doubt many pleasant memories of the visit. The fine museum, which was only completed in time for the reception of the Association, is now filled and admirably arranged under the guidance of Mr. W. S. M. D'Urban, F.L.S. The Dublin people have already begun to prepare for the meeting in that city in 1878. A meeting was held in the Mansion House the other day, under the presidency of the Lord Mayor, when it was announced that subscriptions had already been received to defray expenses. Dr. Ball is one of the hon. secretaries.

AT the conclusion of the last meeting of the Royal Astronomical Society, as we stated last week, a special meeting was held to consider a proposed alteration in the bye-laws. The following is a short account of the business transacted:—Before the last election of officers of the Society (in February) two or three of the fellows printed a balloting list of their own, and having circulated it amongst the fellows without any indication of its private origin, many of them used it as a polling paper at the election, under the impression that it had been issued by the Council. The election was also influenced in another way by the putting up for secretary the name of a fellow who had declined to serve. By these manœuvres a curious anomaly in the bye-laws was made effective—so effective indeed that one member was elected to the council by a few votes, whilst another who had obtained a far larger number of votes was ruled not elected. With the view of avoiding such thwarting of the will of the society in future, the council appointed a committee to revise those of the bye-laws which bore upon the subject. The present special meeting was called to consider the proposed alterations, and they were now submitted for approval or rejection. An amendment, however, which was proposed by Lord Lindsay, the foreign secretary, was carried, deferring their consideration until after the next election of officers.

A VERY satisfactory Report by the Savilian Professor of Astronomy, Oxford, as Director of the University Observatory, has been made to the Board of Visitors for the year between June 1876 and June 1877. The instruments all seem to have worked well except the sun spectroscope, which became seriously deranged in the month of August last, and has not yet been reinstated. 426 photographs of the moon (making altogether, to this date, 652) have been taken with the De La Rue reflector during the year; of these by far the greater number appear to be suitable for micrometric measurement. This will be systematically applied so soon as the Observatory is in possession of the costly micrometer now in process of construction by Mr. Simms, and which is to be the gift of Dr. De La Rue to the Observatory. Then will commence the difficult but interesting research relative to the amount of the physical libration of the moon. 259 complete measures of 117 double stars have been taken during this year with the great equatorial. A second set of observations of six of the satellites of Saturn has been completed. These comprise thirty measures of the co-ordinates of Titan, twenty of Rhea, fourteen of Iapetus, fourteen of Dione, twelve of Tethys, and two of Enceladus. The sun's chromosphere had been observed and delineated on twenty-two days. Eight measures of the difference of the R.A. of Venus and λ Geminorum, and seven of the difference of declination, were taken at the time of their conjunction. Preparations are being made for observations of the planet Mars at its approaching opposition, with a view to the determination of solar parallax. For this purpose the director has devised a new form of micrometer capable of measuring with the requisite exactness distances to the extent of forty minutes of arc. If this instrument realises his expectations he thinks it may supersede Bessel's heliometer. It may properly be called a *duplex heliometer-eyepiece*. The director suggests the advisability of now printing the Proceedings of the Observatory.

A STATUE has been erected at Nancy by public subscription, to Mathieu de Dombosk, the creator of the Roville experimental farm, and one of the earliest scientific agriculturists of France. He was born at Nancy on July 30, 1777.

THE Prussian Government has ordered Berlin to be connected with Hamburg by a subterranean telegraph, in order to avoid perturbations during thunderstorms, which have been very frequent this spring. Similar measures will be adopted for other large towns in Germany.

M. GAUTHIER VILLARS has published in Paris a volume of logarithms, containing tables for all numbers from 0 to 434,000,000,000 with twelve decimals, by M. Namur, secretary of the École Moyenne of Thuin-on-Sambre (Belgium). This wonderful volume, selling at three francs, has been printed by order of the Royal Academy of Sciences of Belgium.

ON Wednesday, June 27, the Harveian Oration at the Royal College of Physicians was delivered by Dr. Sieveking. The orator vindicated the claims of Harvey as the true discoverer of the circulation of the blood, the merit of which had been last year publicly ascribed by the Italians to their countryman Andrea Cesalpino.

LIGHTING experiments with gramme machines are being tried daily at the Palais de l'Industrie, in Paris. The area of the building is 2½ acres, the elevation of roof 95 feet. This immense space has been lighted *à giorno*, with two electric lustres each composed of six electric lamps. The motive power required is fifty-horse power, and the results are very satisfactory, although it has not been stated whether they are superior to those of the Alliance system, and Jablochkoff electric candle. The Great Northern Railway Company regularly use electric lamps for their luggage room. The Paris-Lyons Railway is preparing an experiment for the illumination of the whole of the large Paris station. All these experiments are conducted with the intention of testing several electric systems, in order to obtain an immense lighting power for the 1878 international exhibition.

TOWN Councils are seldom noted for either their intelligence or their foresight. We are glad to find, however, there is at least one exception, in the Exeter Town Council, who have decided to postpone the purchase of their town gas-works, "on account of the success of the electric light, and the probability of its superseding gas." This is creditable to the Exeter Councillors, who, we believe, have been the first public body in this country to recognise the value of this latest application of electricity. We hope their expectations will be fulfilled.

A ROMAN correspondent of the *Times*, writing with reference to the shower of sand which occurred at Rome on June 22, sends a translation of the remarks of Father Joseph Lais, published in the *Voce della Verità*:—"The rain of sand continued although to a smaller extent, on the 23rd of June, on which day the heavens were deeply overcast. The sand fell in small perfectly spherical masses of about 1-25,000th of an inch in diameter, at a *maxi-*

mum. It would appear that vesicular vapour, by the action of the wind, had cemented the grains of sand so as to form globules, analogously to what we see on a larger scale in the formation of hail. We are entitled to assert this, seeing the speedy disaggregation of these globules into grains of sand, when brought into contact with a little drop of water in the field of a microscope. The fall on the 22nd was so abundant in Rome that from the amount, 0·25 gramme, gathered on an earthenware disc of 30 centimetres in radius, we argue a fall of not less than eight quintals per square kilometre." The correspondent himself writes: "I am by no means satisfied that the rain was of sand and water. The drops on my drawing paper were easily absorbed by a pocket-handkerchief, and left no stain on the paper; but my drawing still bears many stains from drops which apparently I had not touched. Since then I have washed the sky over with them, and have afterwards sluiced the surface of the paper with water from a sponge; yet there they remain. If sand they be, that material appears to have a most unusually tenacious affinity for the paper. If the drops were of sand and pure water I should expect to find that as soon as the water had evaporated, the sand would no longer adhere to the paper and that the spots would no longer be on my drawing."

THE *Melbourne Argus* informs us that on May 11 the tide rose from five to eight feet on the eastern coast of New Zealand, and that at Sydney and Newcastle, on the New South Wales coast, the tide also rose above its usual height, though in a less marked degree. It will be noted that the great earthquake-wave which did so much damage to the coast towns of Peru occurred on May 10, the time of propagation of the wave from Peru to New Zealand being, however, not yet precisely stated.

SIGNOR GESSI, the celebrated African explorer, while proceeding to the Lake District, had all his scientific instruments and baggage burnt.

MESSRS. MACMILLAN AND CO. have in the press, and will shortly publish, a translation of Fleischer's Volumetric Analysis. In this work the author's aim is to systematise the volumetric processes. A general scheme of analysis without previous separation of bases is also a feature of the work. The translation is made by Mr. Pattison Muir of the Owens College. The translator has added a few notes and supplementary methods.

THE latest news from Yeniseisk announces the passage through this place of MM. Wiggins and Schwanenberg, on their way towards the north. Capt. Wiggins goes towards his steamer, which has wintered at Zureika, and after having taken on board the tallow he proposes to export, he will return, *viâ* the Kara Sea to England. M. Schwanenberg proposes to undertake an exploration of the graphite mines of the Yeniseisk district, and to take a cargo of graphite to Europe. There is, however, little hope that this latter project will be realised.

WE are glad to learn from the Annual Report of the New Russian (Bessarabian) Society of Naturalists that this young scientific body has displayed during the past year great activity. The following are the more important papers published by the society:—On the family of ephemerides from the stand-point of the Darwinian theory, and on the metamorphoses of axolotls, by Prof. Mechnikoff; the theory of chlorophyll, by Prof. Wolkoff; the algolic fauna of the Black Sea, by M. Rishavy; on the laws of distribution of electricity on surfaces, by Prof. Umoff. The society has, moreover, carried on a considerable number of scientific explorations in various parts of Russia, and has continued the publication of a cryptogamic herbarium of Russia.

THE application of new materials for paper stock which has occupied so much attention of late seems to have attracted some notice in the Philadelphia Exhibition last year. From Jamaica bamboo was perhaps the most important paper-making plant exhibited. Of the young bamboo stems, which are the best for the purpose, a very large supply, it is said, could be annually, by systematic cuttings or croppings, furnished from plants flourishing in the humid parts of the island. It seems that the American paper manufacturers have also wished to make experiments with bamboo with the view, if possible, of introducing it into the American trade; so that, owing to the proximity of Jamaica to the United States, it is supposed that the supply of bamboo may eventually form an article of trade between the two countries.

THE additions to the Zoological Society's Gardens during the past week include two Pig-tailed Monkeys (*Macacus nemestrinus*) from Java, a Black Leopard (*Felis pardus*) from India, two Argus Pheasants (*Argus giganteus*), a Vieillot's Pheasant (*Euplocamus vieillotti*) from Malacca, presented by Sir Harry St. George Ord, C.B.; a North American Reindeer (*Rangifer tarandus*) from Newfoundland, presented by Capt. Edmund Fraser, 60th Royal Rifles; a Javan Chevrotain (*Tragulus javanicus*) from Java, presented by Mr. William Trent; an African Cobra (*Naia haje*) from the Cape of Good Hope, presented by Mr. Eustace Pillans; a Hawk-headed Parrot (*Deroptyus accipitrinus*) from Brazil, purchased; ten Amherst Pheasants (*Thaumalea amherstiæ*), two Temminck's Tragopans (*Ceriornis temminckii*), twenty Common Boas (*Boa constrictor*), born in the Gardens.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The following gentlemen were, on Saturday, June 30, elected, after open competition, to demyships in Natural Science at Magdalen College:—Mr. J. F. Heyes, of Liverpool College; Mr. R. V. Jackson, of Clifton College; Mr. G. A. Buckmaster, of Christ's Hospital and St. George's Hospital, London; Proxime accessit, Mr. A. M. Jackson, Magdalen College School, unattached student. These demyships are of the value of 95*l*. per annum, and tenable for five years from the date of election.

BRISTOL.—The first session of University College terminated on the 30th ult. without any special ceremony of prize-day or commemoration. The result of the work of this the first year must be considered very satisfactory, for in spite of several serious disadvantages, the lateness of the arrangements and appointments of last autumn, and the inconvenience of the crowded temporary premises, upwards of four hundred students have been enrolled. This number exceeds that of the first year of either the Newcastle or Leeds Colleges of Science, or of the Owens College. Lectures have also been delivered at Stroud in connection with the clothworkers' industry in the departments of textile fabrics and chemistry. Prof. Rowley has also delivered a course of lectures in literature at Bridgewater. Most of the courses of instruction only extended until Easter, when several of the temporary appointments expired. In consequence of this arrangement the numbers attending the classes in the third term has not been so great as in the preceding. The chemical laboratory has been in full swing, and evening practical classes have been added since Easter. The only reappointments hitherto concluded are the professorships of chemistry and modern literature, the lectureship in experimental physics, and the assistant lectureship in chemistry. The other reappointments are held over until the election of a principal, which will take place during the present month. It is understood that there are sixty candidates for this important post. No provision has yet been made for a lectureship in engineering.

ST. ANDREWS.—We understand that Prof. Fischer, the present occupant of the chair of mathematics in the University of St. Andrews, has made application to the University Court of St. Andrews for leave to resign his chair on a retiring allowance. As the necessary arrangements will most probably be completed during the present summer vacation, a new appointment will fall to be made before the opening of the session in the United College in November next. The patronage of the chair belongs to the Crown.

TAUNTON COLLEGE SCHOOL.—In reference to our article on Taunton College School, Mr. C. P. Bahin, of Heaton Moor, Stockport, writes that science was taught at that school before Mr. Tuckwell's time. Mr. Bahin forwards us a prospectus of the school for the year 1860, and what position was allotted to science at that time in the school may be inferred from the fact that "Physical Science" comes in as the last subject in the General Department after Fortification, that no mention is made of it in the Classical Department, and that "Monthly Lectures on General and Scientific Subjects are given during the winter season; and in summer, occasional excursions, with a view to the practically illustrating the various branches of Natural History, are taken in one of the weekly half-holidays." This is exactly the state of things we have all along protested against, and which Mr. Tuckwell has managed so successfully to remedy in the case of the Taunton School.

SCIENTIFIC SERIALS

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti, vol. x., fasc. ix. and x.—On the equation of the eikosahedron in the resolution of equations of the fifth degree, by M. Klein.—Further notices and observations on the comets of 1877, by M. Schiaparelli.—On the morphological nature of distigma, by M. Maggi.—Case of fracture of the neck and diaphysis of the femur, by M. Scarenzio.—The combustibility of tobaccos, by M. Cantoni.—Stratigraphical observations on the Province of Pavia, by M. Taramelli.—Experimental researches on heterogenesis, by MM. Maggi and Cantoni.—On the relative length of the index and ring finger of the human hand, by M. Mantegazza.

Fasc. xi.—Contributions to the morphology of Amphizonella, by M. Maggi.—On the Arachnida of Greece, by M. Pavesi.—On the tension of induced electricity, by M. Macaluso.—The albuminous matter of urine, by M. Pellogio.—On the relative and specific weight of the cerebellum and the arch of the cranium, by MM. Colombo and Pizzi.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, June 21.—Dr. Gladstone in the chair. The president announced the following grants from the Research Fund of the Society: Dr. Wright, 50*l.*; Mr. Neison, 25*l.*; Mr. C. Williams, 25*l.*; Mr. G. Harrow, 10*l.* The following papers were read: On diamyl, by H. Grimshaw. This substance was prepared by the action of sodium on amyl bromide. It boils at 160°. A chloride and acetate were obtained and investigated. By the action of caustic potash on the acetate, two alcohols were formed boiling at 202° and 212°. On oxidation acids were formed.—On the action at a high temperature of certain volatile metallic chlorides on certain hydrocarbons, by Watson Smith. *a.* The author investigates the action of antimony trichloride, and tin tetrachloride on naphthalin, benzene, and toluene, when these substances are severally passed in the state of vapour through red hot tubes. Benzene and tin tetrachloride gave a very large yield of diphenyl in one distillation. Toluene and antimony trichloride gave oils boiling at 270–320°. Naphthalin and antimony trichloride: 77 grm. of the former yielded 24·2 grm. of yellow crystalline isodinaphthyl; with tin tetrachloride, in addition to a large yield of isodinaphthyl, a reddish oil, and a citron yellow powder were obtained. *b.* Isodinaphthyl sulpho-acids and salts with certain other derivatives; the α and β sulpho-acids were prepared, also an oxydinapthyl, a nitro-substitution product, and a cyanogen derivative. *c.* A new dinaphthyl. In the purification of crude isodinaphthyl by petroleum spirit, a fine red solution was obtained; from this the author succeeded in separating three substances melting at 75°, 147°, and 253°; the latter is probably Lossen and Otto's polymeric dinaphthyl, the second is an isomeric dinaphthyl already obtained by Lossen, the first is a new isomeric dinaphthyl.—On the action of alkaline oxalates on the earthy carbonates, and of solutions of alkaline carbonates on the earthy oxalates, by Watson Smith. The author having observed that when a solution of ammonium oxalate was brought into contact with chalk or powdered marble, an ammoniacal odour at once became apparent, has carefully measured the extent of this and similar reactions.—Note on thallious platinocyanide, by R. J. Friswell and A. J. Greenaway. In 1871 one of the authors stated that the above substance was colourless, but that a compound of it with thallious carbonate crystallised in dark red needles reflecting a green metallic lustre. Carstangen having confused the two substances and stated that thallious platinocyanide crystallised in blood red needles, the authors have re-investigated the question, and fully confirmed the statements made in 1871.—On crystallised barium silicate, by E. W. Prevost. Pisani having stated that this substance crystallises in barium hydrate reagent bottles, the author has examined similar crystals, and finds that they consist of barium hydrate.—A note on anethol and its homologues, by W. H. Perkin. Methylparoxyphenylacrylic acid, when boiled in a bulb tube, furnishes a distillate, consisting of an oil with the formula $C_9H_{10}O$, which on oxidation yields apparently anisic acid. Methylparoxyphenylcrotonic acid yields anethol, methylparoxyphenylangelic acid yields a similar substance.—Note on persulphocyanic acid, by R. W. Atkinson, Japan. The author discusses the constitution of the above substance, and after investigating various silver and mercury compounds, concludes that the formula proposed by Glutz is probably correct.—On the oxidation products of the aloins, by A. Tilden, D.Sc. Barbaloin and socaloin when oxidised by potassium dichromate and sulphuric acid, yield a yellowish substance, which the author proposes to call aloxanthin, having the formula $C_{15}H_{10}O_6$. This substance, when treated with fuming nitric acid, yields a yellow nitro-acid, having the properties of aloetic acid.

Geological Society, June 6.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—The Rev. Charles Leach, William May, John W. Myers, and John Fletcher Pagen, were elected fellows of the Society. The following communications were read: On the rank and affinities in the reptilian class of the *Mosasauridæ*, Gervais, by Prof. R. Owen, C.B., F.R.S. The author stated that while the Mosasaurians had been originally referred to the Cetacea by Camper, then to Crocodilia by Faujas de St. Fond, and to the Lacertilia by Cuvier, Prof. Cope had recently thought he recognised in them Ophidian affinities, spoken of them as "sea-serpents," and formed of them an order called Pythonomorpha. He then discussed in detail the various characters presented by the remains of these animals. The distinctive characters did not appear to the author to be sufficient for ordinal rank, and with P. Gervais he regarded the Mosasauridæ as a family of Lacertilia equivalent to the Iguanodontidæ and Megalosauridæ in the order Dinosauria. The order Lacertilia among reptiles, being equivalent to the order Carnivora or Feræ among Mammals, the Mosasaurians would be the equivalents of the seals in the latter.—Note on the occurrence of the remains of *Hyænarctos* in the red crag of Suffolk, by Prof. William Henry Flower, F.R.S. The traces of *Hyænarctos*, described by the author in this paper, consist of a right and a left first upper molar, which were obtained from the Red Crag of Waldringfield, and are so much alike, that but for the former being rather more worn, they might have belonged to the same animal. On comparison these teeth were found to show no appreciable difference from the corresponding teeth of the original specimen of *Hyænarctos sivalensis* from the Sewalik Hills, and hence the author did not venture to regard them as representing a species distinct from the Indian one.—On the remains of *Hypsodon*, *Portheus*, and *Ichthyodectes* from British cretaceous strata, with descriptions of new species, by E. Tulley Newton, F.G.S., of H.M. Geological Survey.—On the precarboniferous rocks of Charnwood Forest, Part I., by the Rev. E. Hill, F.G.S., and the Rev. T. G. Bonney, F.G.S. The authors described a mass of slates, grits, and volcanic breccias, accompanied by some knolls and dykes of syenite, spread over a space of about fifty square miles. They showed that the patches marked on the Survey Map as greenstone of Bardon, Birchwood, and Buck Hill, except a very small portion of the latter, are really altered rock; that the syenite knoll of Bawdon Castle carries a mass of breccia in its centre; and that the area of syenite in Bradgate House Woods must be enlarged. Several writers have noticed that part of the porphyritic region of the north-west corner is altered rock. The authors showed that there is in it no igneous rock at all, and that the same is the case with every one of the smaller patches marked as porphyry on the Survey Map. All are volcanic breccias, ashes, or agglomerates, some of enormous size. The extent to which volcanic materials enter into the rocks of the district is remarkable. The authors endeavoured to correlate the stratified rocks, and adduced evidence to prove that the pebble and ash-beds of Forest Gate, the grit and pebble-beds of the Hanging Rocks, the similar beds in the grounds of Mr. A. Ellis, at Swithland, and the quartzites of Bradgate Stable Quarry, Groby Pool, and Steward's Hay Spring, form one horizon; the slate breccias of Blores Hill, Bradgate, Ulverscroft Mill, Markfield, Bardon, and High Towers, a second; the coarse ash-beds of Benscliff, Chitterman Hill, Timberwood Hill, and the Monastery, a third; and the quartzose rocks of Charley Wood, Charley, the Old Reservoir, and Blackbrook, a fourth. Hence they showed that the beds are considerably dislocated near the syenites, which removes the main objection which previous writers have urged against these being intrusive; and they described the evidence they have obtained as to this being their real nature. This evidence included the description of actual contacts of igneous and sedimentary rock seen at two points in the wood south of Bradgate House, and at a third in Bradgate Park. They propose, in a continuation of the paper, to touch upon the faults, and to describe in greater detail the microscopic structure of the rocks.

Photographic Society, June 12.—J. Glaisher, F.R.S., president, in the chair.—A paper was read by Mr. J. R. Sawyer on the action of light, temperature, and atmosphere upon pigmented sensitive tissues; showing that when once the action of light had been set up upon the sensitive pigmented tissue (used in carbon work) the same action was *continued* in darkness and exclusion from the atmosphere; by this action an increased power and facility of producing large numbers of the same subject was obtained; as also the possibility of producing different tones of coloured pigments, by this important discovery, which the paper described.—A paper by Mr. Herbert B. Berkeley—notes on the theory and practice of emulsion processes—was read, relating to the use of zinc bromide in emulsions.—Capt. Abney, R.E., F.R.S., followed with a note giving the details and results of his own investigations upon the same subject.—Mr. R. W. Thomas, F.C.S., read a note on the nitrate of silver bath.

Vienna

Imperial Academy of Sciences, March 8.—On some reactions of amido-acids: on the copper salts of leucin, tyrosin, asparagin acid, and glutamin acid, on the dissolving power of amido-acids for cupric oxide in alkaline liquid, by M. Hofmeister.—On a modification in the determination of vapour densities, by MM. Goldschmidt and Ciamician.—Further experiments on galvanic expansion, by M. Exner. The elongations through the galvanic current were not markedly different from those which would arise from heat developed by the current; the differences did not amount to three per cent. of the whole expansion, and were partly positive, partly negative. Hence the author pronounces against a galvanic expansion.—On the teeth-apparatus in frogs and their larvæ, by M. Wajgel.—Description of a steerable flying machine in form of an eagle, by M. Grois.—The fossil bryozoa of the Austro-Hungarian miocene, by M. Manzoni.—On cosmic vulcanism, by M. Tschermak. He thinks the hypothesis most applicable to it is that which explains volcanic phenomena on the earth by gases and vapours, which have been held absorbed in the supposed liquid interior, but developed in the gradual solidification.—On point systems in rational space curves of the fourth order, by M. Weyr.—On polypes and jelly fishes of the Adriatic, by M. Claus.—On *Sagartia troglodytes* Gosse, by M. v. Heider.—On diffusion of gases through clay cells, by M. Puluj. He finds, *inter alia*, that water vapour diffuses more quickly than air (and here contradicts Dufour's statement that dry air diffuses more quickly than moist). Vapours diffuse approximately in inverse ratio of the fourth root of their densities.

Paris

Academy of Sciences, June 25.—M. Peligot in the chair.—The following papers were read:—On the heat liberated by chemical combinations in the gaseous state; anhydrous acid and water, by M. Berthelot.—On the equivalent of organic compounds, by M. Berthelot.—On a new anthophyllite of Bamle, in Norway, by M. Des Cloizeaux. Anthophyllite (in this specimen) presents new similarities to amphiboles; like them, it may contain a large proportion of aluminium (twelve per cent.) in varieties of homogeneous appearance, and it has a marked tendency to pseudomorphism.—Reply to observations of M. Mouchez (continued), by M. Villarceau.—On an apparatus called a central obturator-inflamer, capable of adaptation to all cartridges, by M. Cosson. The inflamer is a cylindro-conical case forming an air-chamber, in which the priming explodes; the gases are distributed by slits in the top of it. The obturator is a convex sheet iron shield with serrated border, and a central hole for the inflamer. The combination is placed in the socket of the cartridge, and the obturator then flattened, so as to firmly and hermetically close the base. Among other advantages, it is claimed to improve the range, increase the penetration, diminish recoil, and [illegible] intact.—H. M. Don Pedro d'Alcantara was elected foreign associate in room of the late M. Ehrenberg. He obtained thirty-nine votes, M. Van Beneden one.—On the state of the vines of Mezel, near Clermont Ferrand, according to a report of M. Truchot, by M. Aubergier.—Anthogenesis in subterranean pucerons of the Gramineæ, by M. Lichtenstein.—On a means of avoiding the resonance of the seventh minor harmonic of the fundamental in the series of grave cords of the piano, by M. Dien. The damper (which is the cause) is allowed to act in its ordinary place, but it moves, simultaneously, a lever having at its upper end a second damper, which touches the cord at a quarter of its length, and causes resonance of the double octave, destroying completely that of the defective triple minor seventh.—Historical remarks on the theory of motion of one or several bodies, of constant or variable forms, in an incompressible fluid, &c. (continued), by M. Bjerknes.—New method of elimination of arbitrary functions, by M. Minich.—On a solar spot observed during the month of June, 1877, by M. Tacchini.—On the 3rd a small spot (the only one) appeared in the east, and gradually enlarged to 40s., by the 7th continuing of this size (some small spots which presently appeared with it ever changing) till it was near the border on the 13th. On the 14th, when projection and photography revealed hardly a trace of the group, the spectroscope discovered very lively chromospheric flames; higher up, several oblique fragments, evidently from violent eruption, eruption flames on the right, and lastly, a nebulous chromospheric mass, well illuminated and slightly divergent. There was constant commotion of matter. The case is cited as against M. Janssen's view.—On a glass of phosphate of lime, by M. Sidot. It is perfectly transparent, very refringent, (index 1·525), can be cut like ordinary glass, is dissolved by oxides of cobalt and chromium, is not attacked by cold acids, but is attacked by boiling acids and by potash, is not attacked by hydrofluoric acid.—On the dissociation of carburets by means of palladium wire, and on the relation of these facts with actions of presence or catalytic phenomena, by M. Coquillion. To analyse carburets with palladium wire there must be enough oxygen to work complete combustion of the constituent carbon and hydrogen.—On the determination of potash, by M. Carnot.—On the nickelised iron of Santa Catharina, in Brazil, by M. Guignet. The bed is now exhausted; it is thought to have been a meteorite with weight not under 25,000 kilogs. (the Ovifak block was 20,000 kilogs., and so was that of Durango, Mexico, found in 1805). The last portions had very little nickel.—Description of several minerals, by M. Pisani.—Reply to objections raised by M. Naudin against the project of an interior sea in Algeria, by M. Roudaire.—Investigation of the free acids of gastric juice, by M. Richet. Pure gastric juice contains almost only mineral or similar acids; organic acids increase when, left to itself, it ferments. Aliments increase by 20, 50, and even 70 per cent., the acidity of liquids in the stomach. The mineral acid continues predominant so long as there is no putrefaction.—On lymph as an agent of propagation of vaccinal infection, by M. Raynaud. The observations are somewhat discordant, but the virulence of lymph from a vaccinated region is demonstrated.—On the pebbles of a hill near Vailly, in the department of Aisne, by M. Robert.

CONTENTS

THURSDAY, JULY 12, 1877

THE "INFLEXIBLE"

THE question which has been raised respecting the stability of the *Inflexible*, important as it is with reference to that ship, leads to very much wider and more general considerations. It is already known that the same principle, or want of principle, which has brought doubt upon the one ship appears also in the *Ajax* and the *Agamemnon*, and is to be reproduced in the only ship of much size or importance which the Government purpose commencing during the present year. But even in this succession of large and costly ships we see probably but the beginning of a system which, having thus received countenance and sanction in the highest quarters in this country, may not improbably become extended over the navies of the world. We propose, therefore, to explain to our readers the nature of the question itself and the manner in which it has arisen.

And as an essential preliminary we will first explain what is meant by the terms "stability" and "curve of stability." For the purpose of this elementary explanation it will be sufficient to take the case of a ship floating in still water. In Fig. 1, which represents the transverse section of a ship taken through the centre of gravity, M represents the metacentre, G the centre of gravity, and B the centre of buoyancy, W L being the water-line when the ship is in an upright position. Supposing the ship to be inclined through an angle of θ degrees from that position by an external force, and W_1L_1 to become the new water-line; she will now tend to return to the upright position with a righting force equal to her total weight or displacement, acting with the leverage of G Z, and therefore equal to W × G Z. This is obviously the case, because while the ship is held in the inclined position her weight will be acting downwards through G in the direction of G H, which is perpendicular to the water's surface, $W_1 L_1$, and her buoyancy, which may be supposed to act collectively through its centre of buoyancy, B_1, will be pushing upwards through the line $B_1 M$, and therefore the righting effect will be that of the two forces (weight and buoyancy, which are alike) acting at the opposite ends of the lever, G Z, as previously stated. It is equally certain that in all ordinary forms of ship G Z will be changed in length as the ship's angle of inclination is changed, and if we calculate its lengths for a series of angles, and set up the lengths so obtained as ordinates along a base line on which abscissæ are measured off to represent the angles of inclination, we can draw a curve line through the points so obtained, and thus form what is called a "curve of stability." The first instance on record of this being done for an actual ship or design is that given in a paper "On the Stability of Monitors under Canvas," read in 1868 at the Institution of Naval Architects, and published in their *Transactions*, and in several other places. After stating the amount of stability which certain rigged monitors would have under given conditions, and showing that the maximum stability, and even the vanishing stability was reached in them at moderate angles of inclination, Mr. Reed said: "It must be obvious that the danger to be apprehended by these monitors when under canvas is very great; and when we think that they are liable at any moment to be overtaken by sudden gusts of wind, and that if they are heeled over beyond 8 deg. or 10 deg., the further they go the less resistance they offer to being capsised, their unfitness to carry sail must be quite evident."

The curve of stability was next constructed in the case of the *Captain*, immediately before her loss, and from a report by Mr. Barnes, one of the present Admiralty constructors, we take the following:—"We assume that the side plating on the poop and forecastle has been so damaged that the ship may be considered a rigged monitor with a free-board of about 6 ft. At that draught (25 ft. and ½ an inch) with an inclination of 14 deg., the gunwale on the immersed side is level with the water, but the stability of the ship notwithstanding goes on increasing until an inclination of 21 deg. is reached. As Mr. Reed has pointed out in his paper (quoted above) on rigged monitors, with a pressure of canvas which would incline the ship to say 8 deg., the inclination of the ship to the surface of the wave may reach about 34 deg. (in this case) before the ship would upset. As this angle is large we do not consider that even with the sides of the poop and forecastle destroyed, the *Captain* would be unsafe."

The above cases are both those of rigged ships, which the *Inflexible* can scarcely be considered, although it must be acknowledged that, as designed, she carried a considerable spread of canvas on two masts, and the present proposals—which we understand have been made—to diminish the spread of sail at all times, and to do away with it altogether in war time, are no doubt consequences of recent discoveries respecting the stability, or want of stability, of the ship with the unarmoured ends badly injured. After what has passed, however, we must accept the *Inflexible* as a mastless ship in time of war, and therefore a ship which can do with less stability than rigged ships require. In order to illustrate the nature and character of these curves we copy, in Fig. 2, a figure from Mr. Thearle's valuable work on "Theoretical Naval Architecture,"[1] in which he has grouped half-a-dozen curves which may be regarded as types of various kinds of curves of statical stability which occur in practice, viz.:—

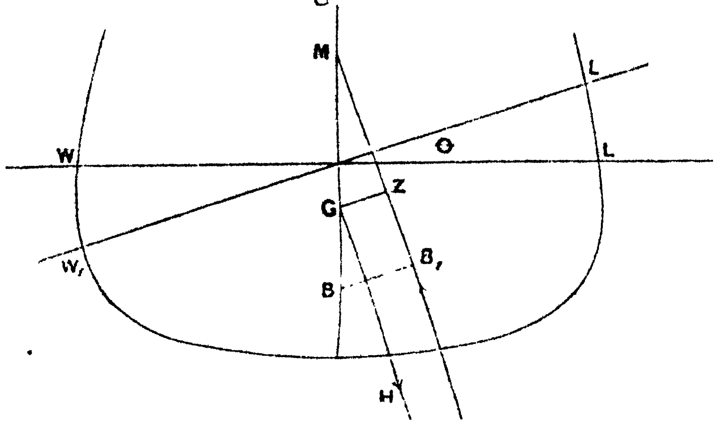
A. A lofty-sided troop-ship, carrying sail.
B. Do. Do.
C. A broadside iron-clad frigate, Do.
D. A turret-ship with high freeboard, Do.
E. A low freeboard iron-clad gun-vessel, not carrying sail.
F. A breastwork monitor, Do.

To facilitate comparison, we have added to Fig. 2 dotted lines showing the stability of the *Captain* as ascertained at the Admiralty just before her loss. The curve marked *a* shows the stability when the ship is fully stored and provisioned, and with the proper complement of coals on board with the poop and forecastle water-tight and assisting stability. The curve *b* refers to the ship under the same conditions, except that the poop and forecastle are supposed to be so damaged as not to assist stability. It will be observed that although Mr. Barnes considered

[1] Published by Collins, Sons, and Co., in the "Advanced Science Series."

the ship safe even when she had only the stability shown by *b*, the ship actually capsised when she had the larger amount shown by curve *a*, the two curves being the same up to about 20 deg. of inclination, but the latter showing much greater stability both in amount and in range after that amount of inclination was passed. Mr. Barnes no doubt expected that the ship would never be pressed under canvas enough to endanger her, but the event

Fig. 1

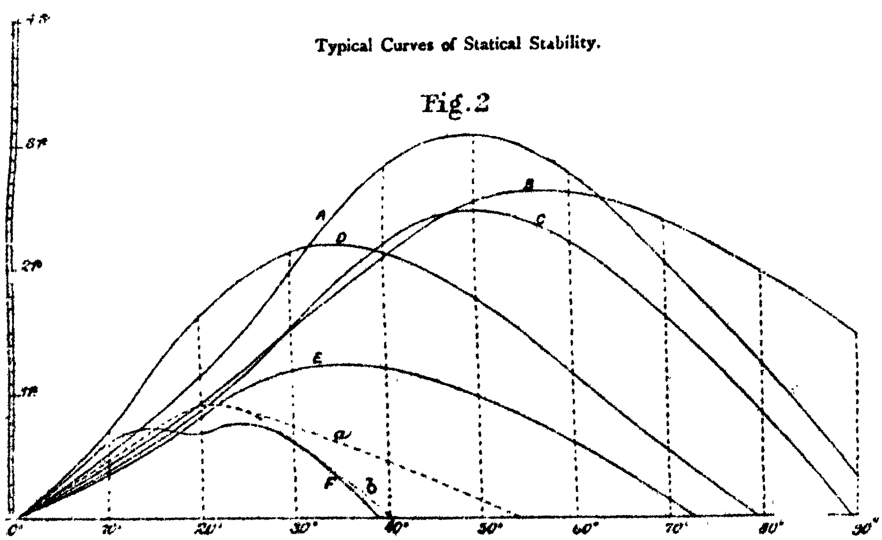


showed that in matters of this kind the measure of safety must be ample, and that we must not trust to the chapter of accidents for the security of our men-of-war against capsising.

We are now in a position to explain the case of the *Inflexible* up to the point at present attained in the discussion, but in order to understand it the reader must take clearly into his mind certain differences between her

Typical Curves of Statical Stability.

Fig. 2

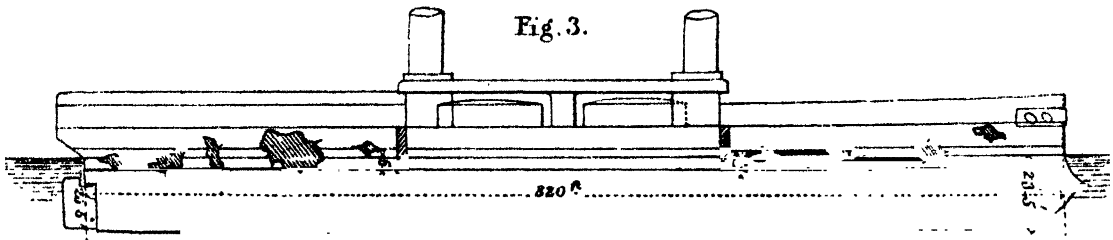


and all previous ships as regards the relations of the armoured and unarmoured parts. In the case of the *Captain* we had a ship with armour rising to a uniform height of six feet above the water from stem to stern, and above this armour at one end a forecastle and at the other end a poop, both of these being of thin iron and unarmoured. It was in view, no doubt, of these unarmoured ends being liable to be so injured in action as to contribute nothing to the ship's stability that the Admiralty officers calculated and stated (as above quoted from Mr. Barnes' report) the ship's stability with the poop and forecastle destroyed. But the reader should carefully observe that as these unarmoured ends were wholly situated in the *Captain* at a height of six feet above the water, their destruction to any extent whatever could not affect the ship's stability at small angles of inclination; and in point of fact by looking at the dotted curves in Fig. 2 we see that the stability is the same whether these ends exist intact or not up to an angle of about 22 deg., for up to that point the two curves are identical. At that angle of inclination the poop and forecastle enter the water, and the curve of stability declines much more rapidly when they are injured than when they are uninjured. In the cases of the *Devastation*, *Thunderer*, and some other ships, there was a different arrangement, and one less favourable to stability, for in them the forecastle (not the poop) was sunk, so to speak, down into the armour, so as to reach to within a foot or two of the water's surface. In such cases, of course, the curve of stability, with the unarmoured ends injured, begins to decline earlier than if the forecastle stood wholly above the armoured side as in the *Captain's* case; but the *Devastation* class are all unmasted ships, and therefore subject to no pressure of canvas, so that much less stability was required in them than in the *Captain* and other rigged ships.

The *Inflexible* class of vessels differ from all the ships previously named in a very marked manner, for in her the ends are entirely unarmoured (excepting as regards a horizontal deck lying seven feet below water), and while the forecastle, and poop, where it exists, in the other ships named are comparatively short, in her they occupy two-thirds the length of the ship—one-third at each end. The central part of the ship, one-third in length, is alone armoured with side-armour, and therefore in considering the stability during an action, we may suppose that two-thirds of the ship's length, viz., the two wholly unarmoured ends, are destroyed, destroyed that is in the sense in which Mr. Barnes obviously used the phrase in the case of the *Captain*; or, in other words, so broken and damaged by shot or shell as to let the sea flow freely in and out of them, and therefore to possess no stability to help in keeping the ship upright. In Figs. 3 and 4 we have, illustrated, the *Inflexible* injured in this manner. One of the contentions of the Admiralty is that these ends cannot be injured during an action to this extent; but whatever the Admiralty officers may now assert in this respect, it is clear that in the case of the *Captain*, they thought this amount of injury possible, and it is equally clear from the quotations given by Mr. Goschen in Parliament, that they thought the same of the *Inflexible*, when they proposed that she should be built, and thought this, notwithstanding the introduction of certain cork-filled chambers and other sub-divisions upon which they now seem disposed to rely for the ship's safety. We may add that even during the present controversy, Mr. Barnaby has published figures which assume the total annihilation of the ends, and if they can be totally annihilated it is clear they may be so far injured as to lose all buoyancy and stability. We may confidently assume, therefore, that the ends can be so far wounded and damaged as to cease to help the ship's stability, and therefore to leave her wholly dependent upon the citadel for the power of keeping from capsizing. In Fig. 3 we have shown several large injuries, such as we may assume modern shells are fully capable of inflicting, merely to help the reader to get clear ideas on the subject.

The question now at issue really is, therefore, what amount of stability has the ship (by virtue of the citadel) with the ends thus injured? The *Times* and Mr. Reed say that careful calculations which have been made show that she has none, or next to none. Hitherto the Admiralty have refrained from saying how much they claim for her. They say that the *Times* and Mr. Reed are entirely wrong in their calculations, and that the ship really has abundant stability for all purposes of safety, and they appeal to a model which is at the Admiralty to prove this. Let us say at once no model can possibly prove anything of the kind; the model must be weighted and arranged entirely to represent the results of calculations, and it is these results which should be clearly, and fully, and authoritatively stated. The Government have laid certain papers on the table of the House of Commons, but they are not yet published, and until they are in our hands it is impossible to pursue the subject further. We shall hereafter give due consideration to them. All that we can now say is that with the *Captain* case fresh in our memory, in which the Admiralty office dangerously

Fig. 3.



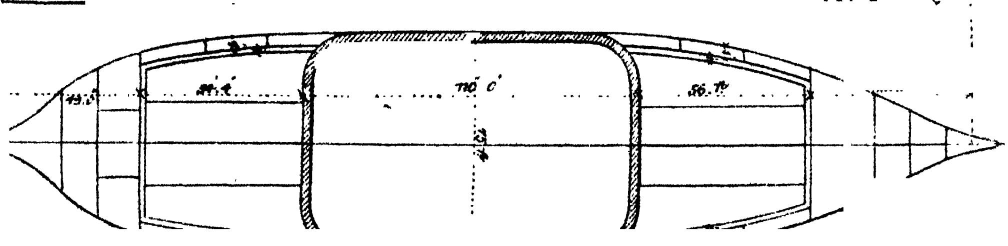


Fig. 4.

overrated the safety of the ship in this very respect, and, remembering as we do that for a ship to be safe at sea, she should have a very large margin of stability over and above that which mere statical and smooth water conditions point to, we shall not ourselves be satisfied with less than the Committee on Designs laid down, viz., "that the angle of vanishing stability should not be fixed at less than 50 deg." Nor shall we be content with this if this range is obtained only in conjunction with a small amount of stability from point to point. Mr. Reed has pointed out, in his letters to the *Times*, the great danger of considering range only, and has attacked the dictum of the Committee on this ground. Dr. Woolley, one of its scientific members, has replied, admitting the accuracy of Mr. Reed's view, but explaining that the truth he enunciates is so elementary and obvious that the Committee thought it unnecessary to mention it, and would indeed have considered it "impertinent" (in the proper sense of the word) to state it. It is difficult to take this view of the matter, however, when we remember that the highest scientific officer of the Admiralty, in a matter affecting the safety of four of H.M. ships of the largest and newest type, has seized this dictum of the Committee as a sufficient and satisfactory guarantee of their security. We fear we must conclude that the Committee either neglected a very serious element in the calculations, or else greatly overrated the skill and discernment with which their words would be interpreted.

THE DEVELOPMENT OF THE OVUM[1]

Bütschli on the Earliest Developmental Processes of the Ovum, and on the Conjugation of Infusoria.

Studien über die ersten Entwicklungsvorgänge der Eizelle, die Zelltheilung und die Conjugation der Infusorien. Von O. Bütschli. (Frankfurt, 1876.)

II.

COMING now to the large and important question of the *Conjugation of Infusoria*, its nature and bearing upon the life-history of the forms, we are bound to state at once our conviction of the inefficiency of the observa-

[1] Continued from p. 180.

tions recorded on account of their discontinuity. Nothing but a close and continuous observation of the same forms extending over an entire life cycle, repeated again and again, can lead to absolute results. Errors fatal to the interests of truth inevitably arise, when minute organic forms are studied, not by continuous watching, but from inferences made from the phenomena manifest at different periods, the intervals between which are blank. Further, whilst the use of reagents on the dead forms taken at various stages is of the utmost value, when they are examined side by side with continuous observation on the living form, these may be not only not instructive but misleading when taken by themselves.

Bütschli's observations are numerous and interesting, but their value will be best estimated, by understanding briefly the nature of the hypothesis they are declared by their author to indicate. Put in its shortest form, it is that conjugation amongst the Infusoria is simply a *rejuvenescence* of the creatures which undergo it, enabling them to become "the stem ancestors of a series of generations" which propagate by fission. As yet the process of rejuvenescence has had, in biology, a limited application, being noticed in the formation of the swarm-spores of Œdogonium and other of the lowliest plants; but its connection with sexual reproduction is not clear, as no union of different elements has been made out, and it is by no means certain that the whole process of reproduction is exhausted by it. When, however, it is combined with conjugation, as in the Bacillariaceæ, it becomes plainer; although, so far as is known at present, it by no means follows that the whole generative process in these forms is known; but it is to the *Auxospores* by which rejuvenescence is secured in these forms that Bütschli appeals for the support of his theory of infusorial conjugation. Pfitzer and Schmitz have made what are at present the most complete observations of the phenomena in question; from which we learn that the customary mode of reproduction is by fission, but at each repetition the individuals dwindle in size, until they can apparently go no farther,[1] then the conjugation of two individuals takes place, the formation of auxospores being the result, that is to say rejuvenated individuals; and from these a new departure of fissiparous generations takes place, well observed by Schmitz in the case of *cocconema cistula*. There is no coalescence; the frustules simply lay themselves parallel to one another, they become surrounded by a common envelope of mucus; the protoplasm of the cells comes into contact, each frustule grows larger and becomes an auxospore. What the influence is which these frustules exert upon each other is wholly unknown; but that it has a real existence is shown in the result; each auxospore forming a stem ancestor of a new series.

This is what Bütschli extends to the infusoria, and contrary to the interpretations of Balbiani, Stein, and others, maintains that the act of conjugation so well known amongst the Paramecia, Vorticellæ, &c., is not a precursor of sexual products, but simply a means by which these forms, exhausted by continued fission, become more highly vitalised and rejuvenated, and again enter upon the process of fissiparous multiplication, which indeed becomes thus their only method of increase.

It should be noted that on the whole the facts adduced by Balbiani and Stein are admitted, but they are submitted to a wholly different interpretation; and it is specially insisted on that the forms that go into the conjugation state are of a minimum size; which fact Balbiani explains as the result of a special development for sexual purposes, but this is disallowed by Bütschli, who insists that it results from exhaustion of vitality at the terminus of a series of fissiparous multiplications. Indeed these weakened and minimised forms unite in conjugation and are neither absorbed into each other nor produce embryos, but increase in size and vitality, separate, and commence again the fission by which alone increase is effected.

The truth of this is insisted on as deriving strong support from some of the very remarkable external changes which the author has seen certain of the Infusoria undergo. In *Euplotes* and *Oxytrichineæ* a great part of the *ciliary system* is said to perish towards the end of conjugation; and afterwards, when separation takes place, to be again renewed. In *Colpidium colpoda* the entire mouth was lost in conjugation, but was renewed again after separation. So in *Bursaria truncatella*, the conjugated animals, it is affirmed, lose entirely the complex apparatus of the peristoma, which by a new growth after conjugation is restored. So also there is declared to be a complete rejuvenescence of the more important internal parts. The "secondary nucleus" in *Stylonichia mytilus*, and in *Blepharisma lateritia* and *Colpidium colpoda* the old nucleus is said to be eliminated and a new one formed. In others, part of the nucleus is thrown off, and part renewed; in others a new nucleus formed and coalesced with the old one. From these and similar observations it is inferred that the "essence of conjugation consists in the rejuvenescence of both the individuals;" and that this is chiefly centred in the "secondary nucleus" which is declared to be of the utmost importance in the life of the creature.

During the process of conjugation, also, the plasma-contents of the individuals have been seen to interchange; this especially in *Oxytrichineæ*, but also in other infusoria.

Against Balbiani's hypothesis—that the nucleus is the ovarium and the nucleolus the testis, containing spermatic elements—Bütschli affirms that in *P. aurelia* and *P. colpoda* the supposed spermatic capsule in some cases wholly disappeared without any following change in the nucleus that could be discovered, and that consequently it did not effect fertilisation. In short, he believes that the observations he has made are quite competent to overturn the sexual hypothesis in these organisms, and to establish that of *rejuvenescence* in its place.

That there is extreme ingenuity in this hypothesis we readily admit; that there is also the utmost conflict of interpretation amongst the best observers of these organisms, we admit with equal readiness. But that the author's observations give *scientific* sanction to his theory on the one hand, or either explain away or harmonise the labours of his predecessors or *collaborateurs* on the other, we are fain to dispute. The exhaustive and continuous

[1] It is impossible not to notice here the extremely interesting and certainly somewhat remarkable paper of Dr. Wallich in the February number of the *Monthly Microscopical Journal* for 1877, "On the Relation between the Development, Reproduction, and Markings of the Diatomaceæ;" for in this paper what is apparently the *auxospore* of Pfitzer and Schmitz is called the *sporangial frustule*. But this, instead of having dwindled in size before conjugation appears to have become enormous in proportion, and within this the "new parents of the race arise," and from the conjugation of *these* the new forms spring as daughter frustules.

method of observation—following a single form through all the phases of its life—has never been thoroughly adopted; and conflict of interpretation inevitably arises. Bütschli has fallen into the same groove, and his results, although valuable and full of suggestion, have no irresistible meaning. They present points of new departure for hypothesis, and nothing more.

Nor can we be quite certain, from the evidence afforded, of the correctness of the larger and more important of the facts stated. We want, for example, more than a mere statement that the "ciliary apparatus" and the important organs of the *peristoma* were actually destroyed by conjugation. That they are suppressed—flattened—deranged by prolonged contact, we have observed again and again in several forms, especially *Stylonichia*, *Pustulata*, and *Mytilus*; but they rapidly regained their *normal condition*, and certainly did not *grow afresh* by "rejuvenescence" as in the cases stated by our author. And this is certainly of moment. In some important sense also this will apply to the nucleus and nucleolus themselves. Doubtless the investigations of Bütschli on the metamorphoses of these bodies, especially the latter, in such forms as *P. bursaria*, *aurelia*, *putrinum*, and others have a large importance; and if they should be confirmed by *continuous observation* on the *living form*, controlled by the evidence of preparations, made at short intervals, under the influence of acetic and osmic acids, and other reagents, not only will Balbiani's hypothesis become modified, but a sequence will be given to the successive stages, often now wanting, in the observations of Bütschli himself. It is impossible not to be struck, for example, with the minuteness of his observations, made on the nucleolus changes in *P. bursaria*; but they are utterly incompetent to accomplish his own purpose and establish his own idea. He declares that both Balbiani and Stein utterly mistook the destiny of the nucleus and nucleolus; and quite repudiates the changes said to come upon the nucleus during conjugation. But to establish his own hypothesis the whole process of morphological change in the nucleus at least should have been followed, and not once but many times. Yet the very first complete change effected in this organ could not be explained; and after following it into fission as the result of conjugation, he observed four "nucleolus capsules" as the issue, in each paramæcium. Two of these became light and clear; the other two diminished in size, and became fibrous, but on the second day they lost their fibres and became homogeneous and dark; and on the third day—*vanished!* that is to say, by the method pursued by the observer, they were lost, and "no trace of them was to be found." From this Bütschli concludes that they were "cast out," and no further concern in relation to them is evinced! Yet it must be remembered that Balbiani describes a similar condition of the same forms, and considers the granules germs or ova. To deal thus lightly with the ejection of apparently organised bodies in a set of observations designed to *prove* that what have been considered ovarian, or at least sexual, products, was erroneous, is certainly remarkable. Clearly no result can be arrived at until the manner of the vanishing of these bodies be understood; and if they were ejected, until their future destiny became known. This is all the more imperative from the fact that *after* the ejection of the "bodies," the paramæcium resumes its normal condition in size and appearance, although the method by which this conclusion is reached is by saltative inferences, and not by continuous proofs.

Again,—in *B. bursaria* and *aurelia*, two "light bodies"—definite products of the nucleolus—are repeatedly seen in successive stages after conjugation, but having been followed to a certain point we are told that "the further destiny of these two light bodies escaped me!" and yet it is assumed that the life history of the creatures is known.

Again,—in these same forms the *nucleus* broke up into a hundred spherules; and yet our author frankly declares "I am not quite certain of the destiny of the . . . fragments of the old nucleus!" This is the more important since Schaafhausen affirms that he has seen *P. aurelia* lay or deposit ova; "the organisms crammed full of egg-spheres, surrounded with clear fluid, extrudes in an hour several times one such egg."

Again,—in *Colpidium colpoda*, after conjugation, two small light spheres appear, these the author "thinks most probably" grow out of the nucleus capsules, while the *nucleus* itself is *cast out;* Bütschli followed it "for some time" and then it was lost, so he does not know its final destiny! Of what service can all the subsequent transformations of the organism itself be when this ejected organism is assumed to mean nothing? In *Blepharisma laterita* a number of "nucleolus-like bodies" were found by "squeezing and acetic acid," but their destiny was never found; while on the third day after conjugation "the *nucleus* which had been present up to this time was not to be found," and so the author meets the emergency by supposing that it was "cast out," and of course had no meaning in the history of the organism. So also in *Chilodon cuculus*, we are told that the "destiny of the original nucleus remains undetermined." In the conjugation phenomena of *Stylonichi mytilus* there is an equal or even more grave defect.

In precisely the same way in the attempt made by Bütschli to establish the position he occupies that the embryonal regions of Balbiani and others as existing in these lowly forms are to be entirely explained by the presence of swarm spores of internal parasites, there is the same want of perfect sequence, and the unscientific "no doubt" which is made to supply the place of facts.

But our space is exhausted. We have not referred to the above defects with any attempt to depreciate a valuable book. It is because it is strong enough in important facts to be a help in the unravelling of biological difficulties that we have not hesitated to point out the difference between the *theories* and the *facts* which it contains. To have attempted exhaustive criticism of such a work would have involved four or five times the space occupied by this article; but after a careful perusal and reperusal of its contents, we are obliged to admit the ingenuity of the author both in the work he has done and the method he has employed for interpreting it. But it is to the former that we attach by far the most importance; for whilst there are many missing links in evidence which make conclusions from the whole unwise, there are facts given us which must help future observers and land us nearer to the desired truth.

It may be finally observed—1. That if the theory of rejuvenescence, as put and insisted on by Bütschli, be established for any one form, conjugation should have no other meaning or place in any part of its history than rejuvenescence can explain. Now *Stylonichia pustulata* is amongst the forms the author has seen to conjugate, and as he believes, as a consequence, to become simply more vital and larger for renewed fissipartition. But Engelmann is undoubtedly right in his affirmation, that there is a conjugate state in which these organisms do *not* again separate, but the pair simply fuse together. One of the writers of this paper has observed it repeatedly under conditions which render error impossible; this is not the place to consider to what this fusion leads, but it is important as a fact, inasmuch as it throws doubt upon the *completeness* of the theory of rejuvenescence, even supposing the facts given us by Bütschli led without exception up to it. Bütschli even admits that this process of fusion may happen, but he simply dismisses it as a "very unusual one"—surely all the more important on this account, inasmuch as we know that in more highly organised creatures not only a long time, but generations may intervene between distinct acts of fertilisation.

2. It does not follow that if rejuvenescence be rejected to the extent and with the meaning Bütschli gives it, that it must be rejected altogether. He gives us many remarkable facts that deserve further experiment and research; and it may result, that what he calls rejuvenescence, is one of the many modes by which rapidity of fissiparous multiplication is in some organisms aided, and the necessity for the true act of fertilisation is made less frequent; and

3. It is clear that there are points in the theory of Balbiani which the facts given by Bütschli overturn; while there are others that certainly remain unshaken, if they be not strengthened. But it is needful to remember that if the facts given by Bütschli wholly invalidated the interpretations of Balbiani the theory advanced by Bütschli by no means follows as a consequence. In the present state of this inquiry we must seek facts industriously, and with persistent honesty, and be assured that their accumulation will lead to important issues; but we shall do well to place theory, however fascinating, in an extremely subordinate place.

W. H. DALLINGER
J. DRYSDALE

VON RICHTHOFEN'S "CHINA"

China. Ergebnisse eigener Reisen, und darauf gegründeter Studien, Von Ferdinand Freiherrn von Richthofen. Band I. (Berlin: D. Reimer, 1877.)

WE are glad to welcome the appearance of the first volume of this long-promised work from the pen of the well-known geologist and geographer, Baron v. Richthofen. We content ourselves at present with a general account of the work, hoping in an early number to be able to examine it in detail. The author has enjoyed rare facilities for the accumulation of material, and has improved them so thoroughly that the published results of his researches will assume a leading position among the late additions to scientific literature. In 1860 he accompanied Count Eulenberg on his mission to China and Japan for the purpose of closing commercial treaties between these lands and the German states. On the return of the expedition Baron v. Richthofen lingered behind, attracted by the many unsolved problems of the Celestial Empire. Up to 1872 he devoted himself to a systematic, thorough investigation of the geography and geology of China, traversing in the course of seven different journeys the whole eastern part of the empire from Canton to Corea, and penetrating westward to the sources of the Yang-tze-Kiang and the frontiers of Thibet. The essential aims of the traveller were to place on a scientific basis the geography of the land, determining the hypsometric relations, and the laws governing the conformation of the mountain-chains, to examine the general geological structure, especially in its relations to the great basins of Central Asia, and to study the laws of climatic changes. Other scientific questions received a minor consideration, and the intellectual life of the people was left entirely out of view. The present volume forms little more than an introduction to the elaboration of the immense number of observations made during the long series of years, which will form the body of the work. It is mainly occupied with an extensive and complete description of the growth of our knowledge with regard to China, forming a valuable index to the literature on this country. No small amount of space is devoted to the book, "Yü-Kung," or imperial geography, forming the sixth in the series of historical works attributed to Confucius, and covering the period 2357–720 B.C. The remaining portion of the volume is occupied with the geographical relations of China to Central Asia, and contains a most important study of the loess regions of Northern China. They are not only considered in their relations to the saline steppes of Central Asia, but are compared with all the great loess formations known, and supply the basis for an interesting theory with regard to the formation in the one case of fertile valleys, as those of the Nile and Mississippi, and in the other of sandy wastes. Scarcely less valuable is the clear and distinct picture afforded of the whole mountain system of this portion of Asia. The author finds the laws governing the conformations so simple, that less time was required to determine the system than would have been necessary for a tenth of the area in Europe. In a closing chapter on the problems of modern scientific geography, the author sharply defines the province of his science, drawing clearly the limits between it and political geography, ethnography, and kindred sciences. The method to be used in the solution of these problems he defines as "the uninterrupted consideration of the causal, mutual relations between the earth's surface from its various points of view, terrestrial physics, and the atmosphere on the one side, and between these elements and the organic world in its broadest sense on the other side." Of the three volumes yet to appear, one will be devoted to palæontology, in which the author will be assisted by Dr. Kayser, Dr. Schwager, Prof. Schenk, and other able geologists The remaining two will contain the author's extended researches into the coal-fields of China, regarded by him as more valuable than the deposits in the United States of America—the geological structure of the land, the climatic phenomena, the population as affected by these two agencies, the river system, means of transport by land and water, chief productions, mercantile possibilities, &c. A generous grant from the Emperor of Germany has permitted the publication of the work in a most sumptuous style, and the introduction of numerous carefully executed maps and illustrations wherever opportunity is offered by the text.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Soldiers' Rations

IN your issue for June 28 (p. 158) Mr. H. Baden Pritchard states in his article on "Soldiers' Rations," "And yet, as we have said, with this apparently liberal feeding, our men do not receive so much actual nourishment, or nitrogenous matter, as the German soldier."

My calculations, based on Prof. Parkes' table of soldiers' rations, and Prof. Frankland's experiments on food and urea, give the following values of the several soldiers' rations:—

		Foot tons.
1. English Military Prison	... ...	4,509
2. English Soldier (Home)	... ...	3,964
3. Prussian ,, (War)	... ...	3,812
4. French ,, (Crimea)	... ...	3,683
5. French ,, (Home)	... ...	3,580
6. French ,, (War)	... ...	3,538
7. Austrian ,, (Home)	... ...	3,242
8. Prussian ,, (on the march)	... ...	3,223
Mean	... ...	3,694

As the average daily external work of a man is 353·75 [1] foot tons, the efficiency of man regarded as a heat engine is 9·6 per cent. of the internal work.

An efficiency of 8·2 per cent. can be obtained by engines working at 40 lbs. pressure and steam cut off at half stroke; so that man regarded as a machine, does not occupy a very high position. The explanation of this is, that man is not a *machine*; he is a *machine maker*. The mechanism of a cat or beetle is vastly higher than that of man, and yet they are immeasurably his inferiors. SAML. HAUGHTON

Trinity College, Dublin, July 7

Printing and Calico Printing

IN your article on the Caxton Exhibition last week, there is the remark that the beauty of execution in the specimens preserved to us of the work of the earliest known printers suggests a doubt whether the date of the actual invention must not be pushed back farther than the accepted one. But does that follow? Is not the beauty of the first printing simply the beauty of the wood engraving of the time? an art which had attained an exquisite perfection before its application to movable type.

That there should be doubt and obscurity as to the date, name, and claim of the first inventor can surprise no one who will ask himself who, for instance, was the inventor of our present mode of calico printing by roller; and, if he cannot answer, shall turn, as he has every right to do, to the current issue, ninth edition, of the "Encyclopædia Britannica" for the satisfaction of his doubt. He will find there, in that long, elaborate, and amply-illustrated article, not the bare mention of the name, even (unless I have strangely missed what I expressly looked for) of the otherwise remarkable man who conceived the idea, mechanically wrought it out for his own immediate purpose, and himself elaborated its application to the printing of calicoes—revolutionising that important branch of our industry—all well within the lifetime of men not half a century old among us! The Rev. Isaac Taylor—turning a moment from his own researches into the Etruscan mystery—should be able to tell us in what precise year it was, after 1840, that his father, Isaac Taylor, the author of the "Natural History of Enthusiasm," and a long series of subsequent works, sufficient alone for a reputation of a high and lasting order—a teacher of teachers, the depth and extent of whose influence and the fulness of whose intellectual stature have not yet been adequately recognised—engraved on the roller illustrations for his new translation of Josephus, undertaken in connection with Dr. Traill. The death of his fellow-worker cut short that enterprise, but a portion of the work appeared; and I myself, as a boy, was often in the little private workshop at Stanford Rives while this idea was struggling on the turning-lathe, through the patient genius of its author, for mechanical existence. In 1855 or 1856 I found him superintending its actual application to the printing of calicoes at Manchester. The discovery received the immediate and inevitable compliment of piracy, and brought to him and his loss instead of gain. But that within five-and-twenty years his very *name* should seem to have wholly dropped away from what was undoubtedly his own unaided invention, and one withal of so much national importance, and in an age of lime-light publicity like ours, is almost a curiosity of injustice, and throws, as I have said, a flood of light on a crowd of similar miscarriages in the indifferent past. As a hundred years hence this also may be beyond remedy, kindly assist me to arrest a moment the remorseless tooth of All-Father Time by the insertion of this contemporary note. HENRY CECIL

Breigner, Bournemouth, July 9

Stamping out Noxious Insect Life

THE subject of insect and germ life in its relation to putrefaction and infectious disease is now assuming such importance from the investigations and demonstrations of Dr. Tyndall, Mr. Murray, and other scientific inquirers, that I think you may consider the following curious facts not unworthy of space in your journal.

I observe in a report of Dr. Tyndall's lecture on Germs, in NATURE, he refers particularly to the varying tenacity of life which germs under certain conditions exhibit, and which he refers to the period of incubation or stage of development up to the state of emergence as complete organisms, when they are readily destroyed. He says: "We now turn to another aspect of the question; following the plain indications of the germ theory of putrefaction, we sterilise in five minutes the very infusions which, a moment ago, were described as resisting five hours' boiling. The germs are indurated and resistant, the adult organisms which spring from them are plastic and sensitive in the extreme. The gravest error ever committed by biological writers on this question consists in the confounding of the germ and its offspring. The active bacteria developed from those obstinate germs are destroyed at a temperature of 140° Fahr. Let us reflect upon these facts. For all known germs there exists a period of incubation, during which they prepare themselves for emergence as the finished organisms, which have been proved so sensitive to heat. If, during this period, and well within it, the infusion be boiled for the fraction of a minute, even before the boiling point is reached at all, the softened germs which are then approaching their phase of final development will be destroyed. Repeating the process of heating every ten or twelve hours, each successive heating will destroy the germs then softened, until after a sufficient number of heatings the last living germ will disappear. If properly followed out the method of sterilisation here described is infallible; a temperature, moreover, far below the boiling-point suffices for sterilisation."

Now as the laws of nature apply to all magnitudes alike, whether it be a grain of sand or the planet Jupiter, to the various stages of incubation of the germs of bacteria or of noxious insect life, I think I may claim some credit for having *stumbled* upon, and for having applied on a practical and large scale, a system for eradicating insect life in animals based on this law of varying tenacity of life in germs and insects. More than two years ago I advocated this system, and in September last issued a circular, in which I stated that "a short time after clip-day I dipped, by immersion, the young lambs, and I repeated the same before harvest; at the same time I made a long narrow pen alongside the stackyard fencing, into which I crammed all my old sheep as close together as possible. I then, with an ordinary watering-pan, watered them all over with diluted fluid; the latter operation was completed in half an hour, and the cost in material was less than one halfpenny per head, the proportions in both cases being 1 to 100. Now for results! I lately minutely examined the whole of my sheep, for the purpose of deciding if it was necessary to give them a final dressing before October, and I can now frankly, and without

[1] "Animal Mechanics," p. 62.

hesitation, state that in the whole flock, old and young, I could not find a single living insect, or the germ of one."

In the month of March last, agreeably to my promise, I issued a faithful report of the results of this system of stamping out insect life. The sheep cleansed on this principle were absolutely clear of insect pests, whilst others not so treated were never free. I shall send with pleasure this report to any of your readers who may desire to have it.

I believe I may say there is exact analogy between this system for exterminating insect life in animals and that adopted by Dr. Tyndall to show that the earliest eggs or germs of bacteria are extremely obstinate to kill, whilst the more fully developed are destroyed without difficulty, clearly showing that more than one treatment is necessary for the complete destruction of germ life as well as for a higher form of insect life, and that the same law applies to both alike.

I am fully convinced of the possibility of stamping out noxious insects that affect sheep and other animals, and sincerely hope Mr. Murray's suggestion at the Society of Arts of united action to effect this purpose under the direction of science and experience may be acted upon with little delay. W. LITTLE

Complementary Colours

IN NATURE (vol. xvi. p. 150) you give a most interesting, though very brief, account of Prof. Rood's researches on colour, the result of which you sum up in these words :—

"The mixture with white is the same as if the colours were moved towards the violet end of the spectrum."

I know of Prof. Rood's results only from your abstract, but your summary is not a perfectly accurate account of the facts which you state immediately before, unless the expression "violet end" is to be used in a new sense, or, what would be better, replaced by the expression, "violet *pole*."

The following will be found a correct summary of Prof. Rood's results :—

Let the colours of the spectrum be arranged, not in a line but in a circle, and the gap between red and violet be filled up with purple. Each colour will then be opposite to its complementary colour. Greenish yellow and violet, which are mutually complementary, are the opposite poles, and the succession will be as follows :—

Greenish yellow.	
Yellow.	Yellowish green.
Orange.	Green.
Vermilion.	Cyanogen blue.
Purple.	Cobalt blue.
	Ultramarine.
Violet.	

The addition of violet to any one of the colours except those at the two poles will bring that colour nearer to the violet pole; the same addition to either of the polar colours will leave them unchanged as to their position in the circle. *The addition of white will have the same effect.*

As regards the effect of the addition of violet, this is what we might expect. Violet added to violet will only make violet. Violet added in small quantities to greenish yellow, which is its complementary, will only make it whiter without changing the colour. Violet added to any other colour will bring it nearer to violet. We might select any pair of complementaries as poles, and obtain a parallel result. But what is new, and if confirmed, most important, is that white has the same effect as violet. I can suggest no explanation of this.

For the fact that every colour in the spectrum has its complementary, see Prof. Grassmann in the *Philosophical Magazine* of April, 1854. His paper appears to be less known than it deserves. The pairs of complementaries according to him are as follows :—

Red.	Bluish green.
Orange.	Azure.
Yellow.	Indigo.
Yellowish green.	Violet.
Green.	Purple.

Most authorities say that purple is not to be found in the spectrum, but Grassman says that under favourable conditions of light it may be. I think that in any observations on the subject where great accuracy is desired, the use of sunlight is to some extent misleading, and that the true white is that of an incandescent solid or liquid at a very high temperature—that is to say the electric light. The sun's light is such a light where it leaves the body of the sun, but part of its rays are absorbed in the sun's atmosphere, and the blue in greater proportion than the red and yellow; and a further loss of blue rays takes place in the earth's atmosphere by scattering, forming the blue of the sky. The blue light of the sky is taken out of the white light of the sun. For these two reasons the sun's light at the surface of the earth is not truly white but yellowish.

I can scarcely doubt that when the spectrum of the electric light is carefully examined, it will be found to contain purple; and also that some simple mathematical relation will be discovered between the wave-lengths of every colour and its complementary. JOSEPH JOHN MURPHY

Phyllotaxis

THE theory which regards the alternate arrangement of leaves as the normal mode receives some support from the arrangement of the inflorescence of opposite leaved plants. In *Lysimachia nemorum* the leaves are opposite, inflorescence indefinite, solitary, and axillary, but it will be observed that the flowers springing from the axils of opposite leaves are never both equally developed at the same time, one will be fully expanded while the other is yet in bud, or one will be found in seed and the other in flower; it will be further observed that the oldest or most fully developed flower appears alternately on opposite sides of the stem; if all the leaves on this plant were separated by internodes, the arrangement would be *tetrastichous*, but owing to the suppression of the internodes between the first and second and the third and fourth leaves, the arrangement becomes opposite. The oldest of the two opposite flowers of each pair of leaves will be found to spring from the axil of the first, third, and fifth leaf, and plants with this alternate disposition of flowers may sometimes be met with; but usually a flower originates in the axil of each leaf, and then the youngest or latest flowers spring from the second and fourth leaves of the verticil; these latter may be looked upon as originating from arrested branches. This view is supported by the fact that plants may be sometimes found which, in place of producing the late flowers in the axils of the third and fourth leaves, produce branches from these points instead. In *Caryophyllaceæ* the opposite sides of the cymose inflorescence never exhibit an equal amount of development at the same time, proving that one of the sides is older than the other, although, owing to non-development of an internode, it is at the same level. A similar arrangement occurs in *Labiatæ* plants, but owing to the crowded inflorescence, it is not so evident, but it is very marked where branches spring from opposite leaves; one is generally two or three times as long as the other, and by tracing the arrangement of these long branches along the stem, the normal alternate arrangement may be determined. In *Scrophulariaceæ*, where both opposite and alternate leaves are met with, all the above-mentioned modifications may be seen. *Veronica chamædrys* has opposite leaves, and when the axillary racemes are opposite, one is invariably more developed than the other; this can be best seen by examining the inflorescence in the young state, as the dissimilarity in size disappears in the pairs of old racemes owing to the younger of the two continuing to grow until it has acquired the size of the other; sometimes this plant may be met with bearing in the axil of one of its opposite leaves a branch, and a raceme of flowers in the other, and in such instances the branches and flowers are produced on alternate sides; in *V. officinalis* this is the usual arrangement. The suppression of the alternate nodes of an alternate-leaved plant with axillary inflorescence would produce the arrangement seen in *Lysimachia*, inasmuch as it would bring together flowers of different ages and in different stages of expansion; but in this instance all the flowers would belong to the same generation or be the product of the same stem, whereas in *Lysimachia* the earliest developed of each pair of opposite flowers alone belong to the stem, while the later flower of each pair belong to another generation, and spring from a branch originating in the axil of the leaf opposite (owing to non-development of an internode) to the early flower; the branch, however, is generally arrested, and the flower alone appears, although sometimes the branch is more or less developed.

G. E. MASSEE

GEOGRAPHICAL WORK IN RUSSIA DURING 1876[1]

THE most important journeys by Russian geographers during 1876 were those of MM. Prshevalsky and Potanin in Central Asia, of Dr. Mikluho-Maclay in Polynesia, and the meteorological journey of M. Wojeikoff round the world. We have from time to time given notes of the progress made by M. Prshevalsky, and of the journeys of Mikluho-Maclay.

M. Potanin left Bulun Tokhoi (NATURE, vol. xv., p. 461) on August 20, and after having followed the eastern shore of the lake Ulungur, and crossed the deep and rapid Black Irtysh at Durbeldjin, he reached the river Kran, at Fulta, close by the Lamaïte convent, Shara Suma. The fertile valley of the Kran is the storehouse for the Southern Altai region; the Kirghises come here to purchase grain from the eastern slopes of the Altai and from the valley of Kobdo. The crossing of the Altai by the Djamaty pass, at the sources of the Black Irtysh, having been reported as very difficult, M. Potanin crossed the ridge by a more southern pass, Urmogaity, at the sources of the Kran river (9,000 feet above the sea), and entered on a wide hilly plateau covered with numerous lakes, and gently sloping to the east by a series of terraces, divided by border ridges. The easternmost of these ridges runs north and south, reaches 10,000 feet at the Terekty-asoo pass, and separates the high terrace of the Deloon river from the low tract on which the town Kobdo is built. This place was reached by M. Potanin on October 16. Rich collections of plants, insects, and birds were made during the journey, as well as a survey and a geological sketch of the route, together with determinations of latitudes and barometrical measurements of heights.

A most important work accomplished by the Russian Geographical Society during 1875 and 1876 is the geometrical levelling made along the Siberian highway, from Ekaterinburg to Irkutsk, on a distance of 2,236 miles. All meteorologists are well aware what a gap in our knowledge as to the distribution of pressure of the air upon the surfaces of large continents, arises from a want of geodetically-measured heights of meteorological stations. All attempts to trace isobars upon the Asiatic continent (one of which was made in the standard work of Mr. Buchan) have failed until now, the heights of the meteorological stations at Omsk, Tonesk, Krasnoyarsk, Irkutsk, and Nerchinsk having only now been directly measured. The Geographical Society has undertaken a geometrical levelling along the whole line, Ekaterinburg to Irkutsk, which levelling will afterwards be continued to Nerchinsk and Tashkend. This difficult enterprise, carried on with all possible accuracy, is now completed with full success, and the superintendent of the levelling, M. Moshkoff, is now busily engaged in computing the definitive results.

A yet more important undertaking, accomplished by the Russian geodesists, Col. Sharnhorst and Capt. Kulberg, during the years 1873–1876, is the precise determination of longitudes, by means of telegraphic signals, carried out along an arc of 103°, between Moscow and Vladivostok, on the Pacific. But this work is so important that we hope to be able to give a special report upon it.

We may also mention the work of Capt. Onatsévich on the shores of Russian Manchooria (NATURE, vol. xv. p. 417), and the important cartographical work of M. Sidensner between the Obi and Jenissei rivers.

Most valuable work was done also during 1876 by the Siberian branch of the Geographical Society. The measurements of depth of the Baikal were continued by MM. Dybovsky and Godlevsky, and showed that the greatest depth of the lake is to be found in its southern part and close to its north-western shore. M. Grebnitsky explored the region of the Southern Usuri and returned with valuable geological and botanical collections. M. Chersky explored the valley of the Irkut river and arrived at very important results, the chief of which are:—(1) that this valley is geologically a very old westerly extension of the Baikal trough; (2) that it contains immense glacial deposits; and (3) that the outflows of basaltic lava in the valley are, with one exception, pre-glacial. We notice also the entomological excursions and the exploration of the Kasbek (Devdorak) glacier, made by members of the Caucasian branch of the Society.

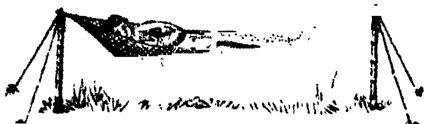
Besides these explorations, the Society has also issued some valuable publications. The most important of them are—(1) the fourth volume of supplements to Ritter's "Asia," being a description, by MM. Semenof and Potanin, of the Altai and Sayan highlands, according to works which appeared from 1836 to 1872; the names of the two authors sufficiently recommend the work; and (2) the second volume of M. Prshevalsky's "Travels in Mongolia," which contains—the Climatology and Ornithology, by the traveller himself; the Herpetology, by Prof. Strauch; and the Ichthyology, by Prof. Kessler. The seventh volume of the *Memoirs* of the Society contains the first part of the work of Prince Kropotkin, "On the Glacial Period in Finland and on the Bases of the Glacial Theory," with numerous maps and engravings. The *Isvestia* (Bulletin) of the Society contains, besides valuable small contributions, two very valuable maps of the Hissar and Koolab beckdoms, by M. Mayeff, and of the Lower Tunguska River, by M. Chekanofsky.

The scientific results of the expedition made to the Amu-daria in 1875 and 1876, will appear very soon. They contain the astronomical, magnetical, and meteorological observations made by M. Dorandt, and a thorough and elaborate hydrographical description of the Amu-daria, by M. Zuloff, with the collaboration of Col. Makshéeff. The first of these works is already printing, and contains abundance of most valuable meteorological data (pressure, temperature of air and of the soil, evaporation, level of water, variations of magnetical elements, &c.). The Meteorological Committee of the Society is engaged in preparing complete tables of the amount of snow and rain during 1872-1876, measured at the numerous stations organised by the Society. Finally, we can only mention some of the various works issued by the Society in the departments of Ethnography, Statistics, and Historical Geography; as, for instance, those on the trade in grain in Western Russia, by M. Rayevsky; the ethnographical description, with maps of South-Western Russia, by M. Gildebrand; the text to the ethnographical map of Russia, published by M. Rittich, being now at press; and many other valuable works of less importance.

[1] "Report of the Russian Geographical Society for 1876," by the secretary, V. I. Sreznevsky.

A POCKET HAMMOCK

IN these days, when exploring tours and extended scientific excursions are so universal, it is a great advantage to be able to take up one's bed and walk, to be in short entirely independent of sleeping accommodation. Even in our own country it is often an advantage to the working geologist, or botanist, or zoologist, to be independent in this respect, and while it is sometimes no great hardship to make one's bed on the heather or grass under the lea of a broom-bush or dyke, still it is seldom advisable to do so if it can be avoided. Many of our readers will therefore be glad to know that Seydel and Co. of Birmingham have devised a handy hammock, which bears the name of the "Ashantee Hammock," from its having been found of great service during the Ashantee campaign, Sir Garnett Wolseley testifying strongly to its manifold utility. It is made of light but strong netting, and can be so folded up as to be slung over the shoulder like a bag, or even carried in a fair-sized coat-pocket. From the arrangement of the ropes, hooks, and screws, it can be used under almost any circumstances, and, as we ourselves can testify, forms a thoroughly comfortable and secure bed or lounge. Mr. Stanley, we believe, was so favourably impressed with the hammock, that he has taken a supply with him in his present exploration; and for explorers in tropical countries, we should think it would prove useful in many ways, as it can not only be used as a bed, but, mounted on a pole, as a travelling litter or palanquin. For those of our readers engaged in explorations of any kind, geological, geographical, botanical, zoological, or even in doing an ordinary tour, in remote districts, we



ASHANTEE HAMMOCK ON SLINGING APPARATUS.

believe the hammock would be found of real service, as it would make them quite independent of sleeping accommodation, and would not increase the weight of their *impedimenta* by very many ounces. An idea of its construction and its adaptability to almost any circumstances may be obtained from the illustrations we give. We can honestly recommend the hammock as likely to answer all the purposes for which it has been designed.

THE SANITARY INSTITUTE

THE lecture by Dr. Richardson, published in our issue of last week, has called public attention to the Sanitary Institute of Great Britain, before which the lecture was delivered. The Institute was founded in July, 1876, at a public meeting held at St. James's Hall, and presided over by his Grace the Duke of Northumberland. The Institute has for its work a wide range of subjects. It has sprung, we may say, out of the necessities of the time, and in the first instance may be considered as a nucleus round which will cluster the many men of science who are now employed in carrying out the executive sanitary or health work of the kingdom. The various medical officers of health, the certifying surgeons under the Factory Acts, the engineers and sanitary surveyors of different localities, the mayors of municipalities, and the chairmen and presidents of local boards, all of these must needs take an interest in and in time form the body corporate of an institution framed for the purpose of becoming as it were a voluntary health parliament. In addition to these sections of the Institute there are many other sections of the community which will, we should think, earnestly join in the work. For reasons plainly stated by Dr. Richardson ladies are invited to take part in the proceedings and to help forward sanitary progress. We feel sure there will also be a large class of active men unconnected professionally with sanitary work who will be ambitious to take a part in the great practical scientific labour of the time, the only labour we may say in which science lends herself immediately to the aid and comfort of domestic life and felicity.

The detailed work of the Sanitary Institute has been in some measure projected by its founders; but it is more than probable that in the course of its natural development it will grow into something different from that which is now supposed. At the same time we are bound to say that the plan is sufficiently simple and practical to warrant the expectations of those who have mapped it out. The objects we have seen proposed are all directed to some useful and desirable end. To obtain a registration of the diseases of the kingdom; to establish communications with medical officers of health; to form local branches of the Institute throughout the kingdom; to examine and grant certificates of qualification to local surveyors and inspectors of nuisances, and to form a register of such certificated officers; to investigate the chemical aspects of the sewage question; to establish a sanitary exhibition, and to form a library of books on health subjects;—these objects, some of which must needs become a part of every sanitary organisation, are sufficiently comprehensive to cover any amount of work, and to tax any amount of industry that may be found in the best organised public body. So far the prospects of the Institute are brought beyond what is common to such undertakings in their earliest days. Members are daily being added, and an effective Council has been elected. Already one of the provincial towns, Scarborough, has invited the Institute to hold its first provincial Congress there, and in France a kindred society has been formed in sequence, and, it may be said without offence, in imitation of the one already founded in London. The visit of Dr. De Pietra Santa, of Marié Davy, and other savants from Paris to the meeting on Thursday last, is a significant sign of the good feeling with which the two rival societies have commenced their labours.

For our parts we welcome heartily both Institutes, and shall enjoy the privilege of watching their onward progress and recording their success.

ON THE SOURCE OF THE CARBON OF PLANTS

NEARLY half the dry substance of plants is carbon; and it is conclusively established that they derive, at any rate, the greater part of it, directly from the carbon-dioxide of the atmosphere, which the chlorophyll cells have the power of decomposing in sunlight, at the same time evolving oxygen. But this function of vegetation, which is so essential a complement to the processes of animal life, gives rise to many problems hitherto unsolved; and an important one is whether or not plants avail themselves of other obviously possible sources of carbon than that existing in such very small proportion, although in large actual amount, in the ambiant air.

Our knowledge bearing upon the subject as it exists in the present day, is the resultant of careful investigations by many observers. In the last century Bonnet discovered the gaseous exhalation; Priestley that the gas is oxygen; Ingenhouz that the oxygen is only evolved in sunlight; Sennebier that it is due to the decomposition of carbon-dioxide, but he believed that the carbon-dioxide is taken up in solution in water. Early in this century de Saussure carried out a long series of experiments on the relations between the carbon-dioxide decomposed, and the oxygen evolved, and on the amount of carbon-dioxide in the air compatible with the healthy development of plants. Since his time many eminent names have been added to the list of patient labourers in this field of inquiry.

Boussingault worked on the question whether the carbon-dioxide is absorbed by the leaves, or taken up by water through the roots; and by direct experiments proved that the leaves of plants do take up the carbon-dioxide, which is so sparingly, though so uniformly, diffused in the atmosphere. His researches led him to conclude that, by far the greater part, if not the whole, of the carbon which enters into the constitution of the organs of plants is derived from atmospheric carbon-dioxide; and while drawing attention to the fact that, for healthy and vigorous action, plants require large volumes of air to pass over them, and to the surprising rapidity with which they absorb the carbon-dioxide from it, he makes calculations as to the surface presented to the air by the leaves of different crops. Taking the average number of plants growing per hectare (about $2\frac{1}{2}$ English acres), he estimates that:—

Artichoke	gives a surface of		142,410	square	metres.
Beetroot	,,	,,	49,921	,,	,,
Potato	,,	,,	39,641	,,	,,
Wheat	,,	,,	35,490	,,	,,

Boussingault also made experiments in regard to the absorption of carbon-dioxide by plants growing under different conditions as to soil and manures. He found that a Helianthus which in twenty-four hours would, without any manure, only decompose 2 c.c. of carbon-dioxide, decomposed 182 c.c. in the same time when supplied with manure containing nitrates and phosphates, 11 c.c. when with nitrates without phosphates, and only from 3 to 6 c.c. when manured with phosphates without nitrates.

That the carbon-dioxide contained in the atmosphere is sufficient for normal vegetation is proved by the abundant growth of heath and other wild plants on sandy hills; and the numerous experiments on water-culture conclusively show that a plant may grow luxuriantly, and store up an abundance of carbon, when supplied only with mineral salts, in a solution which contains little or no carbon-dioxide.

Sachs speaks of it as an unquestionable fact, "that most plants which contain chlorophyll (for instance, our cereal crops, beans, tobacco, sun-flower, &c.) obtain the entire quantity of their carbon by the decomposition of atmospheric carbon-dioxide, and require for their nutrition no other carbon-compound from without." He goes on to say: "The compound of carbon originally present on the earth is the dioxide, and the only abundantly active cause of its decomposition and of the combination of carbon with the elements of water is the cell containing chlorophyll. Hence all compounds of carbon of this kind, whether found in animals or in plants or in the products of their decomposition, are derived indirectly from the organs of plants which contain chlorophyll."

Dr. J. Boehm made direct experiments with seedlings of scarlet-runner, growing them under glass shades, luted with potass lye, in pots containing in some cases quartz sand moistened with a nutritive solution, and in others garden-soil rich in humus. The two sets were quite equal in development and duration of life; those in the garden soil formed quite as little starch as those in the sand; and from this he concluded that the carbon dioxide yielded by the garden soil had taken no share in the growth of the plants.

Liebig had, however, supposed that plants might owe some part of their carbon to the carbon-compounds in the soil, which were absorbed by their roots, and that young plants especially drew their supply from this source. He speaks of the effect of drought as checking the supply of carbon-dioxide by the roots, and throwing the plant exclusively upon that in the air.

But the tendency of more recent investigations points to the conclusion that the atmosphere and the parts of plants living in it are solely concerned in the storing up of the carbon of vegetation.

We may pause for a moment to consider the amount of the carbon so stored up.

Liebig estimated that more than 1,000 lbs. of carbon may be harvested annually from a Morgen of surface—somewhat less than two-thirds of an English acre.

According to the estimates of Lawes and Gilbert, with wheat for twenty years in succession on the same land there was an actual yield of 2,500 lbs. of carbon, per acre, per annum, where no organic carbon compounds were added to the soil, and where these were added (in the form of farm-yard manure) the actual yield in carbon was less. With barley, for twenty years in succession, the average annual yield was 2,088 lbs. of carbon per acre; and the indication is that some other crops, under similar conditions, acquire even more.

Estimates recently made of the forest growth in Germany give as much as 2,700 lbs. In tropical climates where vegetable growth is more luxuriant the amounts are far greater; and in the West India Islands as much as from 2½ to 5 tons of carbon may be harvested per acre in the crop of sugar-cane.

With these large amounts of accumulation on the one hand, we have, on the other, an atmosphere containing carbon-dioxide in so small a proportion as 0·04 per cent.

Then we have to bear in mind the large supplies of carbon-dioxide within the pores especially of manured soils, as determined by Boussingault, and at the disposal of the roots of plants. Also the enormous quantity of water taken up from the soil and passing through plants during growth, probably at any rate more than 200 parts for every part of dry substance fixed, and the fact that carbon-dioxide is present in all natural waters would lead to the supposition that the roots would scarcely either take it up to no purpose, or act as a filter to that which constitutes so important a requirement of the plant.

Dr. Moll[1] has recently, by some interesting experiments, made a contribution to the evidence which is required to answer the question—Can leaves decompose the carbon-dioxide which is at the disposition of the roots? and argues that the proof that one part of the plant—the leaf—takes up and decomposes carbon-dioxide, is no proof that it is not taken up in another part—the root.

He quotes the experiments of Sennebier and de Saussure, but considers that they were not made quantitatively, or with sufficient exactness to solve this problem. For its elucidation he rests his methods upon Sach's theory, that the starch in the chlorophyll grains must be considered as the first visible product of the decomposition of carbon-dioxide, and that therefore, according to him, the presence or absence of starch in the leaves is the crucial test of the decomposition or non-decomposition of carbon-dioxide. In Dr. Moll's investigation of the starch contents he used Sach's modification of Boehm's method.

Five sets of experiments were made to meet the different aspects of the question.

In the first set glass shades were used, in one of which the air was kept free from carbon-dioxide by being luted with potass lye, while the other contained ordinary air, or air with an excess of carbon-dioxide, and was luted with water. The liquid lute was in porcelain dishes, made with a round hole in the middle; the central hole and outer edge being deeply rimmed. The shades, of less circumference than the dishes, were set in them, and were furnished with tubular necks, into which smaller tubes were fixed for the current of air to pass through, and for other requirements of the experiments. The exit tube of the shade in which the atmosphere was kept free from carbon-dioxide was conducted through a test-tube filled with pieces of pumice saturated with potass lye. Preliminary experiments with etiolated plants, with a watch glass containing baryta-water within the shade, satisfied the author that he secured having air absolutely free from carbon-dioxide under that luted with potass lye; and some early failures taught him how to regulate the supply of carbon-dioxide and air in the other shade, so as to grow plants as well-developed and healthy as those in the open air. With thick-leaved plants he found that it was necessary to add as much as 2 per cent. of carbon-dioxide to a volume of air supplied to them of about 2,500 c.c. daily, in order to satisfy their requirements for free growth.

Experiments were made with plants of French bean, nasturtium, gourd, and sugar-beet, growing in the open air in pots in good garden soil. From these was selected a leaf, or the upper part of a stem with several leaves, still organically united with the parent plant, which was passed through the hole in the porcelain dish, under the glass shade, and carefully secured air-tight, and from injury to itself, by cork and wadding. The plants for comparison were as nearly alike as possible in every respect, and a control plant grew in the open air between the shades. Both etiolated seedlings, which became green as quickly without carbon-

[1] "Ueber den Ursprung des Kohlenstoffs der Pflanzen." Von Dr. J. W. Moll (Utrecht).—*Landwirthschaftliche Jahrbücher*, Band vi. Heft 2.

dioxide as in common air, and well developed green gourd leaves, were tried. The gourd leaves, which contained starch at the beginning, entirely lost it within a day or two in the atmosphere deprived of carbon-dioxide, while those in the other shade remained still full of it. The shades, and the contents of the dishes, were then changed, so as to bring the starchless leaves into the shade containing carbon-dioxide. During the day these became again full of starch; while within twenty-four hours it had quite disappeared from the leaves in the other shade. In a similar experiment with sugar-beet the control plant in the open air was covered with a black paste-board box, and it was found that the leaves in the shade deprived of carbon-dioxide lost their starch at about the same rate as those in the dark. In no case was starch found in the leaves while they remained in an atmosphere without carbon-dioxide.

The second set of experiments was made with long leaves of bulrush and bur-reeds, which were etiolated, and then separated from the plants. With the same general precautions as before, the upper end of the leaf was inserted in the shade without carbon-dioxide, the lower in an atmosphere containing five per cent. of carbon dioxide, whilst the space between was left free to the open air. This intermediate part was obscured by tin-foil, so that no starch could be formed in it at the expense of any carbon-dioxide passing through the tissues from the lower shade; and it was supposed that if such a phenomenon were possible, the spacious longitudinal air channels of these plants might be especially favourable to the transmission of the gas. These experiments usually lasted one day, and uniformly gave the same result; starch was formed abundantly where carbon-dioxide was at disposal in the air, while the excess of it in the lower shade had no effect upon the portion of leaf in the upper shade, which remained entirely free from starch.

The apparatus when arranged was always placed in a light window, shaded by gauze blinds if the sun were too hot; and in these latter experiments it was an interesting circumstance that, in the lower portions of these rather thick leaves, more starch was formed on the side next to the window; therefore, in two cases a piece of looking-glass was placed behind the shade, when, being equally illuminated, starch was formed in equal abundance on both sides of the leaf. This variation in the starch-formation, according to the amount of light, showed that that portion of leaf had not always used all the carbon-dioxide at its disposal, and that consequently there was an excess which might have passed upwards through the tissues.

The third set varied from these in having no part of the leaf exposed to free air, thus obviating the possibility of the carbon-dioxide being diffused into it in passing upwards through the plant. A glass vessel containing air without carbon-dioxide was placed within a large shade containing air with 5 per cent. of this gas; and a previously etiolated leaf, with its stem in water, was so fixed as to be partly in the one and partly in the other. After six or eight hours it was examined for starch. Without exception starch was formed abundantly in the parts in the large shade, whilst no trace of it was found in those in the inner vessel even quite close to the junction between the two.

The remaining two sets of experiments were made to ascertain whether starch formation in leaves, in the open air, is accelerated by giving an excess of carbon-dioxide, either to adjoining parts of the leaves themselves, or to the roots. In the first case leaves separated from the plant were divided lengthways. One half, with the stalk in water, was in a shade with air containing 5 per cent. of carbon-dioxide, its upper part projecting under the glass lid of the shade, which was luted with grease, into the open air. The other half of the same leaf was laid on the lid, on filter paper soaked with boiled water to keep it moist, and put as near as possible to the projecting piece of leaf. In the other cases etiolated leaves, organically united with plants whose roots were in rich humus soil, were divided lengthways; one half, quite cut off, was laid near to the other, and the two were examined and compared after some hours' exposure in sunlight. The results of both these sets of experiments were uniformly the same; careful examination showed that starch was formed as readily and plentifully in those portions of leaves excluded from any other source of carbon-dioxide than that in the air surrounding them, as in those having an excess of it at command.

From these experiments Dr. Moll concludes that starch is never formed in leaves in an atmosphere deprived of carbon-dioxide, however much of it may be at the disposal of the other, under- or above-ground, parts of the plant; nor can starch-formation be accelerated in one part of a leaf by an excess of carbon-dioxide being at the disposal of another part of it, either in the air, or through the roots.

The results of these elaborate experiments are doubtless in accordance with the direction of those of other modern inquirers on this subject. At the same time it will probably be felt, that, when long-accepted opinions, which many well-known facts seem to favour, are held to be called in question, we may still ask for further confirmation, before accepting as decisive, conclusions depending on the exact interpretation of experiments made with living organisms exposed to somewhat artificial conditions. It may be hoped, however, that this further instalment of evidence in a given sense will incite to further research.

OUR ASTRONOMICAL COLUMN

De Vico's Comet of Short Period.—It has been already remarked in this column that, according to Prof. Brünnow's last investigations relative to this comet, it appears necessary to admit a very material degree of uncertainty in the value of the mean motion determined from the observations of the year 1844, notwithstanding the comet was discovered on August 22, and followed till December 31, or for a period of more than four months, and, moreover, was observed with a degree of precision which has seldom been attained with these bodies. In Prof. Brünnow's masterly and elaborate discussion, "Mémoire sur la Comète elliptique de De Vico," which gained the prize offered by the Royal Institute of the Netherlands, in June, 1848, the planetary perturbations were calculated to the epoch of next return to perihelion in February, 1850, but in consequence of the computed positions showing that observation in that year would be quite hopeless, the calculation was continued with all possible precision to the ensuing perihelion passage early in August, 1855. The computed track in the heavens for this appearance was by no means an unfavourable one for observation; the comet would remain for a considerable period near the earth, being at its least distance on August 2, just before the perihelion passage, when it should have approached our globe, according to Prof. Brünnow's calculation, within 0·58 of the earth's mean distance from the sun. Nevertheless, it was not detected in this year—an object observed by M. Goldschmidt, not far from its track, in May, being certainly a distinct body, if the star of comparison was correctly identified. It was looked for repeatedly with the large refractors at Cambridge and Berlin. In 1860 again, ephemerides were prepared and a search was made, at least at the observatory of Harvard College, U.S., but ineffectually, indeed the chance of observing this comet when the perihelion passage falls in the winter must be but small.

The later results obtained by Prof. Brünnow, to which allusion is made above, will be found in No. 3 of his Ann Arbor *Astronomical Notices*: he there gives his reasons for concluding that he had placed too great reliance upon the value of the mean motion determined in his memoir, and while obtaining a new value (about 650″) which would assign for the period of revolution in 1844 about 1994·0 days, he intimates the necessity of searching for the comet in future on the supposition that this period may be in error ± 30 days. At this distance of time or at the end of the sixth revolution since 1844, so great an amount of uncertainty of course renders the preparation of limited ephemerides useless, but it may be observed that the period finally deduced by Prof. Brünnow would bring the comet to perihelion again in the present summer, and it will certainly be worth while to keep a close watch upon those regions of the heavens which its path must traverse on this hypothesis; we might indeed expect, if the comet continues in the same condition as in 1844, that it would not escape detection, should the perihelion passage fall between the beginning of the present month and the middle or end of October. On July 14 its orbit is thus projected on the sky, the positions consequently indicating the line in which it should then be found according to the different suppositions as to the date of perihelion passage:—

Time from Perihelion.	Right Ascension.	Declination.	Distance from Earth.	Intensity of Light.
+ 40 days	60·3	+ 19·3 ...	1·89	0·17
+ 10	43·0	+ 13·4 ...	1·12	0·56
− 20	21·2	+ 3·0 ...	0·64	1·68
− 40	350·1	− 13·6 ...	0·39	4·02
− 50	321·6	− 24·8 ...	0·34	4·78
− 60	289·3	− 30·1 ...	0·38	3·60

While it is of importance that an effort should be made to recover the comet, now to all intents *lost*, in the present year, no surprise need be occasioned if the endeavour should prove fruitless. It is quite possible that the mean motion in 1844 was of such amount as would bring the comet, with the influence of planetary perturbation into so close a proximity to Mars at the end of August, 1866, as to occasion very material changes in the elements of its orbit; and again there is the possibility that, as Dr. von Asten suspects has been the case with Encke's comet, it may have encountered one of the minor planets, and with the result of a sensible change in its motion.

And it is to be borne in mind to whatever cause or causes the circumstance may be due, that De Vico's comet has been shown by M. Le Verrier and Prof. Brünnow to be with great probability identical with the comet of 1678 observed by Lahire at Paris; yet in the long interval from 1678 to 1844 there is no record of a comet which can be identified with it, and in the early part of its appearance in the latter year it was visible to the unassisted eye. It does appear strange that in the days of Messier and Pons the comet should have escaped detection at one or other of its returns.

While writing on De Vico's comet we may mention that in heliocentric longitude 339°·6 this body approaches very near to the orbit of the periodical comet of D'Arrest, of which observations may be expected in the present year. The distance is within 0·0055 of the earth's mean distance from the sun, or about 507,000 miles, rather more than twice the moon's distance from the earth, but it does not appear likely that there has been any actual close approach of the two comets during the last fifty or sixty years.

THE LATE PROFESSOR HEIS.—We regret to record the sudden death of Prof. Edward Heis, the well-known German astronomer, which occurred on June 30 from an attack of apoplexy. Prof. Heis was born in 1806, completed his studies at Bonn in 1827, and received in 1852 a call to the ordinary professorship of mathematics and astronomy at the Royal Academy of Münster, Westphalia, which he filled until the time of his death. He was a most diligent and accurate observer in the particular branches of astronomical research to which he devoted himself. His "Atlas Cœlestis Novus" may be considered the standard work for magnitudes of the stars visible in central Europe, his acute vision enabling him to add a large number of stars of what he calls 6·7m. not included in Argelander's "Uranometria." While resident at Aix-la-Chapelle previous to his appointment to Münster he published the results of ten-years' observations upon shooting-stars which were carefully discussed. In 1875 appeared his observations on the zodiacal light, extending over the twenty-nine years, 1847-1875, and forming No. I. of *Publications of the Royal Observatory at Münster*; it is a most important addition to our collection of observations of this as yet little understood phenomenon. From 1858 to 1875 he edited the *Wochenschrift für Astronomie*, a periodical better known on the Continent than in this country. Prof. Heis was also the author of a collection of examples and problems in general arithmetic and algebra, which, we believe, has reached the forty-fifth edition in Germany. His observations of variable stars were conducted upon a system of extreme care, his researches in this direction being encouraged and guided by Argelander; he first established the variability of that irregular star ε Aurigæ, not without a long course of assiduous observation. He was an excellent draughtsman, and produced many fine pictures of nebulæ, though, unfortunately, supplied with very limited optical means.

THE CAXTON EXHIBITION

IT is not too much to say that Science has been advanced by the art of printing more than by any other of the world's inventions, for by it not only has the knowledge of scientific truth been spread throughout the world, but it has been perpetuated to all time, and the names of great heroes in science have been rendered immortal. Long after sculptured monuments, commemorative of the lives and work of great men have crumbled away, their written works remain, and the art of printing has contributed more than anything else to the bringing about of that result. The names of some of the greatest philosophers the world has ever seen would have had but a narrow and comparatively ephemeral celebrity, were it not for the record of their lives and writings which the productions of the printing press have preserved to them.

But great as have been the advantages which Science has derived from the printer's art, she has, in return, conferred as many and as important benefits upon the development of that art; and this is recorded in unmistakable language in the Caxton Collection, which, though (probably for want of space) very deficient as far as modern printing machines are concerned, constitutes a most interesting and instructive series of historical and typical forms, in which the rise and development of printing machinery may be traced from the early screw presses of wood used by Caxton and the early printers, through the Stanhope and lever presses of the last century, to the powerful steam machinery of the present day.

The principal aim of the designers of printing machinery has always been to obtain increased rapidity of working; and during the last fifty years this has been brought to an extraordinary degree of perfection. It was considered a wonderful feat when, in the year 1814, the celebrated König machine was started, throwing off 1,100 sheets of the *Times* newspaper per hour; but this number was doubled by König's second machine, which he brought out ten years after. In the year 1827, by means of Applegarth and Cowper's four-cylinder machine, the yield was raised to 5,000 per hour, and in 1848 the celebrated "Times" vertical machine was erected, which produced 12,000 single impressions per hour. The next advance was made by Richard Hoe, who, in 1857, introduced his cylinder machine into this country, where it was first employed by the proprietors of *Lloyd's Weekly Newspaper.* Shortly afterwards the proprietors of the *Times* adopted it, and by means of a ten-cylinder machine, 16,000 single impressions of the *Times* were thrown off per hour. This was till lately the most rapid printing machine ever invented, but having to be supplied with separate sheets of paper from ten different feeding-boards, it required some twenty men and boys to work it. Since that time a still further advance in the art of printing has been made by the invention of the now celebrated Walter machine, by which the bulk of the *Times* is now produced. This machine works from a continuous roll of paper, printing it on both sides and—requiring the attendance of only a man and two boys—throws off 25,000 single impressions, or 12,500 complete newspapers, per hour.

In all these rapid machines the type *formes* are cast in cylindrically-curved stereotype plates, which are produced by first setting up the matter in type by the ordinary process and then pressing the *formes* so produced into *papier maché* moulds into which the stereotype metal is cast. By this means several plates from the same mould can be produced and therefore the same number of identical sheets may be printed at the same time.

With regard to the actual operation of printing the aid that Science has given has been almost exclusively in the direction of mechanical improvement and perfection. The art of stereotyping or the reproduction of plates and blocks for illustrations has, however, been developed by discoveries in many branches of Philosophy. Electricity has long been employed in the production of copies of wood engravings by the electrotype process, which copies are now almost universally used for rapid work where fine finish is not necessary, and the many processes in which photography is combined with engraving are every day becoming more generally employed for improving and facilitating the art of printing.

It will readily be understood that notwithstanding all the improvements in printing machinery by which such rapidity as we have referred to is insured, the art of rapid printing will be most materially hampered unless the operation of type-setting or composing can be carried on with corresponding rapidity. The importance of this is shown by the attention it has received and by the many systems that have been devised for mechanical and automatic type-setting. A special feature of the Caxton exhibition is the collection of machines for that purpose. Here again Science has lent her aid, and to any one interested in the applications of Science for the assistance of personal dexterity a careful study of the various machines exhibited will be found most interesting and instructive.

One of the most beautiful of these machines is the automatic type-setter of Dr. Mackie, which we illustrate in Fig. 1, and which is a most ingenious application of the well-known principle first invented by M. Jacquard, and applied by him to the operation of weaving, and which has since been employed for telegraphic and other purposes. In this machine a horizontal wheel, carrying a number of little platforms, revolves on a vertical axis beneath a set of upright boxes arranged in a circle round it. Each of these boxes is divided vertically into eight compartments containing the types; and the platforms, during the revolution of the horizontal wheel, pass in succession below, but without touching them. Each platform is furnished with eight adjustable projecting pins, that is to say, as many as there are compartments in the boxes. The use of these pins, or "pick-pockets" as they are called, is to remove the types contained in the corresponding compartments of the boxes at the moment of passing below them; and the types so removed, resting on the platforms, are carried round with them until pushed off at another point in their revolution, where they are collected and delivered in long lines in their proper order, and evenly spaced. The pins are automatically set up or left alone by the Jacquard mechanism to be referred to presently.

Calling the compartments containing the types and the corresponding pins on the platforms by the figures 1, 2, 3, 4, &c., it might at first be supposed that if, for instance, the pins 1 and 3 were set up, they would remove types from the first and third compartments of all the boxes as they passed beneath them, but this is provided against by the platforms being hinged at one end, so as to be capable of rising and falling through a small vertical arc, and by another portion of the Jacquard mechanism each platform is raised only when it is approaching that particular box which contains the compartments to which its projected pins correspond.

The regulation of the movements of both platforms and pins is effected by a set of levers, whose movements are determined by the positions of the perforations on a continuous ribbon of Jacquard paper, which positions correspond to the letters, spaces, &c., required to be set up. This ribbon is fed into the machine at a uniform speed by a

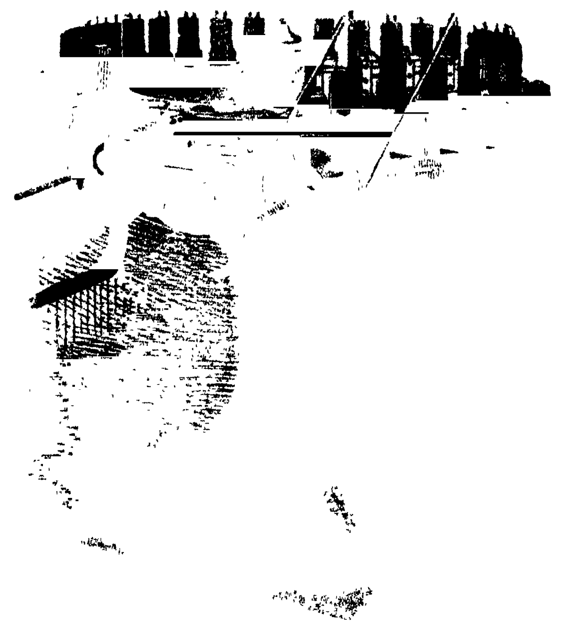


Fig. 1.

revolving spur-wheel armed with pins, which gear into a longitudinal row of holes punched along the centre of the strip of paper, and which is shown in Fig. 2, which represents a piece of the paper ribbon perforated for setting up the name of this journal, "Nature." The four lower rows, which are marked in the figure with Roman numerals, are those by which the rising and falling of the platforms are regulated, and the other eight rows, indicated by ordinary figures, correspond to the eight compartments of the boxes and control the protrusion of the pins or "*pick-pockets.*" On reference to the figure it will be seen that the capital letter N is drawn from the fifth compartment of that box, under which a platform is raised by the dropping of the levers, which are controlled by the combination of the two lines of perforations marked I. and IV.; and again the small letter r is contained in the third compartment of a box whose platform is raised by the single lever corresponding to the row marked I.

The perforation of the paper is done at a separate instrument, which, at the Caxton Exhibition, is, in external appearance, exactly like an ordinary cottage pianoforte, the keys of which are marked with the letters, figures, spaces,

&c., and which, by simple mechanism, punch corresponding holes in the paper when pressed down by the fingers. This operation being quite independent of the machine last described, can be carried on at any slack time, or when the type-setter is in use, and the prepared paper can be put away until the machine is ready to work from it. This is a special advantage of the system which printers will readily appreciate; and it possesses another of great value, and that is that parts of words of two to eight letters, and several short words, can be set up simultaneously, as the compartments are so filled that letters likely to come together are in contiguous divisions and may be released by the mechanism at the same moment. As an instance of this the eight compartments of one of the boxes are filled with types in the following order:—**w i t h a t s** and spaces, so that the ten words **wit, with, it, that, hat, hats, at, as, is,** and **has,** may be drawn by one operation, and the preparation of the paper for such combinations is no less simple, for it is performed by depressing several keys at once, as in playing chords in music.

By this system of type-setting, using one, two, or three perforators respectively, as many as eight, twelve, and twenty-four thousand types may be set up per hour.

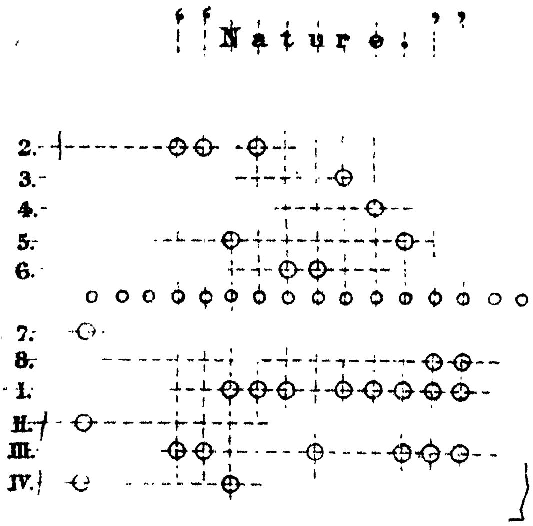

FIG. 2.

We have described Dr. Mackie's machine at some length, because it is a very beautiful application of the mathematical laws of permutations and combinations, and of mechanics to the saving of skilled labour, and is itself an interesting example of some of the services rendered by Science to the printer's art.

Another very ingenious application of Science to type-setting is the "Clowes" electrical compositor, invented by Mr. John Hooker. In this machine the types are contained in forty-eight nearly vertical troughs or reservoirs, and are pushed out through a lateral opening at the lower end by a *striker* under each trough actuated by an electro-magnet, so arranged that, when a current of electricity is sent through its coils, one type is released from its reservoir and drops out. Below the openings of the reservoirs are as many flat running tapes, and when a letter is released it drops on to the tape which is running below it, and is carried by it at the speed of seven inches per second to the edge of the table of the machine, where it is thrown on to another tape running at a quicker speed (about twenty-one and a half inches per second), and making an angle of about 150° with the set of parallel tapes before mentioned. This angle determines the relative distances of the reservoirs from the quick-running tape, and the speeds are so adjusted to these distances that the time occupied by a type in travelling from the reservoirs to collecting apparatus is exactly the same in all cases so that the types are delivered into the composing-*stick* exactly in their order of release from the reservoirs. This part of the apparatus may in telegraphic language be called the "receiving instrument."

The "transmitting instrument" consists of a series of rectangular plates of copper insulated from one another and arranged on a sloping board representing exactly the compartments in the ordinary compositor's "*Lower Case.*" Each of these plates is in metallic communication with one end of the coil of one of the discharging magnets, the other end being in connection with one pole of a voltaic battery consisting of two small Grove elements. The compositor sits in front of this set of plates, having the copy before him, and holding in his hand a copper stile or contact piece which is in connection with the other pole of the battery. Every time he touches with the stile one of the rectangular plates of copper a voltaic current is sent through the coils of its corresponding magnet and a letter corresponding to the plate touched is liberated on to the tapes and is instantly carried to the composing-stick. The collecting apparatus is extremely ingenious and is worked by a quick running cam by simple mechanism, which is a beautiful specimen of workmanship.

By this machine as many as 15,000 letters per hour may be set up; and it possesses the advantage over other systems that it can be worked by any ordinary compositor *at case*, and requires no special training for its manipulation.

Of other type-setting machines there are exhibited in the collection examples of Kastenbein's system, which is adopted in the *Times* office; the Hattersley compositor, in which the types are, by the depression of keys, shot down vertical grooves, by which they are guided to the composing frame, and by which it is said that types may be set at the rate of 8,000 per hour. Muller's machine, which is represented in the collection by a model, is a well-made apparatus, intended to set type at a speed of 5,000 letters per hour. Both this and the Hattersley machine set up the type in columns, ringing a bell at the end of each line.

Heinemann's apparatus is an exceedingly simple machine, depending upon quickness of hand and eye in aiming a pointer at the particular divisions of a comb-shaped series of guides, by which the types are withdrawn from the reservoirs corresponding to those divisions. It is a well-made machine, and its simplicity is a safeguard against its becoming deranged.

The operations of type-founding, of paper-making and folding, of lithography, and steel engraving, which are all more or less dependent upon scientific aid, are all represented at South Kensington, but we must reserve their consideration for a future notice, as well as a description of an interesting gas-engine, exhibited by Messrs. Crossley Brothers, which is admirably adapted for laboratory purposes.

From what has been said it will be seen that the Caxton Exhibition is an exceedingly interesting and instructive one, and will well repay several visits. C. W. C.

NOTES

WE are glad to see that the first grants from the Research Fund of the Chemical Society have just been made. They are as follows: to Dr. C. R. A. Wright 50*l.* for the investigation of certain problems in chemical dynamics; to Mr. G. S. Johnson 25*l.* for a research on double salts with potassium tri-iodide; to Mr. E. Nelson 25*l.* for a research on octyl compounds; to Mr. Carleton Williams 25*l.* for a research on hydrocarbons containing the group isopropyl twice; and to Mr. George Harrow 10*l.* for a research on derivatives of aceto-acetic ether, THE German Astronomical Society, as it is generally called, but really the International Astronomical Society, meets this year at Stockholm, from August 30 to September 1.

Now that the British Association meeting is again at hand, perhaps we may be permitted to urge upon the authorities the necessity for introducing some improvement in the daily programme published during the session. Last year (vol. xiv., p. 463) we noticed the handsome, full, carefully-arranged programme daily published by the American Association, and we have before us the *Tageblatt* of last year's meeting at Hamburg of the German Naturalists and Physicians. This is a quarto publication, each day's issue averaging twenty pages, and containing such important and detailed information that it is well worth binding and preserving. The rules of the Association are given in the first issue, a list of members with their addresses is given daily until complete, the arrangements for the meetings of sections and general meetings are clearly tabulated, a well-arranged general programme and list of all papers to be read each day are given, all information as to excursions, places to be visited, entertainments (including theatres), advertisements likely to appeal to members, summaries of each day's proceedings in the various sections, general meetings, dinners, &c. ; in short every kind of information likely to make the proceedings be carried on with perfect smoothness and give the members the minimum of trouble and worry. Appended is a supplement of 180 pages containing reports of lectures given at general meetings and in connection with the various sections. All this contrasts strongly with the shabby tract-like programme issued during the meetings of the British Association; if the expense is an obstacle we are quite sure no member would object to a small charge if he could only be assured of obtaining each morning a well-printed journal on a scale similar to that of either the American or the German Association.

AT the Congress on Domestic Economy to be held at Birmingham on the 17th, 18th, and 19th instant, under the presidency of Lord Leigh, Prof. Huxley will read a paper on Elementary Instruction to Children in Physiology, Mr. W. S. Mitchell one on the Practical Use of the Food Collection of the Science and Art Department, and Captain Galton on Warming and Ventilation. Many other papers bearing on the subject of the Congress will be read, and an exhibition will be organised.

MANY of our biological readers will be glad to know that Dr. George Bennett, F.Z.S., of Sydney, has arrived in this country, and that any communications directed to the office of the Zoological Society, 11, Hanover Square, will be forwarded to him.

THE Portuguese African Exploring Expedition left Lisbon for Loanda on the 7th inst.

MR. RICHARD S. FLOYD, one of the trustees of the Lick Californian estate, has been for a year past in Europe, investigating the comparative merits of reflectors and refracting lenses, for the great telescope. We are told by the *New York Tribune*, for various reasons, which he gives in detail, he decides against a large reflector, one point being that even if the extreme nicety of adjustment which the reflector requires could be attained in the new observatory, it would be liable to derangement in the high winds of a mountainous position. If a refractor is decided upon, estimates should be asked, Mr. Floyd says, from Cooke and Sons, of York, from Alvan Clark and Sons, and from Howard Grubb. He reports that the reputation of Clark's refractors and Grubb's, from all he can learn abroad, is about equal. The story of Mr. Lick's millions had preceded Mr. Floyd, and he has found it difficult to bring down the estimates of European opticians to the basis of ordinary business profit.

IN the debate on the education estimates, on Tuesday night, Sir John Lubbock, speaking on the extra subjects which had been made compulsory, said he doubted whether under any circumstances it would be desirable thus to stereotype one form of education for the whole of England; but surely we ought not to do so unless we were very clear as to what is the best system. There was, however, very great difference of opinion on this head. The first authority to which he would refer was that of a committee of that House. It was presided over by his hon. friend the member for Banbury, and after careful inquiry they reported that in their opinion "elementary instruction in the phenomena of nature should be given in elementary schools." The next authority which he would quote was the Royal Commission, presided over by the Duke of Devonshire, which unanimously recommended that more substantial encouragement should be given to the teaching of the rudiments of science in our elementary schools. In Scotland, too, great dissatisfaction was felt with the present system. At the last conference of elementary teachers, held in London, which was very numerously attended, it was resolved that the system of payment "embodied in the Code is unsound in principle and injurious to the progress of true education." The inspectors of schools differed greatly as to the most suitable subjects. Even in regard to geography they were not unanimous. It was said as a subject to lend itself very much to "cram." One of the inspectors gave in support some very amusing answers. For instance, in answer to a question of "What are mountains and rivers?" one girl replied that "Mountains in some parts of the world are very useful. In Africa, for instance, they shoot out gold." Of rivers she had not so favourable an opinion, though she thought "they were all very well in some countries where there was very little rain." He confessed, however, that he thought geography a very good subject, though he was not convinced that it ought to be continued during the whole course to the exclusion of other subjects. The mere skeleton of history taught in our elementary schools contained little more than dates, wars, and murders; but dates and crimes no more constituted the history of a nation than sinews and bones made a man. Men of science must be grateful to Sir John Lubbock for so constantly urging upon Government the importance of scientific education.

THE first practical response to the proposal for the establishment of a colonial museum in London has come from the Legislative Council of Ceylon, which has voted as its contribution a sum of 15,000*l*., to be paid in three annual instalments. The Council of the Colonial Institution is about to issue another circular on the subject to the colonial Governments.

AT the last sitting of the French Geographical Society, excellent news was received from M. de Brazza, the French explorer of the Ogové. He reached a distance of 250 miles beyond the place where M. de Compiègne was obliged to retreat hastily to save his life. He finds that Ogové does not bend towards the Zaire. If its course does not change further up, both streams may belong to a single system. It was reported, also, that M. Say, a French officer in the National Marine, had reached the Hoggar, in Central Africa, but the news requires confirmation.

THE *Bulletin* of the Paris Geographical Society for April (just issued) is mainly occupied with a long and elaborate review of the geographical work of the year 1876, by M. Ch. Maunoir. M. de Bizemont discusses some of the observations for latitude obtained by M. de Brazza during his exploration of the Ogové. In connection therewith M. de Bizemont gives a list of the instruments which he considers most useful to explorers in new countries.

AMONG the papers in this month's part of *Petermann's Mittheilungen* is one on the Cartography of the Philadelphia Exhibition; Dr. Güssfeldt contributes an important paper on the exploration, by himself and Dr. Schweinfurth, of that part of the Arabian desert between the Nile and the Gulf of Suez; and Dr. Radde a paper on the plain of the Upper Euphrates. Dr.

C. E. Jung has the first part of an important contribution on the Geographical Outlines of South Australia.

THE *Geographical Magazine* for July contains a masterly paper, with an elaborate and carefully-constructed map by Mr. Trelawny Saunders on the Himalayan system. Both article and map are evidently the result of thorough study and extensive knowledge.

FROM a Report of the Board of Commissioners of the New York State Survey, which is under the charge of Mr. J. T. Gardner, formerly of the United States Geological Survey, we learn that, although the Survey was decided on only in 1876, much has already been done in the way of commencement, and that it is likely to be carried out with a thoroughness quite equal to any of the trigonometrical surveys of Europe.

MR. LANDSBOROUGH, the well-known Australian explorer, recently read a paper at Oxley, Queensland, in which he adduces a variety of interesting facts to prove that dense forests are on the increase in Australia, that the climate is becoming moister, and therefore improving, that the country is gradually ceasing to be favourable to sheep-rearing, and becoming agricultural, and seems to hint that in course of time the great central desert may yet "blossom as the rose." Formerly when there were no sheep to keep down the grass, fires were frequent and terribly destructive to trees and all vegetation, but since the stocking of the country there is less grass for the fires to consume, and their ravages are consequently becoming limited in extent. Queensland, especially, Mr. Landsborough declares, is now so unfit for sheep-pasturing, that no one thinks of making a living by them. The observations of this experienced traveller are well worthy of attention, and it will certainly be interesting to watch the changes caused by the presence of civilised men in Australia, as we know exactly its condition at their first advent.

M. WADDINGTON, the late French Minister of Education, our readers may remember, sent out a number of men to various countries for the purpose of scientific exploration. The following is a list of these missions:—M. Masqueray in Algeria; MM. Pinard and de Cessac, North America; M. la Gaviniere, Celebes; Marignac, Antilles; Armingaud and Malard, Italy; Dr. Harmand, Cochin China; Wiener, Peru and Bolivia; Raffray and Maindron, New Guinea; Ed. Blanc, Maritime-Alps; Ratte, New Caledonia; Ujfalvy, Central Asia; Serre, Say, Sahara; Rochemonteix, Egypt; du Chatelier, Finistere (France); Abbé Ansault, Italy; Mangeot et Bersot, Japan; Mouchez, Algeria; Guizet, Japan and China.

WE have received the *Bulletin*, for 1876, of the Essex Institute (Salem, U.S.), one of the best of the many local societies of the United States. A large portion of the *Bulletin* is occupied with a valuable paper by Mr. E. W. Nelson, on the birds of North-East Illinois. We may state that this Institute is issuing a series of "Historical Collections," which are likely to be of service to those who are interested in the political history and social progress of the United States.

THE *Kansas Collegiate* is the title of a small sheet conducted by the students of Kansas State University, and contains various notes and news likely to interest those for whom it is intended. The number for May 23 contains a Scientific Supplement devoted to subjects of more or less scientific importance. The longest of these is an address by Prof. F. H. Snow, on "The Relation of Birds to Horticulture," and which contains some interesting information on the habits of many of the Kansas birds. Another paper, by Prof. G. E. Patrick, gives the results of an examination of a meteorite found at Wacender, Mitchell Co., Kansas. Prof. Snow, we notice, has formed a fine and constantly-increasing collection of the birds of Kansas.

THE *Commission Supérieure*, or governing body of the French International Exhibition of 1878, has been completed by the appointment of some influential members, among whom are the Duc d'Audifret-Pasquier, president of the French Senate, M. Andral, the vice-president of the Council of State, M. Alphaud, the chief engineer of the Paris works. Amongst the ordinary members are M. Brunet, Minister of Public Instruction, M. St. Claire-Deville, member of the Institute, and M. Rothschild the banker. M. Krantz has given a detailed report on the state of the works, which are much in advance of the specified time. The unexpected success of the exhibition in foreign countries and especially in Great Britain and the British Colonies will fill up the vacuum created by the abstention of Germany. Many nations have asked for an enlargement of the space allotted which it has been impossible to grant. The public will be admitted by tickets and not by turnstiles. The coffee-houses, balls, concerts, theatres, so numerous in the 1867 exhibition, have been abolished, but great experiments for testing the apparatus exhibited, and promoting human knowledge will be tried. China will be represented by an official commission, and Siam will make a magnificent display. Liberia, the negro republic on the Gold Coast, will exhibit for the first time in France.

THAT science in certain of its applications does pay is evident from the fact that a M. Delille, a "professor" of legerdemain, who has practised at fairs in France, and who has died at the age of eighty-eight, gained by his trade a fortune valued at several millions of francs. He began to practice at the early age of sixteen, and was seen operating at the last fair of St. Germain. He dealt largely with electricity. Here is another argument agains the Endowment of Research very similar to one which has been urged before.

FROM the prospectus of St. Thomas's Hospital Medical School, we notice that two scholarships of the value of 60*l*. and 40*l*. respectively will be awarded during the first week in October, after an examination in physics, chemistry, botany, and zoology.

THE King of the Belgians, who has been appointed a second time president of the International Association for Exploring and Civilising Central Africa, has declared that next year he will decline to continue the office. The Society is possessed of an annual revenue of 73,000 francs, principally from subscriptions obtained in Belgium, where the scheme is very popular. It has been decided by the executive committee that a station should be founded in the Trans-Tanganyika region. The head of the station and the explorer have been appointed. A depot will be formed at Zanzibar, and three others in intermediate countries; one is to be placed under a Catholic mission, and two under two Protestants, who have volunteered to help the Association. The works are to be begun without further delay.

A COMPANY is now being formed, we learn from the *Engineer*, to construct a pneumatic railway between the South Kensington Station of the District Railway and the Albert Hall. The line will rise the whole way to the Albert Hall, the ruling gradient being 1 in 48. The train will be blown through the tube by an ejector, in other words, a great centrifugal pump, two feet in diameter, fixed close to the District station, and worked by a pair of condensing engines exerting about 170 indicated horse-power. The tunnel will be of brick, and the floor will be paved. Its cross-sectional area will be 105·5 square feet; at the end of the train is fixed a screen or piston, with an area of 104 square feet, the difference being allowed for windage. The train will consist of six carriages, of very light build, the rail gauge being four feet. This train will hold 200 passengers, and the total load will be thirty-two tons, or ten tons less than the weight of a single engine on the Metropolitan Railway. The maximum resistance at twenty miles an hour will be about 2,420 lbs., requiring to overcome it a pneumatic pressure of 2·6 ounces per square inch, and 162-horse-power, assuming the useful effect to be sixty per cent.

A VERY severe thunderstorm passed over London on the evening of July 5. Between eight and nine there came a very brilliant flash of lightning, followed by a deafening peal of thunder. Many people were stunned and in several cases were found quite insensible. Immediately after it was found at Kilburn that the telegraph wires, running from the top of the Queen's Arms to a house about 300 yards higher up the Edgeware Road, were struck by the lightning, and fell in red-hot fragments, varying in length from six inches to an inch, all along the road, a great deal of yellow smoke attending the fall of the wire. In one or two houses windows were broken, and a little girl who was passing through the street had her hair singed and her jacket burnt. The instruments at the office with which the destroyed wires were connected were much agitated, and the telegraph clerk, a young lady, was much stunned.

THE fourth edition of the "Lists of Elevations principally in that portion of the United States West of the Mississippi," edited by Mr. Henry Gannett, and published in connection with Mr. Hayden's Survey, must prove of great value to the geographer and meteorologist. The first edition, published in 1872, contained only thirty-one pages, the present edition contains 164 pages. It contains, among a variety of other matter, profiles of nearly all the railroads in the part of the United States above mentioned. The results given by these profiles have been made to accord, and the heights of several thousands of points on them have been determined with an approach to accuracy. This edition contains also the heights of many thousands of points determined approximately by means of the barometer. Elevations of many thousands of mountain-peaks are given, from which very correct ideas of the ruling heights of the principal ranges may be derived. It contains also tables of the slopes of the principal streams of the west, which are of value in studying the important question of irrigation. With these various lists of elevations there is given with this edition a map of the United States, in approximate contours of 1,000 feet of vertical intervals, which, in a measure, embodies all the results of this department. Toward the improvement and ultimate perfection of this map this work is to be mainly directed in future. To express still more clearly the facts brought out by the map, it is the intention of the Survey to make shortly a relief model of the United States, on the basis of this map.

WE have on several occasions referred to the association known as the Yorkshire Naturalists' Union, composed of a large number of local scientific societies in Yorkshire. This association publishes a useful monthly journal, *The Naturalist*, intended as a general field club record. We have received the twenty-fourth number of this journal, which, besides several papers on natural history, contains reports of several of the associated societies. From a report of the third meeting of the Union held recently at Wakefield, we notice that the Bradford Scientific Association was admitted to the Union, and that a testimonial, in the shape of a microscope, was presented to Mr. J. M. Barker, late secretary of the West Riding Consolidated Naturalists' Society.

THE additions to the Zoological Society's Gardens during the past week include four Common Kingfishers (*Alcedo ispida*) European, presented by Mr. J. Lyford; two Horned Lizards (*Phrynosoma cornutum*) from Texas, presented by Mr. W. A. Bowie; a Sun Bittern (*Eurypyga helias*), a Sacred Ibis (*Geronticus æthiopicus*), bred in the Gardens; eight speckled Terrapins (*Clemmys guttata*), three Red-vented Terrapins (*Clemmys rubriventris*), two American Box Tortoises (*Terrapene carinata*) from North America, purchased.

THE INFLUENCE OF LIGHT UPON THE DEVELOPMENT OF BACTERIA[1]

WE have been engaged during the last few months on an investigation into the effect of light upon the development of bacteria in certain of those solutions in which they are usually produced.

We reserve the details for a paper which we hope to submit to the Royal Society in the course of their next session, but wish to state, in the meanwhile, that the first portion of our inquiry has led us to the following conclusions:—

1. That light is inimical to the development of bacteria.
2. That under favourable conditions it may prevent their development.
3. That under less favourable it may not prevent but only retard.
4. That for the full effect of light to be produced direct insolation is necessary.
5. That those conditions which tend to neutralise the action of light are the same which are known to favour processes of fermentation and putrefaction.
6. That the fitness of the solution to serve as a nidus is not destroyed by insolation.
7. That, so far as our investigation has yet gone, it would appear that the germs originally present in the solution are destroyed by direct insolation.

We are still pursuing the inquiry, and have devoted much time to investigating the influence of the refrangibility of the ray, but regret that at present we are not in a position to give any definite conclusions on this point.

We are endeavouring also to trace an analogy between facts which we have observed and certain vital and chemical processes, in which light is known to play a part, and are extending our observations to other phenomena of fermentation and to microscopic fungi.

That light is not essential for the development of bacteria has been long known, but that it is absolutely inimical to their production has not, so far as we are able to ascertain, been previously shown, and we are encouraged, therefore, to lay before the readers of NATURE this statement of our results.

ARTHUR DOWNES; T. P. BLUNT

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

LONDON.—The following is the list of the new associates of the Royal School of Mines:—Associates in Mining and Metallurgy—C. W. Folkard, A. K. Huntington, E. W. Voelcker; Associates in Mining—E. H. Liveing, W. H. Merritt; Associates in Metallurgy—A. C. Copeland, J. F. Hogan, C. H. Lemann, W. Leyson, E. T. McCarthy; Associate in Geology—A. R. Sawyer. The Edward Forbes Medal and prize of books was awarded to A. Heilprin; the De la Beche Medal and prize of books to E. W. Voelcker; the Murchison Medal and prize of books to F. G. Mills.

SCIENTIFIC SERIALS

Journal de Physique, June.—On the theory of electrometers, by M. Mascart.—On the dynamical theory of gases (continued), by M. Violle.—Process for measuring the index of refraction of liquids, by M. De Waha.—Application of the electric current to the study of the spheroidal state of liquids, by M. Hesehus.—Temperature and humidity of the air at different heights observed at Upsala during 1875, by M. Hamberg.—Proceedings of the Physical Society of St. Petersburg.

Archives des Sciences Physiques et Naturelles, June 15.—Study on the variations of transparence of the waters of Lake Leman, by M. Forel.—On the different modes of crystallisation of water, and the causes of the varied appearances of ice, by M. Pictet.—Researches on some niobiferous and tantaliferous minerals, by M. Delafontaine.

Annalen der Physik und Chemie, No. 4, 1877.—Johann Christian Poggendorff (memoir).—New experiments on the expansion of bodies by heat, by M. Glatzel.—On the objections of Clausius to Weber's law, by M. Zöllner.—On normal magnetisation, by M. Petruscheffsky.—On stratification of the electric light in Geissler tubes after insertion of a flame and some other resistances, by M. Holtz.—On the cohesion of salt solutions, by M.

Quincke.—On the excitation of electricity through gliding friction, by M. Riess.—On unipolar induction of a solenoid, by M. Zöllner.—Remarks on Prof. Neumann's paper on the number of electric materials, by M. Edlund.

No. 5.—On the reflection of heat rays from metals, by M. Knoblauch.—On the treatment of ponderomotive and electromotive forces occurring between linear currents and conductors, according to the fundamental laws of electrodynamics, by M. Clausius.—On the tensions of vapour in dissociation of salts containing water of crystallisation, by M. Pareau.—On the coefficients of temperature of heat conduction of air and hydrogen, by M. Winkelmann.—On the phenomena of motion of electrified mercury in glass vessels, by M. Herwig.—On divergences from Ohm's law in metallically conducting bodies, by M. Braun.—On the theory of unipolar induction and Plücker's experiments, by M. Riecke.—On heat conduction in sulphate of copper, by M. Pape.—Remarks on the polarisation of the rainbow, by M. Lommel.—On the history of the invention of the areometer, by M. Gerland.—On the significance of the rhombohedric and prismatic surfaces in quartz, by M. Baumhauer.

SOCIETIES AND ACADEMIES

London

Zoological Society, June 19.—E. W. H. Holdsworth, F.Z.S., vice-president, in the chair.—The secretary read a letter addressed to him by Mr. J. M. Cornély, announcing that his female *Hydropotes inermis* had just produced three young ones.—Mr. J. E. Harting, F.Z.S., exhibited and made remarks on a variety of the common Snipe, intermediate between the usual form of that species and the so-called Sabine's Snipe.—Mr. B. Tegetmeier, F.Z.S., exhibited a specimen of a curiously malformed sternum of the Tawny Owl.—Mr. John Murray, Naturalist to the *Challenger* Expedition, exhibited and made remarks on a series of sharks' teeth, whales' ear-bones, and other specimens dredged up at great depths during the *Challenger* Expedition.—Mr. P. L. Sclater, F.R.S., read the first of a series of reports on the collection of birds made during the voyage of H.M.S. *Challenger*, containing general remarks on the collection, which was stated to consist of about 679 skins of terrestrial and 198 of oceanic birds, besides a considerable series of specimens in salt and in spirit, and a collection of eggs, principally of the oceanic species.—A communication was read from the Marquis of Tweeddale, F.R.S., containing a report on the collection of birds made during the voyage of H.M.S. *Challenger* in the Philippine Islands. Amongst them were examples of seven species new to science.—Mr. P. L. Sclater read a paper giving a description of the birds collected at the Admiralty Islands during the visit of the *Challenger* expedition to that place. Amongst these were examples of six species hitherto unknown to naturalists.—A communication was read from the Rev. O. P. Cambridge, C.M.Z.S., on some new species of Araneidea, with characters of two new genera and some remarks on the families *Podopthalmides* and *Dinopides*.—A note was read by Mr. J. H. Gurney on the breeding of the Polish swan in captivity, and on the stages of plumage of the young birds.—A communication was read from Mr. F. Moore, in which he gave a complete description of the Lepidopterous fauna of the Andaman and Nicobar Islands, so far as is yet known.—A communication was read from Mr. Herbert Druce, F.Z.S., containing a revision of the Lepidopterous genus *Paphia*, with descriptions of twenty-one new species.—A communication was read from Mr. E. J. Miers, F.Z.S., containing the description of a collection of Crustacea (*Decapoda* and *Isopoda*), chiefly from South America, with descriptions of new genera and species.—Mr. A. H. Garrod read a description of the brain of the Sumatran Rhinoceros (*Ceratorhinus sumatrensis*).—A paper by Mr. A. D. Bartlett, contained the description of a new Guinea Fowl, from Mombassa, in Eastern Africa, based on a specimen brought home by Mr. Gerald Waller, for which the name *Numida ellioti* was proposed.

Entomological Society, July 4.—Prof. Westwood, president, in the chair.—Mr. J. W. Douglas exhibited a living specimen of *Cerambyx Heros* and a young larva of the same insect, bred from a log of wood imported from Bosnia.—The president exhibited some cases composed of small semi-transparent quartz-like particles and constructed by the larva of a Trichopterous insect inhabiting Southern Europe. They had been described by Swainson in 1840 as a shell belonging to the genus *Thelidomus*.—The president also exhibited a plant-bug (*Capsidæ*) found on the leaf of an orchis which had become covered with blisters from the attack of the insect.—Mr. Jenner Weir exhibited a female specimen of a *Cicada* taken in his presence in the New Forest by Mr. Auld, who stated that he had heard it stridulating. Mr. Douglas, however, suggested that the sound had been produced by a male concealed near.—Mr. S. Stevens exhibited two living specimens of *Tillus unifasciatus* taken on a fence near Norwood.—Mr. J. P. Mansell Weale, who had just returned from South Africa, exhibited a fine collection of insects from that country and read a paper containing the results of his observations and experiments upon the breeding of *Papilio merope* and other insects.—The secretary read a letter from Dumfries stating that *Colias edusa* had made its appearance in that district in the month of June.—The president brought before the Society the recent accounts of the appearance of the Colorado beetle in Canada and in Europe.

Physical Society, June 23.—Prof. G. C. Foster, president, in the chair.—Prof. W. Grylls Adams exhibited a very complete form of optical bench, which, in addition to being provided with all the improvements introduced by Prof. Clifton, carries an arm which can be set at any angle to it and is provided with appliances for studying a beam of light or radiant heat when it deviates from the main axis of the instrument. At the base of a pillar firmly clamped in any position in the manner adopted by Prof. Clifton, is fixed a horizontal graduated circle, and a vernier, attached to a counterpoised arm, which rotates round the axis of this pillar, renders it possible to determine the angle made by the arm with the bench to one minute. At the upper extremity of the pillar is a steel pivot to which various appendages may be clamped, and immediately below this is a second graduated circle by which to determine the angular position of whatever is supported by the pillar. Mirrors, metallic surfaces, prisms, &c., may be placed on this pillar for the reflection, refraction, diffusion, or polarisation of heat and light. For radiant heat the rotating arm carries a line thermo-electric pile and a table on which absorbing media may be placed. Prof. Adams illustrated the use of the instrument by projecting on to a screen the interference bands obtained when a beam of light, after reflection from the two surfaces of a thick plate of glass, is again reflected from the two surfaces of a similar plate placed very nearly parallel to the first. A compensator consisting of two plates of glass of equal thickness is also added between the two thick plates, and an ingenious arrangement renders it possible to incline the glasses at any angle to one another, and to move them either independently or together. He also showed the effect produced in the positions of the bands when the rays from the two surfaces of the first plate traverse air of different densities before falling on the second. The adjustment of this latter was facilitated by fine screws supplemented by springs which rendered it possible to give a slight movement to the plate in any direction, by combining a motion of translation of the plate parallel to its reflecting faces with a motion of rotation about a vertical or horizontal axis.—Mr. F. D. Brown exhibited an apparatus he has arranged, in which to compare thermometers. From a brass hemispherical boiler rises a tube of the same metal two inches in diameter and about two feet long; the steam, after ascending through it, descends a metallic jacket surrounding it, whence it passes into a U-shaped condenser, and from this it is returned to the boiler. The upper end of the condenser is in connection with a large air-tight vessel forming the base of the apparatus, and in which any required degree of exhaustion can be maintained by the use of Lothar Meyer's form of pump. The thermometers are placed in tubes, which pass within the wide brass tube at its upper end, and by varying the nature of the liquid in the boiler, and the pressure to which it is subjected, the boiling point can be retained constant at any required temperature.—Dr. Guthrie and Mr. Akroyd communicated a paper on electrical selection. When a metal or other body is rubbed against some non-conducting substance like caoutchouc, electricity is developed, and the track of the metal may be readily made evident by sprinkling on the caoutchouc a mixture of red lead and sulphur. This sieving imparts negative electricity to the sulphur and positive to the red lead, hence that particular ingredient of the mixture is drawn to the metal track which possesses the opposite kind of electricity. Iron, for example, when rubbed against caoutchouc generates negative electricity, and, after sprinkling the powder, the iron track is revealed by the marked collection thereon of red-lead. A list of mixtures was given which may be used instead of the above, and it was shown that electrical selection may prove of use (1) in making an electrical diagnosis of the metals, (2) in certain experiments where the quadrant electrometer is objectionable, and (3) in teaching, where this instrument is often unavailable on account of its cost. An adjourned special general meeting of the society was then held, after which the meetings were adjourned until November next.

Anthropological Institute, June 26.—Mr. John Evans, F.R.S., president, in the chair.—Three new members, one honorary, and one corresponding member were elected.—Mr. Burt exhibited the prow of a New Zealand war canoe supposed to have been that which met Capt. Cook on his second visit to that country.—Mr. Atkinson exhibited a specimen of gold so-called Irish ring money.—A paper by Mr. Mortimer on an underground structure near Langtoft, Yorkshire, was read. Mr. Mortimer considers it is not a Botontinus; in this opinion he is opposed by Mr. J. E. Price, F.S.A.—Mr. C. H. E. Carmichael, M.A., read a paper on a Benedictine missionary's account of the natives of Australia and Oceania, in which he summarised the principal points of anthropological interest in the *Memoire Storiche dell' Australia*, by Mgr. Don Rudesindo Salvado, O.S.B., and illustrated the missionary's account by reference to the views expressed by Topinard, Virchow, and other foreign writers. Mgr. Salvado maintains the unity of the Australian race and language, and upholds the possibility of raising the aborigines to a fairly high pitch of civilisation, using their extreme quickness in learning to speak and write European languages. Two letters written in Italian by native boys brought to Europe at about eleven years of age, were commented upon by Mr. Carmichael, who laid copies on the table, and promised further investigation of the questions raised in the discussion.—The president, Mr. C. Walford, Sir John Lubbock, and others took part in the discussion.—H.I.M. the Emperor of Brazil was present at the meeting.

VIENNA

Imperial Academy of Sciences, April 12.—Senile changes of the joints and their connection with *Arthritis deformans*, by M. Weichselbaum.—On a new determination of a quantity having reference to the measurement of molecules from the theory of capillarity, by M. Boltzman.—On the orbit of Dione 106, by M. Seydler.—On the decomposition of hydroxylamin by alkaline copper solution, by M. Donath.—On a method of determining the resistance of bad conductors of electricity, by M. Domalip.—Influence of temperature on velocity of evaporation, by M. Baumgartner.—On diffusion of vapours through clay-cells, by M. Puluj. The velocity of diffusion depends on the temperature in the same way as the maximum of tension. There is not direct proportionality between velocity of diffusion and difference of tension. The logarithmic function represents the connection more accurately.—A contribution to the knowledge of viscous substances, by M. Obermayer. Experiment showed that the internal friction in brittle black pitch follows the same laws as fluid friction. That in soft bodies does not exactly follow those laws.—On the internal condition and the latent heat of vapours, by M. Puschl. Very rare aqueous vapour deviates from Mariotte's law in an opposite direction to that of gases and vapours generally, and in this it behaves like very greatly rarefied atmospheric air.

PARIS

Academy of Sciences, July 2.—M. Peligot in the chair.—The following papers were read:—On the generation of the meridian curve of a surface of revolution, of which the mean curvature varies according to a given law, by M. Resal.—Researches on anhydrous chloral and on its hydrate, by M. Berthelot. There is a liberation of heat in the reaction of gaseous chloral with gaseous water, with formation of a gaseous compound, gaseous hydrate of chloral therefore truly exists as a compound distinct from a simple mixture of the two vapours.—Remarks on the subject of M. Mouchez' letter of June 18, by M. Villarceau.—On the distribution of waters coming from natural slopes of the French territory, and on the amelioration of our interior navigation, by M. De Lesseps. M. Cotard has suggested the storing of water in the higher parts and distribution of it to navigation-canals giving cheap transport for materials of small value, and avoiding the formation of unwholesome marshes. M. Sibour advises the opening of a canal (seven kiloms.) between the lake of Berre and the harbour of Marseilles.—Reply to M. Roudaire's last communication on the formation of a Saharan sea, by M. Cosson. *Inter alia*, he urges that the change of the local climate would be fatal to the date, and that new plants introduced would not compensate the loss. The Artesian system is open to being greatly developed. The caravans of Central Africa would not diverge from their route to Morocco and Tripoli. The addition of so much saline matter would make the Artesian water undrinkable and unfit for irrigation. The climate would become very unhealthy from combination of moisture with great variations of temperature, &c.—M. Godron was elected correspondent for the section of botany, in room of the late M. Lestiboudois, obtaining thirty-three votes, against five for M. Duval Jouve.—Trepanation of the membrane of the tympanum, successfully performed in a case of long deafness which had resisted all treatment, by M. Bonnafont. Any deafness not accompanied by weakening of the sensibility of the acoustic nerves (ascertained by placing a watch on the cranial wall near the ear), may be cured or greatly improved (he thinks) by trepanation of the tympanic membrane. The tympanum should be anæsthetised, and the canula should be allowed to remain in the opening till it falls out naturally.—Argilo-calcareous land and phylloxera, by M. Joffroy. A vine-stock planted in such land resists the disease when the surface of the ground is sufficiently inclined from its base, and is preserved from contact with rain-water from higher ground.—Researches on the compressibility of liquids, by M. Amagat. He studied volatile liquids kept liquid by pressure at a temperature above that of their boiling-point (when, it is known, their coefficient of dilatation becomes very considerable). He gives numerical results for ordinary ether and chlorhydric ether, and will afterwards show that these numbers agree satisfactorily with deductions from the formulæ of the mechanical theory of heat.—On the state of the vines treated at Cognac with alkaline sulphocarbonates, by M. Mouillefert.—On the vapour of hydrate of chloral, by M. Troost. Fresh experiments by a method which he describes confirm his former results, which M. Wurtz had questioned.—Dissociation of gaseous iodhydric acid in presence of an excess of one of the elements, by M. Lemoine The most important result is the stability which this excess gives to the combination; in mixing iodhydric acid with increasing quantities of hydrogen the quantity of iodhydric acid dissociated diminishes about half. Still the character of the dissociation seems always to subsist, whatever the inequality in the atomic proportions. This influence of *mass* in dissociation is in accord with several other known facts.—On the dissociation of ammoniacal salts in presence of metallic sulphides, by MM. De Clermont and Guiot.—On the employment of fluoride of bromine as a dehydrating agent, by M. Landolph. He gives several examples of its action (with camphor, &c.).—On the ordinary presence of copper and zinc in the human body, by MM. Raoult and Breton. They give the results of a judicial investigation made by them in 1874. 700 grammes of (moist) liver of a man who had died after an operation for stone, gave 2 milligr. of copper and 7 mgr. of zinc; 400 grammes liver of a consumptive person gave 6 mgr. of copper and 12 mgr. of zinc. To prove poisoning, it should be shown that the quantities of copper or zinc found in a body are greater than the maxima in normal conditions.—On the determination, in weight, of atmospheric ozone, by M. Lévy. This relates to a supposed influence of platinum on arsenite of potash, which, however, was not manifested in the conditions with which M. Lévy operated.

THURSDAY, JULY 19, 1877

THE "INFLEXIBLE"

In our last number we sketched in outline the scientific principles and considerations which lie at the foundation of the important question now at issue regarding the *Inflexible*.

We now proceed to consider the case as set forth in the papers which have since been presented. The fact of a Committee having been appointed to investigate it is no reason for our passing over in silence these papers, which have been already laid upon the table of Parliament expressly to disseminate the information contained in them. We shall not, however, seek to trench in any degree upon the duties undertaken by the Committee.

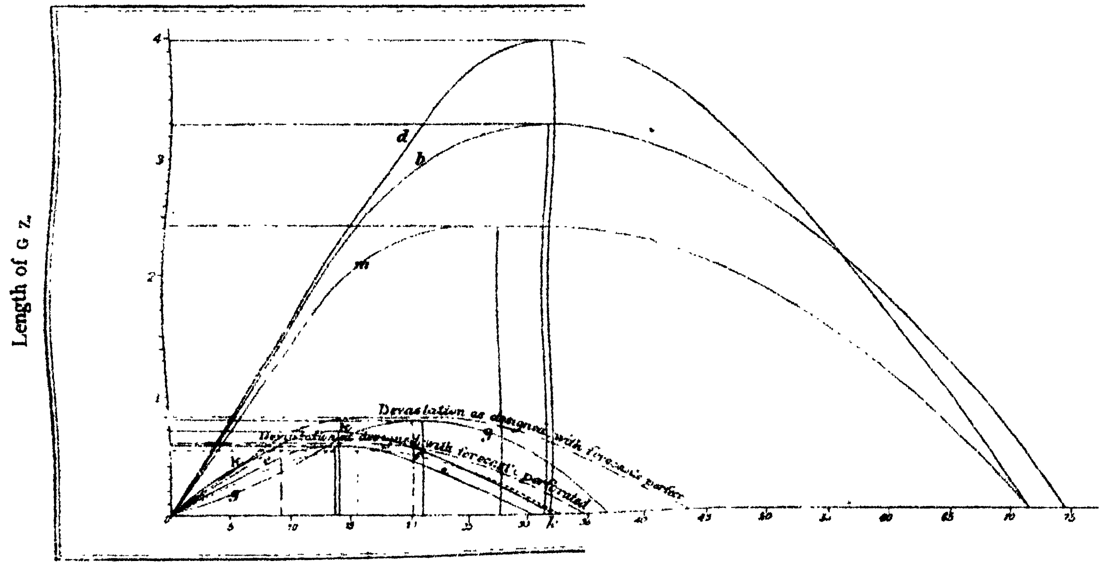
The first question to be asked is the vital one—What stability is claimed by the Admiralty for the *Inflexible* in the condition contemplated by the *Times* and Mr. Reed, and, as is now made perfectly clear by the papers, by the Admiralty office itself when the ship was designed, a condition namely in which the unprotected ends were so far injured as to cease to contribute stability to the ship?

Has the ship that range of 50 deg. which, as we saw last week, the Committee on Designs, as a result of scientific consideration laid down as necessary for a mastless ship exposed to the action of the sea? Has she even that 39 deg. which is the very lowest amount ever mentioned as compatible with safety? And, it must be further asked (since "range" alone is a most insufficient guide to safety), is the *amount* as well as the *range* such as the settled science of the subject would demand? None of these answers lie on the surface of the Parliamentary papers, and some of them are not to be found there at all; but by what Dr. Schliemann would call "the pickaxe method" of investigation, we can get at part of them, and infer the remainder with all necessary certainty. The most difficult and unfortunate part of the inquiry is due to the fact that the *apparent* answers that do lie on the surface are not the true ones, although they bear every outward semblance of being so. The scientific world is turning to these papers for one piece of information before and beyond all others, namely, this very stability of the *Inflexible* with "unarmoured ends giving no stability;" and when they get to p. 10 there they find it plainly set forth, in tabular form, and in full detail: "Maximum stability 6,532 foot-tons; angle of maximum stability 13½ deg.; range 30 deg.;" and reading this they begin to say to themselves that although the ship is, on the showing of her constructor, below the standard of safety which everybody has either laid down or accepted, yet that she is not so alarmingly deficient as they had supposed from the pronounced tone of her critics. Give her, say they, the benefit of the cork (in which the whole Admiralty has so suddenly acquired extraordinary faith), and although she would then be somewhere near the recognised limits of safety, and would be liable to the cork being more or less rapidly got rid of under shell fire, still the case is not so very bad after all. But unfortunately on reading further they come on the following page upon an ugly foot-note by Mr. Barnaby, bearing date June 25—one week after the occurrence of the *Inflexible* debate in Parliament—and in this foot-note is disclosed the fact that the figures which we have quoted, and which are given at p. 10 as expressive of the case when the unarmoured ends give no stability, turn out to be the figures applicable to the case when the cork is in place, and when the unarmoured ends are contributing the stability which arises from the cork! This is not clearly shown on the surface of the foot-note, but it has to be discovered in a roundabout manner. It can, however, be reached in this way. The foot-note implies that the cork was allowed for in the calculations of a certain curve given on the sheet of curves appended (Curve *e* in our present diagram), and by comparing this curve with the figures given on p. 10, we find that they express the same state of things, and thus we arrive at the fact that these figures likewise include the stability due to the cork. We do not propose to offer any comments upon this, except to say that we cannot help thinking that ninety-nine persons out of every hundred who read these papers will be completely mystified and misled by such an arrangement of the information, and more than all by the distinct employment of words which indicate that the cork is unaccounted for, when, in point of fact, the cork is accounted for.

By the means thus indicated we arrive at the fact that the amount of stability previously referred to and quoted is the amount which alone the ship was believed to possess when the First Lord of the Admiralty made his statement in Parliament, and declared that the Board were in every way satisfied with the vessel. It follows that the First Lord of the Admiralty was satisfied that the *Inflexible* should have a righting lever (G Z) less than six-tenths of a foot long with the cork in place, and of course with very much less in the event of the cork being blown out. We are not able to state—for the Admiralty does not give the information—how much stability the constructors and the Admiralty actually believed the ship to possess in the case under notice (viz., the case of the unarmoured ends really contributing no stability), but it is impossible to peruse these papers and to come to any other conclusion than that unless this information was advisedly kept back it ought to have been given. We cannot ourselves, of course, profess to say how much of the measure of stability which we have quoted was due to the cork, but we are able to approximate pretty closely to it by aid of the diagram which Mr. Reed prepared, and which is printed with the papers. That diagram Mr. Barnaby has marked "wrong," and no doubt it does differ a little from Mr. Barnaby's own diagram in its estimate of the amount of stability with the cork in. Indeed Mr. Reed only put his curve of stability forward as approximate, and as being in his opinion "pretty near the truth;" but this diagram may be taken as a sufficient approximate indication of the amount of stability actually due to the cork itself, and by taking that away from the Admiralty diagram we get what the Admiralty themselves would probably allow to be the state of the ship with the cork out. We have performed this operation, and we find that the *Inflexible* is, with the cork out, left almost absolutely without any stability whatever, even when she is judged by the diagram which the Admiralty themselves supply, and upon which they rested when the first Parliamentary debate took place.

N

Subsequently, that is on June 25, Mr. Barnaby put forward a memorandum (the foot-note before referred to) showing that his own previous diagram might be extended a few degrees by introducing such considerations as that the four guns had been increased by 20 tons each (in a ship of over 11,000 tons !), that the armoured deck was to be broken through to let the cables be stowed lower, and that an allowance might be made for immersed materials; and by these means some little show of a curve of stability, even with the cork out, is obtained; but the amount of it must be exceedingly small, as the range claimed is only 17 deg., and the curves which we give in the accompanying engraving indicate by analogy how very small the *amount* of stability must in this case be with so extremely limited a range. We feel bound, however, to demur to any such change in the Admiralty calculations, both because of the doubt which must inevitably rest on the alteration of calculations made to meet a public inquiry already commenced, and because the actual changes made in this case are in themselves improper. It is improper to make new allowances now ostensibly for the enlarged guns, because still larger guns were originally contemplated in the design, as the printed Papers clearly show; it is improper to alter the cables to meet the present state of things, as they were obviously wisely placed in the first instance; and it is improper for the sake of a small nominal increase in the apparent amount of stability of this ship to introduce novelties of calcula-



Range of Stability

DESCRIPTION OF CURVES.

		Angle of Max. Stab.	Max. G. Z.		Metacentre above C.G.
			Feet.		Feet.
b	Ship complete, Cork in place	31·2	3·28	74·3	8·25
d	As in *b* but in light condition	31·7	3·935	71·5	8·53
e	Fully equipped; ends riddled	13·5	·568	30·0	2·0
f	As in *e* but coal between decks (800 tons) removed ...	15·4	·534	32·2	3·09
g	As in *e* but in light condition	20·8	·794	36·8	2·22
k	As in *e* but supposing the water in ship when upright locked	13·9	·705	32·0	
m	As in *k* but supposing main deck kept free of water ...	27·4	2·42	71·5	

tion which will defeat all comparison now and hereafter between the *Inflexible* and other ships, and which will absorb into the substance of the calculations for this one ship those small outlying margins which together make up the dividing ground between safety and risk. For these good and sufficient reasons we stand upon those calculations on which Mr. Ward Hunt rested when he addressed Parliament on the subject, and we are obliged to state that, according to those official calculations, the *Inflexible* is practically without stability when the unarmoured ends have ceased to furnish any.

The next question which arises is, how is the ship circumstanced with the cork in? and the answer to that we have incidentally had before us already. Even by introducing such considerations as Mr. Barnaby adduces in the foot-note he only claims for his curve of stability with the cork in a range of 35 deg., and with the range so increased the righting lever G Z cannot much exceed six-tenths of a foot in amount. It will be easy for the reader of these remarks to imagine, without our assistance, the slight alteration of curve *e*, to which we are here pointing, and when they bring the eye down from the large levers of stability indicated by the curves *d*, *b*, and *m*, to the curve *e*, even when thus enlarged, they will see what a striking difference there is between the ship with her unarmoured ends intact and the ship with those ends broken into by the sea. The fact is that even in this state with the curve of stability extended by the devices to which we have already objected, the ship is in an unsafe condition when judged by the only standards that at present exist for our guidance, viz., those laid down in the Report of the Committee on Designs of 1871.

We have now almost exhausted all that the Parliamentary Papers contain on the essential question at issue, but before concluding this part of our subject we must advert to the case of the *Devastation*. The *Devastation*, as designed, had an unarmoured forecastle, which extended down to within about a foot of the water's surface, and with this forecastle perfect, she had a range of stability of 43½ deg. Mr. Barnaby alleges that with the forecastle perforated, her range of stability would be brought down to 35 deg., and that the maximum angle of stability would be 9 deg. It seems to us that the curves given show something more and something different to that which the table in the text gives. They show something more, because it is clear on inspecting that one which relates to the *Devastation* with forecastle perforated, that although the maximum appears to be reached at 9 deg., there is no perceptible diminution in the magnitude of the stability for nearly another 9 deg. The curve seems to be parallel to the base line, from 9 deg. up to 16 or 17 deg., and the state of the *Devastation*, therefore, is totally different from that which might be expected from the announcement in the text, that 9 deg. is the angle of maximum stability. But even allowing all the stability which the *Devastation* is shown to possess by these curves, we are ourselves disposed to believe that when this ship was altered, the alteration should have been so made as to add to the stability of the ship when the unarmoured bow is perforated. Now the Reports of the Committee on Designs show that the changes made after Mr. Reed left the service were of a kind which, while adding materially to the stability of the ship under ordinary circumstances, burdened her with a large amount of top weight, which, together with the lowering of the armoured freeboard, must have diminished the stability with the bow perforated. In view of this consideration, we should much like to have seen the *Devastation's* curve of stability as it would now be with the unarmoured bow perforated, for we are disposed to think that the production of that curve would disclose a much less satisfactory condition of things as regards stability in the *Devastation* as she now is, than existed at the time of her design; and, as we have already intimated, this ship appears to us not to have possessed even at first all the stability desirable. We are aware that the Committee on Designs expressed a contrary opinion, but we doubt if they duly considered the state of the vessel with the forecastle perforated, and we believe that if they had they would probably have looked less complacently upon the change that was made than they actually did. If we are right in this view of the *Devastation*, Mr. Reed must no doubt bear the blame of having cut this ship's stability somewhat finer than it should have been, and all that could be admitted in mitigation of the fact is that which he would probably plead, viz., that this ship was the first great monitor of the kind that had ever been designed; that calculations of stability at considerable angles of inclination had not then come into vogue; and that he left the service long before the *Devastation* was completed for sea; and therefore that it was not from his hands that she passed into actual service.

But it is no part of our business to distribute blame in such matters, and all that we can say on the point is that we are not satisfied even with the *Devastation*, and that whatever deficiency of stability she might have possessed as originally designed, that deficiency must have been made worse by the modifications which the ship has since undergone.

We must now say a few words upon the question of the cork, and how far it may really be relied upon for giving to the *Inflexible*—not a safe measure of stability when the unarmoured ends have ceased to furnish any otherwise, for we have seen that with all the cork in place the stability is still too little for safety—but some sort of chance of escaping that capsizing which must befall her at sea with the cork gone. The great advocate of cork is the present Director of Naval Ordnance, Admiral Boys; but if the arguments which he sets forth in these printed papers are in truth the foundations on which the hope of the Admiralty is based, their confidence must be very ill-grounded indeed. Admiral Boys is good enough to set forth in a formal manner the reasons which induce him to think the cork can be depended upon. There is one at least to which science at once supplies an answer.

He mentions "the difficulty of striking a ship at or below the water-line, particularly one of the *Inflexible* type, that will scarcely ever roll." Scarcely ever roll! A more astonishing, and may we say a more utterly groundless remark, was probably never made upon a serious subject. It has been established beyond all question or cavil that one of the most fruitful causes of rolling is great stability, and that mastless ships of great stability will roll more than any other. Now, in her uninjured state, which is the state in which she will enter upon an action, the *Inflexible* will have very large stability, and may be expected to roll heavily in a seaway. A glance at our engraving this week will show that the length of the righting lever, G Z, is sometimes over three feet, and in one case (with certain stores consumed) nearly four feet, whereas not one of all the typical curves given in our last number gives a G Z that much exceeds three feet, while all but one are much below that. It is true that the admission of water at the ends may have a perceptible effect in diminishing the rolling, but it would be premature to presume any great results in this respect. And apart altogether from the rolling of the ship, every seaman, including Admiral Boys, must be well aware that the ends of the steadiest ships in the world get much exposed by the mere falling away of the water in a seaway. With regard to Admiral Boys other assumptions they are more out of our province, but we may remark that the enunciation of such views by a high officer of the Admiralty is calculated to fill common minds with astonishment and apprehension. Naval architecture, instead of being a complex and difficult branch of science, would be of all arts the most simple and easy, if all that had to be done were to keep safe the under-water parts of ships that never roll; to encounter projectiles that cannot fulfil the object for which they are employed; and to engage vessels armed in the most suitable manner, and managed in the most suitable way, to let us escape!

The conclusions we have arrived at are, that the *Inflexible* is not a safe ship for battle in her present state;

that the objections brought against her have been much too lightly treated; and that the disclosure of her condition, with the circumstances that have followed it, have excited just surprise and dissatisfaction. The subject must be anxiously watched through its future stages.

THE NEW METEOROLOGICAL COUNCIL

THE final stage of the labours of the Treasury Committee, to which we have made frequent reference, has now been reached. The Royal Society has been appealed to to nominate the new council; they have done so, and the Government has accepted the nominations, which are as follows:—Prof. H. J. S. Smith, Savilian Professor of Geometry in the University of Oxford and Keeper of the University Museum (Chairman); Prof. Stokes, Lucasian Professor of Mathematics in the University of Cambridge, and Secretary of the Royal Society; Dr. Warren de la Rue, Mr. F. Galton, and Gen. Strachey, Member of the Indian Council. In addition to these there is Capt. Evans, the Hydrographer of the Navy, as an *ex-officio* member.

The new Meteorological Council, then, like the old Meteorological Committee, is composed of Members of the Royal Society, who severally hold distinguished positions in special departments of science, and who collectively represent considerable administrative ability. The addition to the new Council of two distinguished mathematicians and physicists, such as Professors Smith and Stokes, will be generally regarded with satisfaction, particularly when it is considered that it is to the mathematician and physicist that meteorologists must always look for information and guidance on many matters affecting the intricate and difficult problems with which they, in the position the science has attained, must now deal.

It is, however, matter of general surprise among meteorologists, or we should rather say of wide-spread regret, that the New Council will resemble the old Committee in having no meteorologist upon it. The omission, so far as concerned the Meteorological Committee, was a serious one, and led to mistakes; so far as concerns the new one it will be well if it does not seriously mar its usefulness and retard the foundation of the future science of physical meteorology. At the same time it is only just to point out that because the science is of the future, the choice of the Royal Society was small, and that considerations not on the surface may have had to be borne in mind. However this may be, there is no doubt that the Royal Society and the new Council have accepted a great responsibility, and that the action of the latter will be most keenly watched. The Royal Society, in a report to the Government, has stated:—

"The Council of the Royal Society is of opinion that the most practical method of advancing meteorology is to endeavour by research and experiment to place that science on a firm basis. They are also of opinion that this can be done only by the devotion of the time of scientific men to the necessary research and experiment."

Men of science, therefore, will be justified in looking both for research and experiment from the new council in addition to the dreary piles of observations which have cumbered all scientific libraries for the last half-century.

And here is the rub. Will the busy—not to say already over-worked—members of the Council adopt this "practical method," and conduct researches? or do they propose to content themselves by going into the market with the 1,000*l.* which is given for *research*, and, be it remarked, not for mere *observations?* In the latter case it is to be hoped that their advances will be met in no narrow spirit; for if the new council only fosters research and experiment, it will be a great gain.

While, on the one hand then, we have a right to expect results of a high order from the new Council, on the other we are glad to see they are to be no longer an unpaid body. Besides the 1,000*l.* devoted to research there is another 1,000*l.* devoted to the payment of the members. This sum is to be spent partly in retaining fees and partly in payment for attendance.

The vote asked for the present year and agreed to on Tuesday is 10,000*l.*, and the Secretary of the Treasury then stated that the Committee had recommended an expenditure of 4,000*l.* a year by the Meteorological Council, and, in the judgment of the Treasury, the recommendation was one that ought to be adopted. A supplementary vote will be asked for this at an early date.

As regards the meteorological societies, on whom must devolve the practical working out of the large problem of the comparative climatology of the various districts of the United Kingdom—the working out of this problem being beyond the scope of the operations of the New Council just as certainly as it is beyond the resources originally placed at its disposal—we cannot but suppose that the Government have, in handing over the administration of the meteorological grant to the New Council, made provision that a portion of the additional 4,000*l.* will be spent in adequately aiding these societies in doing important national work which they are in a position to do so economically, and which, judging from the past, they can do so effectively.

This now seems to be the Treasury view, for in the warm debate very properly raised by the Scotch members in favour of the claims of the Scottish Meteorological Society, Mr. W. H. Smith stated that, as to the tests that ought to be applied in such cases, special regard ought to be paid to two points. The object to be attained ought to be distinctly national, and not one in which particular individuals or classes were concerned, and security ought to be taken that the persons who sought assistance were contributing largely to promote the object in view. There is no doubt that the Scottish Society satisfies both these requirements.

The Chancellor of the Exchequer also stated that it would be for the Council to consider how far they could avail themselves of the services of the Scottish Meteorological Society in the conduct of their business, and on what terms that assistance should be rendered.

The Council have lost no time in entering upon their duties, and it is devoutly to be wished that some sign may soon be given that if its constitution is not what was generally looked for, it is still well qualified to discharge its functions and to merit the confidence of meteorologists, although they have had so little to say to its appointment.

THE "POLARIS" EXPEDITION

Narrative of the North Polar Expedition U.S. Ship "Polaris," Captain Charles Francis Hall, Commanding. Edited under the Direction of the Hon. G. M. Robeson, Secretary of the Navy, by Rear-Admiral C. H. Davis, U.S.N. U.S. Naval Observatory, 1876. (Washington: Government Printing-office, 1876.)

THIS is a handsome record of one of the most memorable, and in some respects most successful of Arctic expeditions. Though dated 1876, a note dated March, 1877, is prefixed, stating that the concluding chapters have been prepared by Prof. J. E. Nourse. We have already (vol. viii., 217, 435 and *passim*) given so full details concerning this expedition that we need do little more now than notice the publication of this record by the U.S. Government. It contains a full general narrative of the expedition drawn up not only from the official records of the responsible officers, but from the diaries kept by many of the subordinate officers and men, many of the latter being unusually intelligent. Indeed it formed part of the instructions to the expedition in its outset that as many of the officers and men as were able should keep diaries, which were to be handed over to the U.S. Government on the return of the expediti··, a praiseworthy feature, we think, which might be advantageously copied by all similar expeditions.

Captain Hall himself is spoken of justly in the narrative in the highest terms of praise. His enthusiasm for Arctic exploration had become almost a religion with him, and had he lived there seems little doubt that much more would have been accomplished than even there was. He had qualified himself by two long residences among the Esquimaux for enduring all the hardships incident to Polar exploration; and while his main aim was geographical discovery he had a sufficient knowledge of and love for science to induce him to do all in his power to look after its interests in connection with his expedition. To quote the work before us, Hall "possessed judgment and sagacity altogether too large and comprehensive not to be fully alive to the importance of its promotion; and not to know that every accession, whether of law or fact, to its domain, tended to the benefit of mankind." We believe that the narrative of Hall's second residence among the Esquimaux will shortly be published for the first time.

The present work will correct some misconceptions that became current at the time that the news of the fate of the *Polaris* expedition reached this country. It was stated, for example, that the ship was not well fitted for her work; but the fact is that everything was done to strengthen her and otherwise adapt her for the special work she had to do that the United States naval authorities could suggest. Hall himself said that no better equipped expedition ever set out for the Pole. The expedition was in every sense a government one, 50,000 dollars having been appropriated for it, and it was governed by the naval discipline of the United States. True, this latter point does not seem to have been rigidly carried out, Hall himself not having been a naval officer, and perhaps a little too soft to be so strict as he ought to have been. Explicit, but sufficiently elastic instructions were given him, and the scientific instructions prepared by the United States National Academy are given in the Appendix. The latter are exceedingly detailed and carefully drawn up, and embrace every department of science. The scientific results of this expedition are, we believe, of very great importance, and we are glad to learn that a portion of them, at least, have just been published by the chief of the scientific staff, Dr. Emil Bessels.

The idea of the expedition was due solely to Capt. Hall, and it was only through his enthusiastic agitation that the United States Government were persuaded to equip it. His death was a great loss to the cause of Arctic exploration, and we may say to science; and it is a relief to find that after rigid inquiry on the part of the Government it has been concluded that his death arose from purely natural causes. Our readers may remember that a handsome tablet was placed at the head of his grave by our own recent expedition.

The present volume, we have said, is a handsome one, and compares favourably with the unattractive blue-books issued by our own Government in similar cases. There are a large number of attractive illustrations and maps, the former, however, executed by a very roundabout process; they are wood-engravings painted in oil from original sketches by Mr. Emil Schumann and Dr. Bessels, photographed on wood and engraved. One may be inclined to fear that their truthfulness will be apt to suffer during this long process. A very fine life-like portrait of Capt. Hall forms a frontispiece.

POLLUTION OF RIVERS

A Treatise on the Law Relating to the Pollution and Obstruction of Watercourses, together with a Brief Summary of the Various Sources of Rivers Pollution. By Clement Higgins, M.A., F.C.S., Barrister-at-Law. (London: Stevens and Haynes, Law Publishers, Bell Yard, Temple Bar, 1877.)

THE pollution and obstruction of rivers by sewage and the refuse of manufacturing processes is, in a country like this, densely populated and depending mainly on its manufactures, a matter of the gravest importance, justifying indeed, a saying of Earl Beaconsfield's, which has met with a good deal of ridicule, that the motto of his government should be *sanitas sanitatum omnia sanitas*. We have on the one hand to preserve as rigidly as possible the purity of our streams, and on the other to interfere as little as can be with those manufactures which are so great an element in the production of our national welfare.

It is now some years since the Government issued a Royal Commission to inquire into the best means of carrying out the problem, and that the matter is now in a fair way to solution is mainly due to the labours of the late Commission, of which Dr. Frankland was the chemical member.

The five Reports presented by it to Parliament, take rank, indeed, as a classical research into the subject, and have an interest to countries other than our own. The Rivers Pollution Act of 1876 is based on the recommendations of the Commission, and it is not too much to say that without them legislation would have been impossible.

The Act in question constitutes four classes of offences as follows:—To pass into any stream (1) any solid matter so as to interfere with its due flow, or to pollute its waters;

(2) any sewage matter; (3 any poisonous, noxious, or polluting liquid from any manufacturing process; and (4) any poisonous, noxious, or polluting solid or liquid matter from any mine.

Mr. Higgins justly remarks that "the successful working of the Act will much depend upon the meaning of the word '*polluting*' as therein used, by those with whom its interpretation rests." In order to understand the drift of this remark it is necessary to observe that the Act of 1876 virtually gives no standard of purity, though the Commission of 1868 recommended an extensive and somewhat stringent list of standards. We think that on the whole the Act is right in the omission, as a suggestion made by Mr. Crookes in his evidence before the House of Lords in 1873, namely, "that the river itself should be the standard of purity, and that no liquid should be allowed to be sent into a river if the liquid contains a greater percentage of impurity than the river itself," seems to be a very feasible standard and one easily and quickly referred to. Again, as Mr. Crookes pointed out, the standard would naturally improve, as nothing worse than the river at any given point would enter it, whence in the course of nature amelioration would ensue, while the process being gradual would give the manufacturer or township time to improve their waste or sewage, and one of the most disastrous sources of trouble the injury to the water-course from the casting into it of solid refuse would be at once prohibited; as would pollution by actually poisonous matter, such as arsenical and other liquids.

It appears to us that guided by *competent* chemical evidence there ought to be no difficulty in obtaining legal decisions as to the polluting or harmless character of any liquid that may be called in question, while as to solid matters, of any kind whatever, the mere fact of their entry into a stream ought to be an offence without reference to their character. On the whole we think the act, though perhaps partaking too much of the "permissive" character, which is so prominent a feature of modern legislation, to be one which, if conscientiously used with due consideration to the facts of each individual case ought to work great good. In the race for wealth we are perhaps too little apt to think of the future. The brooks and running streams like the land we live on are not ours to do as we like with, but like an entailed estate are only held in trust for the next heir, and like national or family honour should be handed down to posterity pure and unsullied.

Mr. Higgins has devoted great care to his treatise on the Act, and his chemical training has evidently stood him in good stead, the numerous references to cases bearing on the various points show a laborious study of the legal aspects of the case and will add greatly to the value of the work in the eyes of the legal profession, for whose information it is primarily intended.

R. J. FRISWELL

OUR BOOK SHELF

The Cradle of the Blue Nile; a Visit to the Court of King John of Ethiopia. By E. A. De Cosson, F.R.G.S. Two vols. With Map and Illustrations. (London: John Murray, 1877.)

ALTHOUGH Mr. De Cosson did not go over any new ground in his tour, and although he was unable even to carry out his original plan, we are sure that most readers will find much that is new and certainly interesting in his volumes. He went slowly southward from Massowah to Lake Tzana, north-west to the lower Bahr-el-Azrek, down the Nile to Berber, and across to Saakim. He won the favour of King John, of whom he speaks as an able, well-meaning ruler, and was thus able to see much of the life of the people, and learn much of the antiquities and the character of the country that otherwise he would have missed. To any one wishing to obtain an attractive account of the past history and present condition of Abyssinia, we strongly commend Mr. De Cosson's work.

The Tiber and its Tributaries, their Natural History and Classical Associations. By Strother A. Smith, M.A. Map and Illustrations. (London: Longmans and Co., 1877.)

THE idea of this work is, we think, a happy one, and its execution successful. The object is to gather under one head everything of interest relating to the Tiber. This has necessarily involved a great amount of research, and the result will be welcomed both by the student of history, the "scholar," and the geographer. Considerable space is devoted to the inundations of the Tiber, and also to its birds and its fishes. Two nicely-coloured plates are devoted to the muræna, the mullet, the lamprey, and the sturgeon. The Tay, at Perth, we should inform Mr. Smith, is no more an "estuary" than the Thames at London Bridge, unless the word is applied to all that part of a river reached by the tide.

A Short Account of the Principal Geometrical Methods of Approximating to the Value of π. For the Use of Colleges and Schools. By the Rev. G. Pirie, M.A. (Macmillan, 1877.)

Elements of Geometry Based on Euclid. Book I. For Elementary and Middle Class Schools. By E. Atkins, B.Sc. Collins's School Series. (Glasgow: Collins, 1877.)

Takimetry. Concrete Geometry in Three Lessons. Accessible, Inaccessible, Incalculable. Translated by D. W. Gwynne, M.D., from the French of E. Lagout. (Glasgow: Collins, 1877.)

THE little pamphlet first named does not attack the problem from the circle-squarer's point of view—the use of the word "approximating" sufficiently points this out—but gives an interesting account of what was done for the question between the times of Archimedes and Huyghens. A few elementary propositions lead up to what was attempted by Willebrord Snell ("Cyclometricus," 1621) and elegantly effected by Huyghens. Mr. Pirie's object is to correct what he deems a defect in our present works on Trigonometry, and to supply a few simple propositions "on the threshold of the subject." We can recommend the book as one suitable for being put into the hands of sixth form pupils. A few references are supplied to fuller sources of information upon the quadrature of the circle.

Mr. Atkins's book seems to differ but little from the ordinary forms of Euclid as now printed. One feature is the addition of short side-notes drawing attention to the objects of the successive steps of the construction and proof. There is a short collection of sixty exercises grouped under the propositions upon which they depend. Some of these appear to us wrongly placed, and a few incorrectly printed. The work is neatly got up and of a handy form.

If all that is said of takimetry by its admirers be true a revolution in mathematical instruction may be speedily expected. "With one hundred lessons of takimetric instruction any one can very well learn geometry, algebra, arithmetic, and mechanics." "The classical geometry of Euclid *disguises its object, its utility*, and thus, for a considerable time, yields a barren and discouraging result, whilst takimetry is able, on the other hand, to produce the miracle of an astonishing progress." In the Fundamental Takimetry (introductory to Takitechny) objects are classified into square, round, pointed, and truncated forms. The three lessons of Takimetry are (1) equivalence; (2) resemblance; (3) the three squares of a right-angled triangle (*i.e.*, "Euc.," i. 47). The subject requires only three lectures, each of an hour's duration. Amongst the subjects for measurement are the accessible, the inaccessible, and the incalculable (*i.e.*, those which depend upon the circle). There is much that is good in this book, though in its present form it is overweighted with a mass of extraneous matter. By aid of the prettily-coloured figures (there are models, also, we are told, to accompany the book) a considerable knowledge of mensuration, we think, might be imparted even to dull boys. We could take exception to the translation in many places.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Museum Reform

"J. P." suggests, under the head of "Museum Reform" (vol. xvi. p. 183), the idea of a conference of museum keepers, out of which a permanent union among museum officers might result. I am of opinion that this idea is an excellent one, and that the administration of the museums of all countries would gain a great deal if an opportunity to museum officers were offered to interchange their opinions and to communicate to each other their different practical experiences. Perhaps some arrangements and rules might *generally* be accepted, as, *e.g.*, to labelling specimens, exchanging duplicates, publishing annual reports in a journal *ad hoc*, &c. A. B. MEYER

Dresden, July 9

Koenig's Tuning-Forks

THE letter of Herr Koenig inserted in NATURE (vol. xvi. p. 162) did not come under my notice till July 8. On October 27 last year I counted all the 64 sets of beats in Herr Appunn's tonometer, one through 15, the rest through 20 seconds with a pocket chronometer which was gaining less than 4 seconds a day, and found every set of beats perfectly true. The perfection of the consonances, more than 80 of which I tested mechanically, by observing the beats that arose on flattening one of the two consonant notes, seemed to me to eliminate all possible error of irregular counting. The suggestion now is that the beats were perfectly regular and uniform, and that no exception need be taken to my counting, but that Herr Appunn's pendulum was originally incorrect, to such an extent that what appeared to him 80 beats in 20 seconds, were only 79·27, and that my chronometer was not sufficient to detect the error. If this were the case all the numbers on Herr Appunn's tonometer would have to be reduced by as nearly as possible 9 in 1,000, which would make them agree with Herr Koenig's. I shall therefore have to re-test the tonometer with a larger chronometer and if possible count each set of beats for a longer time. I shall not be able to undertake this examination at present, but I shall not neglect doing so, and will inform you of the result. It is right, however, to say that on July 9 and 10 I received communications from Prof. McLeod showing that his improved instrument for counting vibrations gave results almost exactly agreeing with Herr Koenig's numbers. The marked difference of Herr Appunn's and Herr Koenig's numbers will I hope lead to such an examination of the subject as will result in an accurate determination of pitch that can be generally accepted. ALEXANDER J. ELLIS

Kensington, July 11

P.S.—I have this morning received a letter from Herr Appunn, in which he tells me that the letter of Prof. Helmholtz, quoted by Herr Koenig, was received eleven or twelve years ago, and that the error of Herr Appunn's pendulum there pointed out was corrected more than ten years ago. He also refers me to pp. 46-7 of Prof. W. Preyer's tract "Ueber die Grenzen der Tonwahrnehmung," Jena, 1876, in which, by a calculation there detailed, Prof. Preyer shows that the absolute pitch of two of Herr Koenig's forks, which should have been 128 and 256, were 129·1 and 258·2; and says that "the determination is as exact as possible, so that the first decimal place can be fully trusted." I made another fork to be 258·4, and I know by comparison of several specimens that Koenig's forks do not always agree within more than ·2 vibrations. A. J. E.

July 16

On a Fish-sheltering Medusa

WHILE collecting some three weeks since on the south shore of Killary bay in Connemara, I observed that out of a number of the common *Aurelia aurita* moving about in a rocky inlet below me, one was invariably accompanied by a small fish, of about an inch or an inch and a quarter in length, which had established itself inside of the hemispherical disc.

Occasionally the Medusa turned in its pulsations, so as to bring the umbrella undermost, when the fish would shoot hastily out, but the Medusa had no sooner righted itself, than the fish returned, and seizing its opportunity, swam in between the marginal tentacles, and close up to the fringes of the actinostome, remaining distinctly visible through the pellucid disc.

I afterwards noticed several other Aurelia similarly attended, but was not able, unfortunately, to identify the fish, which invariably darted off at the most distant approach of a landing-net—it appeared, however, so far as I could judge, to be the young of one of the larger species. Perhaps some of your readers could contribute suggestions on that point.

Associations of a similar character have, I know, been frequently observed in the case of the Physalidæ and other Acalephæ, but not, so far as I am aware, in connection with this species. E. LAWLESS

The Earth and Moon

I HAVE only now (July 12) noticed Prof. Tait's remark respecting a sentence, or rather half a sentence, which he quotes from an article of mine in the *Cornhill Magazine* for June. It runs thus: "What mathematicians call the moving force exerted by the earth on the moon is eighty-one times greater than the corresponding force exerted by the moon on the earth." This admits of an interpretation implying gross ignorance on my part —ignorance, viz., of the fact that the moon pulls the earth just as strongly as the earth pulls the moon It also admits of an interpretation accordant with fact, for the moving force exerted by the earth on each unit of mass in the moon is eighty-one times greater than the corresponding force exerted by the moon on each unit of mass in the earth. I do not think anyone is likely to believe that I made the mistake imputed to me by Prof. Tait, in this instance, any more than that I made an equally absurd blunder which he attributed to me in your columns several months ago, or that he himself made the ludicrous blunder attributed to him (in jest) by my humorous friend, Prof. Nipher, of St. Louis. But as a mere matter of fact, I may point out that the half-sentence quoted by him is completed by a half-sentence leaving no doubt as to my real meaning, and is immediately preceded by the statement that "the moon pulls the earth just as strongly as the earth pulls the moon."

Blue and Yellow Crocuses

REFERRING to Mr. W. B. Tegetmeier's letter in NATURE, vol. xvi. p. 163, I can say that I once had a pony born and bred on Dartmoor, which had never seen oats until it came into my father's stable in the fourth year of its age, and it refused them. We induced it to eat oats by mixing them with hay and gradually reducing the quantity of hay until the oats predominated.

Penzance, July 10 THOS. CORNISH

Japanese Mirrors

MORE than eleven years ago, in February, 1866, I published in *The Reader* (since extinct), a letter giving, I venture to think, a complete explanation of the phenomena exhibited by certain Japanese mirrors (through a mistake as to their nationality I called them Chinese); and as your readers appear to be unacquainted with this, perhaps I may be allowed to reproduce the substance of my former letter. In order to ascertain whether any variations in the form of the surface of the mirror, which was very slightly convex, affected the question, I looked for any distortions that might be produced in the image of the ground-glass globe of a gas lamp, as the point of incidence moved across that portion of the polished surface on the back of which was a raised figure. Let A and B be two lines on the surface immediately over the two edges of such a figure. Then as the limb of the image approached A, it became flattened; when it had passed A it expanded to more than its original size; indeed between A and B the image was sensibly larger than when viewed from any other part of the mirror. When the limb approached B it was again flattened, and beyond B it resumed its original dimensions. This clearly proves that the portion of the surface of the mirror between A and B was, if not actually plane, at least less convex than the rest of the surface; and as upon this supposition the figures when thrown upon a screen should appear *brighter* than the rest of the image, which is exactly what occurs in fact, there can be no doubt that this is sufficient to account for the peculiarity in question. In all probability the mirror had warped in cooling, except in the thicker portions where the raised figures existed. J. PARNELL

Hadham House, Upper Clapton, July 6

Printing and Calico Printing

YOUR correspondent, Mr. Henry Cecil, is under a singular misapprehension as to the inventor of cylinder machine calico printing, and the date of its first practical application. Mr. Isaac Taylor was certainly not the originator of cylinder printing; and that art was developed long before he, "in 1855 or 1856 superintended its application at Manchester." Mr. Taylor, it is true, obtained several patents for inventions connected with cylinder-printing—one, I think, for a form of pentograph, and another for the use of thin sheet copper instead of thick cast cylinders of that metal. These, so far as I know, never succeeded in practice, and it is highly probable they brought their gifted inventor loss instead of gain; but that result was not due to "the inevitable compliment of piracy." Who the inventor of cylinder printing was it would be hard definitely to determine. Nearly a century and a half ago a patent was granted for an invention which embodied the leading principles of the modern machine, and from that time downwards the apparatus gradually developed and perfected in the hands of innumerable practical inventors.

THE WRITER OF CALICO PRINTING IN THE "ENCYCLOPÆDIA BRITANNICA"

LOCAL MUSEUMS

THE importance of local museums is gradually but unmistakably forcing itself upon the country. It may take much time to foster any united action, without which any definite progress is very improbable, but year by year is adding to the ranks of those who are wise enough to see and have influence enough to advocate their value as a part of the educational stock-in-trade of the nation. We rejoice to see that Mr. Chamberlain has enrolled himself among their advocates in the House of Commons. On Monday he drew attention to the fact that the public expenditure for the promotion of science and art was exclusively confined to London, Edinburgh, and Dublin. The amount of the estimate this year, he said, for museums, art galleries, and parks in the metropolis amounted to nearly 400,000*l*., and that for Edinburgh and Dublin to nearly 50,000*l*. To those sums the provinces had to contribute twice over. Birmingham contributed about 4,000*l*., and had to find about 8,000*l*. a year besides for her own local art institutions. It might be said with truth that a national collection should be placed in the metropolis at the expense of the nation, but that argument did not apply to the expenditure on the public parks and still less to that which the Bethnal Green Museum involved. He did not complain of such expenditure. It produced most admirable results, adding as it did to the pleasure and happiness of great masses of the people, and tending to elevate and refine their minds. It was, too, in some sort a commercial investment, as it was calculated to enable artisans the better to compete with those of other nations. What he complained of was that the principle had not been carried far enough. He was anxious to see established in every one of our great centres of population and industry museums devoted to art and manufactures appropriate to each particular district. To show how highly these institutions were appreciated in the provinces, he mentioned that in Birmingham the local museum which had been established by private subscriptions was visited annually by 300,000 persons, and as the population of the town was only 370,000, the attendance was immensely greater than was shown by the returns of the number of visitors to our metropolitan institutions. Results equally extraordinary could be quoted from other provincial towns in which such museums existed. He further stated that although provincial communities were at present legally able to tax themselves to the extent of 1*d*. in the pound for the purpose of establishing museums and libraries, in Birmingham all this money went to the free library, and they had therefore no means of establishing an industrial museum.

We are glad also to see that the Government is now alive to the importance of this action, for, although Lord Sandon in his reply begged that the matter might not be pressed upon them at the present moment, he reminded the House of the great advantage which the country derived from the South Kensington Museum, which was now, in fact, a gigantic circulating museum. Almost all the principal objects in the museum, except those of great rarity or delicacy, were sent on their travels at different times through the provinces, and in this way aid was already given to local museums. The country derived enormous advantage from this vote. Local exhibitions were frequent, and loans from the South Kensington Museum for these exhibitions were very numerous. Eight museums had these objects sent to them, and a great deal had been done as the hon. gentleman wished. The South Kensington authorities were anxious to follow that course, but he could not say whether they would be able next year to do more in that direction. Their hands were to some extent tied by the necessity of economy, but the matter would receive the best attention of the Government, and he hoped that next session they might be able to go further.

Of course, neither Mr. Chamberlain nor Dr. Lyon Playfair allowed the subject to drop without pointing out that the British Museum and the National Gallery had no circulating system in operation, that in fact Lord Sandon was quite justified in adopting that line of argument with regard to the South Kensington authorities; but that many of the London galleries and museums were of no use to the provinces. The British Museum, for instance, and the National Gallery were practically of no use except to London, yet every one knew that they contained many duplicates which would be most valuable to the provinces, and the offer of some important pictures was sometimes declined on behalf of the National Gallery. Nor was this all. Dr. Playfair pointed out that in France the Minister of Education was responsible for all the museums, and constantly sent collections into the provinces; but in England, the management of the galleries was, so to say, dislocated, and not under one authority or one Minister. Why did he not go further and point out the recommendation of the Duke of Devonshire's Commission?

THE VELOCITY OF LIGHT[1]

THE correct determination of the velocity of light is a result on which so much in physical science depends that there is good reason for us to give a description of the details of the apparatus used for the purpose of obtaining the exact value. Until the time that M. Cornu undertook experiments with this object in view the generally received value of the velocity in question was 298,000 kilometres per second. This depended on the experiments of M. Foucault, who used a rotating mirror on which the rays of light from cross-wires fell, and while the mirror was in a certain position were reflected by it to a concave mirror at a distance of 13½ feet, having the revolving mirror at its centre of curvature and so fixed as to return the rays of light to the latter, which reflected them to the point of departure. While however the rotating mirror was in rapid motion, a ray of light reflected by it to the distant mirror and back from it, would not, unless the passage of light were instantaneous, reach the rotating mirror until the latter had moved from its position of first reflection, and would not therefore return to the point of departure, but to some point near it, depending on the angle through which the rotating mirror had moved in the time between its reflecting the ray to the concave mirror and the return of that ray. By placing the cross-wires in the principal focus of a convex lens the rays proceed in a parallel beam, and on returning form an image of the wires, removed from the wires themselves, a distance depending on the angular velocity of the mirror and the velocity of light. The cross-wires and their images are rendered visible by viewing them by means of a diagonal reflector of plain glass in front, which at the same time allows sufficient light to pass through to illuminate them.[2]

In 1849 M. Fizeau devised a method differing from that just described by which he measured the time a ray took to travel from Suresnes to Montmartre and back. The apparatus consisted of a toothed wheel which could be rotated with a known velocity, and having the teeth and intervals equal in size. A pencil of rays was sent through the interval between two teeth to a reflector at Montmartre 28,334 feet distant, which caused the ray to return on itself. So long as the wheel is at rest and the rays pass through an interval, they will be returned through that same interval, but when the wheel turns with sufficient velocity a tooth takes the place of an interval before the ray has time to return from Montmartre and get through, and is therefore interrupted. By rotating this wheel faster the next interval will take the place of the preceding one on the return of the ray, which will again get through, and so on passing and being interrupted as the velocity of rotation increases.

It is obvious, then, that if we know the number of teeth on the wheel and the number of turns per second, say at the instant of reappearance of the spot of light after a disappearance, we shall know the interval between the passing away of the ray by the edge of one tooth to its return by the corresponding edge of the next; and this is the time the ray has taken to traverse the distance to the reflecting station and back, and from this the velocity of light follows. From these experiments M. Fizeau obtained a velocity of 315,000 kilometres = 196,000 miles per second.

At that time the velocity of light deduced from the observations of eclipses of Jupiter's satellites, combined with the then accepted solar parallax, was 190,000 miles per second, closely agreeing with M. Fizeau's result; later determinations of solar parallax have given a smaller result than former ones, and consequently the velocity of light deduced therefrom becomes reduced, which again closely agrees with M. Foucault's direct determination.

In the year 1874 the Council of the Paris Observatory, on the proposition of M. Leverrier and M. Fizeau, decided on the execution of experiments for the direct determination of the velocity of light, and offered the use of the scientific apparatus at the observatory for the purpose, together with funds for the construction of the necessary instruments. To M. Cornu was entrusted the execution of the operations; and after due consideration and experimental comparison, he adopted the method of M. Fizeau in preference to the revolving mirror of M. Foucault. A preliminary series of experiments were carried out in 1871 and 1872, between the École Polytechnique and Mont Valérien, a distance of 10,310 meters, giving a result of 185,370 miles per second as the velocity of light, with a probable error of less than $\frac{1}{100}$. M. Cornu then commenced more careful experiments between the Observatory and the Tour de Montlhéry, a distance of 22,910 metres. The principle of M. Cornu's arrangement we have already described, it being the same as that of M. Fizeau, but the details of the apparatus are somewhat elaborate, and in his Memoir occupy seven large sheets of plates; we can, however, to a certain extent describe them. Rays of light from a highly luminous source issuing from a small hole in a diaphragm, pass through a convex lens, and after reflection at an angle of 45 from the surface of a plain piece of glass, are brought to a focus at the circumference of the toothed wheel; the light then traverses an object-glass of fourteen inches diameter, and the parallel rays travel to the reflecting station; here they are received by an object-glass of six-inch aperture, and about six feet focal length, at the principal focus of which is a reflecting mirror of silvered glass. From this mirror the rays are returned to the toothed wheel, where an image is formed coinciding with the original image of the hole in the illuminated diaphragm, the rays if not intercepted by a tooth, pass onwards, and the greater part of them traverse the diagonal reflector of plain glass and an eyepiece beyond, through which the image formed by reflection from the distant station is viewed. So far we have given an outline of the optical part of the apparatus as well as we can without the use of the drawings by which the details can only be made intelligible. We next come to the toothed wheel, and here certain conditions must be fulfilled: first a velocity of rotation must be obtained capable of admitting a considerable number of orders of extinction; secondly, the motive power must be such that the observer can easily control the velocity of the wheel; thirdly, there must be a means of recording the velocity at any instant of time. The motive power is a weight which drives a train of wheels which rotate the toothed wheel, the latter being constructed of aluminium from $\frac{1}{10}$ to $\frac{1}{15}$ millimetre in thickness; wheels of different diameters were used varying from 35 to 48 millimetres. The velocity is recorded on the surface of smoked paper on a roller of about one metre in circumference and half a metre in length, turning on a horizontal axis. The records are made by the action of electro-magnets on light tracers pressing against the surface of the smoked paper. The velocity of the cylinder carrying the paper is such that a line 20 mm. is traced in a second, and during each revolution the tracers are moved on horizontally 15 mm. One of the tracers is put into action at every second by electric communication with a standard clock; a second is put into action at every $\frac{1}{10}$ second by a trembler governed by the pendulum of the clock; the third moves at each fortieth or four hundredth revolution of the toothed wheel, and the fourth is under the control of the observer. Each of the four tracers is continually in contact with the smoked surface of the paper, and so long as it is not moved sidewise by the electro-magnet, traces a continuous line round the cylinder, but on the passing of a current round the

[1] "Détermination de la Vitesse de la Lumière d'après des Expériences exécutées en 1874, entre l'Observatoire et Montlhéry." Par M. A. Cornu. (Paris: Gauthier Villars, 1876.)

[2] From the experiments of M. Foucault in 1862 a velocity of 298,000 kilometres = 185,157 miles per second was deduced.

electro-magnet, the tracer makes a short mark at right angles to line, and a zig-zag line caused by the vibration of the tracer, back to its original position; the first two lines, therefore, show seconds and tenths of seconds, the third, the instants of completion of forty or 400 revolutions, according to the desire of the operator, of the toothed wheel; a comparison, therefore, at once gives the number of revolutions per second, while on the fourth line are marked the instants of disappearance or reappearance of the light, and the velocities at those instants are then at once known. To make an experiment the aperture in the diaphragm is illuminated by a lime-light or sometimes with sunlight by means of a heliostat. The necessary adjustments in the direction of the rays of light to the distant station are then made by bringing the distant collimator into the centre of the field of the observing apparatus, and the point of light—the luminous echo—is made to accurately coincide with its original at

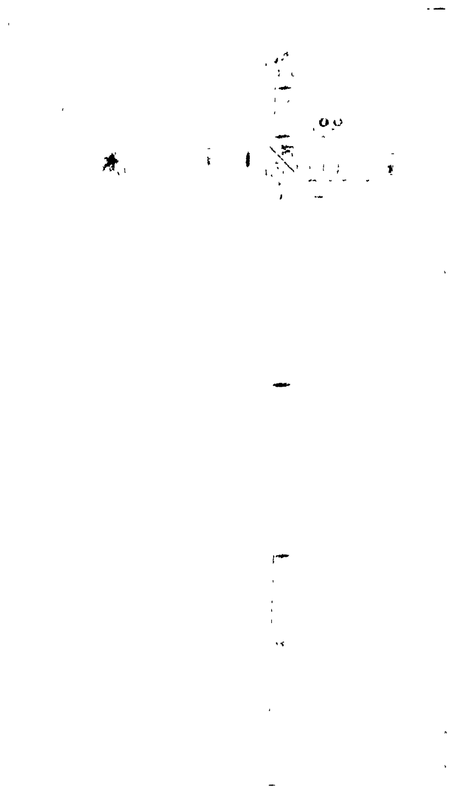

FIG. 1.—Plan of M. Fizeau's Apparatus.

the circumference of the toothed wheel. Particulars of the experiment, as to number of teeth of wheel, direction of rotation, &c., are entered on the paper on the cylinder, and the latter is then set in motion; the observer then sets the toothed wheel going and watches the luminous echo, and on its disappearing touches a key which sends an electric current to the electro-magnet controlling the fourth tracer, which therefore registers the instant the velocity is sufficient to cause a disappearance. As the velocity of the wheel increases, the luminous echo again appears and the key is pressed; a further increase in velocity causes another disappearance and so on to the higher orders, each of which is registered. The velocities at the different instants are read off by a micrometer to $\frac{1}{100}$ of a second.

It is obvious that the state of the air must have a great effect on the definition of the luminous echo, and that although the observation appears extremely simple still there may be large errors due to irregular refraction of the air, causing a motion of the point of light, and a large amount of patience must be required. Two careful surveys showed the distance between the two stations to be 22909·77 metres, and the mean velocity obtained from a large number of observations after the various corrections were made was 300,400 metres per second of mean time.

The Memoir of M. Cornu contains a large amount of theoretical matter and formulæ of corrections which of course we cannot reproduce here.

We may, however, refer to the principal causes of error. The first is a personal error depending on the sensibility of the eye of the observer in determining the disappearance and reappearance of the light at the toothed wheel, and also depending on the intensity of the luminous source; secondly, accidental inequality in the size of the teeth of the wheel; thirdly, irregularity of motion; fourthly, excentricity of wheels; fifthly, optical errors due to imperfections in the adjustment of the lenses and reflector. The first of these is small and can theoretically be reduced indefinitely by increasing the velocity of the

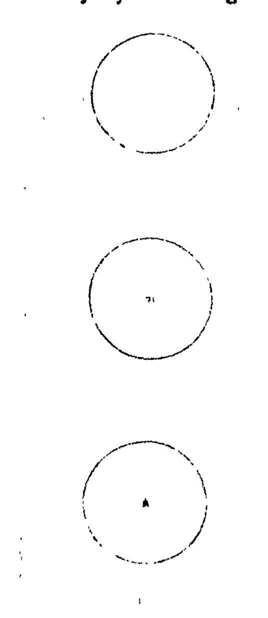

FIG. 2.—Details of Toothed Wheel.

toothed wheel and thereby observing the higher orders of extinction and reappearance of the light, but M. Cornu desires to be rigorously exact, and therefore the effect of this and the other errors is carefully calculated.

Considerable care was exercised in the choice of stations, and those adopted were fixed upon chiefly on account of the distance between them being more easily ascertained from previous triangulation. This distance was determined by Cassini and La Caille in 1740, the result being 22910·196 metres. From the observations of Delambre the same distance was computed to be 22909·34 metres; and 22910 metres, which is nearly the mean adopted by M. Cornu.

The corrected results of the experiments gave a velocity of 300,350 kilometres a second, but this was obtained in air, and therefore 82 kilometres must be added to this result to give the velocity *in vacuo*; and as the result of his experiments M. Cornu adopts a velocity *in vacuo* of 300,400 kilometres = 186,638 miles per second of mean time, with a probable error of $\frac{1}{1000}$, or 300 kilometres.

If from this value we deduce the solar parallax, we find the latter to be 8″·881, assuming the time required for light to travel from the sun to us to be 6m. 13·2 sec., as obtained from observations on Jupiter's satellites, and the radius of the earth 6378·233 kilometres.

Again, the sun's parallax deduced from M. Cornu's values of the velocity of light in conjunction with the value of aberration is, with Bradley's estimate of 20″·25, 8″·882, and with Struve's, of 20″·445, 8″·798. These values of parallax compare favourably with determination by other methods, of which we give a few examples. The value given by the transits of Venus in 1761 and 1769 was 8″·5776 computed by Encke, but increased to 8″·891 by Mr. Stone on a redetermination. By the record of an observation of the occultation of ψ_2 Aquarii on October 1, 1672, M. Leverrier obtained 8″·866; by meridian observations of Mars at Greenwich in 1862, 8″·932; by the latitude of Venus obtained from transits of 1761 and 1769, combined with present latitudes, M. Leverrier finds 8″·853; from the discussion of meridional observations of Venus in an interval of 106 years 8″·859; by the opposition of Mars in 1860 by M. Liais 8″·760; by opposition of Flora in 1873 by Prof. Galle 8″·873. Judging from these results the velocity of 186,638 miles per second is not very far from the mark, and the care in selection of methods and in computing results can scarcely be surpassed.

G. M. S.

EVOLUTION OF NERVES AND NERVO-SYSTEMS[1]

NERVE-TISSUE universally consists of two elementary structures, viz., very minute nerve-cells and very minute nerve-fibres. The nerve-fibres proceed to and from the nerve-cells, thus serving to unite the cells with one another, and also with distant parts of the animal body. Moreover, nerve-cells and fibres, wherever we meet with them, present very much the same appearances. Here, for instance, is a sketch of highly magnified nerve-tissue as we find it in the human brain, and here is one of my own drawings of nerve-tissue as I have found it in the jelly-fish; and you see how similar the drawings are—notwithstanding they are taken from the extreme limits of the animal kingdom within which nerve-tissue is known to occur.

Nerve-cells are usually found collected together in aggregates which are called nerve-centres or ganglia, to and from which large bundles of nerve-fibres come and go. These large bundles of nerve-fibres are what we see with the naked eye as nerves, permeating the body in all directions. When such a bundle of nerve-fibres reaches a ganglion, or collection of nerve-cells, it splits up like the end of a rope which has been teased out, and the constituent fibres pass into and out of the nerve-cells, so interlacing with one another in all directions, as here diagrammatically represented. More true to nature is this diagram, which represents a magnified section of human brain—the human brain being itself nothing more than a collection of very large ganglia.

To explain the *function* of nerve-cells and nerve-fibres, I must begin by explaining what physiologists mean by the word "excitability." Suppose this to represent a muscle cut from the body of a freshly-killed animal. So long as you do not interfere with it in any way, so long will it remain quite passive. But every time you stimulate it either with a pinch, a burn, or, as represented in the diagram, with an electrical shock, the muscle will give a single contraction in response to every stimulation. Now it is this readiness of organic tissues to respond to a stimulus that physiologists designate by the term excitability.

Nerves, no less than muscles, present the property of being excitable. Suppose, for instance, that this is another muscle prepared in the same way as the last one, except that together with the muscle there is cut out the attached nerve. Every time you pinch, burn, or electrify any part of the nerve, the muscle will contract. But you will carefully observe there is this great difference between these two cases of response on the part of the muscle; viz., that while in the former case the muscle responded to a stimulus *applied directly to its own substance*, in the latter case the muscle responded to a stimulus *applied at a distance from its own substance*, which stimulus was then *conducted* to the muscle by the nerve. And here we perceive the characteristic function of nerve-fibres, viz., that of conducting stimuli to a distance. This is the function of nerve-*fibres*; but the function of nerve-*cells* is different, viz., that of accumulating nervous energy, and at fitting times of discharging this energy into the attached nerve-fibres. The nervous energy when thus discharged from the nerve-cells acts as a stimulus to the nerve-fibre; so that if a muscle is attached to the end of the fibre it contracts on receiving this stimulus. I may add that when nerve-cells are collected into ganglia they often appear to discharge their energy spontaneously, without any observable stimulus to cause the discharge; so that in all but the lowest animals, whenever we meet with apparently spontaneous action, we infer that ganglia are probably present. But the point which most of all I desire you to keep well in mind this evening is the distinction which I here draw between muscle and nerve. A stimulus applied to a nerveless muscle can only course through the muscle by giving rise to a visible wave of contraction, which spreads in all directions from the seat of stimulation as from a centre. A nerve, on the other hand, conducts the stimulus without undergoing any change of shape. Now in order not to forget this all-important distinction, I shall always to-night speak of muscle as conducting a visible wave of *contraction*, and of nerve as conducting an invisible or molecular wave of *stimulation*. Nerve-fibres, then, are functionally distinguished from muscle-fibres—and also, I may add, from protoplasm—by displaying the property of conducting invisible or molecular waves of stimulation from one part of an organism to another—so establishing physiological continuity between such parts *without the necessary passage of contractile waves*.

I will now conclude all that it is necessary to say about the function of nervous tissue by describing the mechanism of reflex action. Suppose this to represent any peripheral structure, such as a part of the skin of some animal, this a collection of nerve-cells or ganglion, and this a muscle. The part of the skin represented is united to the nerve-cells composing the ganglion by means of this in-coming nerve-trunk, while the nerve-cells in the ganglion are united to the muscle by means of this out-going nerve-trunk. Therefore when any stimulus falls on the skin where this in-coming nerve-trunk takes its origin, the nerve-trunk conveys the stimulus to the nerve-cells in the ganglion. When the nerve-cells receive the stimulus they liberate one of their characteristic discharges of nervous energy, which discharge then passes down this out-going nerve and so causes the muscle to contract. Now this particular kind of response is called response by reflex action, because the stimulus wave does not pass in a straight line from the seat of stimulation to the muscle, but passes in the first instance to the ganglion, and is from it *reflected* to the muscle. This, at first sight, appears to be a roundabout sort of a process, but in reality it is the most economic process available; for we must remember the enormous number and complexity of the stimuli to which every animal is more or less exposed, and the consequent necessity that arises in the case of highly organised animals of there being some organised system whereby these stimuli shall be suitably responded to. Or, to adopt a happy illustration of Prof. Bain, the stimuli are systematised on the same principle as the circulation of letters by post is systematised; for just as in the case of the letters there is no

[1] Abstract of a Lecture delivered at the Royal Institution on Friday evening, May 25, 1877. By George J. Romanes, M.A., F.L.S., &c.

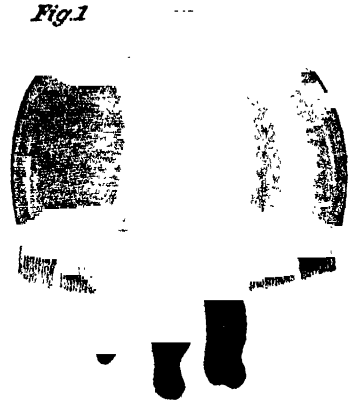
direct communication between one street and another, but every letter passes first to the central office; so the transmission of stimuli from one member of the body to another is effected exclusively through a centre or ganglion.

Those among you who are acquainted with Mr. Herbert Spencer's writings are doubtless well aware how strong a case he makes out in favour of his theory respecting the genesis of nerves. This theory, you will remember, is that which supposes incipient conductile tissues, or rudimentary nerve-fibres, to be differentiated from the surrounding contractile tissues, or homogeneous protoplasm, by a process of integration which is due simply to use. Thus, beginning with the case of undifferentiated protoplasm, Mr. Spencer starts from the fact that every portion of the colloidal mass is equally excitable and equally contractile. But soon after protoplasm begins to assume definite shapes, recognised by us as specific forms of life, some of its parts are habitually exposed to the action of forces different from those to which other of its parts are exposed. Consequently, as protoplasm continues to assume more and more varied forms, in some cases it must happen that parts thus peculiarly situated with reference to external forces will be more frequently stimulated to contract than are other parts of the mass. Now in such cases the relative frequency with which waves of stimulation radiate from the more exposed parts, will probably have the effect of creating a sort of polar arrangement of the protoplasmic molecules lying in the lines through which these waves pass, and for other reasons also will tend ever more and more to convert these lines into passages offering less and less resistance to the flow of such molecular waves—*i.e.*, waves of stimulation as distinguished from waves of contraction. And lastly, when lines offering a comparatively low resistance to the passage of molecular impulses have thus been organically established, they must then continue to grow more and more definite by constant use, until eventually they become the habitual channels of communication between the parts of the contractile mass through which they pass. Thus, for instance, if such a line has been established between the points A and B of a contractile mass of protoplasm, when a stimulus falls upon A a molecular wave of stimulation will course through that line to B, so causing the tissue at B to contract—and this even though no *contractile* wave has passed through the tissue from A to B. Such is a very meagre epitome of Mr. Spencer's theory, the most vivid conception of which may perhaps be conveyed in a few words by employing his own illustration—viz., that just as water continually widens and deepens the channels through which it flows, so molecular waves of the kind we are considering, by always flowing in the same tissue tracts, tend ever more and more to excavate for themselves functionally differentiated lines of passage. When such a line of passage becomes fully developed, it is a nerve-fibre, distinguishable as such by the histologist; but before it arrives at this its completed stage—*i.e.*, before it is observable as a distinct structure—Mr. Spencer calls it a "line of discharge."

Such being the theory, I will endeavour to show how it is substantiated by facts. And here it becomes necessary to refer to my own work. You are all, I suppose, acquainted with the general appearance of a Medusa, or jelly-fish. The animal presents the general form of a mushroom. The organ which occupies the same position as the stalk does in the mushroom is the mouth and stomach of the Medusa, and is called the polypite; while the organ which resembles in shape the dome of the mushroom constitutes the main bulk of the animal, and is called the swimming-bell. Both the polypite and the swimming-bell are almost entirely composed of a thick transparent and non-contractile jelly; but the whole surface of the polypite, and the whole *concave* surface of the bell, are overlaid by a thin layer or sheet of contractile tissue. This tissue is not exactly protoplasm and not exactly muscle, but something between the two. It constitutes the earliest appearance in the animal kingdom of anything resembling muscular tissue. The thickness of this continuous layer of incipient muscle is pretty uniform, and is nowhere greater than that of very thin paper. The margin of the bell supports a series of highly contractile tentacles, and also another series of bodies which are of great importance for us to-night. These are the so-called marginal bodies, which are here represented, but the structure of which I need not describe. Lastly, it may not be superfluous to add that all the Medusæ are locomotive. The mechanism of their locomotion is very simple, consisting merely of an alternate contraction and relaxation of the entire muscular sheet which lines the cavity of the bell. At each contraction of this muscular sheet, the gelatinous walls of the bell are drawn together; the capacity of the bell being thus diminished, water is ejected from the open mouth of the bell backwards, and the consequent reaction propels the animal forwards. In these swimming movements systole and diastole follow one another with as perfect a rhythm as they do in the beating of a heart.

The question as to whether the Medusæ possess a nervous system is a question which has long occupied the more or less arduous labours of many naturalists. Until

Fig. 1



lately, however, there has been so little certainty on the subject that Prof. Huxley—himself one of the greatest authorities on the group—thus defined the standing of the question in his "Classification of the Animal Kingdom:" "No nervous system has yet been discovered in any of these animals." The cause of this uncertainty is to be found in the fact that the transparent and deliquescent nature of the tissues of the Medusæ renders adequate microscopical observation in their case a matter of extreme difficulty; so much so that, looking to the quantity and quality of the labour which has been bestowed on the question, I doubt whether the latter would ever have been satisfactorily settled by the histological methods alone. But those of you who were present at my lecture last year will no doubt remember that by employing methods other than the histological, I was able to set this long-standing question finally at rest. For you will no doubt remember my having told you that on merely cutting off the extreme marginal rim of the bell I was surprised to find that the previously active motions of the animal suddenly and entirely ceased; the paralysis caused by this simple operation was instantaneous, enduring, and complete. On the other hand, you may remember, the severed margin which had just been taken from the swimming-bell invariably continued its rhythmical motions with a vigour and a pertinacity not in the least impaired by its severance from the main organism. For hours, and even for days after the operation, these motions persisted; so that the contrast between the death-like quiescence of the mutilated swimming-bell and the active contractions of the thread-like portion which had just been removed from its margin, was a contrast as striking as it is possible to conceive.

These experiments, then, conclusively proved that in the marginal rim of the Medusæ there is situated an intensely localised system of nervous centres, or ganglia, to the functional activity of which the rhythmical motions of the swimming-bell are exclusively due.

(*To be continued.*)

ON ELEMENTARY INSTRUCTION IN PHYSIOLOGY[1]

THE chief ground upon which I venture to recommend that the teaching of elementary physiology should form an essential part of any organised course of instruction in matters pertaining to domestic economy, is that a knowledge of even the elements of this subject supplies those conceptions of the constitution and mode of action of the living body and of the nature of health and disease, which prepare the mind to receive instruction from sanitary science.

It is, I think, eminently desirable that the hygienist and the physician should find something in the public mind to which they can appeal; some little stock of universally acknowledged truths, which may serve as a foundation for their warnings, and predispose towards an intelligent obedience to their recommendations.

Listening to ordinary talk about health, disease, and death, one is often led to entertain a doubt whether the speakers believe that the course of natural causation runs as smoothly in the human body as elsewhere. Indications are too often obvious of a strong, though perhaps an unavowed and half unconscious, undercurrent of opinion that the phenomena of life are not only widely different in their superficial characters and in their practical importance, from other natural events; but that they do not follow in that definite order which characterises the succession of all other occurrences, and the statement of which we call a law of nature.

Hence, I think, arises the want of heartiness of belief in the value of knowledge respecting the laws of health and disease, and of the foresight and care to which knowledge is the essential preliminary, which is so often noticeable; and a corresponding laxity and carelessness in practice, the results of which are too frequently lamentable.

It is said that, among the many religious sects of Russia, there is one which holds that all disease is brought about by the direct and special interference of the Deity, and which, therefore, looks with repugnance upon both preventive and curative measures, as alike blasphemous interferences with the will of God. Among ourselves, the "Peculiar People" are, I believe, the only persons who hold the like doctrine in its integrity, and carry it out with logical rigour. But many of us are old enough to recollect that the administration of chloroform in assuagement of the pangs of childbirth was, at its introduction, strenuously resisted upon similar grounds.

I am not sure that the feeling, of which the doctrine to which I have referred is the full expression, does not lie at the bottom of the minds of a great many people who would yet vigorously object to give a verbal assent to the doctrine itself. However this may be, the main point is that sufficient knowledge has now been acquired of vital phenomena to justify the assertion that the notion that there is anything exceptional about these phenomena receives not a particle of support from any known fact. On the contrary, there is a vast and an increasing mass of evidence that birth and death, health and disease, are as much parts of the ordinary stream of events as the rising and setting of the sun, or the changes of the moon; and that the living body is a mechanism the proper working of which we term health; its disturbance, disease; its stoppage, death. The activity of this mechanism is dependent upon many and complicated conditions, some of which are hopelessly beyond our control, while others are readily accessible and are capable of being indefinitely modified by our own actions. The business of the hygienist and of the physician is to know the range of these modifiable conditions, and how to influence them towards the maintenance of health and the prolongation of life; the business of the general public is to give an intelligent assent and a ready obedience based upon that assent, to the rules laid down for their guidance by such experts. But an intelligent assent is an assent based upon knowledge, and the knowledge which is here in question means an acquaintance with the elements of physiology.

It is not difficult to acquire such knowledge. What is true, to a certain extent, of all the physical sciences, is eminently characteristic of physiology—the difficulty of the subject begins beyond the stage of elementary knowledge, and increases with every stage of progress. While the most highly trained and best furnished intellect may find all its resources insufficient when it strives to reach the heights and penetrate into the depths of the problems of physiology, the elementary and fundamental truths can be made clear to a child.

No one can have any difficulty in comprehending the mechanism of circulation or respiration, or the general mode of operation of the organ of vision; though the unravelling of all the minutiæ of these processes may, for the present, baffle the conjoined attacks of the most accomplished physicists, chemists, and mathematicians. To know the anatomy of the human body, with even an approximation to thoroughness, is the work of a life, but as much as is needed for a sound comprehension of elementary physiological truths may be learned in a week.

A knowledge of the elements of physiology is not only easy of acquirement, but it may be made a real and practical acquaintance with the facts, as far as it goes. The subject of study is always at hand in oneself. The principal constituents of the skeleton, and the changes of form of contracting muscles, may be felt through one's own skin. The beating of one's heart, and its connection with the pulse may be noted; the influence of the valves of one's own veins may be shown; the movements of respiration may be observed; while the wonderful phenomena of sensation afford an endless field for curious and interesting self-study. The prick of a needle will yield, in a drop of one's own blood, material for microscopic observation of phenomena which lie at the foundation of all biological conceptions; and a cold, with its concomitant coughing and sneezing, may prove the sweet uses of adversity by helping one to a clear conception of what is meant by "reflex action."

Of course, there is a limit to this physiological self-examination. But there is so close a solidarity between ourselves and our poor relations of the animal world, that our inaccessible inward parts may be supplemented by theirs. A comparative anatomist knows that a sheep's heart and lungs, or eye, must not be confounded with those of a man; but so far as the comprehension of the elementary facts of the physiology of circulation and of respiration and of vision goes, the one furnishes the needful anatomical data as well as the other.

Thus, it is quite possible to give instruction in elementary physiology in such a manner as not only to confer knowledge, which, for the reason I have mentioned, is useful in itself; but to serve the purposes of a training in accurate observation, and in the methods of reasoning of physical science. But that is an advantage which I

[1] A paper read at the Domestic Economy Congress, by Prof. Huxley, F.R.S.

mention only incidentally as the present conference does not deal with education in the ordinary sense of the word.

It will not be suspected that I wish to make physiologists of all the world. It would be as reasonable to accuse an advocate of the "three R's" of a desire to make an orator, an author, and a mathematician of everybody. A stumbling reader, a pot-hook writer, and an arithmetician who has not got beyond the rule of three, is not a person of brilliant acquirements; but the difference between such a member of society and one who cannot either read, write, or cipher is almost inexpressible; and no one nowadays doubts the value of instruction, even if it goes no further.

The saying that a little knowledge is a dangerous thing is, to my mind, a very dangerous adage. If knowledge is real and genuine, I do not believe that it is other than a very valuable possession, however infinitesimal its quantity may be. Indeed, if a little knowledge is dangerous, where is the man who has so much as to be out of danger?

If William Harvey's life-long labours had revealed to him a tenth part of what may be made sound and real knowledge to our boys and girls—he would not only have been what he was, the greatest physiologist of his age, but he would have loomed upon the seventeenth century as a sort of intellectual portent. Our little knowledge would have been to him a great, astounding, unlooked-for vision of scientific truth.

I really see no harm which can come of giving our children a little knowledge of physiology. But then, as I have said, the instruction must be real, based upon observation, eked out by good explanatory diagrams and models, and conveyed by a teacher whose knowledge has been acquired by study of the facts, and not the mere catechismal parrot-work which too often usurps the place of elementary teaching.

It is, I hope, unnecessary for me to give a formal contradiction to the silly fiction, which is assiduously circulated by fanatics who not only ought to know, but do know, that their assertions are untrue, that I have advocated the introduction of that experimental discipline which is absolutely indispensable to the professed physiologist, into elementary teaching.

But while I should object to any experimentation which can justly be called painful, for the purpose of elementary instruction, and while, as a member of a late Royal Commission, I gladly did my best to prevent the infliction of needless pain for any purpose, I think it is my duty to take this opportunity of expressing my regret at a condition of the law which permits a boy to troll for pike, or set lines, with live frog bait, for idle amusement; and, at the same time, lays the teacher of that boy open to the penalty of fine and imprisonment if he uses the same animal for the purpose of exhibiting one of the most beautiful and instructive of physiological spectacles, the circulation in the web of the foot. No one could undertake to affirm that a frog is not inconvenienced by being wrapped up in a wet rag, and having his toes tied out; and it cannot be denied that inconvenience is a sort of pain. But you must not inflict the least pain on a vertebrated animal for scientific purposes (though you may do a good deal in that way for gain or for sport) without due licence of the Secretary of State for the Home Department, granted under the authority of the Vivisection Act.

So it comes about, that in this present year of grace 1877, two persons may be charged with cruelty to animals. One has impaled a frog, and suffered the creature to writhe about in that condition for hours; the other has pained the animal no more than one of us would be pained by tying strings round his fingers, and keeping him in the position of a hydropathic patient. The first offender says, "I did it because I find fishing very amusing," and the magistrate bids him depart in peace; nay, probably wishes him good sport. The second pleads, "I wanted to impress a scientific truth, with a distinctness attainable in no other way, on the minds of my scholars," and the magistrate fines him five pounds.

I cannot but think that this is an anomalous and not wholly creditable state of things.

OUR ASTRONOMICAL COLUMN

D'ARREST'S COMET.—M. Leverrier notifies the discovery of the periodical comet of D'Arrest by M. Coggia at Marseilles, on the 8th inst., nearly in the position assigned by M. Leveau's calculations. It was also detected at Florence by M. Tempel, on the 10th.

The comet was discovered by the late Prof. D'Arrest at Leipsic on June 27, 1851, and observed till October 6. The elliptical character of the orbit was pointed out by the discoverer early in August, and his conclusions were verified by the calculations of Vogel and Villarceau shortly afterwards, the latter astronomer commencing, while the comet was yet under observation, a series of elaborate computations of the effect of planetary perturbations upon its motion, which were continued by him until taken up by Leveau. With the aid of Villarceau's ephemerides the comet was detected on its ensuing return to perihelion at the Royal Observatory, Cape of Good Hope, and observed from December 5, 1857, to January 18, 1858. Oudemans, in a memoir published by the Royal Academy of Sciences at Amsterdam in 1854, had also carried forward the elements to this appearance, his results indicating that while the normal positions of 1851 were best represented by a mean motion which would bring the comet to perihelion again on December 5, 1857, there yet remained an uncertainty to the extent of eighty-five days in the length of the revolution. Villarceau, in the *Comptes Rendus de l'Académie des Sciences*, 1852, December 6, considered the period fixed within narrower limits, one of his sets of elements assigning November 28, 1857, for the next perihelion passage, on which day the Cape observations show that it actually occurred. At the second return in the spring of 1864 the comet was not observed, and a very heavy work was involved in the preparation of an ephemeris for 1870, owing to the large perturbations due to the action of Jupiter in 1861, the comet having in April of that year approached the planet within 0·36 of the mean distance of the earth from the sun, and the two bodies remaining in proximity for a considerable time; it was therefore necessary to determine the effect of this near approach to the most powerful of the planets with every possible precision, a long work successfully accomplished by Leveau, who found on continuing the calculation of the perturbations of Jupiter, Saturn, and Mars, to June, 1870, the following material changes in the elements at the perihelion passage in November, 1857.

	° ′		° ′
Long. of Perihelion	− 4 32	Angle of Eccentricity	− 1 52
,, Ascend. Node	− 2 12	Mean anomaly ...	+ 10 10
Inclination	+ 1 43	Mean motion ...	− 15″·82

So that the period of revolution was lengthened sixty-eight days, the comet arriving at perihelion on September 22, 1870. The effect of these perturbations was to alter the geocentric place at this time, no less than 14°·6 in right ascension, and 7°·6 in declination. At all three returns the comet has been a faint object, and it was particularly so in 1870, when it was, nevertheless, sufficiently observed, Prof. Julius Schmidt, profiting by his favourable position at Athens, to follow it until nearly the end of the year.

The following are the dimensions of the orbit of D'Arrest's comet in the present year, according to the elements of Leveau.

Semi-axis major ...	3·54139	Perihelion distance	1·31809
,, minor ...	2·75651	Aphelion ,, ...	5·76469
Semi-parameter ...	2·14559	Eccentricity ...	0·6278048

The period of revolution is 2434·2 days, or 6·664 years, therefore nearly identical with that of Biela's comet up to 1852. The comet passed its perihelion on May 10. It will not arrive at its least distance from the earth until October 20, but the theoretical intensity of light diminishes from the present time, indeed has been on the decrease since the middle of May; the comet may be a test object on the borders of the constellations Eridanus and Orion in September and October.

It is probable that this comet had been revolving in its present restricted orbit for many years previous to its discovery in June, 1851. It certainly does not furnish a parallel case to that of Brorsen's comet, which was detected at its first perihelion passage after the attraction of the planet Jupiter had impressed upon it the actual form of orbit in May 1842. The nearest approach of D'Arrest's comet to Jupiter during the revolution immediately preceding discovery, took place at the end of September 1849, when the distance was 1·136.

THE BINARY STAR α CENTAURI.—Mr. Ellery communicates to the Royal Astronomical Society recent measures of this, the finest and most interesting of all the revolving double-stars. Taking means the following epochs result from the Melbourne measures:—

1876·72	Position	51°·1	Distance	4″·3
1877·25	,,	69·1	,,	3·13

Mr. Maxwell Hall (NATURE, vol. xv. p. 510) supplies the following:—

1877·14 Position 64°·4 Distance 3″·3

Mr. Ellery states that the distance in 1862 was 10″, but this must be an over-estimate with the meridian instrument; a mean of seventy micrometrical measures by Mr. Eyre B. Powell at Madras, gives for 1862·2, a distance of only 6″·79, a result no doubt entitled to great confidence. The first *minimum* of distance appears to have occurred in 1856. Capt. Jacob's measures for 1856·27 giving 3″·89, and a maximum of about 10″ followed in 1868-70. It is to be hoped that the star will now be frequently measured micrometrically with all possible precision, though the brilliancy and closeness of the components may render such measures difficult. A practised computer should be able to throw some light on the real nature of the orbit from the data already in our possession, but the continued regular measurement of the star at this critical period cannot fail to be of great importance in extending our knowledge of the motion in this system. The reliable estimate of its distance resulting from the observations of Henderson, Maclear, and Moesta, vastly increases the interest attaching to it.

GEOLOGICAL NOTES

GEOLOGICAL SURVEY OF THE UNITED KINGDOM.—The gradual progress of the English and Scottish Geological Surveys has brought the members of the two corps almost within sight of each other. The line of demarcation between the two kingdoms being nearer the base of operations from Scotland, has been sooner reached from that side. From Berwick-on-Tweed southwestwards the work has been carried up from the north to the English border through the range of the Cheviot Hills, and down the valley of Liddesdale to the Solway. To prevent any subsequent risk of the lines from either side not fitting accurately, the officers on the Scottish border are at present engaged in running their boundaries into Cumberland and Northumberland for such a short distance as may be required to leave them in a position where they can be easily taken up by the advanced guard of the English Survey. When this and some few isolated areas are completed, the whole of the south of Scotland between the Tay and Clyde and the English border will have been geologically surveyed, and the Scottish staff will then be engaged on both sides of the flanks of the Highlands. Already ground has been broken, and some progress has been made on the north side of the Grampian chain. On the English side the mountainous lake district is all surveyed, while the work is so well advanced in Cumberland that it may probably be completed up to the Scottish border by the end of this year. Considerable progress has likewise recently been made on the eastern side in pushing the survey northwards in Northumberland, though a considerable tract of that country still remains unmapped towards the Cheviots and Tweed. Among the south-eastern counties the survey is advancing through Norfolk, Suffolk, and Cambridgeshire, while in the south-west some of the maps which were made in the early days of the Geological Survey are being re-surveyed and brought up to date in West Somerset and Devon.

GEOLOGICAL SURVEY OF CANADA.—The Report of this Survey for 1875-76 has just arrived. In size, general interest, and geological value, it fully equals its well-known predecessors, while in regard to maps, sections, and other illustrations, it even surpasses them. Briefly told, its story is this—The Philadelphia Exhibition absorbed much of the time and thought which would otherwise have been expended on the field-work, laboratory, and museum duties of the officers. But the director need not regret this temporary suspension of the usual operations of his staff, for there can be no doubt that the display of rocks, minerals, and fossils, made by Canada at the Centennial Exhibition, so universally admired brought the mineral resources of the dominion and the skill of its geological survey before the world with such prominence as could hardly have been attained even with the ablest maps and memoirs. Mr. Selwyn's own labours from April to November, 1875, embraced an exploration of parts of British Columbia where likewise Mr. George M. Dawson, who has lately been appointed to the Canadian Survey, has been actively employed. Prof. Macour, besides his geological work, made a careful botanical survey of the region traversed, and his detailed narrative appears in this Report. Mr. Ellis was sent into the North-west Territory to make a series of borings. Mr. Bell explored the country between James Bay and Lakes Superior and Huron; while in the eastern parts of the Dominion detailed surveys were made in the coal-fields of Nova Scotia, in New Brunswick, and in Cape Breton. Besides these explorations others were continued by Mr. Vennor in Ontario. Of these Mr. Selwyn remarks that they prove the existence in Western Quebec and Eastern Ontario of a massive red orthoclase gneiss without visible stratification, lying probably unconformably under the vast crystalline masses containing *Eozoon*. He suggests that what is called Lower Laurentian may have to be termed Middle, the fundamental red gneiss becoming the Lower.

EXCREMENTITIOUS DEPOSITS IN THE ROCKY MOUNTAINS.—A recent paper to the Philadelphia Academy by Mr. Henshaw, on the excrementitious deposits in the Rocky Mountain region, sustains Prof. Cope's view that they were made by big-eared rats, a species of *Neotoma*, probably *N. cinerea*. They consist of vegetable matter, sometimes with a bitumen-like look, and varying from this appearance to that of pill-like excrements. In a crevice of the rocks one deposit had a depth of two feet, and contained also some small twigs and "birds'" feathers. "The mass was evidently the accumulation of years, and had served as a nest. Throughout was a large amount of hard droppings from which the urine had passed, and whose nature was unmistakable. The urine, charged with a certain amount of excrementitious matters, had filtered through to form the singular deposits." Water or the urine has carried the portions it could dissolve down the faces of walls, and deposited it on shelves where no animals without wings could reach, and sometimes on the roofs of cavities. All the regions where these deposits occur are inhabited by the *Neotoma*, which is essentially a vegetarian.

NOTES

THE inaugural meeting of the Domestic Economy Congress was held at the rooms of the Society of Artists in Birmingham, on Tuesday last. In the absence of Lord Leigh the Mayor took the chair. Prof. Huxley gave a short address, in which he maintained that our so-called education does not fit a man for understanding his social duties. Public opinion was now beginning to take a different view of what education ought to be. Those who supported this Congress were among those who felt most strongly on the subject, and the influence on Government from discussions and meetings would be successful in the long run. The real business of the Congress commenced yesterday, when, amongst the papers read, were:—"Nursing," by Mrs. W. E. Gladstone; "Infant Life," by the Countess of Ebersburg; "Nursing in Connection with Education," by Miss Helen Taylor; "Elementary Instruction to Children in Physiology," by Prof. Huxley; and "Warming and Ventilation," by Capt. Galton. We give elsewhere an account of Prof. Huxley's paper, and we commend the latter part of it especially, not only to those who are interested in the teaching of physiology in schools, but to all who have given attention to that "burning question" of the day—vivisection.

THE annual session of the French Association for the Advancement of Science will take place at Havre on August 23 next, so that the members of the British Association will be able to take part in the proceedings, and a good attendance of these is anticipated. Members wishing to visit Havre are desired to write to the secretary of the French Association, 76, Rue de Rennes, Paris. Dr. Gilbert, local secretary in Havre, will engage rooms if required by previous notice. The president this year is Dr. Broca, Professor to the Faculty of Medicine, and Director of the Anthropological School of Paris. The maritime situation of Havre will supply every opportunity for a number of interesting excursions, especially for members of the British Association. The principal object of the deliberations of the society will be to determine how to secure a large and effective representation of science during the International Exhibition next year. A delegation of the French Society will be sent to the session of the British Association as was arranged last year.

ON Monday the 9th inst. the Haberdasher's Company voted 250 guineas as a donation to the building fund of the new City of London College. This institution is the outcome of the Metropolitan Evening Classes for young men, originally established at Crosby Hall, Bishopsgate Street, in 1848. Since that time it has pursued a most successful career, and now has more than 1,400 members.

THE Albert Medal of the Society of Arts has recently been presented to Sir George B. Airy, K.C.B., "for eminent services rendered to commerce by his researches in nautical astronomy and in magnetism, and by his improvements in the application of the mariner's compass to the navigation of iron ships."

WE understand that the International Meteorological Congress which was to have met at Rome in September, has been postponed to next year.

THE sad death of Dr. James Bryce furnishes another instance of the fact that though geology is in itself an invigorating pursuit it has its own share of risks. This long-known writer had left his home in Edinburgh on Tuesday morning the 10th inst. for a geological tour in the Western Highlands. He had reached as far as the Falls of Foyers on Loch Ness, whither he had undertaken to conduct a scientific excursion from Inverness a little later. On Wednesday, after leaving at the hotel a note addressed to his daughter announcing his safe arrival so far on his journey, he strolled out hammer in hand to make some further observations among the granitic crags of that neighbourhood to which he had already given some attention. He was never seen again alive. A few hours afterwards his lifeless body was found on a slope of *débris* at the foot of a shattered cliff of rock. His hammer lay a few yards higher up at the base of the crags. It is supposed that either from the concussion of his hammer or from some other cause a portion of the cliff had fallen away, crushing his temples, and killing him instantaneously. Dr. Bryce's early researches among the basalt of the north of Ireland, his work on Arran and Clydesdale, his papers on the Secondary rocks of the West Highlands, and his labours in connection with Scottish earthquakes have made his name familiar to geologists in this country. He was seventy-one years of age.

WE regret to announce the death, on the 15th instant, of another well-known geologist, Mr. John Williamson, of Scarborough, the discoverer of the celebrated Gresthorpe plant-beds. His labours in bygone years, when field-workers like him were very scarce, will long be borne in remembrance. He was born in 1784, so that he was ninety-three years of age.

THE Portuguese African explorers, Major Serpa Pinto and Capt. Brito Capello, have returned to Lisbon after visiting Paris and London (whither they had gone to obtain some necessary articles), and are to start for Loanda in the *Zaire*. According to the *Diario de Noticias*, they have got together a magnificent outfit, and M. de Abbadie, the eminent French explorer, pronounced this expedition the best and most scientifically formed that had yet gone out to Africa. He has given them the remarkable universal theodolite with inverse action, of his own invention, which he has called the "Abbas," and with which he made geodetic measurements in Abyssinia; which further he used in Algiers in observation of the transit of Venus. They also take a new apparatus invented by Father Perry for the study of terrestrial magnetism, one of the best equatorials of the Polytechnic School of Paris, a sextant of great delicacy, &c. M. Serpa Pinto has previously made extensive journeys in Africa, to Lake Nyassa and to near the Victoria Falls of the Zambesi.

WE note that a public meeting is to be held at the Mansion House to-day in aid of the "African Exploration Fund," recently commenced by the Council of the Royal Geographical Society to promote the continuous and systematic exploration of the interior of Africa.

AN engineer of St. Petersburg, M. de Kern, announces the discovery of a new metal, which he calls *Davyum*. It is found in the residues got from extraction of platinum. To isolate the element it is necessary, after having precipitated the ruthenium, to treat the mother-lye with nitrate of ammonia. A red precipitate is produced, which on calcination yields davyum. This metal is easily attackable by aqua regia, and much less by boiling sulphuric acid; potash precipitates it in a yellow state, and sulphuretted hydrogen in a brown, passing into black through desiccation. With sulphocyanide of potassium the chloride of davyum gives a red coloration. From theoretical considerations developed by M. Mendeléeff, M. de Kern considers davyum to rank between molybdenum and ruthenium. On this supposition its equivalent should be near 100; and he proposes to test this experimentally.

M. V. OBERMAYER, of Vienna, has proved by experiments that the internal friction (viscosity) of hard black pitch is subject to the same laws as fluid friction. He determined the coefficients of internal friction by three different methods:—1. Pressure of cylindrical plates; 2. Deformation of parallelepipedal plates; 3. Distortion of cylindrical plates. No gliding of the black pitch occurs on the metal plates, between which the pitch plates are cast. For soft bodies, the internal friction appears not to follow exactly the laws of fluid friction.

On July 13 the French Minister of Public Works visited the works of the 1878 Exhibition, which are in course of progression at the Champ de Mars. The number of workmen engaged in actual working was 1,137. Not less than 700 were employed at the Central Pavilion.

A singular accident has been recorded by the *Journal Officiel*. M. Gastard, of Paris, had placed a number of cartridges on a table. Some solar rays having been concentrated by an "eye" in the glass of a window, a terrific explosion took place. Similar catastrophes are more common than is generally supposed in summer, the windows of railway carriages, igniting sometimes overdried plants, or even leaves fallen on railway embankments. It is known also that fires sometimes occur in Algerian forests through drops of water suspended to the leaves and forming lenses.

It is now about a quarter of a century since the first submarine cable was laid, and the telegraph system may now be said to embrace all parts of the world, offering a certain completeness as an object of study. In an interesting *brochure* recently sent us, "Recherches sur la Loi du Mouvement Telegraphique International," M. Madsen sets the problem,—Is there a determinate relation between the international telegraphic movement and the commercial traffic, and what is the mathematical expression of this relation? He arrives, from a comparison of statistics, at a law which may be approximately expressed by the equation, $T = \frac{1}{d} [\sqrt{VN} + N_1 + N_2]$; in which T denotes the number of telegrams between two countries, d the distance between their commercial "centres of gravity," V the value (in pounds sterling) of their commerce with each other, N the tonnage of the ships sailing between them, N_1 the tonnage of ships of the one country (L), but sailing between the other L_1 and other countries; N_2 the tonnage of ships belonging to L_1, but sailing between L and other countries. The law has various applications, some of which M. Madsen points out.

An ingenious new registering thermometer devised by M. Hervé Mangon, is described in *La Nature*. A long and fine capillary tube bent on itself and containing mercury, is supported in an iron frame; it passes through the stopper of a bell jar and terminates with a fine point in a mercury dish placed in one scale of a balance; the other scale contains a vessel of glycerine communicating by glass and india-rubber tubing with another glycerine vessel on the same level in an adjoining frame. When, on rise of temperature, mercury is forced out into the vessel, the balance is depressed on one side and an electric contact made, affecting an electro-magnet in the registering apparatus, which is composed of M. Redier's double wheel-work with differential train (which we must not stay to describe). When the depression referred to has occurred a suspended float in the second glycerine vessel descends, and raises the glycerine in the first, increasing the weight in that scale. The curve obtained (from a pencil on moving paper) is of zigzag form, the wheel-work being in constant motion, now to the right, now to the left.

M. Bertrand having lately made an appeal to possessors of letters from Gauss, with a view to publishing the complete works of the eminent geometer, the grand-daughter of Laplace has responded with five interesting letters. One of them, written in 1807, presents Gauss at the outset of his career, deprived of his fortune and threatened with extreme measures if he did not pay 2,000 francs as a war contribution to the French army occupying Göttingen. In his distress he applies to Laplace, thinking his intervention might prove effectual. At the same time he describes the equally sad position of his colleague Harding. Laplace, unable to influence Napoleon, pays the 2,000 francs, and begs his friend not to disquiet himself further. Meanwhile Gauss obtains the sum from Olber, and now he is in a position to succour Harding. Two years later he paid Laplace back the sum he had borrowed.

An analysis has been lately made by Dr. Alder Wright (*Chemical News*) of two samples of wine, "ruby" and "white," from the Auldana vineyards, South Australia, with a view to determine the proportion of iron as a natural constituent. The average amount obtained by one method was, in both cases, 0·00130, by another method 0·00146, the iron being calculated as FeO (in the former case it is thought there may have been a little loss through incineration, &c.). Two circumstances are noted; first, that contact of the grape-juice with ironwork of any kind is studiously avoided in the manufacture; secondly, that the soil of the Auldana vineyard is exceptionally ferruginous, and as iron is taken up from the soil by vegetation, this seems a probable cause for the occurrence of iron in the finished wine. The identical character of the values, too (the wines being of different vintages) makes it improbable that the source of the iron is outside the grape-juice.

An interesting experiment with regard to the speed of pigeon flight was made the other day. A carrier pigeon having been let off in Dover simultaneously with the starting of the express for London, reached the latter place twenty minutes in advance of the train. This corresponds tc a distance-difference of eighteen miles.

We observe that the recent enlightened decision by the Senate of London University with regard to admission of women to degrees in medicine meets with a good deal of hostile criticism from some of our leading medical contemporaries. We feel sure that no Trades' Union spirit will be allowed to prejudice what must generally be recognised as a step in the right direction.

At a meeting of members of the Birmingham Natural History and Microscopical Society, held at the Midland Institute on July 13, a committee was appointed to make arrangements for another marine excursion, somewhat similar to the one made by this society in 1873 to Teignmouth, but this time it is to be to Arran and the Western Islands of Scotland. The dredging will be carried on in Lamlash and Brodick Bays. At the same time excursions will be made on land to Arran and the adjacent localities, all of which, we believe, yield a number of rare specimens, both botanical and geological; so that the members of each section no doubt will find this an enjoyable and an interesting excursion. It will take place in the first week in September.

A wonderful white aquamarine has been found in Perthshire which, when cut, has produced one of the most brilliant gems ever seen. It is said by many competent judges to be equal to her Majesty's celebrated Koh-i-noor, its refraction being very great both by day and night. It is of a pure pellucid liquid white, and is known as the Scotch Koh-i-noor. Its hardness is 8·0, and specific gravity 2·76. Mr. Bryce M. Wright, F.R.G.S., is its possessor.

The additions to the Zoological Society's Gardens during the past week include a Sambur Deer (*Cervus aristotelis*), a Spotted Porcine Deer (*Cervus minor*) from India, presented by H.R.H. the Prince of Wales, K.G.; a Slow Loris (*Nycticebus tardigradus*) from Malacca, a Prehensile-tailed Paradoxure (*Paradoxurus prehensilis*) from Burmah, presented by Mr. W. H. Richardson; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Mrs. Shand; a Red Howler (*Mycetes seniculus*) from New Granada, four Axis Deer (*Cervus axis*) from India, a Merian's Opossum (*Didelphys dorsigera*) from South America, deposited; two Striped Hyænas (*Hyæna striata*), born in the Gardens, a Black-necked Swan (*Cygnus nigricollis*), hatched in the Gardens.

THE STÄLLDALEN METEORITE[1]

IN the Scandinavian North, so extraordinarily rich in mines and quarries, there have been found during the last few years a number of new minerals, by which many a mine and even many an inconsiderable opening scarce known in its own parish has become world-famous in mineralogical literature. Several of these *finds* are of great interest in a systematic aspect—for instance, the discovery of *barytite*, a new, exceedingly basic variety of felspar containing baryta; of *ganomalite*, the first natural silicate of lead which has been discovered; of *ekdemite*, a new mineral containing antimonic acid, from the mines of Langban; and of *homilite*, a new, beautifully crystallised silicate of boron, containing water, from Brevig. Others again give us a highly unexpected insight into the nature of the chemical forces which are in activity in the interior of the earth—for instance, the Wermland minerals, *manganosite*, or protoxide of manganese, and *pyrokroite*, or hydrated protoxide of manganese, which afford evidence of a powerful reducing action. The latter mineral has during last year been found at a new locality—the mines of Nordmark.

However important these newly-discovered minerals may be, they do not awaken so keen an interest as the stones which from time to time fall from the heavens, and afford us specimens of the matter to be found in spaces so remote that rays of light require thousands of years to reach them. A new and highly instructive contribution to our knowledge of meteorites has been obtained in Sweden through the fall of the meteorite, which took place at Ställdalen, near Nya Kopparberg, in Orebro län, on June 28, 1876, at 11·50 A.M., from a fireball which was visible over a large part of middle Sweden. In the neighbourhood of Stockholm the meteor appeared as an indistinctly-defined fireball, followed by a long streak of fire. The ball was first visible below the zenith in the north-east or north-north-east, and went from hence towards the horizon in the west, where it generally appeared to fall in the immediate neighbourhood of the spectator, sometimes with, sometimes without, the throwing out of sparks. In the town of Gefle the fire-red ball, followed by a streak of the same colour, was seen moving from north-east to south-west. At the neighbouring promontory, Harnäs, it was first seen of the size of a large star, speedily increasing, however, leaving a long streak of fire behind it, and finally disappearing without noise, falling, according to the supposition of the spectator, behind some neighbouring buildings.

At Malmköping the meteor appeared to proceed from the northern heavens towards the west, leaving behind it a fine white streak, which was distinguishable for two minutes. At a height of 25° above the horizon it disappeared without falling asunder. At Linköping the nucleus of the meteor was pear-shaped, of blinding whiteness, followed by a streak of fire which was strongly luminous notwithstanding the clear bright sunshine, and about eight times longer than the nucleus. It was first observed pretty high up in the north-east, but afterwards sank to a height of 10° above the horizon in the west, where it broke up without noise into a number of star-sparks. In Skara the meteor, followed by a beautifully luminous streak of fire, appeared to fall asunder, throwing out sparks strongly at the same time, after having gone from east to west with an apparent diameter of half that of the moon. In Hedemora two fire-balls were seen, one close behind the other, falling from the zenith towards the west, leaving behind them a light grey streak. A minute after the meteor passed from the field of view, a loud explosion was heard, which is also mentioned in reports from the town of Falun and from Gustafs and Stora Tuna parishes. In Mora no explosion was heard, but here the meteor, which left in its path a stream of fire of a deep violet colour, was seen to fall asunder in the south-south-east, with a strongly luminous fire rain, the fire drops of which, however, were extinguished before they reached the horizon. In Karlskoga a fireball of a blinding clear reddish white lustre was seen high up in the zenith. Hence it sank towards the north-north-west to a height of 30°, and afterwards parted into three or four smaller pieces, which speedily went out and resembled the stars which fall from a rocket. The meteor left behind it a white smoke, which in the calm air remained in the direction of the fall about a minute, and afterwards dispersed. In the neighbourhood of Karlstad, the meteor was thought to fall in the north east. It was compared to a falling star rocket. It was very bright, with a white nucleus, having fire-red edges, and passing when bursting asunder to a blinding white, the separate pieces being clearly visible. Its apparent size was compared to that of the full moon, and after its disappearance a white streak remained for some seconds in the sky. In Hoböl parish in Dalsland there was seen in the sky a pointed fire-ball, resembling in form a soda-water flask, at first pretty high in the heavens, afterwards approaching the earth, dividing into two parts and disappearing without any detonation after the lapse of half a minute. At Lysekil the meteor appeared to fall perpendicularly in the north-west, and spring asunder without any noise some few feet above the surface of the water. According to a statement in the newspapers the meteor in question was simultaneously seen at Christiania. In Denmark and Finland it was not visible.

From a careful and critical examination of these statements, and many others which have been collected, it appears that the meteor in question, possibly with the neighbourhood of γ Cephei as radiation point, proceeded in a somewhat oblique direction to the place where the stones fell on the meteor bursting asunder. If with a point 40 kilometres south of Ställdalen as a centre, a circle be described through Christiania, the westernmost place where the phenomenon was observed, its circumference intersects Orust in the south, the neighbourhood of Stockholm in the east, and Gefle in the north-east, and includes all the places where the meteor was visible. At Stockholm, Hedemora, Karlskoga, and Lysekil, the meteor is said to have been visible first in the north-east, somewhat below the zenith, and if the direction is noted where it disappeared in the neighbourhood of the horizon, this direction in general corresponds very well with the direction from the place of observation to the place of fall. The meteor thus went under the horizon or disappeared in its neighbourhood at Stockholm to west, at Gefle to south-west, at Mora to south-south-east, at Lysekil to north, at Malmköping to north-west, and so on.

The meteor thus reached the end of its short luminous path in the region where the fall took place. It became luminous at a height which cannot, after making allowance for errors of observation, he reckoned at less than 300 to 400 kilometres, but was probably greater. At this height the atmosphere, notwithstanding its extreme tenuity, is capable by its resistance of heating red hot a body moving with *cosmic* speed, as of 75 kilometres per second, and if the composition of the atmosphere at this height be the same as at the surface of the earth the meteor will meet with sufficient oxygen to maintain a lively combustion of the combustible matters which enter into the composition of the meteor. It appears to me that we have here an explanation of the considerable height in the atmosphere at which meteors first become luminous—an explanation which is so much the more probable as we now not only know a number of carboniferous meteorites, but also by the meteorite fall at Hessle, in Upland, have distinct proof that the common meteorites may be accompanied, and perhaps are generally accompanied, by an easily combustible carboniferous dust. Only through such a supposition can we obtain an explanation of the large size of these meteors when compared with the stones which fall, as well as of their strong illuminating power, which clearly shows that the light arises from the glowing of solid masses, and not merely from the compressed and heated gases which the meteor has collected before it.

The statements regarding the size of the Ställdalen meteor are very various. The most probable are those which give it a diameter of six minutes, which, supposing the distance to be 250 kilometres, would give the fireball a diameter of 436 metres, or nearly 1,500 feet. In comparison with this size the stones that have fallen are surprisingly small, which yields a further support to the supposition that the main mass of the meteor consisted of substances which had already high up in the air been dissipated in the form of gas or undergone combustion. In the case of the Ställdalen meteor there is also the exceedingly remarkable circumstance that the fireball was not visible in the region where the path of the meteor struck the earth and where the meteorites fell, although this place lay nearly in the centre of the area where the meteor was visible as a luminous fireball, and although the sky here too was clear and cloudless with the exception of the little dark cloud which the meteor collected before it in its path through the air. It was probably this cloud which prevented it from being seen in the region which lay in the direction of the fall. Although no fireball was seen here, loud detonations were heard and some light streaks of cloud were visible in the zenith, from which, according to some, faint flashes of fire

[1] Abstract of an Address by Prof. Nordenskjöld at the Anniversary of the Royal Swedish Academy of Sciences.

resembling lightning were seen darting. Whistling, rumbling, and rattling noises were also heard. The sound was thought, for the most part, to come from the west or south-west. It was not heard in Karlskoga, which lies to the south, but far to the north and north-west. At Falun it was supposed that a fall of rock had taken place in a mine, and at Grandgrufvan, at Ludvika, the sound was heard as of a peal of thunder at a depth of sixty metres underground. At other places a dynamite magazine was thought to have exploded, or it was taken for a loud clap of thunder.

In the neighbourhood of a workman who was cutting trees in a wood several branches of a tree were broken off by a stone weighing nearly a kilogram, in a way which clearly showed no great falling velocity, which was further confirmed by the stone making a hole in the ground only a decimetre in depth. Another person saw a stone fall close beside him, and immediately took it up. It was not at all warm. A girl saw a stone weighing two kilograms fall to the ground "so that the earth smoked." Several fell in the Lake Björken or were picked up in the neighbourhood soon after. One weighing 8¼ kilograms fell in a rye-field. In falling it had gone in two pieces and made an eight-inch deep hole in the cultivated soil. The largest stone weighed 12¼ kilograms.

The number of the stones that have been found, however, amounts only to eleven, with a total weight of thirty-four kilograms. They were scattered within an oval two kilometres broad, whose larger axis had a length of eight kilometres. The largest stone was found in the south-west end of the oval, in a meadow surrounded by wood. It is probable that larger stones have fallen farther into the wood, and thus escaped observation. The stones are of very irregular form, and on their surface are full of the depressions peculiar to meteorites. On the surface they are, as usual, covered with a blackish fused crust of very variable thickness, being so thick on some of the fractured surfaces as to completely conceal the colour and inequalities of the main mass, and on other similar surfaces so thin that the colour and crystalline structure of the main mass may be clearly distinguished. Sometimes the crust is completely wanting, so that the surface of the stone, with the exception of an inconsiderable blackening, resembles a fresh fracture. The stones are thus fragments which have been formed at different times, and exposed for different periods to the action of the glowing envelope. The largest stones are covered in many directions with black friction surfaces which are more clearly marked on these meteorites than on any I know. These too have probably been formed in our atmosphere, and show that with the great pressure produced by the resistance of the air, cracks have been formed in the meteorite along which its different parts before springing asunder rubbed against each other during the rotation of the irregularly-formed mass, whereby the uneven surfaces have been smoothened, and coloured black by the heat developed during friction, the projecting metallic particles flattened, &c. On breaking in pieces the meteorites in question, they are found to consist of a coarse breccia-like mixture of grey and of nearly black portions, little differing from each other in chemical composition. It is remarkable that the grey mass when heated becomes dark, and thereby in appearance quite like the black, which appears to show that some of the breccia-like pieces found in the stones had been heated, while this does not appear to have been the case with the other part. Different pieces of the Ställdalen meteorites thus appear to have been exposed to the action of very different temperatures before they were united into the mass, hard, tough, and difficult to break up, which formed the meteorite.

The stones that fell at Ställdalen have been carefully analysed by Mr. G. Lindström, assistant in the mineralogical department of the Riks Museum, who found them to consist of nickel-iron; a silicate decomposed by acids, chiefly olivine; a silicate indecomposable by acids, probably bronzite; magnetic pyrites, and inconsiderable quantities of phosphide of nickel-iron; of a phosphate, and of chloride of iron. The first-named substance, a metallic alloy of ninety per cent. iron and ten per cent. nickel, is not known of terrestrial origin, but distinguishes most meteorites, and makes it possible to separate with certainty the meteorites which have fallen at Ställdalen from all other minerals occurring in the quarter. The two other main constituents again, olivine and bronzite, are also wanting in our granites, gneisses, and common slaty rocks, but are found commonly entering into the composition of a number of rocks which by most of the geologists and mineralogists of the present day are considered to be of plutonic origin. Many circumstances, however, indicate that these rocks, which in remarkably regular layers cover extensive regions of the earth's surface, *often, but not always*, consist of stratified tuff-like formations which during the enormous duration of geological periods have assumed a crystalline structure. The resemblance between them and various constituent parts of the meteorites is so striking that the question must be seriously and impartially discussed whether a part of the plutonic rocks are not of cosmic origin. By this I mean that it gradually fell to the earth even after its surface formed an abode for animals and plants, and that under favourable circumstances it collected so as to form proper stratified so-called plutonic rocks, in which, through subsequent chemical changes, so great a development of heat has sometimes taken place that volcanic and plutonic incandescent craters have arisen in the interior of the earth.

Many observed facts may be quoted in support of this view, if it for the present appears very strange on account of the great changes it would bring about in the prevailing ideas of the history of the formation of the heavenly body which we inhabit. We have perhaps here the true solution of the many disputed questions raised by the discovery of meteoric iron at Ovifak, in Greenland, a simple explanation of the abundant occurrence of magnesia in certain geological formations, and of many other geological phenomena difficult of explanation according to theories now prevalent.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Mr. W. N. Shaw, B.A., Emmanuel College, 16th Wrangler, 1876, and 1st Class Natural Sciences Tripos (Distinguished in Physics), 1876, has been elected to a fellowship in his College.

LONDON.—The following have passed the recent examination for the degree of Doctor of Science in the branches specified:—

Branch IV.—Inorganic Chemistry.—J. M. H. Munro, Royal College of Science, Dublin.

Branch VI.—Electricity (treated experimentally).—O. J. Lodge, University College.

Branch VIII.—Physical Optics, Heat, Acoustics (treated mathematically).—J. F. Main, Trinity College, Cambridge.

Branch X.—Comparative Anatomy.—A. M. Marshall, B.A., St. John's, Cambridge, and St. Bartholomew's Hospital.

Branch XIV.—Geology.—W. Saise, Royal School of Mines.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, June 20.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Messrs. George Alexander Gibson, Henry P. Gurney, John Higson, and Francis Stevenson, were elected fellows of the Society.—The following papers were read:—On a hitherto unnoticed circumstance affecting the piling up of volcanic cones, by R. Mallet, F.R.S.—The steppes of Southern Russia, by Thomas Belt, F.G.S.—The glacial period, by J. F. Campbell, F.G.S.—The action of coast-ice on an oscillating area, by Prof. John Milne, F.G.S., of the Imperial College of Engineering, Tokio, Japan.—On points of similarity between zeolitic and siliceous incrustations of recent formation by thermal springs and those observed in amygdaloid and other altered volcanic rocks, by Prof. A. Daubrée, F.M.G.S.—On the cretaceous Dentaliadæ, by J. S. Gardner, F.G.S.—On a number of new sections around the estuary of the Dee which exhibit phenomena having an important bearing on the origin of boulder-clay and the sequence of glacial events, by D. Mackintosh, F.G.S.—Discovery of silurian beds in Teesdale, by W. Gunn, F.G.S., and C. T. Clough, F.G.S., of H.M. Geological Survey.—On the superficial geology of British Columbia, by George Mercer Dawson, F.G.S., Assoc. R.S.M., of the Geological Survey of Canada.—The exploration of the ossiferous deposit at Windy Knoll, Castleton, Derbyshire, by Rooke Pennington, F.G.S., and Prof. W. Boyd Dawkins, by Prof. W. Boyd Dawkins, F.R.S.—Description of the fossil organic remains from Bendigo, by M. Carl August Zachariæ, communicated by the president.—Notes on some recent discoveries of copper ore in Nova Scotia, by Edwin Gilpin, F.G.S.—Glacial drift in the North-eastern Carpathians, by R. L. Jack, F.G.S., and John Horne, F.G.S., of the Geological Survey of

Scotland.—On terminal curvature in the south-western counties, by W. A. E. Ussher, F.G.S., of H.M. Geological Survey.—On the chronological classification of the granitic rocks of Ireland, by G. H. Kinahan, M.R.I.A., communicated by Prof. Ramsay, F.R.S.—The Cambrian rocks of South-east Ireland, by G. H. Kinahan, M.R.I.A., communicated by Prof. Ramsay, F.R.S.

PHILADELPHIA

Academy of Natural Sciences.—A valuable list of the fresh-water fishes of Northern Indiana, by Dr. D. S. Jordan, is published in the *Proceedings* for 1877, with remarks on many forms of novelty or interest. This is followed by a critical account of the genera of North American fresh-water fishes, by Dr. Jordan and Mr. C. H. Gilbert. One list gives the whole of the genera in the order of their original description, with full references.

VIENNA

Imperial Academy of Sciences, April 19.—Contributions to the cosmic theory of meteorites, I. Proof of identical meteorite paths, by M. Niessl. Two detonating meteorites, on April 10, 1874, in Bohemia, and April 9, 1876, in Hungary, had apparently the same point of emergence, and observations gave for both a velocity corresponding to a hyperbolic path.—On the action of alcoholic caustic potash solution on ether-like nitro-bodies, by MM. Hess and Schwab.—On the application of the microscope to quantitative determinations, by M. Jonstorff.—On the history of creation of our planetary system, &c., by M. Sedlitschka.—On some remarkable phenomena in Geissler tubes (fourth paper), by MM. Reitlinger and Urbanitzky. Seeking the causes and laws of the repulsions and attractions, they experimented with various gases rarefied in Wüllner's cylindrical tubes (without capillary part), noting simultaneously with a multiplier the changes in the induced current. They were led to the conviction that it is a case of reciprocal action between accumulation of static electricity on the approximated conductors and current electricity in the tubes, and that the chemical character of the gases has a great influence on the apparent progress of the phenomenon.

April 26.—On iron cyanide compounds, by M. Skraup. This relates to superferrid-cyanide of potassium.—On a new derivative of sulpho-urea, sulphydantoinic acid, by M. Maly.—Theory of circular polarisation, by M. V. Lang.—On *Phymatocarcinus speciosus*, Reuss, by M. Bittner.—A geological profile from Osmanieh am-Arcer, on the Sveti Nikola-Balkan, to Ak-Palanka, on the Nisava, by M. Toula.

PARIS

Academy of Sciences, July 9.—M. Peligot in the chair.—The following papers were read:—On the alcoholate of chloral, by M. Wurtz. The dehydration of crystallised oxalate of potash occurs in vapour of the alcoholate as easily as in air; not so in vapour of hydrate of chloral (proving that the latter contains water).—Reply to M. Roudaire's last note on the Algerian inland sea, by M. Naudin. He insists specially on the erosive force the current would have both in its primary state and in time of flooding. The troubled water of the coast, too, would enter and deposit much sediment.—On electric transmission through the ground by means of trees, by M. Du Moncel. Trees are all, more or less, conductors, their conductivity depending on the quantity of liquids in them. The roots act as electrodes. The resistance of a tree, commencing with its leaves, and supposing contact only with a few of them, varies from 200,000 to 400,000 kilometres of telegraph wire (in round numbers). That of the trunk, at a height of 7 to 8 m. hardly exceeds, in strong trees, 3,000 kil. in connection with the ground, and varies from 2,000 to 7,000 kil. between small metallic electrodes. Thus, contact of telegraph wires with leaves need not give much anxiety. The resistance of ordinary houses being about sixteen to twenty times that of trees, the latter, if not under the former in height, may be considered a protection, but as rain usually falls in thunderstorms and diminishes the difference of conductivity between trees and house, a protective effect of trees may only lie in their superior height.—Treatment by sulphocarbonates of vines of Orleans and Saint Jean-le-Blanc, by M. Gueyraud.—On the quasi-circular movements of a point subject to the attraction of a fixed centre, by M. Boussinesq.—On the diamagnetism of condensed hydrogen, by M. Blondlot. Palladium charged with hydrogen M. Blondlot finds to be *less* magnetic than palladium uncharged; which accords with the facts that palladium is weakly magnetic and hydrogen diamagnetic. Graham's opposite experience is thought due to some disturbing cause, probably impurity of the acid used in charging the palladium by means of electrolysis; the least trace of a ferruginous body gives a deposit on the palladium, which would explain Graham's results.—Photometric researches on coloured flames, by M. Gouy. If the quantity of salt introduced into the flame be doubled, the increase of brightness of each line is at most equal to what would be produced by doubling the thickness of the flame, and it is nearly always inferior.—On a new metal, *davyum*, by M. Kern (see p. 236).—On the oxidability of sulphide of manganese, by MM. De Clermont and Guiot.—On a new general method of synthesis of hydrocarbons, acetones, &c. Third note by MM. Friedel and Crafts.—Action of bromine on pyrotartaric acid; second memoir by M. Bourgoin.—On the determination of carbonic acid in blood serum, by M. Fredericq.—Researches on bitter almonds, by M. Portes. Young bitter almonds contain amygdaline; they have always a different composition from sweet almonds; the embryo alone contains emulsine, and it appears pretty late; the amygdaline is localised in the teguments of the seed; its origin is still unknown; by degrees it quits the teguments and penetrates into the cotyledons by the radicle.—On the nickelised iron of Santa Cattarina, by M. Lunay.—On some physiological facts observed in Drosera, by M. Ziegler. It has been observed that Drosera is sensible to the physical action of salts of quinine after excessive indirect animal contact. Many other bodies have this property, and among them is *urea*. Like quinine, urea does not cause any action in normal droseras, but on being united with certain other bodies, it produces contraction (*e.g.*, granules made of a mixture of urea and iron with white wax give contraction; but granules of wax with urea alone, or with iron alone, have no effect).—Comparative study of cupric preparations introduced into the stomach and the blood, by MM. Feltz and Ritter. Insoluble albuminate of copper ingested into the stomach in considerable quantity has hardly any effect; soluble albuminate causes disorders at least as grave as the ammoniacal sulphate in distilled water. Sulphate of copper dissolved in syrupy glycerine is much more poisonous than in aqueous glycerine.—Treatment of rheumatism, gout, and various nervous states, with salicylic acid and its derivatives, by M. Sée. It seems beneficial in some cases.—On testing for salicylic acid, by M. Marty.—On external use of salicylic acid, by M. Grellot.—The advantages of immediate and early trepanations, by M. Gross.

CONTENTS

THURSDAY, JULY 26, 1877

A MANCHESTER UNIVERSITY

THE movement of the authorities of Owens College, represented in their memorial to the Duke of Richmond on Friday last, is certainly one of the healthiest important educational advances of recent years. It is an outcome of an impatience of pure examination and a revived belief in the educative influences of association of young men with each other and with masters of the subjects in which they happen to be interested, which have been gradually but surely growing up among educationalists.

Like a few hundreds of other institutions, including Oxford, Cambridge, and the Scotch Universities, Owens College is affiliated to the University of London. Twenty years ago this meant that only students of these institutions could present themselves for London degrees. But their members multiplied—and every weaker member added to the list of affiliated colleges supplied a new reason for still farther widening the bounds of the University. It was natural that in time the outsiders educated at home, with private tutors, or in unrecognised and unaffiliated institutions should knock at the doors of the university and demand admission. After they did, it was found in the end impossible to refuse them. Since that date the University examines everybody, wherever he has been educated, and its influence is to assimilate what one may call organised institutions of individuality and character to the unorganised or semi-organised types of the crammer's school or the private student of cram books. For the school or the private student it has been and still is of the utmost value. For higher colleges it is a great centralisation, objectionable only because it is not complete, not having really swallowed up the Scotch and Irish universities as well as Oxford and Cambridge. Mr. Lowe's ideal doubtless is that the most intelligent, impartial, perhaps bloodless of examiners, selected from all the world, should prescribe the subjects of examination, and should thereby dictate from the standpoint of the highest human omniscience, the courses of all teaching institutions, and should, like Minos, Æacus, and Rhadamanthus, decide in final award the character and place in the universe alike of teacher and of taught. This ideal has been realised in the Chinese empire, and many excellent arguments can be stated in its favour. It is inadequately realised in this country, because all incorporated universities have been left practically outside of the scheme. Owens College is the first of the non-incorporated actual or possible universities which asks also to be released.

It is possible to offer the petitioners something they do not seek. Owens and other residence colleges object to be controlled by a mere examining board. But there are Universities like Oxford and Cambridge which are not mere examining boards, which have resident students, where the examiners are in frequent and living contact with the students, from whom, indeed, they are often removed only by a few additional years. Five years before, the men who preside over the triposes may have them selves sat for examination. Might not Oxford or Cambridge supply a less narrow and technical examination than London? Could these universities not affiliate Owens College to themselves in some more living bond than has now become possible elsewhere?

There is an excellent and all but final answer. Oxford was asked to do it for King's College, London, and after mature deliberation it deliberately declined. Probably it could not see its way to work out this more living association. There is one kind practicable—such as Oxford and Cambridge practise between themselves. A man may count a certain number of terms at Cambridge for his degree at Oxford, just as he may count so many sessions at Edinburgh for his degree at Glasgow. There is another kind conceivable. The teachers of both places may be associated with each other, with or without outside examiners, for the examination of the students of both, and the programmes of examination, and to some extent of teaching, may thus be settled in common. Oxford was not willing to associate itself with King's College in either of these ways, and there is no reason to believe that it would care so to associate itself with Owens College or any other institution. Such an association would imply an equality which the older universities can scarcely be asked to admit; and the second mode of association would institute a sort of outside interference with them which they would never allow. The simplest and most satisfactory university is self-contained, teaching and examining its own men under the stimulus of rivalry and public criticism, and with the help, perhaps, of outside examiners. Oxford and Cambridge see no reason why they should descend from their own secure and satisfactory position and tempt the dangers of confederation.

It remains to ask what good it can and what harm it might do to grant the prayer of the petitioners. The first question need scarcely be answered. It is an obvious advantage to every district to have a great centre of high thinking and noble living planted in its midst. But there is an equally obvious disadvantage in the undue multiplication of universities. There may be serious objections, as Prof. Huxley puts it, to any official system of branding our young herrings with B.A. or M.A. But so long as we keep to the system of branding we ought not to be too free with our brands. There ought not to be too many, and there are a good many in the United Kingdom with no means of telling which is a good brand and which is a bad one. There is no doubt that, as far as it goes, the objection is sound, and that we ought not to have too many degree-granting bodies. The question is whether we have—whether the precise limit at which we ought to stop has been reached—whether the new claimant is not as fully entitled as some of the old-established institutions to an independent status and existence. In England we have very few branding bodies, and every guarantee is offered by the Manchester authorities that their brand will be of the very first quality. They propose to have outside assessors to help them to see to it; the one thing they ask is that having the responsibility of teaching they shall have an equal share in directing the examinations. It seems a reasonable and modest request.

THE KINETIC THEORY OF GASES

A Treatise on the Kinetic Theory of Gases. By Henry William Watson, M.A., formerly Fellow of Trinity College, Cambridge. (Oxford: Clarendon Press, 1876.)

THIS book does not profess to treat of all that has been written about the kinetic theory of gases. It discusses the ultimate average condition of a material system, consisting of a very great number of parts in motion within a confined space, and it follows for the most part the methods of investigation given by Boltzmann. The discussion is arranged in the form of thirteen propositions, in which the different cases are considered in the order of their complexity. In the earlier propositions the moving bodies are supposed to be rigid-elastic spheres acting on each other only by impact, afterwards external forces are introduced, and finally the bodies are supposed to be material systems, the parts of which are held together by any system of forces consistent with the principle of the conservation of energy.

The ultimate average condition of such a system is investigated in a very satisfactory manner in this book. No part of mathematical science requires more careful handling than that which treats of probabilities and averages. Mathematicians, whose competence to deal with other questions is undoubted, have fallen into errors in treating of probabilities, and even the validity of certain methods of proof is still apparently an open question.

Besides this, some of the consequences to which these theorems lead us are so startling that we are not prepared to admit them without an unanswerable proof, and of the investigations already given, some are so short and incomplete, and others so long and roundabout, that it requires no ordinary exercise both of penetration and of patience to find out whether they are proofs at all. Mr. Watson has conferred a great benefit on the students of the kinetic theory by placing before them in a series of distinct propositions, none of them too long for the mind to grasp, all the necessary steps leading to the result, and none of the superfluous evolutions in which the mental energy of the student is so often dissipated. The book, as we have said before, is confined to the investigation of the ultimate average condition of the system, and does not discuss the processes of diffusion by which that ultimate condition is attained, such as the inter-diffusion of gases, the diffusion of momentum by viscosity, and the diffusion of energy by thermal conduction. These have been recently treated in a larger work,[1] to which we may have occasion to refer.

There are two very different methods of defining and investigating the state of a complex material system. According to the strict dynamical method the particles of the system are defined in any sufficient manner, as, for instance, by their co-ordinates at a given epoch, and the position of any particle at any other time is then defined by its co-ordinates, expressed as functions of the time, the form of these functions being different from particle to particle, and not necessarily continuous in passing from one particle to another which was contiguous to it in the initial configuration.

According to this method our analysis enables us to trace every particle throughout its whole course, and therefore we can apply the laws of motion in all their strictness.

[1] "Die kinetische Theorie der Gase in elementarer Darstellung, mit mathematischen Zusätzen. Von Dr. Oskar Emil Meyer, Professor de Physik an der Universität Breslau. (Breslau, 1877.)

The application of this method to systems consisting of large numbers of bodies is out of the question. We therefore make use of another method which we may call the statistical method, on account of its analogy with the methods employed in dealing with the fluctuations of a large population.

We divide the bodies of the system into groups according to their position, their velocity, or any other property belonging to them, and we fix our attention not on the bodies themselves, but on the *number* belonging at any instant to one particular group. This number is, of course, subject to change on account of bodies entering or leaving the group, and we have therefore to study the conditions under which bodies enter or leave the group, and in so doing we must follow the course of the bodies according to the dynamical method. But as soon as the process is over, when the body has fairly entered the group or left it, we withdraw our attention from the body, and if it should come before us again we treat it as a new body, just as the turnstile at an exhibition counts the visitors who enter without respect to what they have done or are going to do, or whether they have passed through the turnstile before.

The first mode of grouping the bodies of the system is to class those together which, at a given time, are in a given region of space. This is called grouping according to configuration, and what we learn from it is the distribution of the positions or co-ordinates of the bodies in space.

The second mode of grouping is that according to velocity. The best way to understand this is to suppose a diagram of velocities constructed by drawing from a given point as origin a system of vectors representing in direction and magnitude the velocities of the different bodies. The extremities of these vectors are called the velocity-points of the bodies to which they correspond, and by grouping the bodies according to the regions of the diagram in which their velocity-points lie, we learn from the numbers in the groups the distribution of velocities among the bodies.

In like manner we may form groups defined in any other way, as, for instance, those pairs of bodies whose distance from one another lies between given limits, and by confining within sufficiently narrow limits the values of all the properties of the bodies which form the group, we may consider all the bodies belonging to the group as practically in the same state. Whether at a given instant any body actually belongs to the group is, of course, another question.

The object of study in the statistical method is the probable number of bodies in each group. We may get rid of the idea of probability by supposing the system to continue under the same conditions for a very long time. During this time many bodies will enter the group, stay in it for a certain time, and then leave it. If we add together the times of residence within the group of all these bodies, and divide the sum by the whole time of observation, we obtain a numerical quantity which we may call the average number of bodies in the group. The longer the time of observation, the nearer does this number approach to what we have called the probable number of bodies in the group.

The average number of bodies in a group depends on the limits which define the group, being, of course, greater when these limits are wide than when they are narrow. But it also depends on the character of the group, that is to say, the particular set of mean values of the conditions which entitle a body to be ranked in the group.

It appears from the investigation that if ϕ be any property of a body, such that if ϕ_1 and ϕ_2 are its values or two bodies before an encounter, and Φ_1 and Φ_2 its values after the encounter, and if under all circumstances $\phi_1 + \phi_2 = \Phi_1 + \Phi_2$, and if the number of bodies in each group varies as $e^{-h\phi}$, then the distribution of the bodies in the groups will not be altered by the encounters between the bodies.

Now if we make ϕ equal to the sum of the kinetic and the potential energy of each body, the quantity $\phi_1 + \phi_2$ is not altered, either by an encounter between the two bodies or by external forces acting on them; so that a distribution according to the values of the function $e^{-h\phi}$ will satisfy the condition of permanence.

The most general case is that given in the seventh proposition. The bodies are no longer supposed to be smooth rigid-elastic spheres, but molecules, that is to say, material systems consisting of any number of parts acting on each other with forces of any kind consistent with the principle of the conservation of energy. The molecules of any one kind are supposed to have m degrees of freedom, this number being, in general, different in different kinds.

It is also assumed in the enunciation that all the forces in the system are either forces tending to fixed centres and functions of the distances from these centres, or else forces acting between the parts of the same molecule, thus excluding forces acting between one molecule and another except during the encounter of two molecules. This restriction, however, does not appear necessary, and indeed it is easy to remove it.

For the result of the proposition is to prove that if we define the group (A) of molecules as consisting of those whose generalised co-ordinates (q) are between certain limits (q and $q + dq$), and whose generalised momenta (p) are between certain other limits (p and $p + dp$), then the average number of molecules in the group is—

$$A e^{-h(\chi + T)} dp_1 \ldots dp_m \, dq_1 \ldots dq_m,$$

where A is a constant which is the same for all groups of molecules of the same kind, but is different for different kinds of molecules in the same mixture, but h is the same for all kinds of molecules. χ is the potential energy, and T the kinetic energy of a molecule when in the state (A), and $dp_1 \ldots dp_m$ are the differentials of the components of momentum, and $dq_1 \ldots dq_n$ the differentials of the co-ordinates. The continued product of these differentials specifies the extent of the group.

By integrating this expression with respect to any one of the variables, we may ascertain the average number of molecules in a larger group, in which that variable does not form a ground of subdivision. For instance, if we integrate with respect to all the co-ordinates, we arrive at a group consisting of all the molecules whose momenta are between certain limits, or by integrating with respect to the momenta we form a group of molecules whose configuration lies within certain limits.

In this way we obtain two very important results:—

1. The average kinetic energy of a molecule is $\frac{m}{2h}$ where m is the number of degrees of freedom of the molecule. This is independent of the position of the molecule.

2. The average number of molecules whose configuration lies between certain limits is—

$$A e^{-h\chi} dq_1 \ldots dq_n,$$

where χ is the potential energy of the molecule, arising from forces either internal to the molecule or tending to fixed centres, but (according to Mr. Watson) excluding intermolecular forces.

But as our definition of a molecule is of the most general kind, nothing is easier than to take into account any intermolecular forces by simply including within our "molecule" all those molecules between which intermolecular forces are exerted.

For instance, there is nothing to prevent us from defining as a molecule a material system consisting of one atom in Sirius, another in Arcturus, and a third in Aldebaran. If the universe is supposed to have attained that condition of thermal equilibrium to which alone these propositions apply, the average kinetic energy of each of these atoms will be $\frac{3}{2h}$, because each has three degrees of freedom.

That of the system of three atoms will be the sum of the kinetic energies of the three atoms, namely, $\frac{9}{2h}$. We might obtain the same result from the consideration that this system has nine degrees of freedom.

The centre of mass of the three atoms is a mathematical point at an immense distance from any of them. It has, of course, three degrees of freedom, and the kinetic energy of a material particle whose mass is the sum of the masses of the atoms and which moves as the centre of mass does is $\frac{3}{2h}$.

The value of the kinetic energy of the centre of mass will be the same for any system of atoms provided that every atom of the system is liable to encounters with atoms not belonging to the system. Of course if we take into our "molecule" all the atoms of a material system unconnected with any other system, its centre of mass will not be agitated at all by the mutual actions of the atoms during their encounters.

And here we must notice a point to which Mr. Watson has adverted only in a note at the foot of p. 20—the definition of the motion of the medium as distinguished from the motion of agitation of the molecules. For this is connected with the weak point of the demonstration and shows us the way to strengthen it.

The weak point of the demonstration is the tacit assumption that the sum of the potential and kinetic energies of a pair of molecules is the only function which does not change during their encounter. For there are other quantities which are not altered by the mutual action of two bodies such as their masses themselves, the sum of their momenta resolved in any given direction, and their angular momenta about any fixed axis.

Hence if instead of $T = \frac{1}{2} M (u^2 + v^2 + w^2)$ we write in the expression for the distribution of velocities—

$$\mathfrak{C} = T - M\ \{Uu + Vv + Ww + p\,(wy - vz) + q\,(uz - wx) + r\,(vx - uy) + CM,$$

the distribution of velocities will still be a permanent one.

In this expression the quantities U, V, W, p, q, r, may have any values provided they are the same for the whole system of bodies, but C may be different for different bodies, because it is multiplied by the mass of the body, which is invariable. But we arrive at the same expression by substituting in T for u, v, and w the quantities—

$$u - U + qz - ry$$
$$v - V + rx - pz$$
$$w - W + py - qx,$$

or, in other words, by substituting for the absolute velocities of the bodies their velocities relative to a system of axes moving in the most general manner possible; that is to say, the components of velocity of the origin being U, V, W, and the components of the velocity of rotation being p, q, r, and at the same adding to T the quantity

$$\tfrac{1}{2} M \left\{(qz - vy)^2 + (rx - pz)^2 + (py - qx)^2\right\} - C',$$

which depends on the co-ordinates only and not on the velocity of the body.

We now see that the most general case of permanent distribution is when the system of bodies is contained in a vessel of invariable form which moves with constant velocity along a screw, that is to say, in which one point is moving along a straight line with constant velocity, while the vessel rotates about an axis passing through this point with constant angular velocity.

When there is rotation, we must subtract from the potential energy a term depending on the co-ordinates, which shows that the rotation produces an effect similar to that of a centrifugal force at right angles to the axis of rotation.

Returning to the general expression for the number of molecules in a group, we may make it yield us information of other kinds. Thus, if we wish to know the density of a particular gas at any given point in the mixture, we have only to make the limits of the group those of an element of volume, and we find the density proportional to $e^{-h\chi}$, where χ is that part of the energy of a single molecule which is due to external forces, such as gravity. In the case of gravity, χ is equal to $m g z$, where m is the mass of a molecule, g the intensity of gravity, and z the height. This leads to the ordinary expression for the density of a gas of uniform temperature in a vertical column, and it shows that in the ultimate distribution of a mixture of gases the density of each gas diminishes with the height according to its own law, that is to say that of the heaviest gases diminishes most rapidly, so that the proportion of the heavier gases diminishes with the height.

This law of the distribution of gases was asserted by Dalton as a consequence of his theory of gases, and numerous experiments have been made on air collected at different heights in the atmosphere in order to detect a difference in their composition, but we cannot say that such a difference has as yet been satisfactorily established.

The atmosphere, in fact, is eminently unfitted for testing the theory of the ultimate state of a mixture in equilibrium, for the inequalities of temperature in so large a body of gas produce powerful currents which continually carry masses of the mixture from one stratum into another. This tends to produce a uniformity of composition and a variation of temperature which are both of them contrary to our theory of the condition of equilibrium, and which seem to favour certain other theories.

Nor is the case much improved if, instead of the open atmosphere, we substitute a mixture of gases contained in a vertical tube. For in order to obtain a difference of composition at the top and bottom of the tube large enough for experimental verification, the tube must be at least 100 metres high, and it would take more than a year for the contents of such a tube to approximate by one half to their final distribution. In the mean time the slightest difference of temperature in the sides of the tube would produce currents which would tend to equalise the composition of the mixture. To verify the other result of our theory—the uniformity of temperature in the ultimate state of a vertical column—would be attended with still greater difficulties.

But it would be quite within the powers of experimental methods to verify the law of distribution of a mixture of gases in a rotating vessel. Let two bulbs be connected by a wide tube, say 10 cm. long, and let them be filled with equal volumes of hydrogen and carbonic acid, well mixed together. Let this apparatus be placed on a whirling machine, so that one bulb shall be close to the axis, while the other is moving at the rate of fifty metres per second. The same degree of approximation to the final state, which would take years in the long tube, will be effected in minutes in this small apparatus, and the proportion of carbonic acid to hydrogen will be about $\frac{1}{140}$ greater in the bulb furthest from the axis.

The clear demonstration of this proposition given by Mr. Watson is of great scientific value, for almost every one of those who have attacked the question with insufficient methods of investigation have come to the conclusion that the temperature would diminish in a vertical column as the height increases; and those who regard gaseous diffusion from a chemical rather than a dynamical point of view would probably expect the composition to be uniform at all heights.

But the profound scientific value of this proposition becomes more manifest when we make use of it in establishing the definition of temperature and the law of volumes of gases.

In Prop. II. of this book, which corresponds to the original form of the theorem, as I gave it in the *Philosophical Magazine*, January, 1860, two sets of spheres are completely mixed up together in the same vessel, and it is proved that the average kinetic energy of a sphere is the same for either set. We may then assert, as I did, that the two gases are at the same temperature because they are thoroughly mixed together. But this assertion has no scientific meaning, because we cannot test its truth by putting a thermometer first into the one gas and then into the other.

But if we now call to our aid a system of forces acting on the molecules and tending to fixed centres, we may obtain a result capable of experimental verification; for though we are not acquainted with natural forces acting exclusively on one kind of gas, we can calculate the effects of such forces.

Let us assume, then, that the forces are such that the potential energy of a sphere of the set N is much greater in one part of a vessel, which we shall call B, than when it is in the part A, these two parts being separated by a stratum, C, within which the potential varies continuously. The medium consisting of the spheres N will be dense in A, it will become rarer in the stratum C, and there will be hardly any of these spheres in B.

Now let the potential energy of a sphere of the set N' be much greater when it is in A than when it is in B, and let it vary continuously from the one value to the other in the stratum C. Then the spheres of this set will be thickly scattered in B, will thin out in the stratum C, and will be very rare in A.

The two sets of spheres are thus kept in great measure separate in A and B, while free to exchange their kinetic energy by collisions within the stratum C.

Now by definition, the temperatures of two bodies are equal if, when the two bodies are placed in contact, their thermal state remains the same. We cannot apply this definition to the two sets of spheres in Prop. II., for they were inextricably mixed up together, but we have now got them almost completely separated from each other into two distinct regions. They are therefore practically distinct bodies, and we can test their temperatures separately.

Hence the statement, that the temperatures of two gases are equal when the kinetic energy of the centre of mass of a molecule is the same in each, is true, not only of gases mixed together, but of two pure gases in different parts of the same vessel.

If we assume that a powerful external force acts on each molecule tending to a fixed centre belonging to that molecule, each molecule will always remain very near its own fixed centre of force, and the assemblage of molecules will behave like a solid body. But forces of this kind are included among those considered in Prop. IV., so that the relation between temperature and the kinetic energy of the centre of mass of a single molecule must be extended even to solids.

Returning once more to the general expression for the average number of molecules in a group, we may make it yield us information with respect to the average number of sets of molecules which, at a given instant, are in a given configuration with respect to each other.

For instance, if two molecules act on each other, and if χ is the potential energy due to this action corresponding to a distance r, then the number of pairs of molecules whose distance is between r and $r + dr$ will be proportional to $r^2 e^{-h\chi}$. In the case of attraction, χ is negative, so that there will be a greater number of pairs of molecules within these limits of distance than there would have been if they did not attract each other. In the case of repulsion, χ is positive, so that the repulsion diminishes the number of pairs within the distance of repulsion. If the potential energy of a pair of molecules rapidly increases to an enormous value when the distance between their centres becomes less than a given quantity, the number of pairs which are within the given distance will be practically zero, and the molecules will behave like smooth rigid-elastic spheres.

By making the "molecule" include three or more molecules, and making χ the potential energy of this system, we may extend the theorem to the simultaneous encounter of three or more molecules, so that these cases, which were formally excluded in the earlier propositions, do not in any way interfere with the absolute generality of the final result.

The clear way in which Mr. Watson has demonstrated these propositions leaves us no escape from the terrible generality of his results. Some of these, no doubt, are very satisfactory to us in our present state of opinion about the constitution of bodies, but there are others which are likely to startle us out of our complacency, and perhaps ultimately to drive us out of all the hypotheses in which we have hitherto found refuge into that state of thoroughly conscious ignorance which is the prelude to every real advance in knowledge.

If we know from observation either the specific heat of a gas at constant pressure, or the ratio of its specific heats at constant pressure and at constant volume, we can determine the ratio of the rate of increase of its total energy to the rate of increase of the energy of agitation of the centres of its molecules. Now if the molecule has m degrees of freedom, its total kinetic energy is to the energy of agitation of its centre of mass as m to 3. It is probable that the internal potential energy of the molecule increases as the temperature rises, and this would make the ratio of the whole energy to that of agitation of centres greater than that of m to 3, so that if we know this ratio by experiment, we can assert that m cannot exceed a certain value.

For chlorine, ammonia, and sulphuretted hydrogen, m cannot exceed 6; for hydrogen, oxygen, nitrogen, air, carbonic oxide, nitrous oxide, and hydrochloric acid, it cannot exceed 5, and for mercury gas, according to the experiments of Kundt and Warburg, it cannot exceed 3.

Now Boltzmann has pointed out in a paper: "Über die Natur der Gasmolecüle" (Vienna Acad., December 14, 1876), that if the molecules were rigid-elastic bodies of any form, m would be 6, that if they were smooth figures of revolution, the velocity of rotation about the axis of figure would not be affected by the collisions, so that m would be 5, and that if they were smooth spheres, the three component velocities of rotation would each of them be independent of collisions, so that m would be reduced to 3, and these values are in striking agreement with the phenomena of the three groups of gases.

But before we accept this somewhat promising hypothesis, let us try to construct a rigid-elastic body. It will not do to take a body formed of continuous matter endowed with elastic properties, and to increase the coefficients of elasticity without limit till the body becomes practically rigid. For such a body, though apparently rigid, is in reality capable of internal vibrations, and these of an infinite variety of types, so that the body has an infinite number of degrees of freedom.

The same objection applies to all atoms constructed of continuous, non-rigid matter, such as the vortex-atoms of Thomson. Such atoms would soon convert all their energy of agitation into internal energy, and the specific heat of a substance composed of them would be infinite.

A truly rigid-elastic body is one whose encounters with similar bodies take place as if both were elastic, but which is not capable of being set into a state of internal vibration. We must take a perfectly rigid body and endow it with the power of repelling all other bodies, but only when they come within a very short distance from its surface, but then so strongly that under no circumstances whatever can any body come into actual contact with it.

This appears to be the only constitution we can imagine for a rigid-elastic body. And now that we have got it, the best thing we can do is to get rid of the rigid nucleus altogether, and substitute for it an atom of Boscovich—a mathematical point endowed with mass and with powers of acting at a distance on other atoms.

But Boltzmann's molecules are not absolutely rigid. He admits that they vibrate after collisions, and that their vibrations are of several different types, as the spectroscope tells us. But still he tries to make us believe that these vibrations are of small importance as regards the principal part of the motion of the molecules. He compares them to billiard balls, which, when they strike each other, vibrate for a short time, but soon give up the energy of their vibration to the air, which carries far and wide the sound of the click of the balls.

In like manner, the light emitted by the molecules shows that their internal vibrations after each collision are quickly given up to the luminiferous ether.

If we were to suppose that at ordinary temperatures the collisions are not severe enough to produce any internal vibrations, and that these occur only at temperatures like that of the electric spark, at which we cannot make measurements of specific heat, we might, perhaps, reconcile the spectroscopic results with what we know about specific heat.

But the fixed position of the bright lines of a gas shows that the vibrations are isochronous, and therefore that the forces which they call into play vary directly as the relative displacements, and if this be the character of the forces, all impacts, however slight, will produce vibrations.

Besides this, even at ordinary temperatures, in certain gases, such as iodine gas and nitrous acid, absorption bands exist, which indicate that the molecules are set into internal vibration by the incident light.

The molecules, therefore, are capable, as Boltzmann points out, of exchanging energy with the ether.

But we cannot force the ether into the service of our theory so as to take from the molecules their energy of internal vibration and give it back to them as energy of translation. It cannot in any way interfere with the ratio between these two kinds of energy which Boltzmann himself has established. All it can do is to take up its own due proportion of energy according to the number of its degrees of freedom.

We leave it to the authors of the "Unseen Universe" to follow out the consequences of this statement.

J. CLERK MAXWELL

OUR BOOK SHELF

Report on the Progress and Condition of the Royal Gardens at Kew during the Year 1876. (Clowes and Sons.)

SIR JOSEPH HOOKER'S annual report on the Royal Gardens, Kew, for 1876, has just been issued. It is a pamphlet of some thirty-three pages, and is a considerable improvement on the reports of former years. It deals most fully with new plants of economic interest, whether such have been actually received or sent from the Royal Gardens, or have formed the subject of correspondence with foreign or colonial governments. It is eminently satisfactory to know that such useful plants as the Para rubber (*Hevea brasiliensis*), the ipecacuanha (*Cephælis ipecacuanha*), the Liberian coffee (*Coffea liberica*), and others, have been most successfully introduced into India and other countries, through the instrumentality of Kew. Of the 70,000 seeds of the *Hevea* received at Kew about the middle of June last year, all of which we are told were at once sown, and though closely packed together, covered a space of over 300 square feet so soon as August 12th following, upwards of 1,900 living plants, raised from these seeds, were transmitted to Ceylon in thirty-eight Wardian cases, 90 per cent. of the whole consignment reaching Dr. Thwaites in excellent condition. So rapid was the germination of these seeds at Kew that some had actually started into growth on the fourth day after sowing, and many in a few days reached a height of eighteen inches. It has been arranged that these young plants shall "be nursed and established in Ceylon for subsequent transmission through the Indian Gardens to Assam, Burma, and other hot damp provinces of India proper." Besides those sent to India, smaller quantities of plants have also been despatched to the west coast of Africa, Burma, Dominica, Jamaica, Java, Queensland, Singapore, and Trinidad. With regard to ipecacuanha, though Dr. King reports that he fears it cannot be grown so far north in India as Bengal, it is nevertheless in some situations capable of rapid and extensive cultivation, and the roots grown in India have been proved to be quite as efficacious in a medicinal point of view as those from the best districts of South America. In the matter of Liberian coffee, the wide and general extension of this new kind in coffee-growing countries bids fair, in many parts, to entirely supersede the old and better known *Coffea arabica*. Sir Joseph Hooker reports the receipt of numerous favourable notices of the plant, and quotes "two from opposite sides of the world," namely Ceylon and Dominica. With reference to diseases affecting coffee plants—which it is hoped the more sturdy habit of the Liberian kind will help it in some measure to resist—a very exhaustive notice is furnished, which is not only of much interest in a scientific point of view, but cannot fail to be valuable to coffee-planters themselves. It will, moreover, no doubt be the means of causing more careful observations to be made by residents on coffee estates or in coffee-growing countries into the nature and habits of diseases which are still more or less obscure.

Considerable additions are reported to the Museums and Herbarium, the new building for the accommodation of the latter collection being now in a very advanced state. The new Laboratory, which has been erected at the expense of T. J. Phillips Joddrell, Esq., is reported as having been completed during the year, and though not fully provided with the necessary equipment at the time the report was written, has been already, as our readers are aware, used by Dr. Tyndall in several of his recent experiments and researches.

Two new features of the report which we have not already mentioned are—first, the introduction of plates, one being a figure of the new Liberian coffee plant, and the other a view and ground-plan of the Laboratory; and second, the publication of the report, at a charge of sixpence, by Messrs. Clowes and Sons.

Natural History Transactions of Northumberland and Durham, vol. v., part 3. (Williams and Norgate, 1877.)

THIS part is by no means the least valuable of these transactions; on the contrary, it will rank high, owing to the contributions of Dr. Embleton and Mr. Atthey on the structure of the Labyrinthodonts, and the eight excellent plates by which their papers are illustrated. The illustrations of Loxomma and Anthracosaurus are as complete and instructive as any that have yet been published of British Labyrinthodonts. The authors, however, do not recognise the articular surfaces on the exoccipitals of Loxomma as the two condyles; and they speak of a concave articular surface as taking the place of a condyle or condyles on the basioccipital bone. The condyles in all Amphibia are produced by the exoccipital bones, and such a character is not a special evidence of the affinity of Loxomma with fishes. The number also contains several interesting papers on local natural history and antiquities, and the address of the president, the Rev. G. Rowe Hall.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The "Inflexible"

MY attention has been called to an article on the *Inflexible*, in NATURE (vol. xvi., p. 201), and I shall be much obliged by your inserting a few remarks, which I shall make as short as possible. On the general subject of the article I do not propose, nor would it be proper for me, to say a word. I am concerned only with the concluding remarks of the writer on a letter of mine to the *Times*. Nothing has appeared to me more astonishing than the use, or rather abuse, which is occasionally made of the report of Lord Dufferin's committee on ships' designs. If their authority can be claimed for any statement, I see on all sides a readiness to claim it. Should anything they have said militate against a favourite view, their authority is depreciated, and a comparison is sometimes invidiously drawn between the supposed opinion of the majority and that of an intelligent minority. Now if I be included with the unintelligent majority, I am quite content to find myself in such good company; but if, on the contrary, I am included in the minority, I utterly and absolutely refuse a compliment at the expense of my distinguished colleagues, with whom I shall always esteem it no small honour to have served. In fact I am not aware of any scientific point on which that committee was not unanimous. The writer of the article in question in common with many others, seems to have entirely mistaken the position of that committee. He seems to think their duty was to make their report a treatise on Naval Architecture. The absurdity of such a notion is apparent on the face of it. In fact they were required to give an opinion on certain designs of ships submitted to them as to their being in accordance with the latest developments of the theory of naval architecture. It was no part of their duty to descant on the principles which were successfully applied in such designs; but undoubtedly if they observed that in any direction caution was necessary, they were bound to remark it. In none of the designs was there any indication of a tendency to curtail initial and maximum stability of their due proportions; had there been they would certainly not have failed to call attention to it. But while they found the design of the *Devastation* in all respects sound, they yet thought it desirable that the range of stability should in future designs be somewhat enlarged. In recommending such enlargement they by no means committed themselves to any such absurd *dictum* as the writer imagines—that range of stability is all that is requisite for the safety of a ship. But as I have already said, to have laid down all the other requisites of a good ship would have been to write a treatise.

Again, whatever credit according to some, or discredit according to others, is due to the design of a ship like the *Inflexible* with an armour-plated central citadel with unarmoured bow and stern, that credit or discredit cannot be justly imputed to the committee. Mr. Reed, in his evidence, had brought a design with some of the leading features of such a ship before them, and it occupied a considerable share of their attention. Now what do they say on this subject?—"It is not by any means certain that some method may not be devised of securing the requisite reserve buoyancy by other means than armour plating." And after giving a sketch of what such a ship would be, they conclude thus:—"In the absence of any practical experience of the effect of large shells or of torpedoes upon such a structure as we have in view, it is impossible to say with confidence that the object aimed at would be thus attained, but, *if it were*, consequences of so much importance and value would follow that we think it right to *indicate this line of inquiry as worthy of experimental investigation.*"

How far such a bare suggestion of experimental inquiry is from the recommendation of such a structure for adoption must be evident to your readers without further comment.

United University Club, Pall Mall, July 20 JOSEPH WOOLLEY

[The above letter from Dr. Woolley is what might have been expected from a man of his eminence in the science of naval architecture, writing under the restraint of his nomination by the Government to a membership of the Committee which is to report upon the stability of the *Inflexible*. It is no doubt to the concluding words of our first article on this subject (NATURE, vol. xvi. p. 203) that Dr. Woolley's letter refers, and we at once admit that there is very great force in the argument which he now employs. The particular point in question is a very simple one. In his letter published in the *Times* of July 19, Mr. Barnaby wrote:—"According to our estimate the ship, when fully armed, stored for fighting, and manned, will have, independently of the unarmoured ends—*i.e.*, supposing them not to exist—a range of stability of 48 deg. The Committee on Designs considered that 40 deg. was sufficient range for a sea-going unmasted ship." On the following day a letter appeared from Mr. Reed commenting on the impropriety of assuming the *non-existence* of the ends, pointing out that it was 50 deg. and not 40 deg. that the Committee spoke of as the *minimum* angle of vanishing stability, and adding that when the Committee put forward "*range* of stability" as "the one measure of safety" to be considered, "they stated the most dangerous doctrine which probably has ever been propounded in connection with the science of naval architecture." Now, on reconsidering the whole question, we are inclined to think that these words were not, in point of fact, quite fair to the Committee, because there was probably no member of the Committee who would have asserted or admitted that "range" was the one and only measure of safety to be considered. Dr. Woolley, Mr. Froude, Sir W. Thomson, and probably some other members of the Committee, doubtless knew perfectly well that the length of G Z from point to point was not only as important as "range," but far more important in all cases of limited range; and it is now obvious, with the present letter of Dr. Woolley before us, that the absence of any reference to the fact is attributable to the limited extent of the Committee's inquiry. There is great force in the remark that it was no part of the duty of the Committee to compose a treatise on naval architecture. On the other hand we are bound to deny that our remarks were penned under a contrary impression. Our view is that the use to which Mr. Barnaby has put the Report of the Committee proves that the scientific men who composed it would have done well to have employed more guarded language, and to have recognised in some manner the insufficiency of range only as a measure of safety. When they are found speaking of a certain angle of vanishing stability as being "sufficient to ensure the safety" of ships, it must be admitted, even by Dr. Woolley and his colleagues, that some risk of misconstruction was incurred. That misconstruction, or perhaps we ought in this case to say misuse—or even "abuse," as Dr. Woolley expresses it—has occurred in the present case is manifest, because Mr. Barnaby seized hold of the Committee's dictum as to range, and ignored altogether the very serious question of the amount of the stability. What makes the matter more important than usual in the present case is that the curve of stability due to the citadel of the *Inflexible* only is, no doubt, a low and flat curve, G Z being everywhere so small that in order to bring the stability up to a safe amount its range would have to be very greatly extended. It was, no doubt, improper of Mr. Barnaby to make the use he did of the Committee's words, and Mr. Reed took no pains to credit the Committee with anything beyond what was written; but Dr. Woolley is, we think, a little forgetful of the fact that what Mr. Reed wrote, and what we have since written, has had to be said in presence of the circumstance that in a matter of the gravest public importance a free use of the Committee's words has been made by a high authority for the purpose of claiming for the *Inflexible* public confidence in her stability on the ground of range only. It is satisfactory to learn, however, on the undoubted authority of Dr. Woolley that the Committee, whatever its language, not only intended to give no countenance to the doctrine that the *Inflexible* would be proved safe if only she were shown to possess sufficient range of stability, but individually and collectively would consider such a doctrine as altogether absurd.

On the second portion of Dr. Woolley's letter, we entirely concur with him. We have read over again both the evidence and the reports of the Committee of Designs, and we cannot find the smallest justification for the assumption that, right or wrong, the Committee on Designs is responsible for this ship's design. The case to the contrary is absolutely clear and unquestionable. Mr. Reed placed before the Committee the outline ideas of a ship of this description, but making it a *sine quâ non*—let it in justice to him be said—that the ship should not depend "in the least degree" upon the ends, and that the stability of the citadel should be so ample as "to make it a matter of perfect indifference how much the ends might be knocked about by shot and shell." He spoke of the ends as being filled with water, and thus converted into a sort of tanks, and it most naturally occurred to the committee to suggest whether cork or some metallic cellular material, might not with advantage be employed to take in some degree the place of water, a proposal which Mr. Reed thought well worth consideration and trial. Beyond this the Committee did not go in their report, as the quotations cited by Dr. Woolley clearly show; on the contrary, by recommending the course of experimental investigation which they advised they plainly showed that, in their opinion, sufficient grounds for depending upon cork, &c., for stability did not exist, and could not be shown to exist except by large and well-considered experiments. Mr. Barnaby roundly asserts that the Committee "did not agree with Mr. Reed's view as to the necessary dependence of the ship upon her armoured citadel for her floating power;" but the extracts from the Committee's Report which he adduces in support of the statement by no means bear it out. The Committee, for some reason or other, advert to Mr. Reed's plan without mentioning his name, but, while nowhere implying any dissent from his main principle, they plainly enough indicate that armour should be employed to sufficiently protect buoyancy and stability, unless "other means than armour-plating" could be found and proved effectual.

We shall defer to Dr. Woolley's very proper wish to restrict his remarks to the two points above considered, and shall in no way seek to connect them with the general question upon which he has been appointed a judge. We may be permitted to observe, however, that whatever the result may be, it is a satisfaction to us to find that the Committee consists of gentlemen who are in large part not merely masters of the science of the stability of floating structures, and raised high by their individual repute above the suspicion of partisanship, but who also, by serving on the Committee of Designs of 1871, acquired very special fitness for promptly considering the *Inflexible* case. They will know how to go directly to the questions at issue, and after ascertaining what stability the ship actually possesses without aid from cork, or canvas, or other devices, and what she possesses with such aid, they will be able to declare with scientific confidence and precision whether it is or is not sufficient, for they are themselves the authors of the very standards by which that issue must be decided. Nor will they forget that whatever demands for stability existed in 1871, still greater demands now exist when we have the First Lord of the Admiralty, in his place in Parliament, claiming for this very ship the ability to float and fight even after three successive blows from Whitehead torpedoes. If the result should be a disproof of our views of the subject, we know that that disproof will be based upon scientific grounds that will commend themselves to impartial minds. If the result should be to require that additional stability shall be provided in such ships, a great public good will have been accomplished. We need not say which result we anticipate.—ED. NATURE.]

The Manufacture of Leading Articles

THERE is a good old story told of a country editor who once met a pressing demand for copy in a singularly ingenious manner. At the moment of going to press, it was found to the consternation of the printer that a whole column was lacking. What was to be done? The whole staff was in confusion at the unexpected discovery; the editor alone preserved his wonted coolness. Sending for a copy of the *Times*, he clipped therefrom one of the leaders and ordered it at once to be set up in type, prefaced by the words "What does the *Times* mean by this?"

This story recurred to me with some force on reading on the front page of *Land and Water* last week, an article on Soldiers' Food in War; for the original, bearing my signature, appeared on the front page of NATURE (vol. xvi. p. 157). In this case, however, my other self seems to have had more time on his hands than the country editor, since the article in question has been paraphrased in parts, still with such care as not to destroy the identity. H. BADEN PRITCHARD

The Fish-sheltering Medusa

PROBABLY the species of fish to which Mr. Lawless refers as seeking shelter under the swimming-disc of *Aurelia aurita* (NATURE, vol. xvi. p. 227) is *Merlangus carbonarius* (Cuv.), popularly called boat-fish. At least I have seen the fry of this species behaving as Mr. Lawless describes.

The observation stated in the following words appears to me one of great interest:—"Occasionally the Medusa turned in its pulsations, so as to bring the umbrella undermost, when the fish would shoot hastily out, but the Medusa had no sooner righted itself, than the fish returned." Now, if this occasional turning on the part of the Medusa was not merely accidental, but, as Mr. Lawless implies, a reflex act performed with the view of escaping from the irritation occasioned by the fish, the fact would show that the marginal ganglia of *Aurelia aurita* are so far co-ordinated in their action as to enable the animal to steer itself in any required direction. For my own part, I have not as yet been able to satisfy myself that such ganglionic co-ordination occurs in any species of covered-eyed Medusa; so it would be well worth while if Mr. Lawless could repeat his observation a sufficient number of times to exclude the supposition of the somersaults being merely fortuitous.

I may take this opportunity of saying that the cut which illustrates the abstract of my lecture on p. 232 of the same issue of NATURE as contains Mr. Lawless's letter, is intended to represent the species of Medusa to which he refers, viz., *Aurelia aurita*. The cut is about ¼ natural size.

GEORGE J. ROMANES

Phyllotaxis

I HAVE noticed in the laurel and the Spanish chestnut species, in which the leaves have normally a distichous arrangement, that when a vigorous shoot takes a vertical direction—for example, after the stock has been cut down near the ground—the leafage of such a shoot is often quincuncial. The phenomenon suggests three possible interpretations. Is this to be regarded as a fixed adaptive habit, the spiral phyllotaxis being the fittest for the upright, the two-ranked for the more numerous lateral twigs? Or are the exceptional instances endeavours after greater economy of space in the packing of the buds? Or, finally, ought we to discern in the peculiarities of the more vigorous shoots a reversion towards some ancestral condition? W. E. HART

Drumaweir, Greencastle, July 20

Printing and Calico-Printing

As all that I am ever personally concerned to know is the truth of a matter, I am glad to stand corrected by the writer of the article on Calico-Printing in the "Encyclopædia Britannica." The claim I made, however, for the author of the "Natural History of Enthusiasm" was not my own invention; and it would be of interest, I think, to the many who must still, even in our day, revere his memory, to know more fully and accurately what it was that engrossed so many years of his valuable life, and what, if any, have been the practical results.

Bremner, Bournemouth, July 22 HENRY CECIL

THE VISIT OF THE BRITISH ASSOCIATION TO PLYMOUTH

THERE are very good reasons for anticipating that the Plymouth meeting of the British Association will be at least up to the average in interest and success. Indeed, in some respects it is anticipated that it will be unusually attractive; and the attendance is likely to be much larger than from the distance west was at first thought probable. And as the details of the local arrangements approach completion so do the outside attractions, rendered available for the pleasure or information of the visitors, increase and multiply. The Government authorities have kindly consented to render every facility in their power for the inspection of the great establishments which constitute Plymouth and Devonport one of the chief arsenals in the world. The dockyard and Keyham yards will be freely open; those who desire to inspect the famous biscuit machinery at the Royal William Victualling Yard will be enabled to do so; there will be gunnery practice and probably torpedo practice also to be witnessed on board the *Cambridge*. The Breakwater of course can be seen at any time from Plymouth Hoe, and visited whenever weather will permit, which unless a gale is blowing it always does. The Breakwater Fort, reared on an artificial island of stone in the Sound immediately within the Breakwater, granite-capped and iron-plated, is by far the most interesting of the great chain of forts wherewith the Three Towns are girdled, and this too, it is hoped, will be open to inspection. The Eddystone will be visited on the Saturday, as already stated; but it must be understood that it is by no means certain that a landing can be effected. In fair weather, even, there is at times such a swell there as to render landing difficult, and even dangerous, while in rough weather it is impossible.

The excursion arrangements have been somewhat extended since our previous notice. On the Saturday, in addition to the excursions to the Eddystone, Lee Moor, and Iskeard for the Caradon Mines, it is now proposed by the citizens of Exeter to invite a large party of the members to this famous city, which abounds in objects of antiquarian interest, and which is noted for the hospitality with which it receives its guests. Iskeard too, is moving in the same direction; and the proprietors of Lee Moor Clay Works, Messrs. Martin, intend to make provision also for their visitors. After the clay works have been seen and justice done to the luncheon, there will be ample opportunity for a delightful ramble on Dartmoor. Shell Top and Pen Beacon, with their magnificent views and prehistoric remains, are within very easy distance, and good walkers will have the opportunity of enjoying some of the most romantic scenery in Devon, in the valleys of the Plym, and other moorland rivers.

The excursion arrangements for the Thursday remain unchanged; but there has been a considerable addition to the list of available attractions. The engineers of the party, through the kindness of Mr. Margary, engineer of the Great Western Railway for the district, will be enabled to inspect the Royal Albert Bridge to their heart's content—even to a scramble through the tubes. The great granite works and granite quarries of Messrs. Freeman at Penryn; the mines of Dolwath, Tincroft, and Carn Brea (by the kindness of Capt. Josiah Thomas and Capt. Teague); the pneumatic stamps of Mr. Husband, at the Hayle Foundry; the tin smelting works of Messrs. Bolitho, at Penzance, will all, by the courtesy of their proprietors, be available to be visited by members of the Association. And as the Earl of Mount-Edgcumbe has kindly opened his magnificent park and his romantic mansion of Cotehele, so Sir John St. Aubyn permits his famous and historic residence, St. Michael's Mount, to be visited by those members of the Association who may find their way so far west.

The public museums of the two counties will, we believe, be all open to the members. The chief are that at Exeter, that of the Royal Cornwall Institution at Truro, and that of the Royal Cornwall Geological Society at Penzance. Mr. C. C. Ross, of the latter town, has one of the best private collections of minerals in the West of England, and will gladly show it to all who feel interested in mineralogy. Then there are the museums of the Torquay Natural History Society, the specialty of which is its Kent's Cavern collection, which will form one of the attractions of the Torquay excursion, and the Museum of the Plymouth Institution, in which will be found a magnificent collection of flint implements and weapons lent and arranged for the occasion by Mr. Brent.

There will be several local papers contributed to the various sections, but the list is hardly likely to be so long as at the meeting of 1841, when the local contributions were unusually numerous.

The Pharmaceutical Society will, as usual, hold their meeting immediately prior to the meeting of the British Association at Plymouth, and the Mineralogical Society and the Society of Public Analysts, will also meet at Plymouth during the Association week.

THE GORILLA

SINCE Monday last the young gorilla from the Berlin Aquarium has been exhibited, during most hours of the day, at the Westminster Aquarium, in company with a chimpanzee. This is the first occasion on which a living gorilla has been publicly exhibited in this country as such, an earlier specimen some years ago, in a travelling menagerie, having passed for a chimpanzee during its life-time.

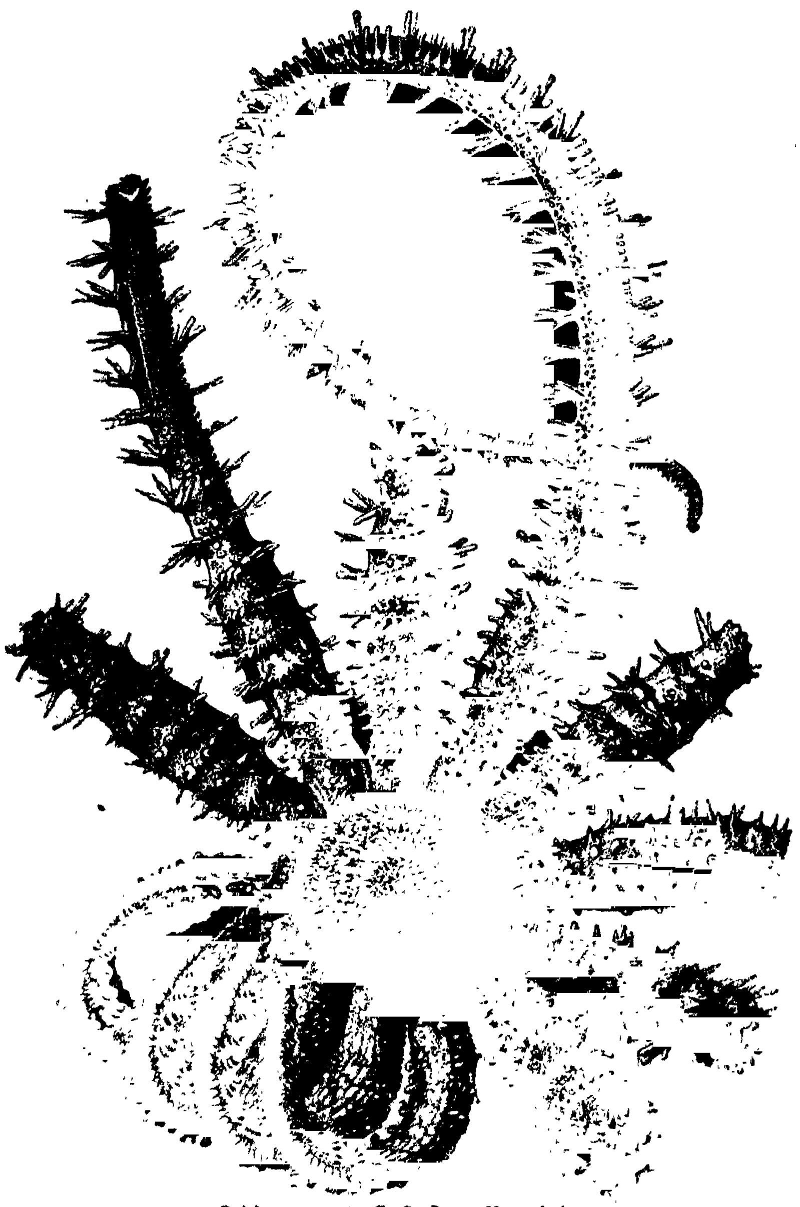
The gorilla, which is about three years old, appears in excellent health, and differs most strikingly from its companion in the blackness of its face and extremities, the smallness of its ears, the shortness of its muzzle, the great development and breadth of the alae of its nose, the shortness and softness of its thick-set body-hair, the presence of a frontal hair-tuft, the breadth and flatness of its back, which is also capable of greater backward bending, the smallness of the four outer toes, which are free for but a short distance, the breadth of its hands, and the massiveness of the nape of the neck. The conjunctiva is black, and the eye intelligent. We think that no one interested in natural history should lose the opportunity of seeing this particularly interesting Anthropoid ape.

BRISINGA

NEARLY a quarter of a century ago the celebrated Norwegian poet and naturalist, P. Chr. Asbjörnsen, was dredging in the interior of the picturesque Hardangerfjord, when, at a depth of about 200 fathoms, the dredge brought up a wonderful new star-like Echinoderm, quite unlike any form that had been up to that moment described. From a little circular disc of about an inch in diameter there issued eleven spreading arms or rays upwards of a foot each in length. These were armed along the edges with several rows of long spines; these arms, while standing near together at their base, generally taper away gradually to their tips. The colour, though variable, was, on the upper or dorsal surface, of a more or less red hue and paler, often to whiteness, on the under surface. On the lower surface of the disc, and occupying the central space, is seen the mouth-like aperture of the alimentary system, and spreading away from it along the centre of each ray-like arm, are the deep ambulacral furrows, so called because from these furrows issue the ambulacra or water-feet. These form two uninterrupted rows, and are flanked by several palisades of strongly-developed spines, the outer ones being the longest. All these spines are enveloped in an integument which is covered with strange-looking Pedicellariæ.

Only an instant's glance at this brilliant novelty was vouchsafed to the poet-naturalist; for beneath his glance the star-fish, thus brought up to quarters new to it, threw off all its arms, and what was once a thing of beauty became now a tangled mass of writhing arms moving away from the disc that had so long borne them company.

From living in great darkness and in the tranquil depths of the ocean's bosom, the being brought so suddenly up into the bright sunlight and to the agitated movements of that ocean's surface was too great a change and too severe a shock, and the catastrophe just mentioned was the consequence. To Asbjörnsen, however, this thing of beauty seemed like a link in the chain of the past. In its unlikeness to most recent forms of star-fishes he saw its connection with certain fossil forms, and in its brilliant sun-like form he was reminded of the "Brising" which, according to ancient Norwegian tradition, was concealed by Loke in the abyss of the primeval ocean, but which had so long served as the ornament to cover the breast of the god Freya, and he gave the name of Brisinga to the new genus.



Brisinga coronata, G. O. Sars. Natural size.

From the number of its arms Asbjörnsen called this new species *B. endecacnemos*, and until quite recently it was the only species known. In one locality of the fjord—Hesthammer—its occurrence cannot be considered as very rare, it has only been met with on rocky bottoms and at depths of from 200 to 400 fathoms. It has also been dredged by Prof. G. O. Sars some miles north of Bergen; by Sir Charles Wyville Thomson in the North Atlantic, and off the west coast of Portugal by Mr. Gywn Jeffreys, an account of the finding of these latter specimens will be found in Prof. Sir C. W. Thomson's most interesting work on the "Depths of the Sea."

A second species of this genus was in 1869 and 1870 brought up by Prof. G. O. Sars at the fishing-place Skraaven, in Lofoten, from a depth of 300 fathoms, and this species has also since been found in the great depths of the Atlantic Ocean; for this species the name *B. coronata* has been selected by Sars, and this name has been adopted by Thomson, from whose work the accompanying beautiful woodcut of this species has been borrowed. It represents the animal as seen from above; five rudimentary arms in one series take the place of those that have been lost, for in this species the number of arms varies from nine to twelve.

This new species has been made the subject of an elaborate memoir by Prof. G. O. Sars, in which memoir the structure and affinity of the genus is also fully discussed. It has been published as the University of Christiania's programme for the latter half of 1875. With the aid of a tolerably large number of fresh specimens and by repeated careful dissections, Sars has been enabled to ascertain most of the points in connection with its histology, and seven plates assist in illustrating the structures described. He considers the functions of the remarkable little organs called Pedicellariæ, which occur in most surprising number in both species of Brisinga, as that of seizing and holding fast the objects which come in contact with them, those that are found on the dorsal surface, thus acting as protectors to the thin skin; and those on the lower surface acting in the service of alimentation.

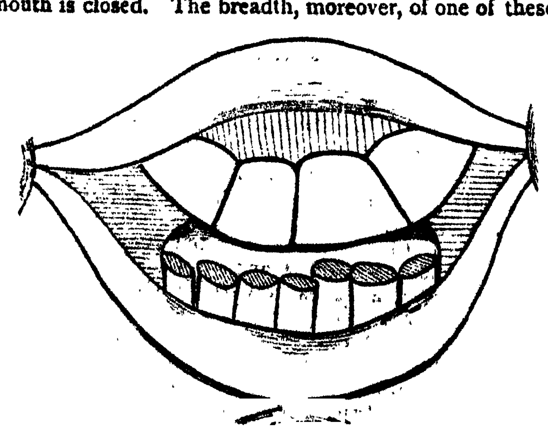
Among living star-fishes Brisinga seems to stand isolated, coming perhaps nearer to Pedicellaster; with the oldest known fossil star-fish Protaster, it shows close affinities, but would seem to be older and less specialised, and if so it would then be the most primitive as well as oldest form known of Star-fishes. It must therefore be kept in a family of Echinoderms by itself which may be called *Brisingidæ*.

E. P. W.

A REMARKABLE DEFORMITY OF THE TEETH AMONG THE INHABITANTS OF THE ADMIRALTY ISLES[1]

THE Russian traveller, M. Miklucho-Maclay, in the course of recent travel in Melanesia, has noticed among the natives of the Admiralty and Hermit Isles a remarkable peculiarity in the teeth, the upper incisors

projecting "shovel like," almost horizontally, and to such a degree as to extend even beyond the lips when the mouth is closed. The breadth, moreover, of one of these



teeth is at times so great as to equal its visible length; being in the specimen figured as much as 19 millimetres to 16 mm. of length, measured, of course, from the edge of the jaws, not from the extremity of its fang. As all the teeth have a blackish polish, due to the prevailing habit of betel-chewing, the mouth presents a somewhat ghastly appearance. M. Miklucho-Maclay has nowhere else met with a similar deformity of the teeth, but heard of such, when on the peninsula of Malacca, the race in which it occurs being called "orang-gargassi."[1]

J. C. G.

[1] See a note contributed to the *Illustrirte Zeitung* of Leipzig by M. Miklucho-Maclay.

[1] *Man-devil. Orang* is the usual Malay word for man, while *gargassi* is equivalent to the German *Quälgeist*, tormenting spirit.—J. C. G.

RAINFALL AND SUN-SPOTS

WE have received the following communications having reference to Gen. Strachey's paper on the above subject, which we printed some little time back.

The conclusions of Mr. Meldrum as to a relation between the amount of rainfall and the frequency of sun-spots have become a subject of much interest with reference to the possibility of being prepared for such a deficiency of rain in India as may result in a failure of crops and consequent famine. That the varying yearly rainfall at Madras showed on the whole a rather marked agreement with the sun-spot period, has been known to me for some time, and Dr. Hunter has lately made an examination of the amounts relatively to an eleven-yearly cycle which has excited marked attention on account of its possible practical application. Gen. Strachey has made a discussion of the Madras observations in a paper read before the Royal Society, a full abstract of which has appeared in NATURE (vol. xvi., p. 171). He has sought to show that there is no evidence in the Madras observations of periodicity at all; and that if the rainfalls for each of the sixty-four years were written on slips of paper and drawn from a bag, so that the first amount drawn should be placed to the first year (1813), the second to the next year (1814), and so on, as well-marked a result would be obtained as is shown by the quantities observed in their respective years. This conclusion he founds on the following method, which he terms a "true criterion of periodicity."

If the differences of the rainfall for each year from the mean of the whole sixty-four years be taken, and the mean of all these differences (without respect to sign) be called the *general* mean difference; if we arrange the yearly rainfalls in horizontal series of eleven successive years (there will be six such series nearly), and the means for the first, second . . . . years of the series be taken, these quantities (periodic means) will show the mean variation in the period of eleven years, if any such exist. If now the differences of the yearly rainfalls from the periodic means for the corresponding years be obtained, the means of these, irrespective of sign, may be called the *periodic* mean differences. In the case of the Madras rainfalls Gen. Strachey finds—

The *general* mean difference = 12·4 inches,
The *periodic* ,, ,, = 11·2 ,,

and his true criterion of periodicity, though not so definitely stated as might be wished when so important a rule is proposed, appears to be that if there be no periodicity the variation in the periodic means will tend to disappear in a sufficiently long series of observations and the *general* and *periodic* mean differences be identical. It seems to me that the disappearance of a variation in the periodic means is here the true criterion of no-periodicity; but though a very large variation exists in the case of the Madras observations, yet Gen. Strachey concludes that since the *periodic* and *general* mean differences agree so nearly, there is no tendency to periodicity shown in the Madras observations.

As an illustration of the true criterion, Gen. Strachey takes the two hourly observations of the barometer for five successive days at Madras, and shows that—

The *general* mean difference = 0·030 inches,
The *periodic* „ „ = 0·014 „

Here, he says, a true period existing, the *periodic* mean difference becomes much less than the *general* mean difference.

I shall now venture to show that this is no criterion of periodicity. If we represent variations of any quantity for a given time by a curved line, and if we have several such lines of exactly the same form placed one over the other, a straight line passing through the curves, with as much space between the straight and curved lines above as below, will represent the *general* mean. In a simple curve of two branches the *general* mean difference will be nearly one-fourth of the amplitude of the oscillation; while, as all the oscillations agree with each other, and therefore with the mean oscillation, the periodic mean difference will be zero. If, however, we displace the individual curves so that as many shall be above as below their mean, both the *general* and the *periodic* mean differences will increase, and the difference between these quantities will diminish, till the individual curves are so separated from the mean that none of them is cut by it, when the two mean differences will be *equal:* between this case and that of general coincidence the two mean differences will have values which will differ more or less from each other, according as the individual curves are nearer to, or more remote from, the mean; and the ratio of the one mean difference to the other will tend to a constant value as the number of cycles increases, a ratio which will depend for its value on the mode of distribution of the individual curves and of the irregular deviations from the mean.

Gen. Strachey's illustration is from a case approaching coincidence; hundreds of cases, however, may be found of the other class, especially when, as in this instance, only a few periods are in question. Thus, taking two hourly observations of the barometer at Simla during six days in the beginning of January, 1845, I find—

The *general* mean difference = 0·0634 inches,
The *periodic* „ „ = 0·0615 „

and if the last day of the six be omitted so as to have an *odd* number of days, I find—

The *general* mean difference = 0·0656 inches,
The *periodic* „ „ = 0·0634 „

Gen. Strachey's conclusion from the Madras rainfall observations is in fact that because the *periodic* mean difference was only one-tenth less than the *general* mean difference, there was no evidence of periodicity whatever; here we have a large and regular semi-diurnal period (the whole mean range being 0·070 inch) where the *periodic* is not one-thirtieth less than the *general* mean difference.

I may add that when the true sun-spot period of ten and a half years is employed for the Madras rainfall observations, I find—

The *general* mean difference = 12·4 inches,
The *periodic* „ „ = 10·2 „

quantities which differ by five times as much as those found for the true periodic variation of the barometer at Simla.

I have taken the variation chosen by Gen. Strachey to illustrate this question, but the fact that the difference of the *general* and *periodic* mean difference is no criterion of periodicity might have been shown equally well with cases more resembling that of the rainfall, where the irregular variations are large compared with those following a known period; I cannot here, however, enter into details and notice only the objections offered by me to Gen. Strachey's paper when it was read before the Royal Society.

It would be easy to show that the Madras rainfall oscillation larger for about ten (nine to eleven) years than for any other duration. 2nd. When the mean variations for a period of ten and a-half years are represented by a function of sines they give the yearly *mean* rainfall (y) in the period, $y = 6.2 \sin(\theta + 310°)$, showing the large range of 12·4 inches. 3rd. This representative equation gives the epochs of maximum rainfall in the years of maximum sun-spots, or as nearly so as would be given by the mean sun-spot areas represented by a similar expression.[1]

On the other hand, the irregularity in the amount of rainfall from year to year is so great that the probable error of the periodic means is too considerable to give any great weight to this result alone.[2] When observations during a sufficiently large number of cycles have been obtained, so as to make the probable error of the means small compared with the range of the periodic variation, then there will be a general acceptation of Gen. Strachey's remark: "It is hardly conceivable that there should be a coincidence with the sun-spot period, such as is supposed to be found at Madras, based on any physical cause which should not in some way be discernible in the rainfall at Bombay and Calcutta" (NATURE, vol. xvi. p. 172). He has then taken *five* cycles of eleven years' rainfall at Bombay, and *four* cycles at Calcutta, and testing them by his criterion he obtains results quite similar to that for Madras.

I have only the periodic *means* for the five eleven-yearly cycles at Bombay now before me, but seeking from these the representative equation of sines as for Madras, and repeating the latter for comparison, I find—

Bombay ... ... $y = 6.1 \sin(\theta + 316°)$.
Madras .. ... $y = 6.2 \sin(\theta + 310°)$.

Both equations give almost exactly the same range of the oscillation and nearly the same epochs of maximum and minimum as the sun-spots.[3] This result, which was wholly unexpected by me, is all the more remarkable that the two places are on the opposite coasts of India, and have their rains from different quarters. Calcutta, with a sufficiently large number of cycles, might also have agreed with Bombay and Madras, which is not the case, however, with four cycles only. In each case the criterion would show that no periodicity exists.

I cannot, then, agree with Gen. Strachey as to his test of periodicity nor to the conclusions he has deduced from it. I will not enter here into the consideration of the weights which may be given to results founded on the known principles of the calculus of probabilities, nor into the question whether the rainfall, not at one or two stations only, but over a country or the whole globe, may not show some relation to the sun-spot period as Mr. Meldrum believes, and as I think quite possible, judging from other results of solar actions. This relation, however, it appears to me has still to be proved, though the observations considered by Gen. Strachey are, on the whole, so much in its favour as to encourage further investigation. JOHN ALLAN BROUN

Lyndhurst, New Forest, July 18

In the paper read by Gen. Strachey before the Royal Society, May 24 (see NATURE, vol. xvi. p. 171), "On the alleged Correspondence of the Rainfall at Madras with the Sun-spot Period, and on the True Criterion of Periodicity in a Series of Variable Quantities," certain conclusions are arrived at which render it desirable to test the value of the criterion of periodicity employed. This is the more necessary when it is considered not merely that the principle, if a sound one, must be of

[1] The years given by the equation, the series commencing with 1813·5, are 1817·8, 1828·8, 1838·8, 1849·8, 1859·8, 1870·8. The condition that an oscillation should agree in its epochs of maximum and minimum with those of a known phenomenon (a very weighty one when the chances are to be considered) has been neglected by Gen. Strachey altogether.

[2] This refers to the periodic means deduced from the observed quantities; the above equation for Madras gives the observed means with a probable

extensive application in physical research, but also, and more immediately that the conclusion arrived at seriously affects the great modern problem of Indian administration, viz., the food-supply of the people. The conclusion is that in the case of the rainfall observations of Madras, which have been discussed by Dr. Hunter, the Director-General of Statistics to the Government of India, the evidence is not sufficient to establish either any periodicity or a correspondence such as Dr. Hunter points out. The correctness or incorrectness of Gen. Strachey's views will, it is evident, materially influence the line of action taken by the Government in dealing with the disastrous famines consequent on the recurring droughts of Southern India.

The criterion of periodicity brought forward by Gen. Strachey will appear from what follows. The mean rainfall at Madras for the sixty-four years is 48·51 inches; if we take the difference between this mean and the rainfall of each individual year, and average the results, we obtain 12·40 inches as the arithmetical mean of the sixty-four differences. If we now partition the sixty-four years' rainfall into six sun-spot cycles of eleven years each, and take the difference between each individual year's rainfall and the mean of that term of the sun-spot cycle in which that year's rainfall stands, and then average these sixty-four new differences, we obtain 11·20 inches as the arithmetical mean. Since 12·40 inches, the mean difference of the individual observations from the mean of the whole series, is, by the latter process, only reduced to 11·20 inches, or about 10 per cent., Gen. Strachey concludes that the supposed law of variation obtained from the means of the six eleven-year cycles hardly gives a closer approximation to the actual observations than is got by taking the simple arithmetical mean as the most probable value for any year; and that the evidence, therefore, is not sufficient to establish any periodicity in the rainfall of Madras, or any correspondence between it and sun-spots.

In illustration of his meaning Gen. Strachey applies his criterion of periodicity to the diurnal barometric oscillations at Madras, in which a well-ascertained periodicity exists. The result of the calculation is that the mean difference of all the individual observations from the mean of the whole series is 30, whereas the mean of the differences between the two-hourly individual observations and the averages of the same hours is reduced to 7, thus indicating, it is added, the distinct presence of a periodicity.

In concluding against the presence of any periodicity in the rainfall of Madras, Gen. Strachey makes these two assumptions:—(1) If there be a periodicity in the rainfall of this part of India, it would be made apparent by applying his criterion of periodicity to the observations; and (2) the difference between the two arithmetical means calculated as above must exceed at least 10 per cent.

The diurnal barometric oscillation at Madras is so regular a phenomenon that it was scarcely worth while to make the calculations, since one could have made a close approximation to the averages 30 and 7 by a simple inspection of the figures. Further, this periodicity which has been selected is altogether inappropriate to the subject in hand, as no one could possibly imagine for a moment that any periodicity which might characterise the rainfall of Madras would exhibit an approach to such regularity of occurrence as characterises the curve of the diurnal oscillation of the barometer at that place. The periodicities which suit the subject before us are such as are presented by the curves of the diurnal barometric oscillation in the British Islands.

Let us then apply Gen. Strachey's true criterion of periodicity in the examination of such a curve, taking for our example the barometric observations at Valencia for the month of December, 1876, as published in the *Hourly Readings* at their seven observatories, by the Meteorological Committee for that month. The examination will at the same time test the value of this new criterion as an implement of scientific research.

The mean of the whole 744 observations is 29·256 inches. The differences of the individual 744 observations from 29·256 inches give an arithmetical mean difference of 0·3372 inch: and the differences between each of the individual 744 observations and the means of their respective hours give an arithmetical mean difference of 0·3369 inch. Looking at the individual hours the largest differences are 0·3434 inch and 0·3413 inch at 10 P.M., and 0·3444 inch and 0·3459 inch at 6 A.M. Thus the difference of these two arithmetic means is only 0·0003 inch, and the largest difference for any hour amounts only to 0·0021 inch.

Now Gen. Strachey concluded against the presence of a periodicity in the rainfall of Madras on the ground that the two arithmetical means differed only 10 per cent. from each other. It follows *à fortiori*, if this new criterion is of any value, that the presence of a periodicity in the diurnal barometric oscillation at Valencia during December last be concluded against, inasmuch as the difference between the two arithmetical means is only $\frac{1}{10}$ per cent., and not rising quite to 1 per cent. for any of the twenty-four hours.

The averages for the month, however, show in an unmistakable manner the presence of such a periodicity. The mean pressure there fell to 29·245 inches the morning minimum at 7 A.M., rose to 29·263 inches the morning maximum at 11 A.M., fell to 29·238 inches the afternoon minimum at 3 P.M., and rose to 29·273 inches the afternoon maximum at 10 P.M., the time of occurrence of these phases of the curve differing no more than an hour from the mean periods for Valencia at this season of the year. The periodicity is, as stated, a well-marked one, the sum of the diurnal oscillations amounting to 0·106 inch, being three-fifths of the sum of these oscillations for Madras which average for December 0·174 inch. We do not require to remind our readers that the phenomena of the diurnal oscillations of the barometer take their place among the most universally accepted and best established periodicities of science.

In the concluding paragraph of his paper Gen. Strachey apparently applies another criterion to the Madras rainfall, which consists in the comparison of the successive combination of the observations, beginning with one eleven-year cycle, and then combining two cycles, and so on, till the whole six cycles were united. The result arrived at by this treatment of the figures, is that the successive means of the differences between the mean rainfall for the combined cycles and the mean for the several years of the cycle when combined, show no appreciable periodicity.

With reference to this mode of testing the question, it may be enough to say that even were the result of such an examination as adverse as possible, it could not be used as a conclusive argument against the existence of periodicity, for the very plain reason that we are investigating a periodicity for which only six terms or separate cycles are available, and in these cycles the non-periodical elements bulk largely. But the following table, referring to the portion of the diurnal barometric curve between the morning and evening minima at Valencia for December last will illustrate the point:—

	inches	in.	in.	in.	in.				
Means for month ...	29·245	·247	·252	·259	·263		·246	·241	·238
Days of month 3	28·511	·533	·550	·561	·562	·555	·546	·535	·516
3–4	28·400	·507	·527	·541	·551	·552	·554	·556	·550
3–5	28·401	·502	·514	·526	·534	·535	·537	·541	·544
3–6	8·580	·600	..	·627	·637	·640	·644	·647	·652
3–7	28·694	·707	·723	·738	·748	·751	·756	·760	·767
3–8	28·863	·880	·899	·918	·931	·935	·942	·947	·957

The observations of the third will be seen to follow, though somewhat roughly, this portion of the curve for the month. The means of the third and fourth show a greater divergence from the monthly curve, and so on through the combinations, each successive combination showing instead of a continued approximation to, a continually increasing divergence from, the mean hourly variation of the month. It is this consideration, to which Gen. Strachey does not appear to have given due weight in his paper, which has led Meldrum and others in their investigation of periodicities of the rainfall and temperature, to extend their inquiries not only over lengthened intervals of time, but also over as wide areas as possible.

It may be added, that this new criterion of a periodicity enunciated and applied by Gen. Strachey at a meeting of the Royal Society in May last would, were it accepted, equally sweep from our view scores of periodicities now everywhere accepted, and effectually foreclose inquiry in many fields of research in which science is certain to reap brilliant results, namely, in those departments of research in which the non-periodical are very largely in excess of the periodical variations, of which meteorology may be regarded as presenting the most numerous and best illustrations.

GEOLOGICAL NOTES

GERMAN GEOLOGICAL SURVEYS—(1) AUSTRIA.—The programme of the Austrian Geological Survey for this year shows that the work is advancing, as it has been doing for some time past, mainly in two directions, one lying on the extreme east, the other on the far west of the empire. In the Tyrol two sections or parties are in the field; one of these, under Dr. Stache, and Mr. F. Teller, is investigating the crystalline masses of the Central Alps along both sides of the Vintschgau; the other, under Dr. E. v. Mojsisovics and Messrs. M. Vacek and A. Bittner, is engaged among the sedimentary formations between Botsen and the Venetian frontier. On the other side of the empire, in Eastern Galicia, Bergrath C. M. Paul and Messrs. Tietze and Lenz are busy among the Carpathians and their spurs to the south of Stanislawow. The vice-director of the Survey, Bergrath D. Stur, will also this year publish his researches on the flora of the Carboniferous period. The whole of the operations of the Survey are controlled and directed by the able hands of Ritter von Hauer.

(2) PROVINCE OF PRUSSIA.—Besides the national survey organised and paid by the government for the investigation of the geological structure of the kingdom of Prussia, there is in progress under the auspices of the Physical-Economical Society of Königsberg a geological investigation of the Province of Prussia with the publication of a map on the scale of $\frac{1}{100000}$. It might seem at a first glance that this wide alluvial plain could hardly offer much opportunity for geological observations or for much variety of colouring on the map. But by means of careful examination of the surface and well-arranged borings below it, much valuable information is being obtained regarding the structure and history of the alluvial, peaty, and drift deposits of the Baltic plain of Prussia. The lively interest which has been raised on all sides by the undertaking has suggested the idea to publish yearly an account of the progress of the work with notices of the more interesting observations and discoveries, and such additional information from other investigators or from other countries as may throw light upon the geological history of the province. Dr. Alfred Jentsch has prepared the first *Jahresbericht*, which appears in the *Transactions* of the Physical-Economical Society. After a brief account of the preparation of the map, and of the various boring operations he gives an interesting *résumé* of the geology and physical geography of East Prussia, including the variations of water-level in the Vistula and Pregel, the peat-mosses, marls, alluvial clays, drifts, brown-coal, and amber-deposits, with the cretaceous, Jurassic, and palæozoic rocks made known by boring explorations.

GEOLOGICAL SURVEY OF NEWFOUNDLAND.—Mr. Murray has published a second edition of the Index Geological Map of Newfoundland on the scale of twenty-five miles to an inch. It is of course brought up to date, and exhibits with great clearness the distribution of the various rocks of the colony. The remarkable serpentines, slates, and metamorphic rocks overlying the sandstones of the Quebec group on the west side of the island, are so inserted as to show distinctly their unconformable relations to the rocks below them. Four sections are likewise placed upon the map for the explanation of the geological structure of different regions. The map, in regard to execution, is all that could be desired, considering its small scale and provisional character. Mr. Murray's Report for 1876 has just been issued. The ice which hugged the coasts so late last year prevented a start being made until the end of June. During the few months available for exploration, Mr. Murray and Mr. Howley succeeded in mapping some portions of the interior about the Gander and Gambo rivers. As usual the routes lay along the river-courses where almost the only geological observations can be made, the intervening country being covered with swamps or forests. The Report shows that considerable areas of good agricultural land lie in the interior, and that while large masses of valuable timber exist they need to be guarded against the ignorant and wanton operations of lumber-men.

CHEMICAL NOTES

NEW CHROMIUM AND MANGANESE COMPOUNDS.—Some new compounds of chromium and manganese have lately been prepared and examined by Mr. J. B. Hannay, who has communicated a paper on the subject to the Glasgow Philosophical Society. On examining any general list of carbon compounds it is to be remarked that, however complicated their structure, they are not as a rule decomposed by water; on the other hand complex compounds of other elements are as a rule decomposed by this substance into two or more simpler compounds. Mr. Hannay was therefore induced to examine whether carbon is or is not the only element capable of forming series of bodies of complicated structure; and whether the existence of water on this earth is the reason of our not having complex bodies with other elements than carbon for their basis. The plan adopted was to take some complicated substance (containing no carbon) which is decomposed by water, find a solvent for it, and act on it with other reagents out of contact of air and moisture. The substance used was oxychlorid of chromium, (CrO_2Cl_2), and the solvents employed, carbon disulphide and carbon tetrachloride. Mr. Hannay has devised an apparatus which allows of the substance being precipitated, filtered, washed, dried, and weighed off for analysis without coming in contact with air or moisture. The following is a list of the chromium compounds prepared by him :-

$Cr_2Cl_4SO_3$.	$Cr_4Cl_6S_3$.	$Cr_2Cl_6P_2Br_6O_2$.
$Cr_2Cl_4SO_2$.	$Cr_4Cl_6S_3O_4$.	$Cr_2Cl_6P_4 6(H_2O)$.
$Cr_2Cl_4Br_2$.	$Cr_4Cl_6S_3O_{12}$.	$Cr_3Cl_6P_4$.
$Cr_2Cl_4S_2O_2$.	$CrCl_2S_2 . H_2O$.	Cr_2Cl_6PCl.
Cr_2Cl_6S.	$CrCl_2S_2$.	Cr_2Cl_6PBr.
$Cr_2Cl_4Br_2S$.	$CrCl_6PSO$.	$(Cr_2Cl_6P)_2O$.
$Cr_2Cl_4S_2$.	$Cr_2Cl_6P_4O_6$.	Cr_2Cl_6P.
	$Cr_2Cl_6P_4O_2$.	

Mr. Hannay has prepared some analogous manganese compounds, but the analyses of these have not as yet been finished.

COMPLEX INORGANIC ACIDS.—Dr. W. Gibbs has lately obtained a series of new inorganic acids formed on the type of the silico-tungstic acids obtained by Marignac. The new series of salts contain platinum instead of silicon, and the salt $10WO_3PtO_24Na_2O + 25\ H_2O$ has been obtained by boiling platinic hydrate $Pt(OH)_4$ with acid sodic tungstate. Two metameric sodium salts have been obtained, one of an olive-green colour, the other honey yellow with an adamantine lustre. The corresponding potassium and ammonium salts of this platino-tungstic acid have also been obtained, but they belong to the yellow series. Mr. Gibbs has not as yet obtained salts corresponding to Marignac's twelve atom silico-tungstates. Acid molybdate of sodium also dissolves $Pt(OH)_4$, giving a green solution, which appears red when viewed in thick layers; the only salt of this series studied, crystallises in amber tabular plates having the composition $10MO_3PtO_24Na_2O + 25H_2O$. He is endeavouring to generalise the results by substituting other hydrates, such as $Zn(OH)_4$, $Ti(OH)_4$, $Sn(OH)_4$, but has, as yet, in these cases not obtained very definite results. He is also engaged in examining the phospho-tungstic acids containing $20WO_3$ obtained some time ago by Scheibler.

A SUPPOSED NEW METAL "DAVIUM."—The discovery of this new element is reported from St. Petersburg by Serjius Kern. It was found by him in the residues of platinum ores after treatment to separate out the metals of the platinum group. The specific gravity of the metal is given as 9·385 at 25°. The author supposes this new metal to occupy an intermediate position between molybdenum and ruthenium, but very strong evidence will be necessary to confirm the existence of a new metal belonging to the platinum group.

EFFECT OF PRESSURE ON CHEMICAL ACTION.—M. Berthelot, in a recent number of the *Bull. Soc. Chem.*, calls attention to the fact that some experiments lately made by Quincke have confirmed a statement made by the former chemist some time ago, that the evolution of hydrogen from zinc and sulphuric acid is not arrested by pressure. The experiments of Quincke show that when these bodies are brought in contact, the pressure of the hydrogen evolved rose in a few days from 1·5 to 10 atmospheres, and in a very much longer time from 25 to 126 atmospheres. Berthelot thinks that these experiments, although not performed for this purpose, prove that chemism is not modified, but only the nature and extent of the surfaces attacked. The evolution of gas would thus go on indefinitely, not arrested, but only modified in rapidity.

AMOUNT OF OXYGEN CONTAINED IN SEA-WATER AT DIFFERENT DEPTHS.—At a recent meeting of the Royal Society of Edinburgh Mr. J. Y. Buchanan communicated some results obtained from his experiments on the above subject during the cruise of the *Challenger*. Mr. Buchanan finds that at the surface the amount of oxygen varies between 33 and 35 per cent., the higher numbers having been observed in a water collected almost on the Antarctic circle; the smallest percentages have been observed in the trade-wind districts. In bottom waters the absolute amount is greatest in Antarctic regions, diminishing generally towards the north. The oxygen percentage is greatest over "diatomaceous oozes," and least over red clays containing peroxide of manganese; over "blue muds" it is greater than over "globigerina oozes." In intermediate waters the remarkable fact was observed that the oxygen diminishes down to a depth of 300 fathoms, at which point it attains a minimum, after which the amount increases. The following figures show the nature of this phenomenon:—

Depth (fathoms)	0	25	50	100	200	300	400	800	Between 800 and the bottom.
Oxygen (O + N = 100)	33·7	33·4	32·3	30·2	33·4	11·4	15·5	22·6	23·5

It is evident from these figures that between 200 and 400 fathoms there is a great consumption of oxygen going on, and, as it is difficult to conceive its being consumed otherwise than by living creatures, the conclusion may be drawn that animal life must be particularly abundant and active at this depth, or at least more abundant than at greater depths; for, at less depths, there is more opportunity of renewal of the oxygen by reason both of the greater proximity to the surface and of the existence of vegetable life. This conclusion is borne out by the experiments of Mr. Murray with the tow-net at intermediate depths, which go to prove the existence of abundance of animal life down to 400 fathoms, vegetable life never extending much below 100 fathoms. Below 400 fathoms life is sparingly met with.

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF 1605, OCTOBER 12.—It is known that Clavius attributed the ring of light which he observed round the moon during the eclipse of April 9, 1567, about the time of greatest obscuration at Rome, to the circumstance of the sun's disc not being entirely covered by our satellite, a narrow rim of light thereby remaining visible. As Prof. Grant relates, in his "History of Physical Astronomy," Kepler maintained that the luminous ring seen by Clavius could not have been the margin of the solar disc, because he found by calculation that the moon was at her mean distance from the earth, when her apparent diameter exceeds that of the sun, even in perigee; and when a similar ring of light was remarked round the moon during the eclipse of February 25, 1598, and attributed to the same circumstance, Kepler again pointed out that such an explanation was inadmissible, the moon's apparent diameter, on this occasion also, exceeding that of the sun. These opinions were expressed by Kepler in his work "Ad Vitellionem Paralipomena," published in 1604, and Prof. Grant remarks that an eclipse in the following year strikingly confirmed them. This refers to the eclipse of October 12, 1605, observed at Naples, of which Kepler writes thus: (*De Stella Nova in pede Serpentarii*, p. 116) "the whole body of the sun was effectually covered for a short time. The surface of the moon appeared quite black, but around it there shone a brilliant light of a reddish hue, and uniform breadth, which occupied a considerable part of the heavens." We follow Prof. Grant's translation of this passage, which clearly proves that the eclipse was total for a brief interval at Naples.

As the eclipse of 1605 first confirmed the accuracy of Kepler's views, in opposition to those of Tycho Brahé, who disputed the possibility of a total eclipse of the sun, it may not be without interest to examine the circumstances of the phenomenon as it would be observed at Naples. For this purpose the same system of calculation adopted for other eclipses mentioned in this column, is followed. The elements are:—

G.M.T. of Conjunction in R.A. 1605, Oct. 12, at 0h. 31m. 44s.

	° ′ ″
R.A.	197 14 51·0
Moon's hourly motion in R.A. ...	35 37·1
Sun's „ „ „ ...	2 19·1
Moon's declination	6 40 27·9 S.
Sun's „	7 31 32·5 S.
Moon's hourly motion in decl. ...	10 50·2 S.
Sun's „ „ „ ...	0 56·4 S.
Moon's horizontal parallax	59 21·2
Sun's „ „	8·9
Moon's true semi-diameter	16 10·4
Sun's „ „	16 3·9

The eclipse would therefore be central with the sun on the meridian in long. 11° 18′ W. and lat. 52° 26′ N., and the following would also be points upon the central line:—

Long. 19° 9′ E., lat. 39° 32′; and long. 14° 23′ E., lat. 40° 48′.

Calculating directly for Naples we find :—

	h. m. s.	
Totality began October 12 at	2 18 18	Mean time at Naples.
,, ended ,, ,,	2 19 28	

The duration of the total eclipse was 1m. 10s., which is in satisfactory agreement with the words of Kepler. The sun was at an altitude of 31°.

THE BINARY STAR α CENTAURI.—As far as can be judged from a projection of the measures published to the present time, it appears probable that the nearest real approach of the components in this binary is already passed, but that they will continue to apparently close-in until the angle is somewhere about 110°, when their distance may have diminished to $1\frac{3}{4}''$. We can only continue to urge upon southern observers the great importance of frequent measures of this object for some years to come, with all the precision that the case will admit of, that a problem of the highest interest in celestial mechanics may be fully investigated.

MIRA CETI.—This variable star is now close upon the epoch of minimum, as calculated from Argelander's formula of sines, and observations so far are much fewer in number near this part of the light-curve than about the maximum. The gradual ascent to the next maximum may be favourably watched in the present year; the date by the formula is November 10, 1877.

D'ARREST'S COMET.—By M. Coggia's observation at Marseilles on the morning of the 10th inst., it appears that M. Leveau's ephemeris gives the position of the comet within about 3'. Subjoined are the calculated places for Paris noon, during the next period of absence of moonlight :—

	Right Ascension. h. m. s.	North Polar Distance. ° '	Distance from the Earth.
August 8	3 57 35	83 45·0	1·559
10	4 1 12	83 53·2	1·555
12	4 4 43	84 2·0	1·551
14	4 8 7	84 11·4	1·547
16	4 11 24	84 21·4	1·543
18	4 14 35	84 32·0	1·538
20	4 17 38	84 43·2	1·533
22	4 20 34	84 54·9	1·529

This comet has not yet been observed under its most favourable situation with respect to the earth. When the perihelion passage occurs early in August, it may approach our globe within 0·3 of the earth's mean distance from the sun, but, so far, has not been seen within a distance of about 0·8. At the next return at the beginning of 1884, observations will probably be difficult, but in 1890, when the perihelion passage (as well as can be foreseen without the calculation of planetary perturbations) is likely to fall in the latter part of August or in September, the comet's track in the heavens will be a favourable one.

NOTES

THE annual meeting of the Institution of Mechanical Engineers opened on Tuesday at Bristol. Mr. T. Hawksley, C.E., in his opening address, said it was the duty of the government to adopt such timely measures as would secure to us the paths of the ocean for our food inwards and our manufactures outwards. He deprecated the building of enormous and unwieldy floating castles, and advocated the construction of a fleet of swift, light, well-engined ships, equally capable of sailing or steaming. He thought the extreme action of some of the working classes the cause of England's trades going abroad. There was a conversazione in the evening.

A REMARKABLE case relating to manufacture and transport of explosives has just been the subject of an inquiry before the Wreck Commissioner. The facts are briefly these :—The passenger sailing ship *Great Queensland* left London for Melbourne on the 5th of August last. After the 12th, when she was spoken at sea, she was never seen; but some wreckage from her was washed ashore the same month on the south coast of England. She had taken on board some thirty-four tons of gunpowder, including two tons of the "Patent Safety Blasting Powder" (a compound made in North Wales by treating wood pulp with acid, and stated to have five times the strength of ordinary gunpowder !). There was also a large quantity of detonators and percussion caps. The stowage seems not to have been up to the mark; still the Commissioner regards it as having been fairly safe, but for the danger of spontaneous ignition of the patent powder, to which the facts apparently point as the probable cause of the disaster. The evidence bearing on the manufacture of the compound is not a little surprising. In 1875, the manager in charge of the process was a Mr. Hunt, describing himself as "an engineer, but no chemist." The powder he turned out seems to have been dangerously impure, and some of it having come into the hands of a Government Inspector was found so bad that a regular visit was made to the Company's works. Eight samples were analysed and pronounced impure and dangerous. Mr. Hunt was displaced. His successor, a Mr. Thistleton, made an attempt, at the directors' request, to re-dip the powder left by Mr. Hunt; but the smoke became intolerable, and at 110 deg. the sides smouldered into fire and dirtied everything about, while the heat broke the windows and charred the woodwork. He accordingly suggested that the only way was to dip it in potash solution. The process of remaking was going on in the early months of last year, and it was a portion of this remade impure powder of Mr. Hunt which was shipped on the *Great Queensland*. A few days after she sailed news came of an explosion at the Patent Gunpowder Works, and Major Majendie, having examined a cartridge found on the works after this, wrote that "accident is hardly the term to apply" to what happened. The conclusion of the Wreck Commissioner, then, is that the same event happened at sea and caused the disappearance of the ship. The facts speak for themselves. The case is evidently one of gross mismanagement based on an ignorance which might be laughable, though not excusable, in people employed in mixing tea and coffee, but shameful in the direction of a company for making an explosive. Considering the scientific knowledge imperative in making and handling our modern explosives, the appointment of the one manager who was "no chemist," and of the other who was so good a chemist (from the Royal Polytechnic) as to proceed to *re-dip* Hunt's material *in order to make it stronger*, at the request of his directors, and was only warned off when this compound nearly blew him into the air, calls loudly for explanation. It is important that the whole responsibility involved in this disgraceful case be fully elucidated by further inquiry.

WE regret to announce the death of Prof. Adolph Erman, the well-known physicist, which occurred in Berlin, July 13th. He was born in Berlin, 1806, and after completing a broad range of scientific study, devoted himself to physics, following in the path of his father, who was then professor of that branch in the Berlin University. In 1828 he joined the Norwegian expedition sent out to Siberia to investigate the phenomena of terrestrial magnetism. His own researches were carried out far beyond the confined limits of the expedition, and after thoroughly examining the hitherto almost unknown volcanoes of Kamtschatka, he terminated his journey by completing the circuit of the world in a Russian frigate. The rich store of magnetic observations made during the entire tour were gathered together into a work of two volumes. In 1834 Erman was appointed Professor of Physics at Berlin, a post which he continued to occupy up to the time of his death. From 1841–1866, he edited the *Archiv für wissen-*

schaftliche Kunde von Russland, a periodical issued at the expense of the Russian Government and designed to keep the world at large informed of the progress of scientific research in Russia. His investigations, extending into nearly every branch of the natural sciences, appeared chiefly in *Poggendorff's Annalen* and the *Astronomische Nachrichten*. The most valuable are his researches on terrestrial magnetism. In connection with H. Petersen he calculated the constants for Gauss's theory of terrestrial magnetism, based on his own multitudinous observations. A most valuable contribution to Gauss's theory is also to be found in his work on the magnetic phenomena of the year 1829, which includes a complete study of secular changes based on all then made observations. An equally exhaustive work on the magnetic phenomena of 1860, was left uncompleted at his death. In 1874 Prof. Erman was elected a fellow of the Royal Society.

WITH the view of extending the rudimentary teaching of physiology and the laws of health in elementary schools, the National Health Society has placed at the disposal of the School Board for London, in addition to a sum of 100*l.* offered previously, a further amount of 25*l.* annually for four years, to be given in premiums to those teachers and children who pass the best examinations in these subjects.

SINCE the institution of the Morgue in Paris, unidentified bodies have, it is known, been exposed, unclad, on stone slabs. It has now been decided (we learn from the *Revue Scientifique*) that the dead shall be placed before the eyes of the public just as they have been found, with the proper exception of those who bear on any part of their body a mark which may facilitate recognition. It is anticipated that this measure will increase by a third the number of identifications at the Morgue.—A course of lectures on legal medicine at the Morgue will be commenced in November. This practice has been discontinued for the last fifteen years.

THE Helvetic Society of Natural Sciences is to hold its annual congress at Bex, canton de Vaud, on August 20, 21, and 22.

THE intention is known to have been long cherished to erect a monument in Stockholm to Linnæus, and a sum of 45,000 crowns has been collected for the purpose. There have been two proposals, and to carry out the smaller of these the sum just named would be sufficient. But since the conviction has of late gradually gained strength that the statue should be raised on the so-called "Flora's Bakke" (Flora's Hill), in the Hop Garden, a desire has also grown to realise the larger proposal, according to which Linnæus would appear surrounded by four allegorical figures representing the four sciences to which he devoted himself, viz., Botany, Zoology, Mineralogy, and Medicine. On the understanding that the commune will supply the necessary means for the pedestal and for erection of the monument, a sum of 30,000 crowns was still required to give effect to the larger scheme, and a subscription list has lately been started by thirty influential citizens of the Swedish capital with this object. These thirty have together subscribed 15,000 crowns, and it may be anticipated that the remaining 15,000 will ere long be forthcoming.

WE have recently received a large number of reports of local societies, several of them containing papers of more than local interest, but to which we can refer only in the briefest possible way. The Norfolk and Norwich Naturalists' Society is numerically and financially stronger than at any previous period. Among the twelve papers published in its *Transactions* is one by Prof. Newton, giving an interesting account of the naturalisation of the Edible Frog (*Rana esculenta*) in Norfolk. Mr. Randall Johnson contributes an approximate list of the extinct mammalia of Norfolk.—The *Annual Report* of the Manchester Scientific Students' Association speaks favourably of its position and prospects, as does also the *Report and Proceedings* of the Manchester Field Naturalists and Archæologists' Society in the case of that Society.—The Cardiff Naturalists' Society is a large one and its thick *Report and Transactions* for 1876 contains several good papers.—Other Reports or Proceedings received are from the Bath Natural History Society, the Miners' Association of Cornwall and Devon, the South London Microscopical and Natural History Club, the Croydon Microscopical Club, the East Kent Natural History Society, the Geological and Polytechnic Society of the West Riding of Yorkshire, the Torquay Natural History Society, the Brighton and Sussex Natural History Society, Quekett Microscopical Club, and the York School Natural History, Literary, and Polytechnic Society. Of one or two of the papers in the Natural History Transactions of Northumberland and Durham we hope soon to give a detailed notice.

THE heat conductivity of hardened caoutchouc has been recently determined by Prof. Stefan, of Vienna. With six plates of equal thickness a parallelepipedal vessel was formed, and arranged as an air thermometer. The apparatus having acquired the temperature of a regularly-tempered room, it was inserted quickly in a vessel of broken ice; the time of insertion, and the position of the mercury in the manometer immediately observed, and then the times noted at which the mercury reached particular heights. The thermometric conductivity was found about $0\cdot000928\frac{\text{cm}^2}{\text{sec.}}$. Taking the specific heat of unit mass of vulcanised caoutchouc $= 0\cdot23$, and the specific gravity $= 1\cdot22$, it follows that the thermal conductivity $= 0\cdot00026$.

THE American expedition round the world, recently organised by Mr. Woodruff, of Indianapolis, is to start in October, and continue two years. Among the naturalists that have been engaged are Prof. Burt G. Wilder, of Cornell University, Dr. W. G. Farlow, Prof. Jenney, of Michigan University, Prof. Sidney J. Smith, of Yale College, Prof. S. C. Russell, of the School of Mines, Columbia College, C. Hart Merriam, and Dr. J. H. Kidder, U.S.N. The number of students is limited to eighty. The whole expense to each student is $5,000.

AT the last session of the Berlin Photographic Society a report was presented on the extent of photography in Germany from which we glean some interesting statistics. In the German Empire there are 3,000 photographers, who require each on an average 3 lbs. of nitrate of silver annually. Austria possesses the same number of photographers, but the average annual consumption of nitrate of silver is but 1 lb. Germany manufactures 20,000 reams of albuminised paper annually, of which but 1,000 are for home use. 40,000,000 cartes-de-visite were prepared in Germany during 1876.

THE Italian Committee for the exploration of Africa held its first session in June at Turin, under the presidency of the Crown Prince. It was decided to co-operate vigorously with the International Committee. The Italian Committee will devote its energies at first to the establishment and maintenance of a station at Shoa, where the Marchese Antinori is at present, regarding this as one of the most desirable positions from which to send out expeditions into the interior of Africa.

THE Scottish Meteorological Society holds its half-yearly general meeting in Edinburgh to-day. The business includes reports by Mr. Buchan on the temperature of the sea at Peterhead, and on the relations of the herring fishery to meteorology, for the four years 1873-76.

THE first number of Prof. Hoppe-Seyler's new quarterly journal, the *Zeitschrift für physiologische Chemie* has appeared. It contains valuable papers on the process of urea-formation in animal bodies, and the influence of ammonia salts on this

(Salkouski).—On aromatic substances in the animal body, and determination of sulphuric acid in urine (Baumann).—On animal and plant albuminous bodies (Weyl).—On lactosuria (Hofmeister); and on the physiology of lactic acid (Spiro). The journal is a decided acquisition to scientific literature.

We have received the programme of excursions of the Manchester Field Naturalists' and Archæologists' Society for July to October. The seven excursions arranged (for Saturdays) appear to be of a varied and interesting character.

The additions to the Zoological Society's Gardens during the past week include an Egyptian Gazelle (*Gazella dorcas*) from North Africa, presented by Mr. H. B. Benson; a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, presented by Mrs. Escott; a Burmeister's Cariama (*Chunga burmeisteri*), a Brazilian Stilt Plover (*Himantopus brasiliensis*) from Buenos Ayres, two Black Swans (*Cygnus atratus*) from Australia, two Piping Guans (*Pipile cumanensis*) from Bahia, an Urumutum Curassow (*Nothocrax urumutum*) from Brazil, deposited; a Wapiti Deer (*Cervus canadensis*), an Indian Muntjac (*Cervulus muntjac*) born in the Gardens.

ASTRONOMICAL SYMBOLISM OF THE EAST[1]

THE two stars which in the book of Job are connected with Orion, and to which the Indian Orion-legend referred, are connected with the two red stars or Kohini of Indian traditions. It is shown that these two fixed stars, observed as contemporaneously rising and setting on the horizon, formed the unchangeable starting points for regulating the lunations, and that they thus brought about in course of time an absolute correct chronology. The early discovery of equinoctial precession led to the substitution of these fixed stars by the changeable equinoctial points, till Copernicus, by separating the latter from the solar path, re-established the correct measurement of time by referring the solar motion to fixed stars. The determining single stars, later, constellations nearest to the equinoctical points, to which former, both Chinese and Persian, traditions refer, became the symbol of the order manifested by the heavenly bodies, which cosmical order was attributed to the Deity. The symbol of the two cherubs or kirubs, that is "bulls," in the language of cuneiform inscriptions, are shown to have referred to the rising and setting of the constellation of Taurus, which being called Kirub at its rising, was called Seraph, or Ser-Apis, literally, "the grave of the bull," at its setting. The Pleiades in the neck of Taurus stand in the same relation to this constellation as the god Sebaot, the god of the Sheba-ut, or seven stars, the Sibut of the Babylonians, to the Cherub. The symbol of the chariot of the Cherubim, and of Jehovah riding on the Cherub, as the Pleiades may be said to be riding on Taurus, are thus astronomically explained, and connected with the representations of Ormuzd riding on the winged bull, as also with similar Mithraic representations. The fortnightly period of the Hebrews, from the new moon to the full moon, in connection with the precessional cycle of seventy-two years, probably known to the Hebrews, is shown to have formed the basis of the Osiris-Typhon legend, which was fully developed before the commencement of Egyptian history. The fourteen divisions of the litanies of Thot, the god riding on the moon, and whose secret number was seventy-two, are explained by reference to fourteen moon-stations of the lunar zodiac, the hidden Mazzaroth or mansions of the moon in the book of Job, and to the precessional cycle of seventy-two years, with which can be connected the solar year and the Phœnix period of the Egyptians, the Saros of the Babylonians, and the Mosaic period of one day like a thousand years, as well as several other Babylonian periods; also the number of the sons of Japhet, and the genealogies in Luke from Seth to Joseph, the husband of Mary. When the solar zodiac had taken the place of the lunar zodiac, when the two determining fixed stars had been replaced by the changeable equinoctical points, and the commencement of spring and of autumn became the fundamental symbol of all religions, the ideal heroes of light were connected with the spring-equinox, at first in Taurus, and the ideal heroes of darkness with the autumn-equinox, at first in Scorpio, close to which is the constellation of the Serpent. Thus to Ormuzd, Indra, Osiris, Dionysos and Apollos, were respectively opposed the serpent deities Ahriman, Ahi, Typhon, the Titans and Python. So also the Messiah, "The Sun of Righteousness," and "the day-spring from on high," was opposed by Satan, literally the antagonist, "the old serpent" the devil. The transition from the sacrifice of bulls to the sacrifice of lambs, and the vicarious and sin-removing character of these sacrifices in pre-Abrahamic times, is shown to have been connected with, and probably to have been caused by equinoctial precession, by Aries having taken the place of Taurus. Some of the mysteries of the Great Pyramid are explained by Eastern astronomical symbolism and the two passages pointing north and south are shown probably to have referred to the approximatively contemporaneous midnightly culminations of Aldebaran and Antares at the autumn equinox, as observable at places in the latitude of the Great Pyramid, and likewise in the latitudes of Bactria and Northern India, during a period of about 150 years, within which the year 3300 B.C. falls. The fact that Chinese, Indians, and Arabians, at a remote period, counted twenty-eight moon stations, but that there is nowhere a trace of twenty-nine mansions of the moon, is submitted as possibly implying a date for the earliest astronomical observations of the East transmitted to us, at a time when the lunar month, now having a duration of about twenty-nine and a half days have only twenty-eight days, or rather, not yet twenty-nine. As the mean motion of the moon is the same in long periods, this period of twenty-nine days would have probably commenced about 600,000 years ago, if the retardation of the earth's rotatory motion, by which alone the prolongation of the lunar month seems to be explainable, really does amount to twenty-two seconds in a century, as now asserted by high authorities.

[1] Abstract of paper read at the Society of Biblical Archæology, "On Astronomical Symbolism of the East, as transmitted by Hebrews and Christians," by M. Ernest de Bunsen.

THE NORWEGIAN EXPEDITION TO THE NORTH SEA

FROM a letter by Prof. G. O. Sars, in the *Christiania Dagbladet*, dated Bodö, June 24, we make the following quotations with reference to the progress of the Norwegian expedition which left Bergen on June 11:—

"On the 16th of June we had arrived sufficiently far northward to commence our labours, and sounding-lines, thermometers, dredges, and trawling-nets were at once called into use. Since then the work has been pursued unremittingly, despite stormy weather, and we have every reason to be satisfied with the results so far. The hitherto-unknown contour of the sea's bottom between Folden fiord and the Lofoten Islands is now so clearly ascertained by means of our transverse section, that we can map out to the north with a certain degree of precision the curve of the extended barrier, which keeps back the cold water coming from the depths of the Polar Sea. We have found the curve somewhat different from our expectations, especially in the neighbourhood of the Lofoten. The soundings appear to indicate the presence of a remarkable indentation, similar to the one on the southern part of the coast, and we have found a precipitous slope of the sandbank resembling that of the well-known "Storeg" near Aalesund. It is evident that we have encountered here a most important submarine conformation. The consideration of its effect on our sea-fisheries will be delayed until more detailed surveys have been carried out. In the course of our soundings on the way to Bodö, we were able by means of the improved Negretti-Zambra thermometer to establish beyond the range of doubt the presence of a layer of warm water below a layer of cold water of considerable depth.

"Our zoological acquisitions have been highly satisfactory, especially those in the cold zone. We have added several species to the list of the previous expedition; amongst them some hitherto detected in the Polar Sea only and others entirely new.

"The voyage will be pursued to Röst, where several days will be spent in magnetic observations, and in gathering zoological specimens. The latter promise to be of value on account of the zoographical interest of the locality, which has as yet been left unvisited. The section from Röst will be followed carefully in order to determine with certainty the expected bend in the sandbank. The progress of our expedition shows us more and more the fundamental importance of an accurate knowledge of the physical nature of the North Sea, not only for Norway, but also for the solution of the general questions with regard to the physical and biological conditions of the ocean in general."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

BERLIN.—No small degree of excitement has been caused in the university circles of Germany by the expulsion of a Privat-docent, Dr. Dühring, from the University of Berlin, not only on account of the great rarity of the occurrence, but on account of the circumstances leading to the act. Dr. Dühring, who has suffered from blindness since the commencement of his pedagogic duties in 1865, has developed, notwithstanding, a remarkable degree of mental activity in a variety of directions, issuing works on political economy, metaphysics, mathematical physics, &c., and attracting a numerous auditory by the radical and unfettered character of his utterances on these subjects. His unsparing denunciation of the more shadowy side of German universities, the system practically in vogue with regard to the appointment of professors, &c., has induced a somewhat wide-spread feeling of bitterness towards him, which has led to an accusation before the university based on the unmeasured personal criticism of his colleagues, especially Prof. Helmholtz, in lately issued works. The expulsion has led to the holding of meetings and issuing of addresses by the more radical portion of the students, who regard the section of the Prussian constitution, "die Wissenschaft und ihre Lehre ist frei" as endangered; and the whole affair has led to a thorough ventilation of the condition of the universities in the press of the empire.

RUSSIA.—The Russian Government expends 2,140,000 roubles (over 300,000*l.*) on its seven universities, of which sum the Moscow University receives the most—425,000 roubles.

SALARIES OF GERMAN PROFESSORS.—From a recent statement with regard to the salaries in the Berlin University, we notice that the two well-known professors of chemistry and physics receive each 1,500*l.* independent of the lecture receipts, while 900*l.* is the salary of a number of other leading professors. These figures are, however, much above the corresponding ones of other German universities.

STRASSBURG.—According to an imperial order the University receives in the future the title "Kaiser Wilhelms Universität." The present attendance—658—shows for the first time since the re-establishment of the University a decrease in the number of students. The faculty embraces 106 professors and privat-docenten. The large anatomical laboratory is approaching completion.

TÜBINGEN.—The present number of students in attendance on the University amounts to 1,103, the largest number attained since its foundation. Extensive preparations are being made for the celebration in August of the 400th year of its existence.

ZURICH.—The University has at present an attendance of 324, of which the majority are in the medical faculty. Of the seventeen female students fourteen study medicine and three philosophy.

SCIENTIFIC SERIALS

THE *Quarterly Journal of Microscopic Science* for July contains several articles of special interest. First is the fourth part of Mr. Archer's *résumé* of recent contributions to our knowledge of "Fresh-water Rhizopoda," in which *Lecythium hyalinum*, *Chlamudophrys stercorea*, *Platoum parvum*, *Gromia paludosa*, and *Cyphoderia truncata* are described and figured.—Following is an abstract of Mr. E. C. Baber's researches on the lymphatics and parenchyma of the thyroid gland of the dog, with illustrations, published at length in the *Philosophical Transactions*.—Dr. Watney also, from the same *Transactions*, gives, with a plate, an account of his study of the minute anatomy of the alimentary canal.—Dr. Angelo Andres describes and figures a new genus and species of *Zoanthina Malacodermata* (*Panceria spongiosa*).—Prof. Franz Boll follows with his "Contributions to the Physiology of Vision, and of the Sensation of Colour."—Mr. A. Sangster has observations on the muscular coat of sweat glands, in which it is shown that the epithelium of the gland rests directly upon the muscle surrounding it.—Dr. Klein contributes a paper on the minute anatomy of the omentum, describing certain bud-like structures occurring on the fenestrated portion, the method of production of the fenestræ, and some points in the formation of the blood-vessels.—Mr. F. Darwin writes on the protrusion of protoplasmic filaments from the glandular hairs on the leaves of the Common Teasel, in which he helps to develop the important principles of the incipient steps in the formation of special organs.—Mr. H. N. Moseley gives notes on the structure of several forms of Land Planarians, with a description of two new genera and several new species, and a list of all species at present known.—Notes and memoranda conclude the number.

Bulletin of the Buffalo (N.Y.) *Society of Natural Sciences*, 1877. This society has published a valuable list of the freshwater fishes of North America by Mr. D. S. Jordan. Mr. M. C. Cooke is contributing a similarly exhaustive list, with references, of the hyphomycetous fungi of the United States.—An interesting paper by Mr. F. S. Dellenbaugh gives some account of the so-called Puebla Indians of the Rocky Mountain region, also known as Shinumos. They were not really of Indian race; they seemed to have died out in consequence of the incursions of the true Indians. The name Moquis, by which seven of their villages are designated, signifies "the dying race." In their retreat before the enemy they occupied the most inaccessible retreats in the cañons, built cliff houses, cultivated minute patches on the cliffs, lived in caves, &c. They appear to have had considerable artistic skill, from the designs, and even paintings, left on sandstone in the walls of houses, &c. The writer urges a careful exploration of all the extant remains of these people, for they are rapidly being destroyed by careless and ignorant settlers.

SOCIETIES AND ACADEMIES

LONDON

Meteorological Society, June 20.—Mr. H. S. Eaton, M.A., president, in the chair.—Henry Hearder and Henry Law, M.Inst.C.E., were elected fellows of the Society.—The following papers were read:—On an improvement in the mechanism of self-recording meteorological instruments, by the Rev. C. J. Taylor. In order to obviate sluggishness in self-recording aneroids and ordinary small-bore mercurial barometers, the author places a small electric bell apparatus, from which the bell has been removed, so that the clapper when in action shall strike on the top of the vertical brass bar on which the recording pencil slides; by this means a very rapid succession of light taps can be administered at a point which affects all the moveable parts of the mechanism.—Results derived from the sunshine records obtained at the Royal Observatory, Greenwich, by means of Campbell's self-registering sun-dial, during the year ending April, 1877, by W. Ellis, F.R.A.S. The instrument consists of a very accurately-formed sphere of glass four inches in diameter, supported concentrically within a well-turned hemispherical metal bowl in such a manner that the image of the sun formed when the sun shines falls always on the concave surface of the bowl. A strip of some material being fixed in the bowl, the sun, when shining, burns away the material at the points at which the image successively falls, by which means a record of periods of sunshine is obtained. The duration of sunshine in hours for each month of the year ending April 30 (excepting from May 1 to 6, July 31, and October 27 to 31), was as follows:—

	hrs.		hrs.		hrs.		hrs.
May	152·3	Aug.	216·9	Nov.	35·9	Feb.	36·4
June	184·5	Sept.	106·1	Dec.	6·5	Mar.	99·3
July	214·3	Oct.	47·3	Jan.	18·7	Apr.	71·8

The greatest daily duration was 13·9 hrs. on June 11, daily durations exceeding 10 hrs. occurred six times in May, eight in June, ten in July, and eleven in August. One of the most remarkable periods was August 7 to 14, the duration having exceeded ten hours on every day during this time. It appears that in the months of August, September, and October, the mean maximum and minimum temperatures were both, on the average, higher on days of greater sunshine than on days of lesser sunshine, whilst in the months of January and February, an exactly opposite condition existed. In the remaining months the mean maximum temperature of the greater sunshine group was higher, and its mean minimum lower, than the corresponding mean maximum and minimum temperatures of the lesser sunshine group. It also appears that there was more sunshine after noon than before noon in every month, except August, March, and April.—On the diurnal variation of the barometer at the Royal Observatory, Greenwich, by W. Ellis, F.R.A.S. The Astronomer-Royal having communicated the numerical values of the variations of the barometer as deduced from the photographic records at the Royal Observatory, during the twenty years ending

1873, the author adds a few general remarks thereon. Comparing together the different months of the year, it is observed that the morning minimum and the forenoon maximum both occur earlier as the year advances; they are earliest in summer, and become later again on the approach of winter. The afternoon minimum and evening maximum, on the contrary, occur later as the year advances; are latest in summer, and become earlier again towards the end of the year. They all change in a certain degree with the changes in the times of sunrise and sunset. As a consequence of this the intervals between the morning minimum and the forenoon maximum, and between the afternoon minimum and evening maximum do not change very much through the year, whilst that between the forenoon maximum and afternoon minimum is much shorter in winter than in summer, and that between the evening maximum and morning minimum is much longer in winter than in summer.—On the rainfall of Jamaica during the seven years 1870-76, by Griffith N. Cox.—Contributions to the meteorology of Cannes, by William Marcet, F.R.S.—Mr. Marriott exhibited and described Bogen's hygrometer and new standard siphon barometer. The barometer possesses the following special features:—It is so constructed that it can easily be put together and taken to pieces again. The long leg consists of a tube of the same diameter throughout, and is supplied with a glass stopper which has a very fine bore passing through its centre, enabling one to fill the tube with mercury in one or two minutes and to completely exhaust it of air in one or two minutes more. The open end of the long leg is ground air-tight to the short (curved) leg and can be instantaneously put together or separated. The long tube alone is graduated so as to have only one scale, but by a peculiarly-constructed screw of given length placed on the short tube a precise and accurate reading can be easily obtained. The barometer is mounted on a peculiarly-shaped stand which has three adjusting screws by means of which the perpendicularity of the instrument can be ensured.

Paris

Academy of Sciences, July 16.—M. Peligot in the chair.—The following papers were read:—Anthrax and septicæmia, by MM. Pasteur and Joubert. Anthrax may be called the disease of (what the authors call) *bacteridie*, as trichinosis is the disease of the trichina. The blood of a healthy animal contains neither microscopic organisms nor their germs. That of an animal having anthrax contains no organisms but the *bacteridie*, which is aerobic, so that the anthracic blood is imputrescible of itself. In the carcase the blood putrefies through vibrios lodging in it. The *bacteridie* disappears in liquid, in presence of CO_2. It is a mistake that putrefaction, as such, destroys the anthracic virulence. The development of the *bacteridie* takes place difficultly when in the presence of other organisms. These observations the authors apply to certain facts of practical experience. They state that septicæmia is produced by a *vibrionien* as anthrax is by a *bacteridie*.—Experiments, according to which the fragmentary form of meteoric irons may be attributed to a rupture under the action of strongly compressed gases, such as arise from explosion of dynamite, by M. Daubrée. To steel prisms were attached charges of dynamite, which were exploded in clay pits, so that the parts could be brought together after rupture. The alveoli produced (often grouped) with projecting rim, were of more pronounced character than those from powder. The surface was sometimes raised in long bulging ridges. The surfaces of fracture were some of them polished, others striated.—Researches on the tertiary strata of Southern Europe, by M. Hebert. This first paper relates to the eocene and lower miocene of Hungary.—M. Dumas, referring to a recent paper by M. Sée, affirmed that the real inventor of salicylic acid was the eminent Italian chemist M. Piria.—On a disease of the grape in the vineyards of Narbonne (June and July, 1877), by M. Garcin.—Observations of D'Arrest's periodic comet at the Marseilles Observatory, by M. Stephan.—Note on the theory of quadratic forms with any number of variables, by M. Frobenius.—Demonstration of two geometric laws enunciated by M. Chasles, by M [illegible]uret.—On the division of the circumference into equal parts, by M. Lucas.—Researches on the compressibility of liquids (continued), by M. Amagat. *Inter alia*, the coefficient of compressibility increases when the pressure increases for all liquids in which it increases with the temperature. The compressibility of successive terms of the family of formenic carburets decreases regularly as we descend in the series, both at 100° and at ordinary temperature. The presence of sulphur, chlorine, or bromine, in liquid bodies, tends to render them less compressible.—On the electric and capillary properties of mercury in contact with different aqueous solutions, by M. Lippmann. When mercury is in contact with pure or acidulated water, the addition of a small quantity of certain substances to the water changes notably the capillary constant and the electromotive force. M. Lippmann proves that for each value of the latter the capillary constant has one, and only one, determinate value independent of the chemical composition of the liquid. That is, if for two different combinations the electromotive force is the same, the capillary constant is also the same.—On the vapours of alcoholate of chloral, by M. Troost.—Action of light on hydriodic acid, by M. Lemoine. Hydrogen and iodine do not sensibly combine in the cold state under the influence of light. It may be inferred that the decomposition of hydriodic acid by the sun is unlimited. The slow decomposition in light might be used to measure the degree of illumination of the sky in large meteorological observatories. In a month of insolation in the cold state 0·80 of gaseous hydriodic acid is decomposed, whereas heating one month at 265° decomposes only 0·02, and even at 440° during a few hours, only 0·20.—Note on a new derivative of indigotine, by M. Schutzenberger.—On the properties of resorcine; thermo-chemical studies, by M. Calderon.—On the reform of some processes of analysis used in the laboratories of agricultural stations and observatories of chemical meteorology; second memoir, acidimetry, by M. Houzeau.—On the nature of acids contained in the gastric juice (continued), by M. Richet. There is in gastric juice an organic acid soluble in ether, and it is probably sarcolactic acid.—Note on numeration of blood corpuscles in diphtheritis, by MM. Bouchut and Dubrisay. In this disease there is a considerable increase in the number of white corpuscles, and a diminution of that of the red.—On the influence of excitations of organs of sense on the heart and the vessels, by MM. Couty and Charpentier. Such phenomena seem to be produced, not by the sensorial perception itself but by an ulterior cerebral work which might be called *emotional*.—Experiments proving that neither pure air nor oxygen destroy the septicity of putrefied blood, by M. Feltz.—Researches on a case of congenital ectopia of the heart, by M. François-Franck.

THURSDAY, AUGUST 2, 1877

THE PHYSICAL BASIS OF MIND

The Physical Basis of Mind, with Illustrations, being the Second Series of Problems of Life and Mind. By George Henry Lewes. (Trübner and Co., 1877.)

WHEN the first volume of "Problems of Life and Mind" appeared, I ventured to say that perhaps Mr. Lewes promised too much in undertaking to exhibit "how the sentient phenomena may be explained by neural phenomena." I also directed a criticism, as pointed as I could make it, against a proposition placed by Mr. Lewes at the foundation of his psychology; namely, that "actions are prompted and really guided by feeling." The present volume is, in addition to much else, Mr. Lewes fulfilment of his promise and his reply to the criticism.

Considering the limited amount of space at my disposal, I shall, I believe, put it to most advantage by confining myself to these two points. As regards the first—the possibility of finding a physical basis of mind—a sentence in the preface rouses misgivings: "Materialism, in attempting to deduce the mental from the physical, puts into the conclusion what the very terms have excluded from the premisses;" "the attempt to interpret the one by the other" is a legitimate undertaking only "on the hypothesis of a physical process being only the objective aspect of a mental process." This is of ill omen; that which can be done as science does not seek its justification in metaphysics. But let the interpretation be taken on its merits. What is it? Though prepared for disappointment, readers will doubtless be surprised to hear that when looked for, it is nowhere to be found. "The sensation, or state of consciousness," says Mr. Lewes, "is the ultimate fact; we can only *explain* it by describing its objective conditions." In place of the second proposition, "we can only *explain*," &c., most thinkers prefer to say we *cannot* explain it, we can only describe its objective conditions. The difference, then, between Mr. Lewes and others, is not that he has any new light to offer, but that he insists on calling that an explanation which others cannot see to have that character. The sense in which Mr. Lewes thinks he can correctly call a description of neural processes an interpretation of mental facts rests on his statement of the metaphysical hypothesis that these are but "different aspects," "the two faces of one and the same reality." "It is thus indifferent," he continues, "whether we say a sensation is a neural process or a mental process; a molecular change in the nervous system, or a change in feeling." Suppose all this to be understood and granted, where is the explanation or interpretation of the one by the other? Is a description of one aspect of a thing an explanation of a very different aspect of the same reality? Not even metaphysical legerdemain can give the illusion of a physical basis of mind. Mr. Lewes sees that it is impossible to conceive a neural process as *causing* the mental process. He does not say that molecular movement becomes, or is transformed—in any sense, conceivable or inconceivable—into sensation. Mind is not the outcome of physical conditions or combinations; it is an *aspect*, "the spiritual aspect of the material organism." Readers may now judge whether Mr. Lewes can claim to have explained sentient phenomena by neural phenomena, to have shown the manner in which the Self and Not-self "are combined in feeling and thought."

Against Mr. Lewes' proposition that the movements of living beings are prompted and guided by feeling, I urged that science has carried us to a point at which we have but to pause and reflect to see that all movements must be the consequents of purely physical antecedents; that the amount and direction of every nervous discharge must depend solely on physical conditions. And I contended that to see this clearly is to see that when we speak of movement being guided by feeling, we use the language of a less advanced stage of enlightenment. This view has since occupied a good deal of public attention. Under the name of Automatism it has been advocated by Prof. Huxley, and with a firmer logic by Prof. Clifford. It has been argued about in the *Spectator*, zealously combated by Dr. Carpenter, and now Mr. Lewes makes it the subject of one of his Problems, devoting seven chapters to its discussion.

Mr. Lewes cannot think that Prof. Huxley really holds the repulsive doctrine in question, though "*supposed* to hold (it) by those whom his expressions mislead." Yet, curiously enough, it is against Prof. Huxley's statement that Mr. Lewes' polemic is specially addressed. It is not my affair to reply for Prof. Huxley. Mr. Lewes has, however, mentioned me as having insisted "with iterated emphasis" on the view he now "most earnestly desires to refute." I must give my own statement. Here it is as given in my review of "Problems of Life and Mind" (*The Examiner*, March 14, 1874):—"Using the word feeling in its ordinary acceptation, as a name for subjective phenomena alone, we assert not only that no evidence can be given that *feeling* ever does prompt or guide action, but that the process of its doing so is inconceivable. How can we picture to ourselves a state of consciousness putting in motion any particle of matter, large or small? for this is really what it comes to. . . . Puss, while dozing before the fire, hears a slight rustle in the corner, and darts towards the spot. What has happened? Certain sound-waves have reached the ear, a series of physical changes have taken place within the organism, special groups of muscles have been brought into play, and the body of the cat has changed its position on the floor. Is it asserted that this chain of physical changes is not, at all points, complete and sufficient within itself? Mr. Lewes, we believe, will not assert this; he will admit that the material succession is unbroken. Once more, then, in what sense can we take the proposition that actions are prompted and really guided by *feeling?*" Putting in the place of my cat hunting for a mouse, the analogous case of a wolf springing on a sheep, Mr. Lewes replies: "Unless the term *physical* is here used to designate the *objective sequence*, as contemplated by an onlooker, who likens the process to the sequence observable in a machine, I should say that from first to last the process has been *not* physical, but *vital*." The word "unless," with which the reply opens, might be objected to, as implying that the term "physical" might be here employed to designate something else than the objective sequence—that succession of external events which can be seen or imagined in terms of vision. Quite irrelevantly, as it seems to me, Mr. Lewes specifies a particular kind of on-looker—one who likens the process to the sequence observable in a machine. I will only say that for myself I decline the honour of a place among those physiologists and philosophers who, according to Mr. Lewes, have failed to perceive the "radical difference between organic and inorganic mechanisms." However, Mr. Lewes has put it on record that *if* when I spoke of a series of physical changes taking place within the organism I meant series of *inorganic* changes—that the movements of the cat resulted from something of the nature of a combination of levers, springs, and pulleys, then, he "should say that from first to last the process has been *not* physical but *vital*." And who will question that Mr. Lewes would be quite right in so saying? But why suppose anything so unlikely? Yet this is the meaning Mr. Lewes gives to the word "physical" when it occurs in the mouths of those against whom he directs his arguments. For instance: physiologists are in the habit of describing unconscious reflex movements as physical processes. Of this description Mr. Lewes says: "Restate the conclusion in different terms and its fallacy emerges; 'organic processes suddenly cease to be organic, and become purely physical by a slight change in their *relative* position in the consensus.'" But to proceed. Not having used the word "physical" in any peculiar sense, but in accordance with ordinary usage, my question remains—"Is it asserted that the chain of physical changes is not, at all points, complete and sufficient within itself?" So far is Mr. Lewes from denying the physical succession to be unbroken, that he states this, or something very like it, over and over again, as a truth almost too self-evident to require expression. Thus we read: "So long as we are dealing with the objective aspect we have nothing but material processes in a material mechanism before us. A change within the organism is caused by a neural stimulation, and the resulting action is a reflex on the muscles. Here there is simply a transference of motion by a material mechanism. There is in this no evidence of a subjective agency; there could be none." But we also find statements that seem to have a contrary implication. Here is one: "The physiologist is compelled to complete his objective observations by subjective suggestions; compelled to add feeling to the terms of matter and motion, in spite of the radical diversity of their aspects." How is he *compelled* to infer that of which Mr. Lewes has just told us there could be "no evidence"? Again, while the volume abounds with detailed descriptions of the behaviour of dogs, frogs, and men, given as instances in which it is "evident enough," to Mr. Lewes, that their actions were "determined by sensations, emotions, and ideas," yet Mr. Lewes is equally positive that we are "passing out of the region of physiology when we speak of feeling determining action. Motion may determine Motion, but Feeling can only determine Feeling." Where, then, are we, when we talk of feeling determining action? In, I maintain, the gray morning of that intellectual light which is still far from having reached its noon-day splendour.

In the minds of our savage ancestors *feeling* was the source of all movement. Every one of them had what Mr. Lewes, after all he has written about scientific method, can call "the irresistible evidence each man carries in his own consciousness, that his actions are frequently—even if not always—determined by feelings;" and they spoke according to their light. But while we shall continue to speak of feeling determining action, it will only be as we speak of the rising and the setting of the sun. Mr. Lewes is of a different opinion. He says: "We do so speak and are justified. For thereby we implicitly declare, what psychology explicitly teaches, namely, that these two widely different aspects, objective and subjective, are but the two faces of one and the same reality." If Mr. Lewes did not go farther than this I should not care to quarrel with his endeavour to put a new metaphysical meaning into the language of old error. But he thinks that on the strength of this hypothesis the material succession may be regarded as unbroken, and yet a rational interpretation found for the proposition—actions are prompted and really guided by feeling. Because the molecular changes in the brain which form part of the series of material changes involved in the production of motion may be held to be, in a metaphysical sense, the other side of what we know as feeling, Mr. Lewes somehow concludes that "we must declare consciousness to be an agent (in the production of motion), *in the same sense that we declare one change in the organism to be an agent in some other change*" (the italics are by the author). Let us see. The word "consciousness" here denotes two things assumed by Mr. Lewes to be two faces of one thing. If we substitute for this word one of these denotations and say "we must declare the molecular changes involved in the production of motion to be an agent, &c.," the statement becomes the most empty tautology. If we give to the word "consciousness" its other meaning—*feeling*—the proposition becomes what Prof. Clifford calls "nonsense;" and is, as Mr. Lewes says, placing feeling where "there is obviously no place for it—among material agencies." If by "consciousness" Mr. Lewes means neither the molecular changes nor the feeling, but the something of which both are but aspects, then he is altogether beyond science, and for the moment it is enough to say that this metaphysical entity is *not* an agent "*in the same sense*," &c.

Corresponding to those feelings, which Mr. Lewes will have it inspire and guide movement, there are conditions of the organism which can be conceived as the causal antecedents of the movements—the feelings, as admitted, cannot. Our instinctive faith in the unity and constancy of things leaves us no room to doubt that identical organic conditions will ever be accompanied by identical feelings and followed by identical movements; but this does not bring into view any scientific sense in which the feelings can be said to inspire and guide the movements. These for ever remain parts of an infinite series of physical consequents following on physical antecedents. This is the thesis at present so repulsive to many minds. Against this Mr. Lewes has nothing to advance. If any look to him for comfort they will find that, promising them bread, he gives them a stone—the same stone that has already set their teeth on edge.

One word to correct a false impression that the foregoing critical remarks would leave on minds unacquainted with Mr. Lewes' writings. Let no one suppose that I have not read the book with admiration. Like all Mr. Lewes' works, it is a repertory of suggestive fact and of equally valuable and suggestive thought; and if any reader derive from its perusal a tithe of the intellectual stimulation it has afforded me, he may regard his time as well spent. Reflective minds are diligently working towards clearer conceptions in a region that has hitherto been all obscurity. There is reason to believe that ere long philosophic thinkers of the highest rank will for the first time agree as to one or two fundamental conceptions. Few living men have done as much as Mr. Lewes to usher in this new era. Knowing my criticisms to be inspired solely by the same impersonal motives by which he has himself been sustained throughout his extensive labours, I am sure Mr. Lewes would be the last person to suggest that I could have made better use of the space at my disposal. Others, better qualified than myself, will draw attention to the importance of those parts of the work that I have not mentioned, as, for instance, the splendid essay on the Nervous Mechanism.

DOUGLAS A. SPALDING

GORE'S "ELECTRO-METALLURGY"

The Art of Electro-Metallurgy; including all known Processes of Electro-deposition. By G. Gore, LL.D., F.R.S. Text-books of Science Series. (London: Longmans, Green, and Co., 1877.)

DR. GORE has evidently spared no pains to make this text-book a complete manual of the art of electro-metallurgy. Beginning with the history of the subject, he gives an interesting account of the rise and development of the art, full of names and dates and references, and makes the early inventors tell, as far as may be, their own story by quoting freely from their published papers. Then comes a "theoretical division," about which we have something to say presently, and this is followed by what forms the greater part of the work—a detailed account of practical methods of depositing the various metals. This portion of the book, at once thoroughly circumstantial and comprehensive, cannot fail to prove most useful to the practical electroplater as well as to the scientific student. The metals most commonly employed in the arts receive, of course, most attention; but almost none, even of the rarest metals, pass without notice, and the experiments are described with the precision that comes only of experience. An admirable feature of Dr. Gore's book is the habit he has of giving specific references to the authorities he makes use of, so that any one with a library at his command may, if he choose, turn up the passages cited. The remainder of the book is filled by a "special technical section" containing various practical directions and details, and, in conclusion, we have a list of the books previously published on the subject and of the English patents referring to electro-metallurgy. The author is to be congratulated on the accumulation and systematic arrangement of an immense mass of information of a kind that will be welcomed alike in the workshop and in the laboratory.

If Dr. Gore had given us only the practical parts of his book we should have had little to say beyond praise and thanks. Unluckily, however, for himself as well as for his readers, he has introduced a chapter on the theoretical principles which underlie the art of electro-deposition. Such theoretical *réchauffés* are often to be found in practical text-books, but their existence is surely a thing to be protested against even when they are tolerably well written. No one can hope to give a satisfactory account of chemical and electrical theory in fifty pages, and when his work is to form one of a series in which chemistry and electricity have already been treated of in separate books, the attempt is not only useless but unnecessary. These short abstracts are certainly not to be recommended to the novice; and to the student who has already studied the subjects at greater length they are little short of an impertinence. In a book which stands by itself they might be tolerated if they were at once concise and accurate, giving what is needed and no more. In the case before us these extenuating circumstances are all absent. That Dr. Gore's "theoretical division" is not concise the following quotation will suffice to show:—

"The strength of the current is equal to the electromotive force divided by the resistance; this is known as Ohm's law; it is directly proportional to the electromotive force, and inversely proportional to the resistance; if the resistance remains the same, and the electromotive force varies, the strength is directly proportional to the electromotive force; and if the electromotive force remains the same, and the resistance varies, it is inversely proportional to the whole of the resistance in the circuit" (p. 71).

As an instance of matter which might very well have been left out, take the following. After giving a table of conductivities, Dr. Gore proceeds:—

"If the conduction-resistance of distilled water is so great in relation to that of copper, we can easily un-understand, by referring to the previous table, that the resistance of gases must be enormous. The electric conduction-resistance of air heated to redness (*sic*) is 30,000 greater than that of water, containing a 20,000th part of its weight of sulphate of copper in solution" (p. 31).

Why this long-buried result of E. Becquerel's (here, by the way, the authority is not cited) should be unearthed for the benefit of students of electro-metallurgy is almost as puzzling as is the strange piece of *à priori* reasoning in the first sentence, which, it is distressing to find, we are expected to understand easily.

The vagueness and inaccuracy of some parts beggar criticism, and leave the reviewer but one weapon—a severe one indeed, but he has no other—he can only quote. Here are a few specimens chosen almost at random.

"The fundamental act or principle of magneto-electric action is, *wherever there is varying magnetism, there is an electric current induced in an adjacent closed circuit at right angles to it*" (p. 57); the italics are the author's.

"The electromotive force, or strength of the current to overcome resistance, depends upon the degree of difference of strength of chemical affinity of the two metals for the electro-negative constituents of the liquid" (p. 70).

"The electromotive force (commonly called 'the intensity') of the current . . ." (p. 337).

"*As the electromotive force is diminished by resistance, a diminution of resistance in any part of the circuit will increase it*" (p. 337); this extract we have ventured to italicise.

"Motion of the articles is very advantageous . . . it greatly diminishes the electric conduction-resistance which would be produced by polarisation, due to layers of liquid of opposite electrical nature, collecting in contact with the electrodes" (p. 344).

"*Potential and tension.*—Previous to the completion of the circuit and formation of an unimpeded current, the free ends of the polar wires attached to the two metals are charged with the two kinds of electricity in an accumulated or free static condition, and are in a state of *electric potential*, *i.e.*, possessing a capability of doing electric work. These accumulated electricities in the wires may be detected by means of a very delicate electroscope. The free electricities are also in a state of *tension*, constantly tending to escape and unite; and their degrees of tension may be measured by means of an electrometer" (p. 71).

From which it would appear that the difference between potential and tension lies in the fact that the one is to be detected by an electroscope, and the other measured by an electrometer. It would be just as satisfactory a distinction, and would besides have the merit of being true, to say that "potential" is the shibboleth of the electrically unlearned, while "tension" is their refuge at all times.

Over and over again we find such phrases as these:—"If the current to be measured is one of low electromotive force" (p. 73); "a current of less quantity and greater electromotive force" (p. 338); and after we have been expressly told on p. 72 that there is no difference between currents except as regards their quantity per minute, it is surprising to learn that "as a general rule, the greater the electromotive force, and the smaller the quantity of the current, the harder and brighter is the deposited metal" (p. 344).

But it is needless to multiply examples. We have given enough to show how much Dr. Gore has done to mar a really good book by adopting a precedent which, however well followed, is of very doubtful utility. In the present instance it may, perhaps, serve the good purpose of acting as a warning to future practical writers.

We have noticed comparatively few typographical errors. Is it the author, or the printer, or the author's evil genius, or the printer's devil that we have to thank for this bewildering statement on p. 182?—

"Silver may be cleaned in water in which potatoes have been boiled, and a superior polish is thus imparted to them."

OUR BOOK SHELF

Enumeracion de las Plantas Européas que se hallan como silvestres en la Provincia de Buenos Aires y en Patagonia. Por Cárlos Berg. (Buenos Aires, 1877.)

THIS is a very interesting list of European plants introduced by various means into the two above-mentioned countries. It gives the relative abundance of each species and the conditions under which it is found. Altogether 116 Dicotyledons, 30 Monocotyledons, and 8 Cryptogams are mentioned. Of these no less than 108 are common to Britain. As might be expected, the natural orders Compositæ and Gramineæ, each with 20 species, and Caryophylleæ with 12, are the strongest in point of number of species. Many notes are scattered through the twenty-four pages, from which we learn that under such extremely different conditions some of our British plants attain extraordinary dimensions.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Optical Spectroscopy of the Red End of the Solar Spectrum

BEING now, with my wife, on the return voyage from a private spectroscopic experiment on solar light in Lisbon, there appear to be two or three reasons why I should request your leave to send this preliminary note to NATURE before attempting to publish anywhere a full account of what was seen.

As the *first* of these reasons, I may mention that the continual assistance kindly afforded us by M. Oom, the Astronomer-Royal of Portugal, and the several facilities obligingly granted to us, through his intervention, by the Portuguese Government, render an early and hearty acknowledgment imperative. All the more so, too, as the last and most successful series of observations, through four successive days of blazing sunshine, without the smallest speck or suspicion of a cloud anywhere from morning to evening each day, was made in a new suite of rooms recently prepared for the local astronomer's residence in the Royal Park of the Ajuda.

The *second* reason is the pleasing one to confess, that out of four prismatic arrangements tried in the same spectroscope—the one which had the highest dispersion (viz., 32° from A to H) gave also the best and most satisfactory definition, showing thereby such wondrously fine and minute detail amongst close lines as to cause it to be almost invariably employed, and *that* prismatic arrangement, I am happy to say, was lately made for me by Mr. Adam Hilger, of 192, Tottenham Court Road, London, on his own long-approved plan of three powerful and symmetrical compound prisms, while the eye-piece of the telescope, also by him, was of rock-crystal, and fitted with his peculiar reference line for micrometer mensuration.

The *third* reason is the total contradiction given by the best of these observations to some conspicuous features of the Royal Society's last publication on the red end of the solar spectrum, when seen at a high altitude with their second and most improved "Indian Spectroscope."

Our late Lisbon measures, though made at a station close to the sea-level, were yet, near the noon of each day there, and on a midsummer sun in that latitude, taken through almost the very same *thickness* of atmosphere, as the Royal Society's, and Mr. Hennessey's high-sun series on the Himalaya Mountains. But those Indian observations having been printed in the *Philosophical Transactions* so long ago as 1874, I should be glad to know whether either the Royal Society or anyone else has published further particulars of the extreme red end of the solar *optical* spectrum since then. PIAZZI SMYTH,

Astronomer-Royal for Scotland

The Cretaceous Flora of America

NEAR the close of his very interesting lecture "On the Tropical Forests of Hampshire," published in NATURE (vol. xv. pp. 229, 258, 279) Mr. J. S. Gardner says:—"I have great doubts, however, as to the correct position of many of the foreign so-called cretaceous beds. Those of America, from which most of the list of dicotyledons of this period is derived, appear to me, from the character of their fauna, to be rather lower eocene, or at most, filling in the gap between our chalk and London clay. Most of the shells have a marvellously eocene-like aspect, and I take it that the presence of an ammonite, and some few other forms of shells which in England do not reach above the chalk, should not be taken as conclusive evidence of the antiquity of the bed, as, although migrated from our seas, they may very well have lived on in other regions. It is inconsistent to assume that no ammonite lived on in any part of the world to a more recent period than that of our chalk."

From these remarks it is evident that Mr. Gardner is not fully informed in regard to the evidence which exists on the question he has raised; and as the subject is one of great interest, and one which it is necessary should be carefully understood by those who write upon the progress of plant life on the globe, I take the liberty of reporting briefly what we really know in regard to the cretaceous flora of the North American continent.

Some twenty years ago numerous impressions of angiospermous leaves were brought by Dr. Hayden and myself from the group of sandstones which lie at the base of our cretaceous system. Outline sketches of a part of these were sent by Mr. Meek to Prof. Heer, of Zurich. He pronounced them miocene tertiary. To this conclusion he was led by their high botanical rank, their generic affinities with miocene plants, and the supposed identity of some of them with miocene species.

The announcement of Prof. Heer's decision led to a somewhat earnest discussion, in which Prof. Heer, M. J. Marcou, and Mr. Leo Lesquereux supported the view that the plants in question were tertiary, while Messrs. Meek and myself asserted that they were cretaceous, because the strata which contain them are overlain by more than 2,000 feet of limestones filled with characteristic cretaceous fossils, a number of which are identical with those found in the gault and chalk of Europe. An end was finally put to this debate by M. Marcou and Prof. Capellini, of Bologna, going to Kansas and collecting a large number of these leaves from beds overlain by unmistakable cretaceous strata. The true position of this flora was then not only acknowledged but proclaimed by these gentlemen, and since that time every geologist in America has accepted the statement which I made in my letter to Messrs. Meek and Hayden in 1858, and in my article on the Ancient Vegetation of North America (*American Journal of Science*, vol. xxix., 1860, p. 208), that "the American flora assumed nearly the botanical character it now has in the cretaceous age, and that our lower cretaceous rocks contain the remains of sixty or seventy species of angiospermous trees, many of which belong to our most common living genera, such as *Quercus*, *Salix*, *Magnolia*, *Platanus*, *Liriodendron*, *Fagus*, *Alnus*, *Liquidambar*, &c."

Since the settlement of this question a large number of additions have been made to the then known species of this flora, and it is probably not too much to say that we have obtained leaves of nearly one hundred species of angiospermous trees from the base of our cretaceous system, the equivalent of the upper greensand of England.

All the leaves figured in Lesquereux's "Fossil Flora of the Western Territories," part I., were obtained from this horizon, and a large number of additional species have been described by Prof. Heer in his "Phyllites Cretacea," or by myself in "Our Later Extinct Floras," while many others yet wait publication.

The plants of our upper cretaceous and tertiary rocks have not yet been fully described, and there is some difference of opinion as to where the line should be drawn between these two systems, but it is quite certain that a large part of the species described by Mr. Lesquereux from the "lignite beds," and referred by him to the tertiary, are really cretaceous; not only because they are associated with *Ammonites*, *Inoceramus*, and other cretaceous fossils, but because the strata which contain them underlie unconformably the *Coryphodon* beds, the base of our eocene. Whatever shall be ultimately decided in regard to the line of separation between our later cretaceous and earlier tertiary strata, this will in no wise affect our conclusions in regard to the general facies of the American cretaceous flora. The statements made many years since are confirmed by all fresh evidence, and now stand unquestionable, that between the trias and the chalk—we know nothing of our Jurassic flora—the vegetation of North America was revolutionised, and that at the beginning of our cretaceous age it had assumed essentially the character and consisted chiefly of the same generic elements that it exhibits now.

I may also add that up to the present time no species of *Ammonites*, *Baculites*, or *Inoceramus* have yet been found in America above the cretaceous system; and that so far as we now know, these genera are as decisive of the age of the strata which contain them here as in the Old World. J. S. NEWBERRY

Columbia College, New York, June 19

Meteorological Notes from Lisbon

THE following meteorological notes, compiled in great part from the daily bulletins of the Observatorio Real of Lisbon, supplemented by observations made by myself, by means of a Casella's self-registering thermometer and a good aneroid barometer, during a seven months' residence in that city, may not be without some value to weather observers. I arrived on October 15, consequently the observations for this month refer only to the latter half. The records were made at 9 A.M. and at 5 P.M. To save space the readings will be given throughout (except for October) in the following order:—I. Barometer (reduced to sea-level), (*a*) the average of observations taken at 9 A.M, (*b*) the highest, and (*c*) the lowest reading of the month. II. Thermometer (Fahrenheit), (*a*) average of daily observations made at 9 A.M., (*b*) average of the highest, and (*c*) of the lowest readings in the twenty-four hours; (*d*) the highest, and (*e*) the lowest reading of the month. III. Direction of Wind: N. S. E. W. represent the directions indicated, or any point thereof, after which the number of days is given on which it blew from that quarter. IV. The rain of the month is stated in inches.

OCTOBER, 1876.—The morning temperatures ranged from 54° F. to 70°; midday, from 62° to 80°; and evening, 53° to 72°; the average of the night temperature for the half-month, 52·2; and the average rainfall for the same period was 3·8 inches. No wind record was kept.

NOVEMBER, 1876.—I. (*a*) 29·95, (*b*) 30·44, (*c*) 29·44. This last reading is the record of the 12th, and was accompanied by a terrific gale from the south-west, which wrought much damage both on land, on the river, and at sea. Several residents, who were not unfamiliar with earthquake shocks, averred that they felt a distinct tremor of the earth about 4 A.M., at which time the barometer registered 29 inches. In the Bay of Biscay on the same morning the lowest point reached by the mercury was 28·25, as I was, I believe accurately, informed by the captain of a Glasgow steamer which arrived in the Tagus some days later. II. (*a*) 57°·59, (*b*) 63°·9 (*c*) 54°·09 (*d*) 70°·98 (*e*) 46°. III. N. 7 days, S. 10, E. 7, W. 2; of 3 days no record. IV. Rain, 10 inches, which fell on 17 days. This was one of the most rainy Novembers for many years. The rainfall of the year 1874 was 17·2, and that of 1875, 18·3 inches. The total amounts for the months of November from 1873–1875 was 5·5 inches. The mean of this month for the last twenty years is 4·3 inches. Most destructive floods occurred during the month.

DECEMBER, 1876.—I. (*a*) 29·96, (*b*) 30·3, (*c*) 29·4 inches. II. (*a*) 54°·8, (*b*) 59°·5, (*c*) 51°·6, (*d*) 65°·5, (*e*) 44°·2. III. N. 5, S. 18, E. 0, W. 5, calm 3 days. IV. Rain 19·19 inches on 28 days, greatest fall on 1 day (6th) 3·2 inches, and least ·003.

JANUARY, 1877.—I. (*a*) 30·18, (*b*) 30·58, (*c*) 29·54 inches. II. (*a*) 52°·93, (*b*) 58°·96, (*c*) 50°·8, (*d*) 65°·66, (*e*) 44°. III. N. 17, S. 9, E. 0, W. 3, calm 2 days. IV. Rain which fell on 14 days, 7·007 inches; from 1st to 10th, 6·669 inches.

FEBRUARY, 1877.—I. (*a*) 30·35, (*b*) 30·54, (*c*) 29·92 inches. II. (*a*) 52°, (*b*) 56°·64, (*c*) 48°·29, (*d*) 67°·38, (*e*) 42°·9 (the lowest temperature of the seven months). III. N. 25, S. 1, E. 1, W. 0, calm 1 day. IV. Rain, which fell on 2 days, 1·28 inches.

MARCH, 1877.—I. (*a*) 29·94, (*b*) 30·39, (*c*) 29·36 inches. II. (*a*) 47°·63, (*b*) 59°·34, (*c*) 48°·5, (*d*) 71°·6, (*e*) 43°·3. III. N. 10, S. 9, E. 1, W. 6, calm 1, of 4 days no record. IV. Rain, which fell on 13 days, 2·5 inches.

APRIL, 1877.—I. (*a*) 29·92 (*b*) 30·13, (*c*) 29·60 inches. II. (*a*) 65°·5 (*b*) 62°·9, (*c*) 51°·9, (*d*) 71°·7, (*e*) 48°·2. III. N. 8, S. 8, E. 1, W. 11, 2 days unrecorded. IV. Rain in 17 days, 6·5.

I would draw the attention of those threatened with bronchial or pulmonary complaints to this locality as a winter and spring refuge. The site of the city of Lisbon is finely chosen, facing almost due south, and the position of the principal part of the town in which the chief hotels are, is nearly sheltered from the northerly and easterly winds by surrounding heights. It is of easy access from England—3½ days, and sometimes fewer, from Southampton by a royal mail steamer. Fires are rarely to be seen in a Portuguese sitting-room, and during the seven months of my sojourn there it was necessary only once or twice to have one in our room for an invalid's sake. I had an opportunity of seeing many sufferers both *en route* for, and again returning to England from, Madeira. Some of them complained much of the weather experienced there, and said how they wished they had remained in Lisbon, where the climate seemed equally to suit them, and where they should have had at least more comforts, more cheerful society, and more varied means for killing the Enemy—time. HENRY O. FORBES

Fertilisation of Flowers by Insects

IN my last article on Alpine Gentiana species, I supposed that the chief, if not the only fertiliser of *G. bavarica* and *verna* might be *Macroglossa stellatarum* with its proboscis of 25·28 mm.

length. Yesterday, near the Albula pass, I was happy enough to confirm this supposition by direct observation. Altogether I saw five specimens of *Macroglossa stellatarum* at work, one on *Gentiana bavarica* and *verna*, three on *Primula integrifolia*, and one on *Viola calcarata*, each of them in a few minutes fertilising some hundreds of flowers. For instance, the last of my five Macroglossa specimens, which I observed with the watch in my hand, in less than four minutes visited 108, and in other 6¾ minutes 194 flowers of *V. calcarata*.

As an illustration to what I have said in a former article on alpine orchids generally being adapted to cross-fertilisation by Lepidoptera, I may mention that near my present domicile there grow nine species of orchids, eight of which (*Nigritella Angustifolia*, *Platanthera bifolia*, *Grymnadenia conopsea*, *odoratissima*, *albida*, *Habenaria viridis*, *Orchis globosa*, and *ustulata*) are adapted to cross-fertilisation by Lepidoptera, whilst only a single one (*Orchis latifolia*) is adapted to cross-fertilisation by other insects. Wissenstein, Albula Valley, Switzerland, July 23

Local Museums

I HAVE read with very great interest both the letters and articles which have lately appeared in NATURE on the subject of local museums. The suggestions offered by your various correspondents are in every way admirable, and my only excuse for adding my own name to the number is because I think that although a great deal has been said on the matter next to nothing has actually been done. If local museums are to be established amongst us as a means of promoting advancement in education the sooner the matter is taken in hand by those most competent to deal with it the better.

What I would strongly advocate is that a society be formed in London for the promotion of local museums. If Prof. Boyd Dawkins, and any others possessing the requisite attainments for taking the matter in hand, would form an association of this kind, I, for one, and doubtless many others of your readers, would gladly subscribe and co-operate for the realisation of the scheme. J. ROMILLY ALLEN

34, James Street, S.W.

Proposed New Museum

Now that the new Natural History Museum is approaching completion, will you allow me to call attention to a need which has probably been felt by others beside myself, and which we may hope will be met in the new institution? This is a museum or collection of varieties of plants and animals produced by domestication. I need not enlarge upon the value of such a collection to the student of biology. The revolution in the philosophy of biology created by Mr. Darwin was founded upon an examination of such varieties, and I have small doubt that my plea will be seconded by botanists and zoologists who will speak with much greater authority than I can.

I base my own request upon another ground, and one which touches very closely the science I am chiefly conversant with, namely, ethnology. Rutimeyer in Switzerland, Busk, Dawkins, and others in England, Brandt in Russia, and others elsewhere, have shown how invaluable the evidence furnished by varieties of domestic animals is for elucidating the earlier history of our race. Yet there is no collection known to me anywhere except the one made by Mr. Darwin himself, illustrating the subject, and if one wishes to examine the various breed of cattle, sheep, dogs, or pigs, of vegetables and fruits, &c., which have become localised in various parts of the world, as the companions of man, one is entirely at a loss for materials in an accessible form.

May we hope that the very efficient staff of the National Museum will see their way to setting apart one room at least in which the variation of animals and plants under domestication may be shown, and the glorious discoveries of the greatest biologist of modern times may be fitly illustrated in the National Museum of the country whose science he has so adorned.

HENRY H. HOWORTH

Adaptation of Plant Structure

I HAVE lately observed a curious adaptation of plant-structure which has not, to my knowledge, been recorded in books, and which may be interesting to your botanical readers.

There is in the Himalayas an Arum bearing a remarkable resemblance to a cobra with its hood raised, which is well known to natives and many Europeans by the name of the "cobra plant." Standing immediately behind and above the spathe is a large ternate leaf, the two lower leaflets of which, at an early stage of growth, enfold the spathe and spadix, and subsequently stand in front of and partially conceal them from view. When, however, the anthers or the stigmas, as the case may be (for the plant is diœcious), are mature, the lower halves of these lateral leaflets fold close up over their upper halves, thus leaving the whole of the spathe conspicuously exposed to the notice of passing insects. I inclose a rough sketch made from a living plant. It will be observed that if the lateral leaflets were extended they would conceal the flower from insects flying at a higher level than the mouth of the spathe. It is therefore an advantage to the plant that they should assume this abnormal position.

I may add that the resemblance of this arum to the cobra snake is very close, and cannot easily be accounted for. The diamond-shaped markings of the cobra's head are counterfeited on the spathe, as also are the lines on the neck; while the tongue-like prolongation of the spadix and of the mid-rib of the spathe serve to complete the resemblance of the plant to a living animal. As the cobra is almost unknown in the localities where this arum grows, it seems that the strange mimicry can be nothing more than accidental coincidence, even if any theory of advantage to the plant therefrom could be devised. But the "counterfeit presentment" is so striking that I am convinced any person who unexpectedly saw this plant "rearing its horrid head" above the rank herbage of an Indian jungle would start back with horror. Nagkunda, near Simla, June 15

Rattle-snakes in Wet Weather

I HAVE had much pleasure in reading Mr. Frank Buckland's edition of "White's Selborne." Among the notes on page 448, Mr. Buckland says:—"I know that rattle-snakes cannot play up their rattles in wet weather. The horn of the rattle becomes more or less saturated with water, and no sound can then be produced from it. By placing a rattle in a glass of water, and letting it soak a while, I find this is the case."

Mr. Buckland's dried rattle has led him into an error. The live rattle-snake can "play up" his rattle in the very wettest of wet weather. I have taken them alive on two occasions in the midst of a heavy rain, and I could discover no difference in their rattling powers. It is true, however, that rattle-snakes are seldom found in low moist places; they frequent, by preference, high and dry ground.

During the year 1873 I kept in my room a rattle-snake for eight months. In this time I came to know that "Rattler," so I called him, could "play up" several different notes indicative of anger, of pleasure, and of loneliness.

I think that it will be found, upon proper examination, that the fangs of the rattle-snake are shed just as the teeth of other animals. HUNTER NICHOLSON

Meteors

AT 9.48 last evening I saw a bright meteor pass downwards towards a Aquarius, where it disappeared. It emitted a bluish light, and although the moon was up, it shone for a few seconds with the brilliancy of Venus. A second smaller meteor passed upwards towards the zenith about 10.5. In both cases the vanishing point was near Delphinus. W. AINSLIE HOLLIS

Brighton, July 30

OUR ASTRONOMICAL COLUMN

THE HERSCHELIAN COMPANION OF ALDEBARAN.—In a communication lately received from M. Camille Flammarion, it is endeavoured to show that the change of relative situation of the small star with respect to Aldebaran, is not accounted for by the proper motion of the latter, as was stated by Struve ("Positiones Mediæ," p. ccxxvi.), but that it is necessary to admit the existence of a very appreciable proper motion of the companion, which would be the first instance of the kind in so small a star. M. Flammarion collects the various published measures and adds to them measures made by Mr. Gledhill in 1876, and by himself in 1877. Sir W. Herschel's measures may be set aside at once as not sufficiently exact for a discussion of a moderate proper motion; his angle in 1781 is the result of a single measure, and his distances, as is well known, are in defect, when they exceed a minute. Taking then Struve's epoch, 1836·06, as the earliest reliable datum we possess, and bringing it up to Dembowski's epoch, 1863·37, with Leverrier's proper motion for Aldebaran, we find no greater difference than may be accounted for by unavoidable error of observation, so that Struve's inference on comparing the Pulkowa measures, in 1851 with the Dorpat measures of 1836, "itaque comes motus non est particeps, sed in cœlo quiesca videtur," and Dembowski's conclusion when speaking of this object and of λ Aurigæ," "Les différences s'accordent assez bien avec les mouvements propres des deux principales," are thus supported. The angle, however, should now be less than is assigned by Mr. Gledhill and M. Flammarion from their own measures (35°·5), and further careful measures will be desirable to clear up a possible question of personal equation. If we reduce Struve's angle for 1836 with Leverrier's proper motion of Aldebaran to the present year, we find an angle nearer 32°·5 than 35°·5.

THE THIRD COMET OF 1759.—This comet was not observed until January, 1760, but appears in our catalogues as comet 1759 III., from the circumstance of the perihelion passage having occurred in December of that year. It approached very near the earth, but was not a conspicuous object more than a few days. There are several references to the comet in the *Annual Register* for 1760, where we learn that it was "discovered and astronomically observed by Mr. Dunn at his Academy at Chelsea," who had determined the positions of Halley's comet on every evening during the first week of May previous. Pingré states that the sky, having been constantly overcast at Paris for several days, all the astronomers of that capital, including Cassini de Thury, Maraldi, Lacaille, and Messier, detected the comet on the evening of January 8; Dunn is credited with having found it on January 1. It was seen at Lisbon on January 7. For the purpose of these remarks we shall adopt the elements of Lacaille, in deducing the apparent places of the comet.

There is no reason why the comet should not have been found on January 1, if atmospherical conditions had been favourable, but it must have been on the morning, not on the evening of that day. In fact, the comet would rise soon after 1 o'clock A.M., in London, and would be upon the meridian a few minutes before six at an altitude of more than 23°. It is, however, distinctly stated in the *Annual Register* that Dunn discovered the comet in the evening, that "it appeared to the naked eye like Jupiter or Venus through a thick fog, and made a near appulse to the star in Orion's right knee, and moved more than four degrees of the heavens in four hours of time." This can only refer to the evening of January 8. The elements give the following positions:—

	d.	h.		R.A. ° ′		N.P.D. ° ′		Distance from earth.
January	8	8	...	88 59	...	99 55	...	0·0734
"	8	12	...	84 17	...	98 34	...	0·0760

There was, therefore a motion of upwards of four degrees in as many hours, and soon after midnight the comet would not be more than 1¼° from Orion's right knee, or κ Orionis. It is therefore pretty certain that Dunn did not precede other observers by a week, as might at first sight appear from the statement in the *Register*. Clouded skies had evidently prevailed in Western Europe for some days, and the comet was detected on the same evening, January 8, on the heavens clearing, in England, France, and Holland.

The rapid course of this retrograde comet will be apparent from the following positions, calculated for Greenwich midnight.

			R.A. ° ′		N.P.D. ° ′		Distance.
Jan.	5	...	165 36	...	109 22		0·112
	6	...	147 11	...	110 3	...	0·083
	7	...	116 27	...	106 58	...	0·068
	8	...	84 17	...	98 34	...	0·076
	9	...	64 9	...	91 30	...	0·101
	13	...	39 22	...	82 33	...	0·248

Between January 7 and 8 the comet passed over 32½° in arc of great circle, and was nearest to the earth soon after midnight on the former date. On January 9 in the evening Dunn says the comet passed near μ and ν in Eridanus, and we find from Lacaille's elements that at 5h. 39m. P.M. it would have the same right ascension as μ, with only 40′ greater declination. So far as regards position the comet might have been observed as early as the day of perihelion passage, December 16, when it was in R.A. 199° and N.P.D. 103°, rising in London at 2h. 45m. A.M.; but the intensity of light was only $\frac{1}{120}$th of that on the evening of January 8, when it was generally discovered. It is rather unfortunate that it was not observed over a longer period, since it appears certain that in its approach to perihelion it must have passed very near to the planet Jupiter, and we might expect a sensible deviation from the parabola. On November 7, 1758, Lacaille's orbit would give the comet's distance from Jupiter less than 0·05.

METEOROLOGICAL NOTES

SUN-SPOTS AND RAINFALL OF CALCUTTA.—Mr. E. Douglas Archibald, of Naini Tal, has written an interesting letter to *The Englishman*, the leading Calcutta newspaper, in which he shows from the observations made from 1837 to 1876, that the winter rainfall (Nov. to April inclusive) of Calcutta is marked by a distinct periodicity, the maximum rainfall occurring during the years of minimum sunspots, and the minimum rainfall during the years of maximum sun-spots. The following are the figures for the years of the sun spot cycle beginning with the year of minimum sun-spots:—

		Average Rainfall.
1st and 2nd year of cycle	...	6·44 inches
3rd and 4th		5·93
5th and 6th		4·44
7th and 8th		5·03
9th and 10th		6·15
11th		8·49

the average rainfall for the forty years being 5·41 inches. Mr. Archibald is of opinion that this peculiarity, which is the reverse of what obtains as regards the rainfall of the whole year, in its relation to sunspots, will be found not to occur much farther south than Calcutta, and that it will be more decidedly marked over the region farther to the north lying more immediately under the great range of the Himalayas. The point is one of very considerable interest and deserves the fullest investigation, since, if the supposition proves to be correct, it will doubtless lead to a more exact method of examining the rainfall in its relation to sun-spots. It may be remarked that the winter rainfall at Sydney (in the southern hemisphere) from 1840 to 1876, which is situated within the latitudes indicated by Mr. Archibald, exhibits the same peculiarity as that of Calcutta in its relation to the sun-spot period.

WINDS OF THE SOUTH ATLANTIC.—M. Brault announces the publication by the French Marine of a series of new meteorological charts giving the direction and force of the winds of the South Atlantic for each of the four seasons, the charts being similar to those published by M. Brault about two years ago on the winds of the North Atlantic. The new charts contain the results of 189,573 observations of the wind. The general movement of the winds in summer over this portion of the globe resembles an immense whirl whose centre is about 30°–35° lat. S., and 10°–20° long. W. The whirling movement is in a direction contrary to that of the hands of a watch, being thus opposite to the general circulation of the atmosphere over the North Atlantic in summer. Out from this centre winds blow in all directions, the more important being the south-east trades, which are deflected to south and south-south-west off the coast of Africa, and to east-south-east and east on approaching America; then in succession north-east, north, and north-west winds on advancing southward along the coast of America, merging finally in the westerly winds which blow across the Atlantic from Cape Horn to the Cape of Good Hope. Looking both at the direction and force of the winds, M. Brault concludes that the results establish beyond a doubt the fact that, contrary to views entertained up to a comparatively recent date, there does not exist any tropical zone stretching across the South Atlantic, characterised by the prevalence of calms and light variable breezes. These results are in entire accordance with recent researches into the atmospheric movements over this region, and are of peculiar interest when viewed in connection with the distribution of atmospheric pressure and its variation with season over South America, the South Atlantic, and South Africa.

Climate of Kosseir, on the Red Sea.—In the last number of the *Journal* of the Austrian Meteorological Society, p. 225, there is an interesting article on the climate of Kosseir, on the Red Sea, based on a year's observations by Dr. Klunzinger during 1872-73. The interest of the climate of this region lies in its extreme character in certain directions, and the regularity of occurrence of its changes from season to season. The mean atmospheric pressure is 30·020 inches, rising to the maximum 30·213 inches in January, and falling to the minimum 29·863 inches in July, showing thus a variation of 0·350 inches in the monthly means. The mean temperature is 76°·3, the warmest month, August, being 84°·9, and the coldest, January, 64°·9. There is little cloud in any season, and in summer the skies are constantly all but cloudless. A prominent feature of the climate is its dryness, the mean relative humidity for the year being only 56, falling in June to 51, and rising to 62 in November. This great dryness is due to the winds, which are northerly and north-westerly during the whole year, the only change being from about north-north-west in summer to north-west in winter. Occasionally, however, when easterly winds set in, the air becomes so saturated that everything is wetted with the vapour with which it is heavily charged. On June 4, 1873, a "Samum" commenced (north-north-west, force 7), the horizon having a grey troubled appearance, the sky cloudless, and the air hot and dry; it continued till the 6th, and it was during this strong dry wind that the highest temperature, 93°·9, was observed.

Drought in Canada.—An unusual drought has prevailed in Canada during the past spring. Little rain having fallen for ten weeks, the waters of the Ottawa and St. Maurice, two of the principal lumbering rivers, have been reduced to their summer level, having never before been so low at this season. A serious consequence of this state of matters is, that very large quantities of the finest timber of the dominion must remain in the woods till next year.

EARLY ALLUSIONS TO THE MAGNETIC NEEDLE

At recent meetings of the Literary and Philosophical Society of Manchester interesting contributions to the subject were made. In a paper by Mr. H. Grimshaw he refers to such an allusion in a work entitled, "An Apologie of the Power and Providence of God in the Government of the World; or, An Examination and Censure of the Common Error touching Nature's Perpetual and Universal Decay: Divided into Four Books." The author is one "G. H.," D.D. (Doctor of Divinity), and the work is printed at Oxford by John Litchfield and William Turner, "Printers to the famous University," Anno Domini 1627, being therefore exactly 250 years old.

The third book of the four into which the work is divided treats of "The pretended decay of mankind in regard and duration, of strength and stature, of arts and wits." The tenth chapter of this third book is said to be "Touching diverse artificiall workes and usefull inventions, at leastwise matchable with those of the ancients, namely and chiefly the invention of Printing, Gunnes, and the Sea-Card or Mariners Compasse." This tenth chapter again, for such is the orderly division of the subjects, is subdivided into four sections, and the fourth of these is headed "Of the use and invention of the Mariners Compasse or sea-card, as also of another excellent invention sayd to be lately found out upon the Load-stone, together with the conclusion of this comparison touching Arts and Wits, with a saying of Bodius, and another very notable one of Lactantius."

It is in the account of this "excellent invention sayd to be lately found out upon the loadstone" that a curious prevision or dream, so to speak, of the application of electricity as a means of communication occurs, and there is small wonder that the old philosopher called it as he does further on, "an excellent and secret conclusion upon the stone," for, whilst perusing his description, one can hardly imagine that the writer has not in his mind's eye one of our most modern telegraphic instruments. The paragraph is as follows:—

"Another excellent and secret conclusion upon this stone, pretended to be found out in these latter times, is, that by touching two needles with the same stone, they being severally set so as they may turne upon two round tables, having on their borders, the *Alphabet* within circlewise, if two friends agreeing upon the time, the one in Paris, the other in London (having each of them their table thus equally fitted) be disposed upon certayne dayes and at certaine houres to conferre, it is to bee done by turning the needle in one of the tables to the *Alphabet*, and the other, by *Sympathie* will turn itself in the same manner in the other table though never so farre distant: which conclusion if infallibly true, may likewise proove of good and great consequence; howsoever, I will set it down as I find it described by *Famianus Strada* in imitation of the stile and vaine of *Lucretius*."

Magnesi genus est lapidis mirabile, &c., &c.

Then follows the extract in Latin, with the English translation in verse attached.

It will be acknowledged by any one familiar with the instrument, that the dial telegraph of Cooke and Wheatstone, invented subsequently to their first upright needle form, most curiously carries out the ideal description of this old author, and it will be seen that the date at which his work is written was nearly 200 years prior to the first attempt made to communicate at a distance by means of magnetic needles.

Prof. Stanley Jevons, in a subsequent paper, stated that ten years ago he spent some trouble in investigating this curious anticipation of the telegraph, but only published the results in the form of a brief anonymous article in a weekly newspaper. This curious subject, Mr. Jevons thinks, has not received the attention which it seems to deserve, but it was not wholly unknown. The Abbé Moigno, in his "Traité de Télégraphie Electrique" (Paris, 1852), alludes to what he calls this "Charmant rêve, ou operation necromancienne," and he points out that Addison had quoted the remarkable verses of Famianus Strada in the *Spectator*, No. 241. Addison speaks of "a chimerical correspondence between two friends by the help of a loadstone." Strada's remarkable lines are also quoted and translated in Mr. George Dodd's account of "Railways, Steamers, and Telegraphs: a Glance at their Recent Progress and Present State" (Chambers, 1867). Mr. Jevons found allusions to a magnetic telegraph running through many scientific, or quasi-scientific, works of the sixteenth and seventeenth centuries. Sir Thomas Browne, in his "Pseudodoxica Epidemica," says:—"The conceit is excellent, and, if the effect would follow, somewhat divine;" and he speaks of it as a conceit "whispered thorow the world with some attention, credulous and vulgar auditors readily believing it, and more judicious and distinctive heads not altogether rejecting it." Sir Thomas, it would seem, submitted the matter to experiment, but found that though the needles were separated but half a span, when one was moved "the other would stand like Hercules' pillars."

Joseph Glanvill, in his *Scepsis Scientifica* (1665), discusses the objections of Sir Thomas Browne, and concludes that "there are some hints in natural operation that give us probability that it is feasible." How can we read without wonder these words written by Glanvill more than 200 years ago? "Though this pretty contrivance possibly may not yet answer the expectation of inquisitive experiment, yet 'tis no despicable item that by some other such way of magnetick efficiency it may hereafter with success be attempted, when magical history shall be enlarged by riper inspections; and 'tis not unlikely but that present discoveries might be improved to the performance." It is evident that Glanvill treats the matter quite seriously as a scientific possibility. The Marquis of Worcester probably refers to the magnetic telegraph when he speaks of "intelligence at a distance communicative, and not limited to distance, nor by it the time prolonged." (Dirck's "Life of Worcester," p. 357.)

Mr. Jevons tried to trace these notions to the first inventor, but, as might be expected, without much success. Strada attributed the invention to the celebrated Cardinal Bembo, the secretary of Leo X., but as Bembo (who died in 1547) was a historian and literary character, it is hardly likely that he would originate a scientific conception of the sort. The earliest books in which Mr. Jevons found allusions to a magnetic telegraph is the *Natural Magic* of Baptista Porta, published in 1589. In the seventh book he describes the "wonders of the magnet," saying in the preface, "I do not fear that with a long absent friend, even though he be confined by prison walls, we can communicate what we wish by means of two compass needles circumscribed with an alphabet." In the eighteenth chapter of the same book, he describes the experiment of putting a magnet under a table and moving thereby a needle above the table. This experiment, as Porta remarks, was known to St. Augustine, and an exact description will be found in his "De Civitate Dei," a work believed to have been begun A.D. 413. It seems probable that this passage in St. Augustine suggested the notion either to Porta, Bembo, or some early Italian writer, and that thus it came to be, as Sir Thomas Browne says, "whispered thorow the world."

Mr. William E. A. Axon refers to the passage in Strada in which he supposes the loadstone to have such virtue that "if two needles be touched with it, and then balanced on separate pivots, and the one be turned in a particular direction, the other will sympathetically move parallel to it. He then directs each of these needles to be poised and mounted on a dial having the letters of the alphabet arranged round it. Accordingly, if one person has one of the dials and another the other, by a little pre-arrangement as to details, a correspondence can be maintained between them at any distance by simply pointing the needles to the letters of the required words." The date of the first edition of Hakewill's "Apologie or Declaration of the Power and Providence of God in the Government of the World" is 1627; but the work of Strada's from which he quotes was published ten years earlier. Famianus Strada was born at Rome in 1572, and his "Prolusiones Academicæ et Paradigmata Eloquentiæ" appeared at Rome in 1617. Several editions of his "Prolusiones" have been printed in this country. The particular-poem referring to the loadstone has been translated into English, and is printed in "The Student; or, Oxford and Cambridge Miscellany," 1750. The passage is referred to by Addison in a paper in the *Spectator*, No. 241, and in the *Guardian*, No. 119. In the former of these he adds: "In the meanwhile, if ever this invention should be revived or put in practice, I would propose that upon the lover's dial-plate there should be written not only the four-and-twenty letters, but several entire words which have always a place in passionate epistles: as flames; darts; die; language; absence; Cupid; heart; eyes; hang; drown; and the like. This would very much abridge the lover's pains in this way of writing a letter, as it would enable him to express the most useful and significant words with a single touch of the needle."

The subject is an interesting one, and seems to us well worth being followed out.

EVOLUTION OF NERVES AND NERVO-SYSTEMS[1]

II.

As the Medusæ are thus the lowest animals in which a nervous system has yet been discovered, we have in them the animals upon which we may experiment with the best hope of being able to elucidate all questions concerning the origin and endowments of primitive nervous tissues. I have therefore spent much time and labour, both last year and this year, in cultivating this field of inquiry; and as it is a field whose ground had never before been broken, and whose fertility has proved itself prodigious, it is not surprising that I should have reaped a rich harvest of results. So far as these results have any bearing on the general theory of evolution, their character is uniformly such as that theory would lead us to expect. For if I had two hours at my disposal instead of one, I might mention a number of facts which tend to show, in a very striking manner, that the primitive nervo-muscular tissues of the Medusæ, in respect of their physiological properties, present unmistakable affinities, on the one hand with the excitable tissues of certain plants, and on the other hand with the nervo-muscular tissues of higher animals. But not having time to go into this matter, I shall on the present occasion restrict myself to describing such of my results as tend to substantiate Mr. Herbert Spencer's theory concerning the mode in which nerves and nervo-systems have been evolved. And I adopt this course, not only because I feel that any facts bearing on so important a subject cannot fail to be of interest to all intelligent persons, but also because I think that this is a place best suited for publishing the somewhat speculative inferences which I have drawn from my facts. If these inferences are correct, their philosophical as well as their scientific influence will be great and far-reaching; but until they shall have been more completely verified I have not thought it desirable to adduce them in my communications to the Royal Society. Referring, therefore, those among you who may be interested in the research as a whole to the *Philosophical Transactions*, I will now invite your attention to a connected interpretation of some of the facts that it has yielded—an interpretation which I here publish for the first time.

To begin, then, with this diagram, Fig. 2. It represents *Aurelia aurita*, with its polypite cut off at the base, and the under, or concave, surface of the bell exposed to view. The bell, when fully expanded as here represented,

[1] Abstract of a Lecture delivered at the Royal Institution on Friday evening, May 25, 1877. By George J. Romanes, M.A., F.L.S., &c. Continued from p. 233.

is about the size of a soup-plate, and in it all the ganglia of the margin are collected into the eight marginal bodies; so that on cutting out these eight marginal bodies total paralysis of the bell ensues. But although the bell is thus paralysed as to its *spontaneous* movements, it continues responsive to stimulation; for every time you prick or electrify any part of the contractile sheet, a wave of contraction starts from the point which you stimulate, and spreads from that point in all directions as from a centre. Such contractile waves, at ordinary temperatures, travel at about the rate of a foot and a half per second; and the important question with regard to them which we shall have to consider to-night is this—Are they merely of the nature of muscle-waves, such as we see in undifferentiated protoplasm, or do they require the presence of rudimentary nerve-fibres to convey them—the *stimulus* wave in the rudimentary *nerve*-fibres progressively causing, as it advances, the *contractile* wave in the rudimentary *muscle*-fibres?

Now the great argument in favour of these contractile waves being muscle-waves, and nothing more, is simply this—that the contractile tissue is able to endure immensely severe forms of section without the contractile waves in it becoming blocked. For instance, when the bell of *Aurelia* is cut as here represented, Fig. 3, and any part of the circle is stimulated, a contractile wave radiates

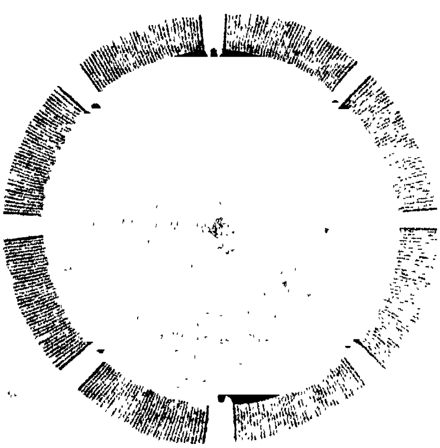

Fig. 2.

from the point of stimulation just as it did before the cuts were introduced, notwithstanding the wave has now to zig-zag round and round the ends of the overlapping cuts. Similarly, if instead of employing artificial stimulation, a single ganglion (*g*) be left *in situ* while all the other seven are removed, contractile waves will radiate in rhythmical succession from the single remaining ganglion, and course all the way round the disc. Now this experiment seems to prove that the contractile waves depend for their passage, not on the conductile function of any primitive nervous net-work, but on the protoplasmic qualities of the primitive muscular tissue. The experiment seems to prove this, because so severe a form of section would seem of necessity to destroy the functional continuity of anything resembling such a nervous net-work as we observe in higher animals.

Here, again, Fig. 4, is another form of section. Seven marginal bodies having been removed as before, the eighth one was made the point of origin of a circumferential section, which was then carried round and round the disc in the form of a continuous spiral—the result, of course, being this long riband-shaped strip of tissue with the ganglion (*g*) at one end, and the remainder of the swimming-bell at the other. Well, as before, the contractile waves always originated at the ganglion; but now they had to course all the way along the strip until they arrived at its other extremity, and as each wave arrived at that extremity it delivered its influence into the remainder of the swimming-bell, which thereupon contracted. Hence, from this mode of section as from the last one, the deduction certainly appears to be that the passage of the contractile waves cannot be dependent on the presence of a nervous plexus; for nothing could well be imagined as

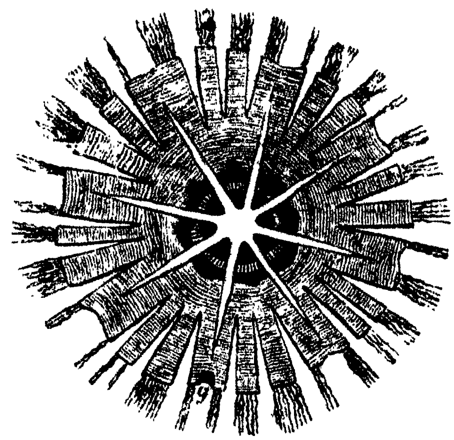

Fig. 3.

more destructive of the continuity of such a plexus than this spiral mode of section must be.

Nevertheless there is an important body of evidence to be adduced on the other side; but as I can only wait to state a few of the chief points, I shall confine my observations to the spiral mode of section. First of all, then, I have invariably found it to be the case that if this mode of section be carried on sufficiently far, a point is sooner or later sure to come at which the contractile waves cease to pass forward: they become blocked at that point. Moreover, the point at which such blocking of the waves takes place is extremely variable in different individuals of the same species. Sometimes the waves will become

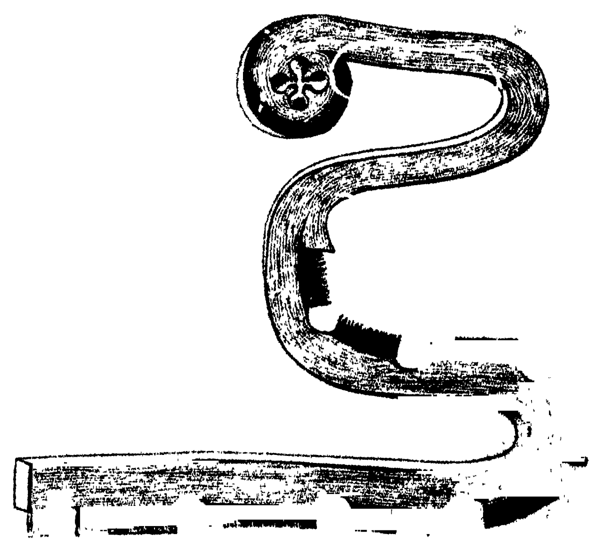

Fig. 4

blocked when the strip is only an inch or less in length, while at other times they continue to pass freely from end to end of a strip that is only an inch broad and nearly a yard long; and between these two extremes there are all degrees of variation. Now if we suppose that the influence of the ganglion at the end of the strip is propagated as a mere muscle-wave along the strip, I cannot see why such a wave should ever become blocked at all, still less that the point at which it does become blocked should be so variable in different individuals of the same species. On the other hand, if we suppose the propagation of the ganglionic influence to be more or less dependent on the presence of a more or less integrated nerve-plexus, we encounter no difficulty; for on the general theory of evolution it is to be expected that if such fibres are present in such lowly animals they should not be constant as to position.

But there is a still stronger argument in favour of nerve-fibres, and it is this. At whatever point in a spiral strip which is being progressively elongated by section the blocking of the contractile wave takes place, such blocking is sure to take place completely and exclusively at that point. Now I cannot explain this invariable fact in any other way than by supposing that at that point the section has encountered a line of functionally differentiated tissue —has severed an incipient nerve.
