JOURNAL.

SHIP CANAL COMMUNICATION ACROSS THE ISTHMUS OF SUEZ.

Inquiry into the means of establishing Steam Navigation. By JAMES VETCH, CAPT. R.E., F.R.S. Pelham Richardson, Cornhill.

The Suez Navigable Canal for accelerated communication with India. By MR. CLARKSON. British and Foreign Agency Office, 57, Lincoln's Inn Fields.

Observations on the Red Sea and Mediterranean. By ARTHUR ANDERSON. Smith, Elder & Co., Cornhill.

THE attention of the scientific world has, for many years past, been directed to the design first sketched out by Napoleon Buonaparte, of connecting the Red Sea with the Mediterranean, by means of a navigable canal, and many endeavours have been used to influence the Pasha of Egypt to undertake the task single-handed: but engaged in protracted and expensive wars, which had the effect of desolating many of the most fertile provinces of his dominions, and the crippled state of his finances, have precluded the possibility of his engaging in this magnificent undertaking, however really desirous he may have been to compass this ambitious project. Since the cessation of war, with the loss of Syria, his sources of revenue have suffered a still further diminution, being now barely £4,000,000 sterling per annum; and we are therefore not surprised to hear, that within this few weeks past, he has wholly abandoned all ideas of carrying it out in person: but, at the same time, expresses his wish that the project should be taken up by European capitalists, who, provided his interests are duly considered, will receive from him all the necessary assistance and protection. Urged on by this consideration, the desire to shorten the distance between Great Britain and her immense territorial possessions in the East, and to facilitate commerce, several projects have from time to time been put forward with a view of engaging the attention of the British Government and of the monied classes, emulous to employ their capital in all important undertakings of acknowledged utility and likely to prove profitable. A very excellent article in the *Foreign and Quarterly Review*, has been followed by two able pamphlets just published, one of them by Mr. Anderson, the other by Captain James Vetch. It is not our intention, however, to follow either of these writers through their several statements, but merely to remove some erroneous impressions entertained by all of them, and to give a general idea of the question under consideration, with our own opinions thereon.

Pelusium, from whence it is proposed to conduct the canal, lays a little to the east of the Pelusiac branch, aod, according to Strabo, about two and a half miles from the sea; its circumference measured the same distance, and it was guarded not only by massive walls, but also by extensive morasses on every side; being situated in the midst of a naked level, between the sand desert passing into Syria, the sea, and the morasses, which now form a part of the lake Mansaleh. Its ruins may now be seen about two miles from the sea, the land having gained seven miles and a half upon the Mediterranean since that period. The Pelusian branch, which was of considerable magnitude in those days, is little more than a wide stream of mud as it crosses the arid plain from the lake Mansaleh to the sea. On its banks stands the fortress of Tineh, built by the Turks, and said to be a place of considerable strength. This branch of the Nile is now known as the Canal of Abu Manejji; it is the second branch issuing from the Damietta arm, which it leaves at about six miles below Cairo: it then passes by Bibers and Tell Bastah (Bubastes) and at length enters the sea, much contracted in width, and almost choked up with mud.

The lake El Mansaleh is formed in the low lands near the sea, which extend from the Pelusiac branch nearly to the Rosetta branch. It receives the Canal of Ashmin-erromman, which formerly passed through the territory of El Mansaleh, and then branched out into two divisions, one of which ran northward, and the other, making a bend, flowed into the lake of Tennis: this canal, from its uniform depth, is thought to be the Mendesian arm of the Nile; and the lake Boheïreto el-zar has been considered the Tanitic branch. "This lake," says Sicard, "begins half-league to the eastward of Damietta, and ends at the castle of Tineh, anciently Pelusium. It is twenty-two leagues in length from east to west, and five or broad from north to south. Its bottom is muddy and full of weeds. It is seldom more than five feet deep, and is separated from the sea by a strip of sand, at most a league in width; it communicates with the sea by three mouths, that of Tíneh the easternmost, Omm-ne-ferrej, and Díbeh. In summer, during the inundation, its waters are sweet, during the rest of the year they are salt. This lake contains many islands, most of them uncultivated, those of Matareyyeh near El Mansaleh are the most populous: two others are covered with the ruins of ancient cities. The bed of this lake is several feet below the level of both seas, the depth of mud and sand being very considerable; the original bed on which they rest being compact gravel, and calcareous matter, similar to the general formations of Egypt. The Pelusiac branch was considered the most important one, being denominated the *key* and *strength* of Egypt.

Nechos, the son of Psammetichus, and the Pharaoh Necho of Scripture, was the first who attempted to open a communication between the Nile and the Red Sea, which Darius, King of Persia, afterwards continued to the bitter lakes, from thence it is said to have been carried to the Red Sea by Ptolemy Philadelphus; it commenced from the Pelusiac branch, and extended as far as Arsinoe, now called Aggeroud, or Ajeroud: the length of this canal, says Herodotus, is equal to four days' voyage, and it is wide enough to admit four triremes abreast: the water enters it from the Nile, a little above the city Bubastes; it terminated in the Red Sea, not far from Patumos, an Arabian town. In the prosecution of this work under Nechos, it is said that one hundred thousand Egyptians perished, nor is this to be wondered at, when we consider the baneful and pestilential marshes through which it had to be carried, and the inevitable long exposure to the nightly dews, and burning heat by day, to which the workmen were alternately subjected: this writer says, "Darius carried on the undertaking (began by Nechos) but desisted from finishing it, on the false opinion that, as the Red Sea is higher than Egypt, the cutting of the isthmus between them would necessarily lay the country under water. The Ptolemies disproved this error, and by means of weirs or locks, rendered the canal navigable to the sea, without obstruction or inconvenience." Diodorus confirms this account. Pliny tells us that Ptolemy of Egypt, the second of that name, continued the canal to the bitter fountains; at this point the work was interrupted, for it was found that the Red Sea lay higher than the land of Egypt by three cubits (4½ ft. or 5ft.): he denies that the canal was ever completed to the Red Sea, but speaks of the river called Ptolemæus that passes by Arsinoe.

With all due deference to learned commentators on this subject, we are inclined to believe, with Pliny, that the canal was never carried beyond the bitter fountains, and that the river he mentions was the natural channel from this series of lakes to the Red Sea, through which the waters of the Red Sea flowed towards the Mediterranean: that in the days of Nechos the communication from sea to sea was continuous, that it continued so long after his days, and even to the time of the Ptolemy in question: that the waters of the Red Sea continuing to retire beyond their ancient limits, the channel from the bitter lakes to the sea dwindled down from a broad expanse of waters above the present head of the Red Sea, to a narrow channel or river, and were eventually cut off. In confirmation of this, we find throughout this depressed portion of the isthmus, a series of sea beaches, heaps and ridges of accumulated sea shells, and reefs of coral, of precisely the same species as now belong to the Red Sea, but not to the Mediterranean: these deposits are found in the bitter lakes at a very slight depression below the present level of the Red Sea, and from thence a series of depressions takes place throughout the whole chain of communication. It would appear, also, that as the communication was gradually cut off, the labours of man were called into requisition to remedy the mischief, artificial channels being made from the head of the sea, much above where it now is, to the bitter lakes; or, as Pliny terms it, the *Lacus Amari*, and thence from lake to lake. M. Linant's report tells us, that at the bottom of the two gulfs of Suez and Akaba the sea has advanced; this is positively ridiculous, and disproved by facts: the great salt plain at the head of the sea of Suez gives decisive evidence of its oceanic origin, and of having been in remote periods a part of the Red Sea, and Arsinoe, once a sea-port town, is now six or seven miles distant from the sea: even modern Suez is removed far from the ancient site. This head of the sea is not merely filling up by sands, but its formation is analagous to that of deeper waters, and common to the sea, and of such is the isthmus, showing throughout a gradual decrease in the volume of waters, and not merely a displacement of them. Granted that the remains of a town may be found under water, this merely proves that points of land, subject to the incessant motion of the waves, often give way, and become submerged: Yambo is built on a recent reef. Most of the large towns on the Arabian coast have become so barricadoed by the reefs and consolidated rocks as to be unapproachable for miles; and even Macullah, at the eastern mouth of the Red Sea, is built on a recent reef: the original boundaries of the Red Sea are on both sides of it, numerous and strongly defined, and in some places embrace desert plains many leagues in extent.

All the natural phenomena of the isthmus demonstrate that the communication of the two seas was kept up by a current always flowing from the Red Sea to the Mediterranean, through the valleys or depressions constituting the chain of lakes, that the hard gravel, marl and sand forming the desert is such as represents the bed of the sea at Suez, the whole of the extensive plain passing into Syria was at this remote period covered by the sea, and formed part of the Mediterranean. Hence it is evident that no danger is to be apprehended from again opening this line of communication, either of its overflowing the fertile valleys of Egypt, or causing a rise in the Mediterranean Sea. It is not on historical record that this line of communication was made available to the fleets of the ancients, nor does it appear to have been the desire of the Egyptians to maintain a passage for the ocean waters, the sea passage being prevented by a solid dyke or wall constructed across the channel near its entrance to the gulf; on the other hand, their chief aim appears to have been to make all the cultivatable portions of the land of Egypt available to its then dense population; thus the canal from Bubastis passed through the fertile Wadi, the Goshen of the Israelites, to Thaubastum, where it entered the Bitter lakes, which were the natural reservoirs of both the ocean and river waters, and lest the salt waters should flow over the cultivated tracks, or the channel between the two seas, should receive too great an impetus from the overflow of the Nile, large mounds were thrown across the Wadis.

Proceeding to the consideration of the several proposals for reopening the communication between the two seas by means of a ship canal or channel, we shall notice Mr. Anderson's pamphlet. This gentleman after a preliminary condemnation of all previous statements and speculations as superficial, crude, and erroneous, enters upon his subject by giving a somewhat lengthy extract from what he is pleased to term the report of M. Linant, a French civil engineer, in the employ of the Pasha of Egypt, which he obtained for a consideration: in this we suspect he has bought a bargain, for the report in question is copied almost literally from the one drawn up for the French engineers, and published in 1798, "*Description d' Egypt:*" in fact, in the extract in question, M. Linant observes "by many repeated observations made during my numerous journeys through the Isthmus of Suez, as well as from the levellings which were taken with great care during the occupation of Egypt by the French army. I assume that the level of the Red Sea is higher than that of the Mediterranean, and that it has once covered the Isthmus:" there is not the most remote reason to suppose that any triginometrical survey has been taken by him, or that he is acquainted with the country east of the chain of lakes. In the words of the French engineers M. Linant observes:—"The topographical position of the place shows, that from the Red Sea to a distance of 22,000 metres (nearly 14 miles), the spot where the ancient canal was re-dug by Amrou, or where the canal of the Prince of the Faithful still exists, it is only necessary to dig this canal to a depth of 290 metres (9 ft. 6 in.) when there would be at once established a current of water towards the Mediterranean; because, at the end of this distance, you enter the bed of the bitter lakes, now dry, which are there about 5 metres (16 ft. 4 in.) lower than the Red Sea. From thence the ground becomes lower and lower, as far as the point which separates the bitter lakes from the lake Themsah, where the ground for a distance of about 6,000 metres (6,560 yards) is at its greatest elevation 0·50 (19½ in.) above the level of the sea; the soil is here sandy. Next comes the basin of the lake Themsah, much lower than the Red Sea, and which is covered by the waters of the Nile during the inundations. The distance between this lake and the low marshy swamps of El Karish, is, at the most, only 3,000 metres (3,280 yards), and the land is not more than 1 metre (3 ft. 3 in.) higher than the Red Sea; this ground is also sandy. Leaving the basins of the lake Themsah, and passing behind the hill of Chek Amedek, near which the ancient canal must have passed, we find the ground is nearly everywhere on a level with the Red Sea as far as El-Karesh. From thence to Dus-el Cassah, and afterwards in a direction towards Bir-el-Divietor, we follow the traces of the ancient canal, in a direct line from the one sea to the other, the ground being all sandy, and much lower than the Red Sea. From thence to the ground which is inundated during the floods of the Nile, by the waters of the lake Mansaleh, there is again found a bed or sort of excavation, or sandy valley, which may probably have been the ancient canal. From thence to the entrance of Tineh, passing between Faramah and the ruins of Pelusium, the land is 9 metres lower than the Red Sea."

He proposes to begin at or near the remains of the ancient jetty, made at the entrance of the canal at Suez, making two embankments or piers, leaving between each an opening, which should form the section of a canal to be dug: the excavation to be carried on to the bitter lakes, a distance of 13½ miles, 130 ft. in breadth, and 9 ft. 9 in. in depth: to clear out the land between the lake Themsah and El-Karesh, a distance of 3¾ miles, leaving only a width of 32 ft. 6 in., a dyke being run across westward of the lake to prevent the waters spreading over the cultivated portions of Egypt: at the Das-el-Ballah, and also the inundated lands about Pelusium, similar dykes are to be constructed. He assumes that from the difference of level, the water being once let in this superficial bed, and flowing with the velocity of about four miles per hour, that the stream would soon scoop itself a channel to any required depth. He would supply the want of a port in the Pelusiac coast by a breakwater or pier, to be placed on the bar, which would be naturally formed at the embouchure of the canal, and concludes with estimating the expenses of excavation, embankments, masonry, and pier, or breakwater, at £150,000.

It is true that the estimate made about 50 years ago was much less, but both are equally absurd, when we come to consider the magnitude of the works required, independent of the canal. To commence the canal at the head of the sea would have been all very well in the days of Nechos, but no engineer practically acquainted with the nature of the sea above Suez, would ever recommend a plan which would entail the necessity either of the deepening the whole upper portion of the gulf, a work of vast magnitude and expense, or otherwise of carrying the canal through the very midst of it to deep water, a mode almost equally expensive. The whole head of the sea is extremely shallow, its bottom consisting not only of mud and sand, as we are generally led to believe, but also the same kind of clay, marl, and limestone formation which distinguishes this portion of the coast. Again, we very much doubt his obtaining a current of four miles per hour by the small depth of excavation he proposes: and granting that it is to be obtained, we doubt its efficacy in scooping out a channel to the requisite depth, believing, as we do, that the Red Sea, once flowing through these narrow valleys with a fall as great as in the present day, was unable, in its own strength, to preserve a passage, so that art was obliged to come to the aid of nature in order to preserve this passage for a more extended period of time than otherwise would have been the case. The estimate of the French engineers, embracing both branches, was £691,000.

Captain James Vetch, R.E., proposes to open the communication between the two seas by the shortest possible line: observing "that the shortest line would give the greatest velocity and scouring property to the stream; and, under equal circumstances, would cost least money. A straight line would also be most controllable, and with the least expense; for as soon as bends and angles are introduced to the channel of a large body of running water, an action immediately and inevitably commences on the banks, which would have to be provided against by a heavy expenditure in strengthening them to resist the erosion of the water; but with no reasonable expense could the banks be rendered secure, if the bends were considerable and numerous; for if they gave way in one place, the whole current might be changed and numerous breaches ensue, requiring equal expenditure of time and money to repair." These objections cannot, however, apply to the communication *via* the chain of lakes, which are the natural boundaries of the sea communication: the only points vulnerable to erosion are the communications between the lakes and the lower plains towards the Mediterranean.

An important point appears not to have had due consideration, and which must have weight in all plans put forward for connecting the two seas. For about 300 days in the year the winds and breezes set in towards the Red Sea; but during the period of the *Kamseen* they blow towards the Mediterranean: thus vessels will be enabled to sail one way and come down by the current on the other. This peculiarity of the atmospheric currents favours the passage by the chain of lakes, rather than by a straight narrow channel; these fine expanses of water enabling the mariner, in the passage to and fro, to avail himself of every capful of wind: again, by the circuitous route, the pressure of the waters of the Mediterannean upon the waters of the canal would, in some measure, regulate their height and velocity. The velocity of the current should be so apportioned as to enable sailing vessels to bear up against it; steam tugs might also, if necessary, be employed; tracking or warping would be of no service whatever.

Pursuing the circuitous route by way of the lakes, the only artificial excavations required are those which exist between them and also between them and the respective seas: in additional to the westward embankments proposed by M. Linant, we are of opinion that through the levels towards the Mediterranean the channel ought to be embanked on both sides, thus permitting the waters to be above the plains, preserving uniformity in the currents and height of waters, and protecting them on the one side from drifting sands, which, passing from the desert situate on the Eastern side, may otherwise in a few hours fill up local portions of the bed; and, on the other side, from the inundations of the Nile. In some places this precaution will be absolutely necessary, inasmuch as the morasses are below the level of either sea. Captain Vetch, in proposing a new line directly across the desert, candidly states that he has no knowledge of the nature of the soil over which he proposes the canal to pass, and even to those who have traversed those plains, it is very problematical whether the possibility exists of forming a canal by a direct route: he errs in supposing that the land above the head of Suez is wholly composed of drift sand. Again the greatest velocity is not wanting, for not only must this canal, if direct, be lined throughout, but it must also be protected by high and strong enbankments, otherwise it would be in continual danger of filling up in localities by sudden drifts: he proposes to construct a basin at its issue from the Red Sea, which he, with great propriety, proposes to be between three and four miles below Suez, where there is already four fathom water, regulating the issue of water by means of several parallel channels, constructed of masonry, and each capable of taking the largest class of ships navigating the canal, and capable of being closed on occasions of necessity, the several channels uniting at a little distance north of the basin; he would obtain a current of 2·15 miles per hour as the most likely to be effective for scourage, and yet not difficult to navigate against, and in these latter points we fully concur: his estimate of the expence of excavation, masonry, piers, basin, &c., for the direct line proposed by him, is £2,102,000, reckoning the total length of the canal at 75 miles, or 132,000 yards: the total quantity of excavation being 42,504,000 yards; presuming the canal to be 21 ft. deep, 96 ft. wide at bottom, and 180 ft. wide at top at water line. The actual cost for excavating and embankment must depend upon the people employed, for if Egyptians supplied by the Pasha of Egypt, wages are not more than 2*d.* per diem, if the labourers are to be brought from other places, greater expences would necessarily be incurred.

Further particulars of plans laid down by the French engineers have been so long before the public, that it is needless to notice them more than by saying that they proposed to preserve the level of the water in their canal at Ras el Moyeh equal to the low water level at Suez, and to throw all the remainder of the fall 26·64 English feet on the remaining distance of 30 English miles; and by so doing they conceived that energy would be given to the current of the canal to clear its bed from drift sand, and to hollow out and maintain a chanel in the shallow muddy bottom of the bay, so as to afford the requisite depth of water at Tineh.

The plan of Mr. Clarkson, who gives an extended review of the history of the ancient canal, embraces the same idea as Captain Vetch, in carrying the canal in a direct line from Suez to the Mediterranean near Tineh; he also considers that the descent of about five inches per mile is amply sufficient to secure the communication: he would carry the two lateral walls of the canal into the Mediterranean sea for six or seven miles into deep water; this eight miles he conceives would be no large addition to the extended labour and expence; we differ widely from him in this; the watery base is much deeper than he imagines, and embankments to run this length into the open sea, must of necessity be attended with very great expense, and require great engineering skill to execute; the Mediterranean is no fishpond in stormy weather.

REFERENCES.—T. Tineh; P. Pelusium; S. B. Lake Subaket-Bardoil; P. B. Pelusiac branch; T. B. Tumetic branch; Bu. Bubates; B. Belbeis.

The several routes proposed are marked on the accompanying map.

1. The line called by Captain Vetch the Bir Makdal line.
2. The Thanbastum line.
3. The Ras el Moych line as proposed by himself.
4. The French line as marked out by M. Linant.
5. The lines proposed by us.
6. The interior French line.
7. Ancient canal.
8. Waghorn's present route.

The time consumed by the present route through Egypt is four days, the distance travelled over being 346 miles: the time required by the canal route would not exceed 3 or 4 hours—this is important in a political, commercial, and pecuniary view: but even this is as nothing compared to the vast advantage of having a route independent of any power, and so long as British greatness exists, of being able to secure it, whatever events and fluctuations take place in Egypt, or whatever disagreements take place among European states. The way of Egypt is at present by courtesy alone, and might be put a stop to to-morrow, and very probably will be jeopardized on the death of the Pasha.

Besides the plans already laid before the public, there is another route we have marked out in the accompanying map, the possibility of which is based on the authority of an experienced and scientific man. Starting from the Red Sea below Suez, the canal passes into the beds of the bitter lakes, and from the head of these lakes to Cateih, passing by which, and entering the Mediterranean Sea through the great lake Subaket Bardoil, or King Baldwin's lake; this route is by the way Hebrash, Assebbie, Hassivon, Masinak and Bucaria, a distance of about eighty-three miles from the lakes. Should this route be thought too circuitous, let the line be direct from the head of the Red Sea below Suez, to Subaket Bardoil, following the base of the elevated plains of the desert towards the east. The advantages of this route we conceive will more than compensate for the increased distance: we avoid all the possibly cultivatable soil of Egypt, and form a natural boundary to that country: we avoid all the land periodically overflowed by the waters of the Nile from lake Mansaleh: we secure a much better outlet to the Mediterranean, and a fine capacious basin in the lake itself: we pass eastward of the sand hills through a firm soil of gravel and marl, which, from its elevated position is seldom incommoded with shifting sands at any time. The lake communicates with the sea by a wide mouth, from whence a salt water river passes into Arabia.

With all due deference to the opinions of Mr. Anderson, we believe that previous to any measures being taken by English or other European capitalists for carrying any one of these plans into effect, full security must be obtained from the Pasha of Egypt, guaranteed by the great European powers, that those who speculate in it shall have the fullest protection, enjoying, unmolested by any power, the fruits of their labours. A canal suited to the spirit, wealth, and enterprise of the present day, should be a magnificent one, open to all nations, and under the influence of none: it should be large enough to admit ships of the largest burthen: its tolls should be settled by the cabinets of Europe; wholly independent of the Pasha, who should have no power of interference beyond that of a member of the associated proprietary: nor should the joint body have the power of shutting their gates against any country or community. To accomplish this object the first important movement is, to obtain by grant or purchase a certain width of land across the Isthmus, which should embrace the proposed line of route: the western side of the canal throughout being considered the boundary towards Egypt, the eastern-side advancing, say, 10 miles in breadth from sea to sea: this tract of land should be erected into an inferior Pashalisk, tributary to a small amount to the ruling powers of Egypt or Turkey, but otherwise wholly independent of them. The corporative body should have power to erect forts at each entrance, sufficiently strong to defend their rights and enforce their tolls: they should also have on payment for the same, all the facilities of labourers and material which Egypt can furnish, food, pay, and accommodation being provided for the Pasha's subjects employed by the company. Is this, we ask, to be obtained? for otherwise capitalists will hardly be found to carry out this truly universal project, and incur enormous expenses, that the Pasha may reap the benefit by receiving the tolls, the only mode for re-payment for the outlay: the avarice of the Pasha is well known, against this no security can be given; and even, during his life, secured from imposition and consequent loss, who can foretell the issue of events under his successor? This, therefore, is the first preliminary step to any company being formed, to any capital being expended. It does not appear that Mahommed Ali would be averse to it, and even if so, whether, from pecuniary considerations, he might not be induced to consent to it: £150,000 or £200,000 would be well disposed of this way, and ultimately saved to the speculators in the hire of Egyptian labourers. It is impossible that the right of tolls, as Mr. Anderson assumes to be necessary, should be vested in his family: the Pasha loses nothing but a strip of desert, he gains a means of communication to various parts of Egypt, exemption from toll, if he desires it, for himself and his Egyptian subjects, a passage to his dominions on the borders of the Red Sea, and an annual sum of money. The Pacha's and the Sultan's consent being obtained, then, and then only, are we called upon to consider the most eligible route or a canal, for, of the physical practicability of making one, not the least shadow of a doubt exists. If the Pasha undertakes it himself, there is no more to be said on the subject: other than this, that his tolls be regulated according to the wishes of those who would avail themselves of it. It is barely reasonable to calculate on a union of European powers to effect an object in which England has so preponderating an interest, as consolidating our power in the East: it is true that all the nations bordering the Mediterranean will benefit largely by it, but in a vastly inferior degree. Austria might not be altogether averse to it, but Russia would be decidedly hostile, and France would look with jealousy upon a plan which, after all that can be said, is to increase the commercial greatness of this country. The question, therefore, should be confined to a company in which the Pacha will be a shareholder, such company having powers like that of the Honourable East India Company, and to be amenable only to appointed trustees and regulators of the tolls. "Political considerations," says Mr. Clarkson, "are foreign to this inquiry;" but the question resolves itself into a political one: the British flag must then float in perpetuity upon the plains of Egypt, who shall tell the result of it. The expense of cuttings, embankments, piers, &c., must of necessity depend upon the extent of operations carried on: the canal in size must be suited to the object, and great outlay consequently be incurred in forming harbours in the respective seas; the estimates laid before us vary from £175,000 to £2,500,000: our opinion is, that to be judiciously completed, the minimum of expense will be £1,500,000, which, to pay 5*l.* per cent. per annum requires an annual revenue of £75,000 per annum, indepeodent of incidental charges. We therefore say, with the *Foreign Quarterly Review*, that, "The expense, compared with the magnificent result, is so trifling, that the wonder is that it has not been carried into effect before now, either by a company having the support of Mahommed Pacha, or by the Pacha on his own account." The advantages to a body of shareholders are undoubtedly great, for independant of the great trade which would be carried through it, independent of its opening Abyssina, and the whole of the interior of Africa to the arts, civilization and religion of European nations, the Red Sea abounds with natural riches, and the fishermen of the Mediterranean would resort there in numbers, for its pearl and pearl shell, tortoise-shell, sponge the finest in the world, coral of commerce, and for domestic ornament, oils from black fish, besides sharks, dolphins, bonatas, and other numerous varieties, subservient to the wants and purposes of man. For other numerous and important particulars, we must refer our readers to the pamphlets in question, as well as to other statements which have been already laid before the public. We cannot, however, conclude this notice without calling the attention of our readers to another pamphlet from the indefatigable Mr. Waghorn, in which he strenuously urges the propriety of forwarding mails fortnightly instead of monthly, in which desirable object we most heartily concur.

CANDIDUS'S NOTE-BOOK.

FASCICULUS LV.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. It is a thousand pities that Buckingham Palace, and not that alone, but several other buildings, cannot be sent to keep company with the model of the British Museum, and like that, be discreetly secluded from the impertinence of public gaze. Instead of being further exposed to view, the south side of the Palace ought to be completely shut out from view; for it will now look more pitiful than ever—a mere higgledy-piggledy collection of architectural scraps and patches, more especially since the accession of—the little knick-knackeries lately added. Royal taste is, of course—royal taste, and, perhaps, ought to be exempt from vulgar criticism; but I suspect that the new chapel would be too much for even the loyalty of Camdenists to stomach. Not much of symbolism there!—on the contrary, it is most unutterably heterodox in that respect. Well! symbolism is not at all in favour in court: that's pretty evident; so neither is precedent, though the lynx-eyed in such matters cannot detect heterodoxy there. What a comfort it is to be occasionally purblind!

II. Although some of them are a degree or two better than those in the Regent's Park, the "Pimlico Palaces," as Professor Donaldson wickedly styles them, are very much akin to them, and partake of a similar littleness of manner. Intended to be imposing, they nevertheless do not impose, but, on the contrary, they generally tell their own tale very indiscreetly. Instead of being made, as they might be, to look like distinct mansions upon a noble scale, by only two or three houses being comprised within one design, the same general elevation is frequently continued along the entire side of a street or square, consequently, while uniformity is pushed to monotony, the impression of greatness aimed at is lost, it being evident at the very first glance, that such a façade consists merely of a row of houses put into uniform, therefore, of "speculation" houses—not such as are erected for their own residences by wealthy proprietors. As far as the builder is concerned, such system is convenient enough: a single elevation will serve for the whole job. Its pattern once set, a Pecksniff "terrace" or "place" may be stretched out as long as—a Chancery suit, and be the external design ever so bad in point of taste, that gives the occupiers of the houses no concern, because they are comparatively but birds of passage.

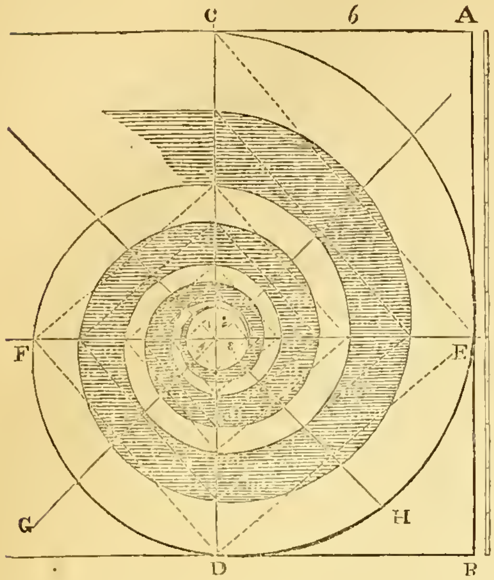
III. It is to be regretted that a little more public spirit and liberality of feeling in the cause of architecture is not shown by those among the noble and opulent, who possess magnificent mansions, worthy of being made known to all, yet are kept, in a manner, almost under lock and key. It is to be presumed that Chatsworth, for instance, and more especially that portion of it which was added by Sir Jeffry Wyatville, must contain a very great deal not only worth seeing but worth studying—and between the two the difference is considerable; nevertheless, there is nothing to inform us what it really is, neither are we likely to have anything, although it would be a mere bagatelle to such a man as the Duke of Devonshire—perhaps not the cost of a single fête—were he to employ the best artists of the day to make drawings and engravings that should completely illustrate the whole of the edifice. Very probably his Grace would not refuse the privilege of making drawings for such purpose to any one who might apply for it, and might even promise him subscribers, yet that kind of liberality does not go far—certainly not far enough for the purpose. It is almost in vain to look to the enterprize of trading speculation, whether on the part of publishers or artists, for works of that class, requiring a very great outlay, and promising but a very limited and a very slow sale. They ought not to be left for others to take up—or rather to the mere chance of its being done, but should be engaged in *con amore*, and with no more idea of profit than a man has when he gives a sumptuous banquet. As little would it matter though the world should set it down to vanity and ostentation: where there are so many other vanities besides, one more or less makes little difference in the sum total of them: neither would such kind of vanity be the emptiest of all.

IV. As this is the age of surprising discoveries of all kinds, we need not be particularly astonished at some one's having just discovered a "*bright halo*" irradiating the character of Sir Robert Smirke as a man and an architect, and claiming distinction for him on account of his "noble and generous nature!" With his private character the public have nothing to do, more especially as he is not one of those who are perpetually thrusting themselves forward into notice, and who advertise themselves and their doings in newspaper puffs; on the contrary, Sir Robert invariably "keeps himself quite to himself," as the saying is, and is no doubt fully entitled to the praise of being in his private station a very gentlemanly and highly respectable individual. Yet there are many others such—at least, so it is to be hoped, many truly excellent and worthy persons, who nevertheless are not on that account paraded before the public. It is in his professional capacity alone that Sir Robert stands exposed to notice, and his personal character belongs not to criticism but to biography. However justly such character may be claimed for him, his "noble and generous nature" does not discover itself by any overt acts: on the contrary, he shows himself to be of a very reserved and cold—not to call it a churlish disposition—not that he is on that account to be singled out for reproach, since even that is merely a negative defect, and one which does not at all concern the public. When, however, a man is officiously extolled for qualities which he does not appear to possess, it is but fair that the world should make some inquiry. To call upon us to admire the high character, and the noble, and generous nature of Sir Robert, is, however intended, not a little indiscreet: most assuredly his professional character for talent does not stand very high, among those at all capable of appreciating it, since, considering the numerous and ample opportunities which have been afforded him, no one in the profession has done less, or has manifested less of artist-like ability and feeling. So far from displaying any sort of invention or fertility of mind, his buildings present merely a few obvious and common-place ideas, hashed up over and over again; and are one and all must tame and insipid—even to poverty, in their detail. To talk of fancy and Smirke in the same breath would be preposterous; his Grecian designs and composition are purely mechanical, such as any one may attain to, merely by literally copying the Ilissus Ionic on all occasions, and sticking its columns against fronts which belong not to a columnar but a *fenestrated* style. Therefore even his so much cried up purity, is, after all, only impurity—mongrelism of the very worst kind, exhibiting in marked contrast to each other, two opposite styles, without any attempt to reconcile them, and thereby bring them in some degree into æsthetic harmony. All that Smirke has done has been quite as well done—in some instances, better, by others of the same school. Foulstone was quite equal to Smirke, and the buildings of the one might very well be mistaken for those of the other; therefore, it is hard for poor Foulstone—the late "Plymouth Vitruvius," and rather puzzling that he should be so little thought of by those who admire his *duplicate*. Possibly it is because he lacked the talismanic prefix of *Sir* to his name. Putting Foulstone, however, out of the question, it does not say much for the superior talent of Smirke, or for the heartiness of his admirers, that none of the latter—even those who consider him to have been unfairly treated, should have attempted to vindicate him, by directly pointing out in his works some of those excellences for which they so largely give him credit. Instead of so doing, they adopt the more cautious yet far less satisfactory mode of speaking of them in the lump, without particularizing any one of his buildings or its peculiar merits. Alas; for his classical taste shown by such a maudlin affair—such a jumble of Grecian and anti-Grecian, as the hall of the Post Office; or such another specimen of his, as is the church in Wyndham Place, or in the Mint on Tower Hill, or the Long-room of the Custom House, or his buildings in the Temple, or those of Serjeants' Inn, or King's College, or the College of Physicians and Union Club House, or the Conservative in Pall Mall. Is it for all—for every one, or for any one of these that our admiration is demanded? If so, and justly so, then has Sir Robert Smirke been, notwithstanding all his success, one of the most unfortunate gentlemen in his profession, for they are all sent to Coventry—are never referred to, spoken of, or mentioned in any way—most certainly not for admiration. As to his "noble and generous nature," the proofs of that are not more striking than are the beauties of his architecture. Is it his generous feeling which withholds him from ever joining the exhibitors in the architectural room of the Royal Academy? Are his ideas too precious to be there submitted to vulgar gaze, or would his designs so entirely absorb attention that everything else would be passed by unheeded, and they are therefore kept away out of compassion to others? His enthusiasm for art—supposing it to exist at all, must be of a particularly quiet kind, for never does it burst out on any occasion. Externally he wears much more that looks like indifference for art, and haughty contempt for public opinion. Most assuredly it is a very strange sort of generosity which determines him not to allow the public to view the Museum model, notwithstanding clamours and remonstrances. In that matter we may give him credit for discretion, but hardly for generosity of any kind, or for the warm feeling of a genuine artist who looks to public approval as his most prized reward. Very rarely, if, indeed, ever, has Sir Robert Smirke's name appeared in connexion with any scheme or plan for furthering the interests of art generally, or those of his own profession. He encourages no one, nor any thing: of course he is at perfect liberty so to act, without being responsible to any one for his conduct; but then let him not be held up as a pattern character; let us not be told of his noble and generous nature. If Sir Robert chooses to let the world misunderstand him—to veil the feelings of a warm-hearted and enthusiastic mind beneath the garb of a frigid and repulsive indifference, he must take his account accordingly, nor will *he* at least be surprised or disappointed at finding himself judged of from appearance. However, his hypocrisy, if such it be, is not of a very dangerous kind, for very few will be tempted by his example, to dissemble their virtues, and completely disguise all signs of "a noble and generous nature."

V. Singular paucity of invention is displayed by the surveyors of private fêtes—a greater disregard of money on the part of those who order, than of ingenuity and contrivance on that of those who have the management of them. One stock conceit—and one that would seem to be a piece of etiquette on such occasions—is to lumber up vestibule and staircase with such a profusion of evergreens and plants, that one might fancy Covent Garden market had been invited to the party, and was making its way up stairs before him; or else that he has mistaken the house, and has got into that of some horticultural and florist society. If there be ample space for them, and they are introduced sparingly, and just where an artist would place them for effect, plants and flowers—N. B. artificial ones would answer the purpose just as well and even better, besides being cheaper in the end—are admissible as embellishments on such occasions: but to have a mere crowd and mob of such things does not argue the most elegant taste. What is squandered away by some persons in a season or two, in temporary and trumpery decorations, would enable them to decorate their staircases and rooms in a style of superior and permanent beauty.

SYSTEM OF DRAWING VOLUTES.

By Mr. Maddox.



The size of the volute being first determined, the depth A B is divided into 12 equal parts; from the seventh part draw the right line E F, as shown in diagram; then number 6 parts at the top of the volute from A, and draw a line at right angles with E F, which will give the eye of the Volute. Lines are to be drawn (dotted in the figure) from C to E, E to D, and from D to F, and so throughout the volute, each square diminishing to the centre, as shown above, taking care to have them exactly parallel to the opposite ones. Quadrants of circles are struck from the diagonal lines G H (45°), which quadrants of circles all terminate where the dotted lines cut the lines C D E F. The first centre will be on the diagonal line H at 1, the second centre on the line G at 2; in going through the second time for the inside line the centres will be a trifle nearer the eye of the volute. The diagonal lines *only* are to be used for the centres. When the volute is on a larger scale, a small thin piece of transparent horn or ivory is generally used to avoid the unsightly punctures in the paper.

CONTROVERSIES ON CHURCH ARCHITECTURE.

Sir—It is not long since there appeared in the *Times* newspaper two interesting letters, signed "C. S.," on the state of the church, describing "the discrepancies of condition, feeling, and opinion amongst the clergy," and dwelling on the "depressing and perplexing effects on the young clergyman." Take pity, Sir, on another class who hardly suffer less from these "discrepancies," and with your valuable advice enlighten the path of the ecclesiastical architect. In the last number but one of the *Cambridge Ecclesiologist*, there are the following sentences on the proprieties of church architecture:—"A stone altar may be provided in two ways; either make it plain, a solid mass of masonry; the slab of block granite or marble projecting beyond the masonry, and *marked with five crosses*, or let the slab be supported on plain massy brackets fixed in the eastern wall." "*We assume the absence of altar rails and chairs.*" It is as easy to "*assume*," as Liston argued it was to *say* "read:" and very easy for critics of the Pugin school, who know nothing, and allow nothing, for all the difficulties engendered by this "discrepancy of feeling and opinion," to hurl their thunder at the unhappy architect employed by clergymen opposed to their "controversial arrangements," or who are so far "heretics" as to disallow the "dicta" of the Camden Society. Suppose the architect employed alternately by members of the "go-a-head," and by those of the "things as they are" school. In the former case he finds the clergyman originating the building or restoration, anxious to have "a stone altar," sedilia, lettern, faldstool, and perhaps, in painted glass, the representation of the saint or saints to whom the Church may be dedicated. On such instructions he prepares his plans: the work commences, and is perhaps completed, before the bishop of the diocese (an alarmist) becomes aware of the full extent of these "innovations," and objects to their introduction. The work is suspended; the plans and arrangement have to be altered, and the original spirit and feeling of the design become lost. This is no imaginary difficulty! In two cases within my own knowledge the churches were finished; in one, an Archbishop refuses to consecrate because the "solid stone altar" is introduced; in the other, a bishop threatens the same course if figures of saints (already painted) are introduced in the east window.

Suppose the architect employed by one of the latter class, the advocate of "things as they are." He is *cautioned* against these "modern innovations," these "shadows of coming Popery," and is required to embody in *these plans* the box pew, the twin preaching and praying pulpit, ground glass, and arm chairs! and if the employer in this case be a utilitarian, an advocate of the *least accommodation* for the *greatest number* principle, you have the monstrosities of galleries round the church (the east end perhaps excepted). This preaching house is finished and ready for consecration; the bishop of *this* diocese (not an alarmist) condemns its coldness and poverty; and in the next number of the *Ecclesiologist*, the production is criticised, its arrangements held to be "totally indefensible," "very objectionable," in fact, "one of the worst things they ever saw," "a perfect disgrace to the parties *responsible* for it." Now, Sir, it is this very *responsibility* I want to have defined. How, in the absence of all uniformity as to church proprieties, or church arrangement, is the unhappy architect to act? The question of surplice or academic gown is not more perplexing to the young clergyman, than the form and *aspect* of the reading desk, the pew or open seat to the architect (young or old). *His* province it cannot be to determine whether these novelties or "trifles" (as the Bishop of Rochester calls them) have "positive danger in them," whether "they indicate more than appears on the surface, or whether, considering the temper of the times, and the present unsettled state of the Church, they are calculated to irritate and vex the minds of congregations, and to become the badges of party distinction." Nor should he be called upon to justify and perpetuate what he believes to be inconsistency and slovenliness in worship. To refuse employment in those cases where the character of these arrangements is not in accordance with his own "private judgment," will not facilitate his children's support; and

> "There is no end to eating! legs of mutton
> Are vanquished daily by this little host."

To accept it when he knows that the result will *inevitably* draw down on his devoted head, the flagellations of these ready-made critics ("for a man must serve his time to every trade save censure"), is an act of heroism and self-devotion worthy so good a cause.

Forgive this long story from a constant reader of your journal, and

An Unhappy Church Architect.

December, 1843.

ROYAL ACADEMY.

Sir—Not finding in the last number of the *Journal* any remarks upon the architectural drawings, beyond the mere notice of the successful competitors for the prize medals offered by the Royal Academy to the students, I beg leave to submit a few remarks which occurred to me in the course of a rapid glance of these drawings, taken after the distribution of the medals.

There were six sets of designs sent in for the gold medal, amounting to thirty-two drawings, consisting of plans, geometrical and perspective elevations and sections. This, I understand, is the largest number which has been sent in for some years. For the silver medal there was but one set of drawings, this is the smallest number received for some years. The subject for the gold medal was a Metropolitan Music Hall, and Royal Academy of Music. I was struck with the general appearance of inattention to the purposes of the building exhibited in the plans and other drawings, excepting in those of Mr. Garling, to whom the medal was awarded. I say, excepting Mr. Garling's, because he, unlike the rest (from each room being assigned to some purpose described, and from a short sketch and description sent with the drawings), appeared to have studied well the arrangement of his building. As in almost all designs where outlay is not thought of, columns, pediments, statues, &c., were in great abundance; indeed it appears to be the idea of many young architects, as well as some old ones, that the more of these, they can crowd together, the greater the grandeur and beauty of the edifice. In some of the designs the Music Academy appeared to be lost sight of; a large central hall, surrounded by a suite of galleries, nearly a fourth part of which were appropriated as royal entrances, &c. In others they introduced court-yards, but still having no rooms, properly so called, for the academical department. One of the perspective views looked like a large temple on the top of a hill, the base of which was hidden by a crowd of small low buildings with domes, pediments, &c. In another, from the number of columns introduced, and from the point of view chosen, not a single window or door was to be seen, and it therefore looked like a tomb or some such building. Although having spoken so much in dispraise, I must acknowledge that all the drawings exhibited great care in the drawing, and, I might almost say, beauty of colouring; but the most of them departed from the printed directions of the Academy, namely, that no colour but sepia should be used, for in some I noticed red, blue, yellow, brown, &c. And, again, in the introduction in the perspective drawings of figures, such as soldiers, horses, stalls, with their attendant old women, boys, &c., which, in my opinion, instead of adding to the beauty of the design, turned it into a pretty picture, and no more. I fear from some little pieces of bad perspective, also introduced, that some one had been employed to put in that which certainly did not add to the beauty of the architectural design.

The drawings for the silver medal, sent in by Mr. G. Perry, of the West Wing of Greenwich Hospital, from actual admeasurement, exhibited great care, both in the drawing and colouring. The Academy reserving the power of withholding the medal, in a case like the present where only one competitor sent in, have signified that they considered the drawings of Mr. Perry worthy of the prize. Although these drawings did not exhibit the artistic handling shown in the gold medal drawings, they give promise of superior abilities. A student informed me that the probable cause of there being no other drawings in this class was owing to the council's description of the part required to be drawn, being very unintelligible, and that he had no doubt the students were afraid of commencing any drawings, as they might turn out after all to be of a wrong part. But why did not they make inquiries? I apprehend that either the Keeper of the Academy, or some other member, would have set the student right.

Yours, truly,

January 3, 1844. Q.

A MARINE SALINOMETER.

For the purpose of indicating the Density of Brine in the Boilers of Marine Steam-Engines. Invented by J. Scott Russell, M.A., F.R.S.E., F.R.S.S.A., Civil Engineer.

Read before the Royal Scottish Society of Arts, 28th February 1842, the Honorary Silver Medal of the Society awarded, and reported in their Transactions.

It was very early in the history of steam navigation that the inconvenience of raising steam from salt water was experienced. When the *Comet* descended below Port Glasgow in 1812, the boiler was found to boil over, or prime, as it is technically called by engineers, when part of the water of forced up so violently, along with the steam, as to pass over into the cylinder of the engine—a circumstance always detrimental, and sometimes destructive to the engines. This arises from the thickening of the water, its density being increased by the retention of the solid substances which compose sea water, and which remain and accumulate in the boiler, while the fresh portion of the water is passing off in the shape of steam. This process of accumulation of solid matter in the marine boiler is by no means slow. The whole of the water which a marine boiler usually contains is evaporated in three or four hours, leaving the solid substances in the cubic content of boiler behind it, and being replaced by salt water, with an equal quantity of depositary matter, accumulating as rapidly as before; and since it is known the solid matter amounts to as much as $\frac{1}{30}$ of the whole mass of water, it would follow, if the process of ebullition could continue so long as 150 hours, there would be deposited in the boiler a quantity of solid matter equal to the number of tons of water in the whole content of the boiler.

Long, however, before this degree of solidification can take place, evils of a different description intervene to impair and put an end to the functions of the boiler. The solid constituents of salt water which are left behind do not diffuse themselves uniformly over the whole liquid mass, so as to constitute a homogeneous brine; on the contrary, the new supplies of sea water, as they enter the boiler, remain secluded from the former more saturated brine, rise by their less specific gravity into an upper stratum, while the denser brine forms a bed in the lower part of the boiler, and surrounds the fire box and heater flues occupying the water spaces and legs, which are usually at a high temperature, and which, in double tiered boilers, are generally the most intensely heated. The intense heat of the metal expels the water from the brine in contact with it most rapidly in the hottest places, and salt is deposited on the hottest parts of the furnaces and flues, extending rapidly to those less heated, and so not only diminishing the evaporative power of the boiler, but injuring its substance, and endangering its existence.

The remedy for these evils was very early invented. But I have not been able to discover the inventor of the cleansing process commonly called "blowing down," or "blowing off." It is almost universal, and is performed in the following way:—There is forced into the boiler, at each stroke, rather more water than is required for the supply of steam, so that the boiler becomes too full. Openings are then suddenly made at the bottom of the boiler, and the brine at the bottom being violently ejected, carries with it any solid substances that may have accumulated near the bottom—the boiler is thus cleansed; and before the water has got too low, the openings are again closed, and the boiler continues to be fed as formerly. Another remedy, pretty generally adopted, is the brine pump, by which, for every portion of water supplied to the boiler, about one-fourth part of that quantity of brine is withdrawn from it. This process does not so thoroughly carry off all the impurities as the former; but it is attended with a saving of fuel by a contrivance for giving to the feed-water entering the boiler a portion of the heat of the discharged brine. The recent introduction of this process is due to Messrs. Maudslay & Field of London.

In whatever way the saturation of the water with solid matter may be remedied, it is essential to the accomplishment of this object, that some simple apparatus should be contrived for the purpose of showing when the cleansing process is required, and whether it is successfully applied. If this be not obtained, the usual consequence of acting on wrong data are sure to follow. A contrivance was patented, which was thought promising, but was found liable to be mechanically out of order when most wanted:—a ball of greater specific gravity than salt water was connected with an external index, by which there was indicated on the outside, the fact of the brine becoming sufficiently saturated to float this ball. Another was to place in the glass gauge of the boiler a glass hydrometer bead, which would float when the brine became saturated to a given point, and fall to the bottom in the ordinary state of the boiler. But this fails entirely of accuracy, although very elegant; for the brine of which we wish to indicate the density is in the lower stratum, not the upper one, where the usual glass gauge is placed, and irretrievable mischief might be done before the indication would show any change.

I have lately employed, in some large ships destined for transatlantic voyages, a species of brine gauge, or index of saturation, which is found to possess every advantage, and which I therefore desire to communicate to the public through this society. The drawings sent are such as may enable any engineer to construct them for himself. The details of the arrangement of the apparatus were made under the direction of Mr. James Laurie, formerly one of my assistants; and he also has obliged me by writing out the annexed description of the operation of using the index.

The principle I have used is the well-known law, "that the heights of equiponderant columns of liquids vary inversely as the densities of those liquids."

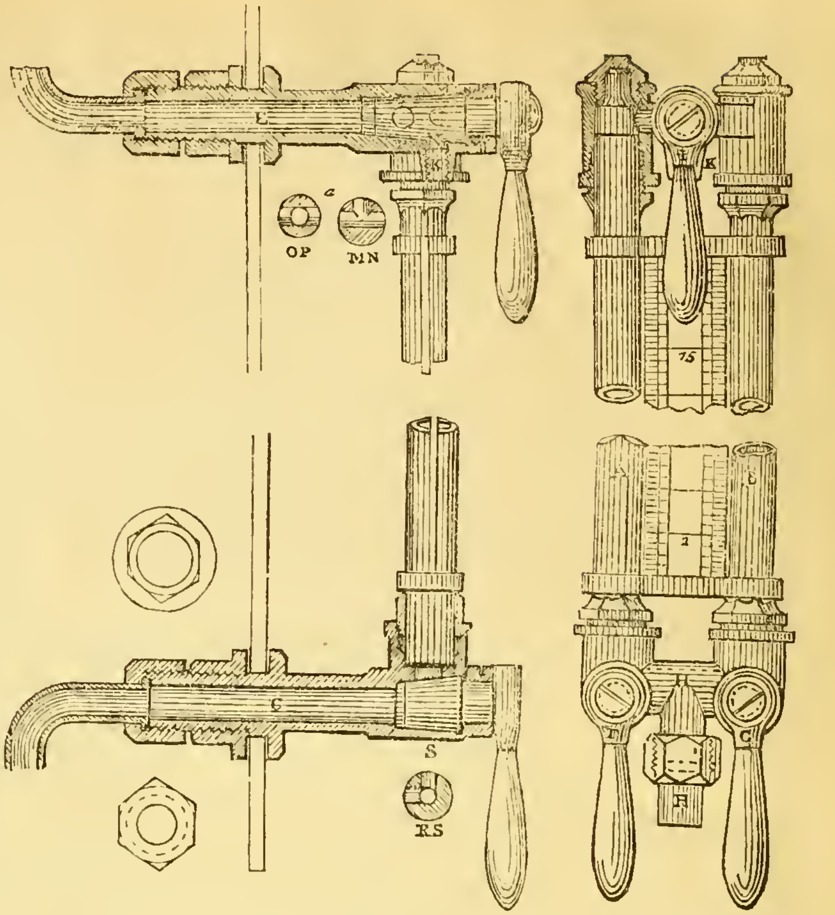
If I take open glass tubes bent in the form of the letter U, and pour one fluid into one of the sides, and another fluid into the opposite side (taking care to use the heavier liquid *before* the other); the one being mercury, and the other water, they will stand at the height of 1 in. and 13 in. respectively. If I use alcohol and water, they will stand at the height of 10 in. and 8 in. respectively, the height of the one fluid being always greater than that of the other, in the proportion in which its weight, density, or specific gravity is less. In like manner fresh water and salt water will stand at heights of 40 in. and 41 in., showing a difference of 1 in.

The use which I make of this principle is as follows:—I reckon the best scale of saltness of a boiler to be that which takes the common sea water as a standard. Sea water contains $\frac{1}{30}$ of saline matter. When the water has been evaporated, so as to leave only half the quantity of distilled water to the same quantity of saline matter, I call that two degrees of salt, or brine of the strength of two, and such brine would show, in fig. 3. the columns 40 and 42, or double the saltness of sea water, indicated by a difference of 2 in. A farther saturation would be indicated by a difference of 3, 4, 5, and 6 in. between the columns, and so indicate 3, 4, 5, 6, and any further degrees of saltness—a range which may be made to any degree of minuteness by the subdivision of the scale of inches. This scale is that which appears to me most simply applicable here—and it is that which I adopt for marine boilers.

The mechanical apparatus which I have employed to give this indication is perfectly simple, and has the advantage of being such as the engineer already perfectly understands. To the marine boiler I apply two water gauges of glass, instead of one as at present used; they both serve the purpose of the present glass gauges, and the pair would be valuable for this, if for no other reason, that there would always be a duplicate when one is broken, an accident not unfrequent. To these gauges I simply attach small copper pipes, so that one of them may be placed in communication only with the salt brine in the lower part of the boiler, and the other with the feed-water which is entering the boiler; the one then holds a column of brine, and the other of pure sea water, and each inch of difference shows the degree of saturation.

Without the use of any attached scale, the engineer, by a little practice, comes to know in his particular vessel, what difference in inches can be admitted without danger, and at what difference of height it is imperative to blow off. But it is convenient to have an attached scale. It may be satisfactory to state, that the practical range of scale in an ordinary boiler in the ordinary working, is 6 in. to 10 in., a difference sufficiently great to be easily observed. The rule of working them is nearly this:—Continue the operation of blowing off until, if possible, the difference of the columns is less than an inch; it will be unnecessary to blow off again until the difference is at least 6 in. As a practical rule, I find that it is necessary to blow off when the brine at the bottom has about three degrees of saltness. But this will vary exceedingly, according as the construction of the boilers is more or less judicious. When the heat is greatest in the lowest portion of the boiler, and the flues return above, they will be most liable to salt, and require the most frequent cleansing.

The following is Mr. Laurie's description of the instrument. The drawings give the details of the apparatus.—J. S. R.



The fact that the specific gravity of salt water is greater than that of fresh, and that it increases with the degree of saturation, is what the operation of this instrument depends on; by its means two columns of water, the one feed and the other brine, are poised against each other, so as that any difference of weight betwixt these columns immediately becomes apparent by the lighter of the two requiring an accession in quantity to resist the upward pressure to which both columns are subjected. This is accomplished by having two common glass gauge-tubes close together, each of which is connected with a separate tube; that inside the boiler descends to the level of the water, the specific gravity of which is to be measured, and having either or both of these tubes so connected with the feed-pipe of the boiler, that by opening a cock one of the pipes will be filled with feed-water, while the other remains filled with brine, which cock being shut, the tubes remain so filled; but inasmuch as feed-water is of less specific gravity than brine, it will be forced up and stand in the glass tube at a higher level than the brine, which difference of levels increases with the saturation—and hence the index to judge of the saltness.

Fig. 1 and 2, A, B, are the two glass gauge tubes; C, one of the tubes forming the connexion betwixt one of these glass gauge tubes and its tube D, that descends inside of the boiler to near the bottom; E, the tube forming the connexion betwixt the upper ends of these tubes and the inside or the boiler and ascends to near the top; F, G, two cocks so made, as shown in the drawing, that by their means each of the tubes inside of the boiler may be shut off from the glass tubes, and also may be connected with the tube H, leading from the feed-pipe of the boiler; I, a cock affording the means of shutting off the tube E from the glass tubes, and also of connecting either of these glass tubes with the tube K, leading to the bilge of the vessel; each of these cocks has a handle, and when the instrument is indicating, the three handles hang perpendicularly downwards. To bring the instrument into operation, the three handles must first be put in the position ¡ ¦ which has the effect of allowing the brine to flow right up the glass tube A, and out through the tube K, into the bilge of the vessel; this having been done for so long a time as that A and its tube inside the boiler be thoroughly cleansed and filled with brine, the handles are then to be put in the position ¦ ¡, which, in like manner, cleanses and fills B and its tube inside of the boiler with brine; finally, bring the handle of the top cock into its original position, and put either of the lower handles horizontal, which forming a connexion of the feed-pipe with one of the tubes inside of the boiler, fills that tube with feed-water; thus there are in the two tubes inside of the boiler two columns of water of different specific gravities, the one being brine, the specific gravity of which is to be measured, and the other feed-water, the specific gravity of which is pretty nearly constant, so long as the temperature of condensation is the same, and does not vary much, let the temperature of condensation be what it may; but, inasmuch as these columns of water are of different specific gravities, the pressure on the bottoms of them will force the lighter up the glass tube, until such a quantity of brine has followed it as makes it of equal weight with the other; and hence, in the two glass tubes, the water stands at different heights, the magnitude of which difference becomes known by means of the scale fixed betwixt the glass tubes, and therefore also the degree of saturation of the brine.

The use of this instrument, which might be called a Salinometer, is not confined to this one subject, for it answers thoroughly all the purposes of the common glass gauge, the position of the surface of water in the boiler being midway betwixt the surfaces of water in the tubes.

When either or both of the glass tubes is broken, put the handles in the position ! ¦, and nothing can escape from the boiler. T. W. L.

CHURCH BUILDING IN IRELAND.

It at all times affords us much pleasure to notice the works that are in progress in Ireland, particularly when we have to record buildings of a public character, such as the one we are about to describe; for the description, together with the preceding remarks, which are slightly abridged, we are indebted to the *Newry Examiner*. The architect is Mr. Duff, whose ecclesiastical works we have before noticed in this *Journal*.

We hear of continual comparisons between England and Ireland, in which the relative prosperity and poverty, civilization and crime, learning and ignorance of these two countries, are descanted upon with no small share of skill. There is, however, one prominent part which these balances of national characteristics have, either through inattention, or incompetence to do justice to the subject, left almost unalluded to. This is the more to be regretted, as nothing more tends to introduce good feeling between countries, and a sense of emulation, than judiciously pointing out to the less improved country the causes and consequences whereby the more cultivated has arisen in eminence.

England has been remarkable for the richness of its churches since immediately after the conquest, when William, the Conqueror, with arms, introduced arts, and when the simple strength of Saxon edifices was supplanted by the more stately splendour of Norman towers. The temperament of these hardy Normans must have been more than tinctured with piety. They must have been essentially devout, for, whilst we find the castles of their nobles of comparative plainness, in no instance does aught beneath grandeur suffice them when they erected temples of religious worship. This may be accounted for by the prevalence then in repute of joining the priestly functions and architectural duties in the one person. The churches of England are almost all constructed after the designs of bishops and priests, and, perhaps, never again may the world expect to behold Gothic architecture carried to such perfection as when such men as William of Wykeham, though wearing the sacred purple, deemed them sanctified duties to resign, with compass and square, inspect stone-hewers, learn the relative bearing of timbers, and, in a word, all but became artisans, by spreading out the protecting span of roofs, and by sheltering civilised society.

Unfortunately for Ireland, its distracted state of society, ever in a turmoil between the invader and the invaded, afforded no shelter for arts to thrive. Hence its almost total want of magnificent churches; and Christ's and St. Patrick's in Dublin, and Armagh Cathedral, may be said to constitute the only pious preserves of ancient days. Better times are upon us now, and church building, within these last twenty-five years, durably marks the vast spread of civilization, learning and religion, which have come, as it were, in well regulated abundance upon the people. More Catholic churches have been built in Ireland within that period than were for the preceding two centuries; yet few of them are in the Ecclesiastical or Gothic style of architecture. Dublin has been especially blameable in this respect, and out of the hundreds of thousands sterling, its citizens dedicated to erect houses of worship these last ten or fifteen years, we look in vain for a Gothic building.

The Metropolitan Cathedral is Grecian, and, though grand, is less striking in appearance than a Gothic pile of equal magnitude. The church of Saint Xavier is the paragon of prettiness, and its panelled ceiling and vestibule are extraordinarily beautiful in their way, nor is its portico deficient in symmetry and justness of proportion. Much of the beauty of Saint Paul's church is lost from its propinquity to the river, its portico, tower, and dome, are worthy of a better situation, but the interior greatly disappoints the eye that looks even for a small portion of effect. The churches of Saints Michan, Michael, and John, though externally Gothic, retain little of the style in the interior except the altars. St. Andeon's is still too far removed from completion to form any competent judgment upon its probable effect; yet if we might hazard an idea, we opine meagreness shall be its characteristic. The Church of Saint Nicholas is also unfinished, but the magnificence of its ceiling and altar is unparalleled in this kingdom. The altar is a noble arrangement of columns and pilasters worthy the best designs of Claude Perault. The Church of Saint Francis is a spacious building, but in nothing remarkable for either elegance or judicious arrangement. The Church of Saint Andrew is the largest and least to be praised of any; its vastness is unrelieved by one solitary attempt at grandeur, or even taste in detail. Throughout all these religious edifices we seek in vain for the dim religious light found in Gothic buildings; and, whether to blame the architects or building committees, it is not here to determine.

Ulster, however, has to boast that it did not follow the example of the metropolis, and the new Cathedrals of Armagh and Newry, and the church of Dundalk, designed, erected, and erecting under the superintendence of Mr. Duff, of this town, are enduring monuments of the Gothic style. Newry first set the example, and its Catholic Church is a splendid edifice. Dundalk followed, and, with that independent tone of rivalry or emulation for which the people of Louth are celebrated in secular, as well as political affairs, the building committee of the town appointed Mr. Duff their architect, who succeeded in adding another triumph to the resuscitation of Gothic architecture. He was the only professional gentleman in the kingdom who had attempted to overcome the difficulties that lay in the way of arousing the hierarchy and the clergy to a just appreciation of the glories of the old, neglected, ecclesiastical style. Nor was he unsuccessful; and it must be confessed the people of Dundalk actively co operated to carry out his extensive designs.

ROMAN CATHOLIC CHURCH, DUNDALK.

This church is built entirely of fine hewn granite stone, and in the pointed style of architecture which prevailed during the early part of the fourteenth century. It contains a nave and side aisles, the north-west constituting the principal front, which apparently consists of three divisions, the central being separated from the lateral aisles by graceful turrets, octagonal in form, appropriately buttressed, panelled, and crowned by crocketted pinnacles. The upper stage of these turrets is composed of perforated panel-work, possessing peculiar lightness and beauty. The centre division, which projects considerably beyond the aisles, has a majestic doorway, leading to the interior porch and body of the church. This doorway is of ample dimensions, deeply recessed; and enriched with small pillars and hollow mouldings, with a lofty pointed arch, with rich tracery panel-work, and a bold label, enclosing carved spandrils, of a tasteful and elaborate design. On either side of the doorway are handsome tabernacle niches, for the reception of statues. Over the grand entrance rises a magnificent window, of lofty proportions, of six lights, and subdivided by a transom. The heads of these lights, with the pointed arch above, are filled in with varied tracery, of a beautiful description, the jambs are recessed and moulded, with a large hood moulding sustained at the springing, by beautifully carved corbelled heads. In the upper part of the pointed gable appears a circular opening, for ventilation of the roof, *octofoil*, moulded, and cusped; above which, an enriched cornice laterally sustains an open parapet of panel-work, capped and embattled. On the apex rises an appropriate pedestal, supporting a large ornamental cross. The angles of the side aisles are bounded by graduated buttresses, terminated by lofty pinnacles and finials. The principal entrance to the aisles are on the front, with moulded jambs, painted arches and carved spandrils, and hood mouldings. On a large cornice over the doorways, are windows of three lights, the heads filled with tracery of perpendicular arrangement, and corresponding in dimensions with those of the aisles—the inclined gables of the roof being finished with panelled parapets, capped and embrazured. The next portion of the church claiming attention is the south-east end, which, like the front, projects considerably beyond the termination of aisles, and flanked with turrets containing circular stairs which lead to the leads of the roofs. These turrets are of plainer character than the principal front; but the upper stages, when finished, will correspond, in every respect, with those already completed. The great window which lights the choir is fifteen feet wide by thirty-eight feet high, divided and subdivided by moulded transoms, into fifteen lights, which are designed to contain appropriate subjects in stained glass. The tracery of the pointed arch is beautifully varied. The aisles are embrazured, and sustained by buttresses and pinnacles, and lighted by eight lofty windows of three divisions, divided by a transom, the heads of each window having perpendicular tracery work. The nave, or clerestory, which rises high above the aisles, displays a similar arrangement, having windows, buttresses, pinnacles, and embattled parapets.

The dimensions of the building are as follow:—

Length of the nave, taken on the walls	179 feet.
Breadth between the pillars	33 do.
Length of the aisles, including porches	140 do.
Breadth of the nave and aisles, including walls ..	78 do.
Height of the nave from base of pillars to apex of roof	62 do.
Altitude of front to top of cross	78 do.
Height of the octagon towers	86 do.

The interior is not yet entirely completed, but much is executed to arrest and gratify the attention. It is divided by two ranges of granite stone pillars, having moulded bases and capitals, sustaining pointed arches of various appropriate mouldings, over which, upon a horizontal cornice, rests the clerestory windows that light the body of the house. Between the windows, slender shafts rise from the pillars below that support angel brackets; from these spring the ribs of groins forming the roofs, having bosses and exquisite foliage at the points of intersection. The ceiling is truly grand, and reminds us of those beautiful remains of olden time. The sanctuary is very spacious, in which are the three splendid altars, composed of elegant tabernacle-work, and executed in white marble.

The altar screen is to be of a most elaborate design, which is to separate the sacristy from this portion of the church.

ROYAL SCOTTISH SOCIETY OF ARTS—SESSION 1843-4.

This Society held its Annual General Meeting on *Monday*, 13*th November*, 1843.—James L'Amy, Esq., F.R.S.E., in the Chair.

1. The meetings for this session were opened by an interesting exposition of the construction and management of light-houses, given at the special request of the Council of the Society, by David Stevenson, civil-engineer. After alluding to the great importance of the subject, and giving a brief outline of the early history of light-houses, from which it appeared that the open coal fires, formerly employed in lighting our coasts, were superseded by a more perfect system only towards the close of last century, Mr. Stevenson proceeded to explain—*First*, The systems at present in use for producing signal-lights, by means of the *catoptric*, or reflecting, and the *dioptric*, or refracting apparatus, and also by the combination of these two, to which the term of *catadioptric* is applied; *Second*, The means employed for varying the characteristic appearances of the lights, describing the seven methods at present in use on the coast of Scotland; *Third*, The construction of the erections from which those lights are exhibited, *viz.*, the ordinary lighthouse stations which occur on the coast, those erected on sunken or isolated rocks —such as the Eddystone, Bell-rock, and Skerryvore—the floating light, screw-pile light, &c. &c.; and, *Fourth*, The construction of beacons and buoys, adopted in situations where light-houses cannot be erected. Mr. Stevenson concluded by offering a few remarks on the management of light-houses generally. The exposition was illustrated by a variety of models and drawings, together with specimens of the different kinds of apparatus employed, the use of which was granted by the Commissioners of the Northern Lighthouses. Thanks were voted to the Hon. the Commissioners of the Northern Lighthouses for the use of the models, and to Mr. David Stevenson for the exposition, which were given to him from the Chair.

The report of the committee appointed to award prizes for communications read and exhibited during the last session was read, by which it appears that not less than 21 prizes were awarded.

The office bearers for the current year were elected; when Prof. Thomas Traill, M.D., F.R.S.E., was announced the President for the year ensuing.

November 27.—Prof. Trail in the chair.

The President, on taking the chair, addressed the Society, thanking the Fellows for the honour they had done him in placing him by the chair. He stated that he took a great interest in the proceedings of the Society, and that it should be his earnest endeavour to promote the prosperity of the Society, and to forward its laudable object, the encouragement of the useful arts.

Several communications were made and referred to committee for consideration.

Sir Geo S. Mackenzie, Bart., exhibited a beautiful specimen in ivory, copied by Cheverton, by machinery, from the "Clytie," or (according to Flaxman) the "Isis," one of the finest antique busts in the British Museum.

A motion by James Thompson, Esq., F.R.S.E., civil engineer, "That the Society shall memorialize Government or petition both Houses of Parliament on the present neglected state of the Ordnance Survey of Scotland, and urging that it be resumed and prosecuted with vigour," was unanimously adopted, and a remit made to a Committee to prepare a draft and to report.

December 11.—George Buchanan, Esq., F.R.S.E., in the Chair.

The following communications were made:—

"1. *Description of the new Dock Gates at Grangemouth, on the Forth.*' By James Thomson, Esq. C.E. Glasgow.

Mr. Thomson exhibited a model and drawings of the dock gates recently constructed at Grangemouth, where the entrance lock, upon which are four pair of gates, is 250 ft. long, 55 ft. wide, with a depth of 25 ft. water over the sill into the new wet docks. The gates, which are wholly built of timber consist of a double framework, the front framing, or that next the sill, being straight, and the back curved, both, of course, uniting together in the heel and meter posts. The back or curved framing is formed with arched ribs, composed of plank in three thicknesses of four inches, firmly bolted together, and to the corresponding front ribs; this double framework, being braced together with horizontal and diagonal tension rods of iron, is planked on both sides, and made perfectly water-tight. The gates constructed in this manner are extremely light and buoyant; and by the admission of more or less water, with additional balance weights, the buoyancy of the gate is so adjusted that its whole weight is borne by the water, and, consequently, very little power required for opening and shutting, besides the great saving in tear and wear thus reduced to a minimum; in proof of which it was stated, that instead of from ten to twelve minutes, with four men, the time and power usually required for opening or shutting gates of similar dimensions, these gates, by means of improved crab gearing, are opened or shut in three and a half minutes, with only two men; and with a longer allowance of time, even one man is able to work them. Thanks voted, and given from the chair.

2. "*Observations upon Iron Lattice Bridges.*" By the same.

Mr. Thomson illustrated his observations with numerous drawings and models of several lattice bridges already completed, or at present carrying into execution, by Mr. Macneill and himself. The principle of lattice bridges, applied in timber, has for some time back been in use in America; but the adaptation of the principle to iron bridges, as now so successfully applied by Mr. Macneil and Mr. Thomson, is likely to supersede, in a great degree, the use of timber, and will supply a desideratum hitherto felt in establishing internal lines of communication, &c., where the expense of stone bridges not unfrequently precludes their being carried into effect, while the objection to wooden structures on the score of durability is obviated by the substitution of iron. The first bridge of this kind, recently completed by Mr. Macneil on the line of the Dublin and Drogheda Railway, and of which drawings were exhibited, is 85 ft. in span, consisting of two lattice-work frames or beams, one on each side, resting upon stone abutments; the lattice-work beams are composed of small bars of malleable iron, about 12 ft. long, and only a quarter of an inch thick, placed so as to cross each other at right angles, and forming a net or lattice-work, rivetted at every intersection; the lattice frames, so constructed, and stiffened with angle iron, support the roadway by means of light transverse beams, also of malleable iron, secured to the lattice-work at each end. This bridge, which altogether weighs only fourteen tons, sustained a load across its centre of twenty-four tons, under which the deflection amounted only to 3-10ths of an inch. A viaduct 230 ft. in length, with a central span of 140 ft., is now being constructed by Mr. Macneil, over the Royal Canal in Ireland, for heavy locomotive traffic. This viaduct, of which Mr. Thomson exhibited drawings, has a third lattice-frame in the centre, and is composed of malleable iron bars half an inch thick. Mr. Thomson described a very useful application of this principle to the widening of the roadways of existing bridges: and exhibited a pretty constructed model of one of the arches of a stone bridge, about 400 ft. long, with the addition of footpaths on each side, as at present executing under his direction, the old width of roadway being only seventeen feet, while, with the new footpaths, supported by iron lattice-work, the width will be increased to thirty feet. The appearance of these bridges, which may be either perfectly straight or slightly curved, as circumstances require, is light and graceful, combining as they do great strength with the least possible quantity of materials, and seem to be admirably adapted for crossing wide and deep valleys, rivers, &c. at a small expense, as also for ornamental bridges in parks, or approaches to gentlemen's seats, &c. The expense of construction, Mr. Thomson estimates at less than half the cost of stone; but he stated that he was at present making an investigation into their principle, with experiments upon a different arrangement of the lattice-bars, which he hoped would lead to a considerable saving both in the quantity of material and workmanship.

NOTES OF THE WEEK.

The sculptural decoration of the metropolis seems to be a great attraction just now. The statue of Nelson has been elevated to the top of the pole in Trafalgar Square, where it has produced such an effect, although a meritorious work of art, that we question whether any more monostylar monuments, supporting nothing, will be erected for some time. We must say that the present is a luckless specimen; we have heard of midshipmen being mastheaded, but we never saw an admiral mastheaded before. It seems that discontent and disgust have even afflicted the committee; they are going to have the cable at the feet of the Admiral altered, so as to give greater solidity to the statue. We wish while the statue is up, that they would knock off the cocked hat, which is too great an attraction, catching the eye from every point. The statue of George IV., by Chantrey, is also mounted on the pedestal near St. Martin's Church. It seems, on a cursory view, to be a good likeness of the King, and the horse, which is a powerful charger, planted on his four feet, with his head slightly turned, is a fine one. We must, however, see more of it. George III. is, it seems, to come from Pall Mall to the North West pedestal opposite the College of Musicians. We hope the pigtail of this statue will also be cut off. The statue of William IV., by Nixon, is nearly ready. It is to be placed at the junctions of King William-street and Gracechurch-street. We hope the artist has not, agreeably to the practice of modern art, represented the Sailor-King with a doodeen in his mouth, or some other attribute of the ruling habit of the living man; the statue, of Devon granite, is fourteen feet high, and cost £2,200, voted by the Corporation of London. What inconvenience would it be to the Corporation of London to vote a similar sum every year, for a statue of some man of genius born in London, and who has a right to such honours at the hands of its municipal authorities. We can give some names to keep them going for a few years, and tell them where to put them. Milton, Bread-street, Cheapside; Pope, Lombard-street; De Foe, Cripplegate, (or Finsbury Pavement).

Mr. Nixon has finished the series of the Four Seasons for Goldsmiths' Hall. The last statue is that of Autumn. He has in hand a statue of Mr. Carpenter, the founder of the City of London school, to be placed in the vestibule of the school; and also of Sir John Crosby, for Crosby Hall. It has been noticed, as in some degree singular, that statues are now being erected to two contemporaries and near neighbours—Whittington and John Carpenter. Mr. Bailey, R.A., has in hand a marble statue of that excellent statesman, Sir Charles Metcalfe, to be 9 ft high, and cost £3,000, to be placed opposite the Senate House, Kingston, Jamaica. A bust is also to be sent to Calcutta. He is also occupied with the statue of Sir Astley Cooper, for St. Paul's, which will soon be placed on its pedestal.

Some noise is being made about cheap imitations of bronzes in zinc, but we have not seen any of them.

As an example of the increased attention paid to decorations, we are glad to instance the three new doors just completed for York Minster, from the designs of Sydney Smirke. The three doors are alike of the decorated style, 16 ft. high, and 6½ ft. broad. The tracery in the upper part is very rich, supported by slender Gothic columns. The hood mouldings spring from the tops of the capitals, and terminate in rich finials and crocketting. Three trefoils, bearing shields, occupy the centre of the arches, and the lower part of the door is divided into six decorated compartments. The work is executed by Mr. Wallace and Mr. Scott, of Newcastle.

Mr. Rigby has taken the contract for the erection of the new Marine Barracks at Woolwich, for £70,000. The works have been commenced. The barracks are to accommodate a thousand men.

The Woods and Forests have begun pulling down the Rookery and neighbourhood, to make way for the new road from Buckingham Palace to the Vauxhall Road. The embankment of the Thames is also to be proceeded with.

The Glasgow and Ship Bank, at Glasgow, has been completed. Six emblematical statues, by Mr. Mossman, jun., occupy the pedestal. They are, Britannia, the City of Glasgow, Wealth, Justice, Peace and Industry; each seven feet high.

Hess, of Munich, the painter, has finished his grand painting of the Battle of the Borodino, or the Moskowa, for the Emperor Nicholas. It is looked upon as something grand in the great way.

The splendid gallery of Cardinal Hesch is at last to be sold, at Rome, and is the object of much attraction, from the value and intrinsic merit of the collection. It contains good specimens of nearly every school.

St. Stephen's, Coleman-street, has got a new altar window, of painted glass. It is well executed, but the subject is ill chosen, being Ruben's Descent from the Cross. All imitations of historical pictures are bad.

Barbarism is not, as some have surmised, a pure English quality. Even German artists go the length of destroying rival works, by stillettoing frescos in public places.

A triumphal arch is to be erected in the Ludwig Strasse, at Munich, by Von Gärtoer, the sculpture to be by Wagner.

The Commune of Hornu, near Brussels, intends to erect a church, the interior of which, it is said, will be entirely of iron.

It is announced that the British and Foreign Institute has now reached to nearly 1000 members. The Institute will, therefore, be opened on the 15th instant; the lectures and the *soirées* on the assembling of parliament. The literary department is to be under the direction of Mr. Buckingham; and besides the attractions of the reading-room and library, with the public journals of various countries, there will be engravings, pictures, and works of art and *vertu*, to be collected for the inspection of visitors, it is also intended to introduce occasional music, vocal and instrumental. It is determined also to divest these entertainments, as much as possible, of the formality of a public occasion, and make them resemble, in every particular, an evening party, conducted with all the ease of a private assemblage in the best circles. The hotel department, for which a separate mansion has been taken, will be under the direction of Mr. Whitmarsh.

Patent Bearings for Locomotives.—At the Liverpool Polytechnic Society, Mr. Dewrance (superintendent of the engine building department of the Liverpool and Manchester Railway) exhibited some very perfectly cast and beautiful specimens of the "*Patent Metallic Bearings, or Steps, for Locomotives,*" which had been found to be superior in practice to those previously used, and which, the metal being soft, considerably diminished the friction, by working more smoothly, while, at the same time, they lasted much longer than was anticipated. One engine had run with them a distance of 4,480 miles without requiring renewal or repair, and another (the identical bearings of which were produced) had run 1,000 miles, without additional giving or vibration. The substances for the part in which the axles worked, which he had combined in one instance, and found to be effective, were, six parts of tin, eight of antimony, and four of copper, forming (as we understood him) a solder. Mr. Dewrance also pointed out various plans of giving an equal supply of oil.

GLASS, WATER AND GAS MAINS.

(Translated for the Civil Engineer and Architect's Journal from the Bulletin du Musée de l'Industrie.)

The subject of glass mains is attracting some attention in France. Earthenware pipes have also been used on a small scale; they must not, however, be subjected to a pressure of two or three atmospheres, as the joints being difficult to lute, give way, whatever cement may be used. For luting, some gas companies have used Roman cement, but the gas escapes by imperceptible fissures at the joints, and they have been found so objectionable, on account of the frequent escapes and disturbance of the pavements for repairs, that the local authorities have objected to the use of earthenware mains in such situations. The glass mains, manufactured by Messrs. Bergeron of Rive de Gier, are luted with bitumen, and may be screwed together. The weight is about a third of that of cast iron, and the cost laid down about 7*s.* 6*d.* per yard run for a 4¼ in. bore. The process at present will not produce pipes of more than 8 in. bore. Of course, in England, with the low price of cast iron and the duty on glass, glass pipes are out of the question on economical grounds.

AGRICULTURAL CHEMISTRY.

Report of two Lectures delivered by Professor Brande, F.R.S., *to the members of the Royal Agricultural Association of England, at the Royal Institution, Albemarle-street, on Wednesday and Thursday the 6th and 7th December, 1843. (Specially reported for this Journal.)*

Lecture I.

In compliance with the request of your noble President, I have the honour to deliver to you two lectures upon subjects connected with agricultural history. The subjects which I have chosen are those of lime and clay; and I have fixed upon these for reasons which I shall presently describe to you more at length. I think you will agree with me that under existing circumstances, the union of practice with theory in the subject that is engaging our attention is more than ever desirable; and that the important bearings of chemical science upon agriculture become daily more and more evident. Why *chemical* science? Because experience teaches us that that sort of superficial knowledge which may enable a man to make rough analyses of soils, to discover their leading constituents, and to ascertain their relative proportions, is far from being sufficient to satisfy the demands which the scientific agriculturist thinks it right to make upon the practical chemist; much more than this must be expected from the chemist—information, indeed, which can only be furnished by the experienced analyst.

It was long ago shown by Sir Humphrey Davy, and the celebrated Liebig has proved more recently, that the fertility of a soil, as relates to the production of particular crops, may depend upon the presence, or absence, of very minute and almost imperceptible portions of inorganic substances—alkalis, for instance, and the salts of metals—substances which, a few years ago, were either entirely overlooked, or thought not worth looking after or mentioning if discovered; the necessity, for example, of sulphate of lime to clovers, silica to grasses, phosphorus to wheat, and so on, was quite disregarded. But now these matters are beginning to attract notice, and to open up new fields of chemical inquiry, which can only be successfully cultivated by the joint labour of the farmer and the chemist; hence every one interested in the welfare of chemistry—and what rightly constituted person is not so?—must see with unlimited satisfaction, and with a happy anticipation of the future, the good feeling that is beginning to dawn between practice and theory—between the agriculturist and the chemist. We are beginning to "scent the morning air," as it were, of a better order of things, and it is with great satisfaction that I myself see, that you, gentlemen, impressed with the importance of this union, have associated an eminent chemist with your body, and that many valuable papers are beginning to appear in your useful *Journal.*

Soils are made up of organic and inorganic constituents. We are now to confine ourselves to the latter, and these we class under two heads; first, those which constitute the bulk of the soil, and on the mechanical texture of which the growing crops depend, such as clay, sand, and lime; and secondly, those particular substances involving the fitness of a soil for particular crops, such as sulphate and phosphate of lime, soda, ammonia, magnesia, &c.

Lime is an article no doubt of great importance to agriculture, and some of its salts perform such important, though often obscure, functions, that I propose first to consider it, and then to call your attention to silicious and aluminous substances as existing in soils, which constitute clays.

First, I may ask, what is lime? The chemist will tell you it is a compound of a metal and oxygen, being what he calls a metallic oxide, consisting of 20 parts by weight of calcium and 8 of oxygen. I cannot show you this metal, calcium; but I can show you the counterpart of it. It has hitherto been obtained in very minute quantities. It is one of those extraordinary metals discovered by Sir Humphrey Davy which is most difficult to procure, in consequence of its high affinity for oxygen. The moment it is obtained and exposed to the air, it passes into lime. At the instant when deprived of oxygen, we see it as a brilliant metal, but the moment the air is admitted it passes into lime.

I will now show you, as its counterpart, the metal potassium, which is a white brilliant metal, resembling silver or lead in appearance, and distinguished by its strong affinity for oxygen, and by burning when put into water. If it is thrown into water, it will take fire, dissolve, and produce a solution of metallic oxide—so also with the metal calcium, the base of lime. There is another character belonging to this solution, which likewise belongs to lime, and that is, that it is what chemists call an alkali; and the test of an alkali is that it reddens blue litmus paper, and browns paper tinged with yellow.

Lime does not exist in a native state—small quantities have been found in some of the lakes of Tuscany, but it may be said not generally to exist in a native state. What then are its sources? The best known is carbonate of lime, which is very abundant, and which recommends itself especially as a source of lime, in consequence of the facility with which it admits of decomposition. Carbonic acid has a weak affinity for other bodies, and can therefore be easily got rid of. But I must stop here, to tell you that carbonic acid is a substance which combines with lime, and exists with lime in all its natural spars. It is composed of charcoal and oxygen. Lime, as was just told you, is composed of a metal and oxygen, and on the one hand we have a compound of oxygen and a metal producing an alkali, and on the other hand carbon and oxygen producing carbonic acid. (The learned Professor then proceeded to illustrate by experiment the formation of carbonic acid from carbon and oxygen, and for this purpose he inserted a piece of burning charcoal into a glass jar containing oxygen gas;) he then observed, there is charcoal introduced into oxygen gas burning vehemently—doing, in fact, what it does in the common air, where it burns by virtue of the oxygen which the air contains. If the charcoal be allowed to continue burning as long as it will, we shall find that a large quantity of it has disappeared; the oxygen has lost all its original qualities, has combined with the carbon, and become carbonic acid, and that acid combining with lime, produces, as before said, carbonate of lime. We here employed first, combustible metal, then charcoal, and then oxygen, and these are the ultimate elements of carbonate of lime; the proximate elements are carbonic acid and lime.

Now you must not forget that all we do here, and in fact all the bases of chemical combination, are bound down by the strictest laws of weight and measure; and though charcoal is burnt in oxygen without any reference to weight, it can only *combine* in certain weights. So also when the metal of lime is thrown into water, it burns, but requires a particular quantity to be combined with a particular quantity of oxygen to produce lime. Six parts of carbon added to 16 parts of oxygen produce 22 parts of carbonic acid; 20 parts of calcium added to 8 parts of oxygen produce 28 parts of lime; and thus 28 parts of lime added to 22 parts of carbonic acid will produce 50 parts of carbonate of lime.

Carbonate of lime constitutes in various forms mountains and hills and strata, covering immense distances; and it is common to speak of it as primary, secondary, and tertiary limestone, meaning that it occurs in those series of rocks considered generally under those terms, which may be explained as signifying the older, intermediate, and newer strata of our globe. There are a number of specimens of limestone upon the table, but I will only select a few to show you the distinct characters of each.

The primary or primative limestone, illustrated in marble of different kinds, more especially in the crystallized white marble of Carrara and the Alps, in statuary marble, and other varieties of limestone, has no organic remains, because it has been subjected to great fires and heat, in which it has been fused, and thus lost all traces of organic remains. In the secondary limestone we discover more or less of organic remains, and we may trace in some of them the aggregates of corals and other bodies. The Derbyshire spar is a specimen of this limestone. We now come to lime of the newest or tertiary strata, and here we can trace the remains forming at the present time. Shells are ground up and cemented in various ways, producing a variety of limestones.

In regard to chalk, it is right I should remind you that there are strata distinguished as chalk with, and chalk without, flints. One particular property of the latter is that mortar made of it hardens under water, and it is hence valuable as a hydraulic lime.

There are a number of varieties of carbonate of lime producing calcareous spars. Coral and shells, for instance, are made up of carbonate of lime. And I will now remind you, that to whatever source you go for carbonate of lime, it is composed of carbonic acid and lime. You may easily recognize calcareous stone by the test of its effervescing in acid; and if you take any kind of limestone, and pour upon it a weak acid, effervescence ensues arising from the escape of carbonic acid, and this may be taken as a test of the presence of carbonate of lime. In all cases, where we take common soil and see effervescence, it may be attributed to carbonate of lime.

The chemist goes from this to ascertain what quantity of carbonate of lime there may be in any soil which he may think it right to examine, and this is a simple operation. The following is the process:—Put into the pan of a balance, two flasks, one containing a previously weighed quantity of the soil, the other some muriatic acid, and counterpoise them. Then pour some of the acid on to the soil, so long as effervescence takes place from the escape of carbonic acid, which will, of course, leave that pan so much lighter. The weights which are requisite to be added to the pan containing the flasks to restore the equilibrium, will give the weight of carbonic acid that has escaped; and then, by adding 28 parts (for the lime) to every 22 parts of loss, you will ascertain the weight of the carbonate of lime originally present. (Or, what will do equally well, multiply the loss by 2·2727.)

There are a number of foreign matters occasionally associated with carbonate of lime, which were once entirely overlooked. These foreign matters are now frequently considered of great importance; whether they are of that immense importance which some seem to attach to them, is a matter for future experience to determine. True it is, however, that there are in limestones certain bituminous substances, as well as potassa, soda, magnesia, phosphate of lime, &c. Upon this latter, very great stress has been laid, and it has been considered a very important ingredient of the soil, especially in limestones. It is found in limestones certainly in very minute quantities, forming less than one per cent., but it must be remembered that if the soil contain only one grain in a pound of foreign matter, that when you multiply it by the quantity of soil in an acre of ground, it soon mounts up amazingly, so that the smallest quantity may be a matter of the utmost importance. The chalk about Brighton, upon being examined by Ehrenberg with a microscope, was found to consist of a multitude of animalculæ. This led us to look at phosphate of lime, which is always found associated with corals and relics of that kind as important. No doubt such chalk would form a very valuable manure, if we may allow the term, to chalk which does *not* contain phosphate of lime. We now now come to an important subject—the converting of limestone into lime—that is, how to get rid of the carbonic acid. And first, as to the characteristics of carbonic acid. If you collect it in the form of gas, as I have done, you will find it a very heavy gas, and it extinguishes flame. An instance of its weight may be seen by decanting a vessel of it into one containing atmospheric air, when you will find that it will displace the atmospheric air at the bottom of the jar. For this reason it collects in pits and wells, where it is known under the name of the choke damp. It is extraordinary, that if a person descends into a well containing it, he will be immediately suffocated; but if it is diluted to a certain extent he can then breathe it, and it acts as a narcotic poison—drowsiness comes on rapidly and he dies. But there are a number of gases which extinguish flame; we must not rest satisfied therefore that carbonic acid is the gas, unless you have this other test by lime water, which it will convert into carbonate of lime.

I have said, that carbonic acid and lime have but little affinity for each other; and now to get rid of the carbonic acid. You have seen that the acid drives it off by effervescence. But the common mode of getting rid of it consists in burning the limestone. If you take a quantity of chalk, suppose 50 cwt., and expose it in a proper kiln to the action of a proper heat, you will find that 22 cwt. goes off in the shape of carbonic acid, and that 28 cwt. remains, and this which remains is lime, known under the name of caustic or quick lime.

I will not go into the question of burning lime, but it is a very important one. It should be burnt in a current of air, and if damp, so much the better. You may take a piece of chalk, and put it into a close vessel and keep it hot for days, and yet not get rid of the carbonic acid; so that you see the affinity between carbonic acid and lime is not so feeble after all: but when you expose it to a current of air and moisture, their joint operation carries away the carbonic acid, and thus you may in a short time entirely divest the carbonate of lime of its acid. Now I nearly remember the time when it was thought that when you burnt lime the limestone absorbed the fire, and that that was the reason why lime was so hot. Now, we know, in consequence of Dr. Black's discoveries, that the mildness of chalk is owing to the presence of carbonic acid, and that the heat of lime is the consequence of its expulsion.

Lime is possessed of many important properties which fit it for agricultural purposes. One of which is, the changes it undergoes upon being exposed to the air. If you expose quicklime to the action of the air, it gradually crumbles down into a powder. In doing this it absorbs water from the atmosphere, and it also absorbs carbonic acid, so that lime, after being exposed to the air for a week is no longer quick lime, but part of it has become chalk, and part hydrate of lime, *i.e.* lime in connexion with water. The strong affinity which lime has for water makes chemists sometimes use it as a means of drying air. This strong affinity is best illustrated in the operation of slaking lime—that is, throwing water upon it. Here we have two kinds of lime, one contains a quantity of aluminous earth, the other is pure lime. If we pour water upon these, we shall find that the temperature begins to rise enormously, and that is a proof that chemical combination is taking place; and this occurs much more rapidly in what is termed "fat lime," than in "meagre lime." A great deal of heat is evolved in the operation—often enough to set fire to sulphur or matches. The lime then crumbles into a fine white powder, and this powder is slaked lime. Every 28 parts of lime combine with 9 of water; so that 37 parts of slaked lime are equivalent to 28 of quick or caustic lime.

Now having slaked the lime, if you expose it to the air it gradually absorbs carbonic acid, it parts with water, and ultimately passes back to the state of chalk. If to slaked lime you add excess of water, you will obtain a solution of lime called "lime water." About 700 parts of water are required to dissolve 1 part of lime; and from this you may obtain a notion of the strong alkaline power of lime, for this solution, though it contains only 1 part of lime in 700 of water, has a nauseous bitter taste, and by applying the common tests, it will be found to be a powerful alkali. Now if you expose this to the air it will become turbid, as lime water does if added to carbonic acid.

Carbonic acid is derived from various sources, amongst others from our lungs, and if I blow into lime water, you will see that the air from my lungs precipitates the carbonate of lime. Or if you take some air from a candle, you will find that that is pure carbonic acid. So if we go to a brewer's vat and collect the gas escaping in fermentation, that is carbonic acid. If you burn charcoal and oxygen you obtain carbonic acid. If you burn dung in oxygen you obtain carbonic acid. If you burn plumbago, or black lead, you get carbonic acid—that, therefore, is another carbon. If I take some spring water, and test it by lime water, I shall find carbonic acid there—it becomes turbid. In Thames water there is an immense quantity of carbonic acid. I do not point these out as so many isolated facts, having no particular bearing, for they have all their agricultural uses. Waters, in many instances, are important as containing carbonic acid, for water readily permeates the soil, and finds it way to the routs of plants. Air also contains a little carbonic acid, in the proportion of about 1 in 1000.

As regards the uses of lime, it may be stated, first, that its alkaline property makes it a powerful destroyer of worms. If mixed with dead leaves or turf it tends gradually to decompose them, and converts them into mould. Another property is, that it neutralizes acids. Another and most important property is, that it decomposes the salts of iron. Water containing a salt of iron does a vast deal of mischief to the soil it permeates. This will be corrected by lime. If to ferruginous water slaked lime be added, you will see it decompose, the iron is precipitated, and has become oxide of iron. Lime also decomposes aluminous compounds. It has also an important action upon animal matter. If a little quick lime be mixed with almost any animal matter, ammonia will be the result. If bone dust be added to quick lime, ammonia will be produced: there is, however, no ammonia in bone, and none in lime, but there are the elements of ammonia in bone. Another effect is that after ammonia has been formed, if there be certain substances in the soil the ammonia passes into nitric acid; and if it contains potass or soda, nitrate of potass or nitrate of soda is formed. It is probable that the lighter soils of India and America derive their fertility from ammonia. Here the elements of ammonia, mixed with air, produce nitrate of ammonia.

Felspar mixed with lime, and exposed to the action of water and air, reacts, and potass becomes evolved with a certain portion of silica. In this state it is thought particularly favourable to the growth of grasses and wheat, which require silica in connexion with potass. With regard to the general tests for lime, the one most commonly used by chemists is oxalic acid. There are other tests, but this is the best. If you take a precipitate of oxalate of lime and heat it, you can convert it into carbonate of lime; and thus you can come at the quantity of lime in any soil.

When lime has passed again into a state of chalk, it becomes a valuable ingredient in the soil. It is the same as broken limestone of another kind, but it has this advantage, that it crumbles down into an impalpable powder; and though you may mix ground limestone with the soil, it is never so effective as when it has been reduced from the state of quick lime to carbonate of lime by slaking, when it comes much more readily into contact with the roots of vegetables.

I will not go into this subject now, but I may say that roots of plants appear to be capable of secreting certain acids.

There are peculiarities derived from the presence of magnesia in certain limestones. When it exists in limestone, which is burnt into lime; such lime will remain caustic, and resist the action of the air and water for a long time. If mixed, therefore, with the soil, it will be found to retain its causticity long after the common lime has become inert. The presence of magnesia may be ascertained by applying nitric acid, which will not dissolve the magnesia. Some limestones contain argil, or clay; others, oxide of iron, and they derive certain peculiar properties from the presence of those substances.

The other salts of lime which claim the agriculturists attention, are the sulphate and phosphate of lime, of which I shall speak in the next lecture.

AGRICULTURAL CHEMISTRY.

Lecture II. By Professor Brande, F.R.S.

(Specially reported for this Journal.)

The history of lime and its salts, which we commenced in the preceding lecture, necessarily leads us to speak upon that important article, sulphate of lime, or gypsum, which is a compound of sulphuric acid and lime; and as I have called your attention to the ultimate elements of lime, so must I do with regard to sulphate of lime, which is to be regarded as containing the metallic base of lime, united with sulphur and oxygen. Sulphuric acid is a compound of sulphur and oxygen. Lime is a compound of calcium and oxygen; therefore, the ultimate components of sulphate of lime are sulphur, calcium, and oxygen.

Now I will proceed to build up this substance; and for this purpose I will first make sulphuric acid, which I do by burning sulphur in oxygen, as I previously made carbonic acid by burning carbon in oxygen. To burn the sulphur in this way it must be mixed with a small portion of nitre. In the atmosphere sulphur burns with a thin pale light, but when introduced into oxygen, it burns with a beautiful purple light, and produces sulphuric acid. If I take this substance, then, and add it to lime, I have sulphate of lime. The same substance may be obtained by using the sulphuric acid at once and lime, then you may see the immense affinity that exists between sulphuric acid and lime, and how much heat is evolved during the combination. In all cases their proportions are quite definite, and we have 40 parts of sulphuric acid always combining with 28 parts of lime.

Sulphate of lime is met with in a variety of forms, and is known under a variety of names. There is a variety met with in this country called anhydrous sulphate of lime, which is sulphate of lime minus a certain quantity of water. This substance is very difficult of solution in water, requiring about 350 parts of water to 1 for that purpose. It is often met with in the form of crystals, and is frequently found in digging wells about London in the blue clay; it is also pretty abundant in the clay at Shotover Hill, near Oxford, and elsewhere. It contains 68 parts of dry sulphate of lime, with about 18 parts of water. If a gentle heat be applied to this, the water goes off, and the substance crumbles down to what is well known as Plaster of Paris. If it is mixed with water it regains the water it had lost by the heat, and reproduces a crystallized or solid compound. It deserves notice, however, that if you overheat sulphate of lime it loses this property of re-combining with water, and you thus may destroy its property as a plastic stone.

Now you will find sulphate of lime diffused pretty generally through common spring water in the neighbourhood of London, and some of the shallow wells of London are almost concentrated solutions of gypsum. Its presence may be readily tested by oxalate of ammonia, which immediately renders water turbid which contains it. It is this which renders water hard, and unfit for mixing with soap. When organic matter of any kind comes into contact with sulphate of lime and water, there is a tendency to mutual decomposition, whereby the sulphuric acid loses its oxygen and becomes converted into sulphur, and then we have sulphuretted hydrogen very often evolved. It is not uncommon to find rivers of Africa and Asia which contain great quantities of sulphuretted hydrogen.

I have called your attention to the existence of sulphur in sulphate of lime, putting aside its secondary combination, sulphuric acid, because there are certain crops which contain not only sulphate of lime, but sulphur, in its peculiar and, comparatively speaking, free state, such as mustard, horse-radish, and other plants having their flavour.

The principal sources of sulphate of lime in this country are, first, the red marl and salt deposits. It is found in great quantities in the salt-pits of Cheshire; it abounds also in the Alps and other primitive rocks; and it is also met with in abundance in the tertiary strata in the neighbourhood of Paris, from which circumstance it derives the name of plaster of Paris.

With regard to the uses of sulphate of lime in agriculture, there can be little doubt that owing to its action it may be called the life of plants; for if we examine a plant, we shall find that it constitutes a considerable part of its texture. The notion of its attracting and retaining moisture is incorrect, as it does neither one nor the other, nor does it promote decomposition. It does, however, assist the growth of certain crops, and if we examine the ashes of them when burnt, we shall find sulphate of lime. It is found in the ashes of clover and trefoil; but not in any considerable quantity in those of wheat, barley, oats, beans, or peas. And it is found that to these crops sulphate of lime is of no use whatever, whereas it is a fertilizing manure to others. The fact is, that plants which do contain it never grow well on soils that are destitute of it, and this is found to be the case with other inorganic substances. Plants which contain carbonate of lime will not grow in a soil that does not contain it. There are many plants which contain salt, and they will not grow where it is not. Wheat must have phosphate of lime, because wheat possesses it, and so on.

It is stated upon good authority that an ordinary crop of clover requires from about 1½ to 2 cwt. of sulphate of lime per acre. And this proportion is recommended for use by those best versed in the subject. Of course it is of no use where the soil already contains it; and it is of importance in practical agriculture to ascertain what the soil does contain. If fields which once gave luxuriant crops of red clover no longer do so; if the young plants spring up soon, but die as the summer advances, it may be concluded, without any chemical analysis, that gypsum is wanted. There are other sources of gypsum amongst manures which are known. Peat ashes contain 12 or 14 per cent. of sulphate of lime, and it is also found in coal.

There is another statement with regard to gypsum, which we do not find borne out by experience—that is, its capability of fixing ammonia. We know that it is highly essential to vegetation. Anything, therefore, which would tend to fix it, and collect it, would be very valuable. Carbonate of ammonia is produced in stables and other places where animal matter is undergoing particular stages of decomposition, and though very injurious both to man and beast, it is a substance of great value as a manure. It has been said that sulphate of lime will fix this substance, and that if a stable be strewed with it, that purpose will be effected. But it does so very imperfectly. If I take sulphate of lime and add to it a solution of carbonate of ammonia, I shall find, after a time, that sulphate of ammonia will be formed, and that carbonate of lime will be thrown down; and it is stated that this change will take place when stable manure is mixed with sulphate of lime. We can do it in the laboratory, but it is a very doubtful process in the stable; and we should always take care that we do not apply particular experiments of the laboratory to practical general cases—the reasoning may be good, but the practice is bad.

Another salt of lime on which we must say a few words is, phosphate of lime. This substance occurs in considerable quantities in the bones of all animals, and it is quite clear that all the phosphate of lime in our bones must come from the soil. Plants contain it; so do animals, and we are constantly taking it in, in wheat, bread, &c. It consists of phosphoric acid and lime—and now we come to the production of phosphoric acid. That extraordinary substance phosphorus, which is a part of our bones and blood, and which is an essential part of that most important organ, the brain, exists in the vegetable world in the state of phosphoric acid. If we burn phosphorus in oxygen we have a brilliant combustion, and phosphoric acid is the result, and to this we have only to add lime to produce phosphate of lime, or what has been called bone earth. 28 parts of lime, 36 parts of phosphoric acid, and 18 of water, are the components of 78 parts of crystallized phosphate of lime.

How is the soil supplied with phosphate of lime? This is a question which has lately very much engaged the attention of agricultural chemists. In the first place, it derives it from artificial manures, from bones, and in bones you have an extraordinary compound. Bone is composed of an earthy part and an animal part. If we digest bone in acid we dissolve the earthy part and have the animal part remaining; and if we burn bone we destroy the animal part and leave the earthy part. We find that this earthy part of bone is indestructible, but the animal part undergoes decay; and if we examine bones that have been long exposed to the air, we find that they are comparatively light, and that a great deal of the animal part is gone. The animal part of bones may, however, be preserved for a long time, which is proved, by taking bones that have been long immured in caverns, where we find the animal part quite perfect. Dr. Buckland, indeed, out of some antediluvian bones made very good gravy and soup.

There is another very curious source of phosphate of lime, although it is one which has been over-rated as regards its quantity. This is a substance called the *coprolite*, which is the excrement of certain antediluvian animals who were so voracious that they fed on each other. They consequently ate a great quantity of bones, and their excrement is little more or less than phosphate of lime. This excrement does exist in some soils, but when Liebig tells us that here we have stores of phosphate of lime that are to suffice for all agricultural purposes, I think he goes on at rather too rapid a rate. The subject is, however, an important one, and any source of phosphate of lime that can be discovered is of great importance. Another source is *guano*, which is the excrement chiefly of birds, and it contains, amongst other things, a large quantity of phosphate of lime.

Phosphate of lime, as a mineral product, has been discovered in various places in this country. Some beautiful crystal specimens of it from Devonshire are on the table. It has been found also in Bohemia; and at Estramadura, in Spain, where Dr. Daubeny discovered considerable quantities of it almost in a pure state. How far it is available as a manure, is a question which I cannot go into now. It is also found in some marls, and in chalk, in oyster shells, corals, the crust of metals, and in clay-slate; or when I say phosphate of lime is found, it is in reality phosphate of alumina, which afterwards appears occasionally to form phosphate of lime.

Such is the importance attached to phosphate of lime by Liebig, that he considered it the most essential ingredient in the soil with reference to particular crops, and more especially wheat. There can be no doubt that, to a certain extent, this is the case, and a number of important questions arise as to the best mode of obtaining and applying it. The finer the state of division in which it can be applied the better, and, as bone dust is a fine substance, it is often used with advantage. When bone was first employed, it was imagined that it was only the animal part that was worth anything; the bones were therefore broken up, and as long as they emitted a disagreeable effluvium it was thought they were doing their duty. It was afterwards found that the earthy portion also did its part, which is by no means an unimportant one.

Phosphate of lime, instead of being applied as ground bone, should be dissolved and mixed with sulphuric acid, when it may be applied with considerable advantage. It may, perhaps, be said, that the acid might be fatal to the crop, but this is not the case, the soil, in all probability, contains lime, and the sulphuric acid acting on this, produces sulphate of lime, and you would thus procure sulphate of lime, and phosphate of lime, both of which are valuable substances. Some notion of the immense quantity of phosphate of lime contained in certain vegetables, may be gained by referring to the quantity contained in the bones of animals. In the intestines of horses, especially, we occasionally find large masses of phosphate of lime derived from the hay and oats which they consume.

I must now pass on to what should have been the exclusive subject of our meeting this evening, namely, the consideration of clays. This is a very important subject, but one which we can only attend to, on the present occasion, as regards the leading points connected with them. In the first place, we know that a great part of the surface of all countries consists of what is called clay. We also know that very different substances pass under this name; all, however, agree in containing one element which is peculiar to clays. This element used to be called argil or argillaceous earth, but it has lately been called alumina because one of the elements of alum. To obtain it you may take a common solution of alum, and then add an alkali, which will decompose the alum and produce a white flocculent precipitate, which is alumina. It is this which gives to clay its elasticity, and its retentiveness with regard to water. It is a substance which has a strong affinity for water, and if, therefore, we take the pains to collect this precipitate, and dry it, we shall find that it takes up a considerable quantity of water. This is one important property belonging to this part of clay.

Another important property is, that it has a strong affinity for vegetable matter; and now, when we talk of fixing elements in agriculture, we may say that aluminous earth fixes organic matter. Here is an experiment. You see a quantity of clear water with a brown precipitate at the bottom: this is merely an infusion of vegetable extract which has been mixed with aluminous earth. The aluminous earth has taken all the vegetable matter out of the water. Thus I fix organic matter; and if this would happen in the soil it would be very useful, as it would keep the organic matter in that position in which it would be most useful to the crops.

There are some chemical peculiarities belonging to this substance by which aluminous may be distinguished from other earths. If to the above precipitate I add soda or potass, or an acid, the precipitate will be re-dissolved; and I must tell you that alumina is soluble both in alkali and acid. Alumina is on the whole a very extraordinary substance.

Another component part of clay is silica. You are all acquainted with this substance in its pure form, as a beautiful mineral, rock crystal; it is also known as common flint, and is sometimes beautifully coloured, as in the amethyst. There are a great variety of rock crystals exhibiting themselves in different form. Chalcedony is another form of silica which must have been in solution; and we may infer that silica has been dissolved in water and has not been fused. Another form of silica is common sand, a substance which we frequently do not regard in all the important bearings which belong to it. But it is beautifully applied, as the boundary of the ocean, being insoluble in water, and well adapted to resist the influx of the waves; it is the only substance indeed that would be applicable to that purpose save hard rocks, for we all know the effect of the ocean upon soft rocks and banks of shingle. Besides being insoluble in water, sand cannot be solved in any common acids; it can, indeed, only be solved in one acid, and that is a very rare one. Now we see the difference between silica and alumina, the latter being soluble in all.

If we fuse a mixture of silica, potass, and soda, we obtain glass; if we increase the quantity of silica, we have glass not easily fusible; if we increase the quantity of soda, we get glass very fusible, and ultimately we may obtain it soluble in water. Now here I have that extraordinary substance flint in a soluble state, and if I considerably dilute it I shall have what the old chemists called "liquor of flints;" and I find now, if I add acid to it, that I can throw down the silica first in a gelatinous state; then if I use a stronger solution, I find that it will become as hard as flint.

As you will find that silica constitutes an essential ingredient in grasses and a great variety of plants, you can understand that it gets to them by being brought into a soluble state, principally by the action of an alkali.

With regard to the term clay, it is sometimes thought to be applied to pure alumina, but this does not exist in a native state, except in the sapphire and other magnificent gems, which are composed of it. Common clay contains a greater quantity of silica than alumina, yet it derives its leading properties from alumina. We find, for instance, that when a soil contains a great quantity of alumina, it is known under the name of "strong clay" or "stiff clay," and so on through the different varieties of loam, sands, &c.; as, for instance—

When in 100 parts of soil there are 10 of clay, it is termed sandy.
When from 10 to 40, sandy loam.
" 40 to 70, loam.
" 70 to 85, clay loam.
" 85 to 95, strong clay.
" 95 to 100, agricultural clay.

Clays also contain potass, soda, and sometimes phosphate of lime, and it is in consequence of the soda and potass which they contain that they become such important ingredients in the soil. We know how much the texture of the soil depends upon clays—that is mechanical; but their great chemical properties depend upon their power of retaining water, and their containing a certain quantity of potass and soda.

If clay contains a large quantity of potass and soda it contains a great agricultural treasure, and if we can get out these alkalis they become very valuable. The question, therefore, occurs, "How are we to ascertain if the soil does contain much alkali?" This is done easily by a common chemical process, which, however, I cannot go through here, because I cannot bring a furnace before you. I will, however, make use of electricity, to show you that there is alkaline matter in this clay. And I do it so:—I take some of this powdered clay—it contains some oxide of iron—and I place it upon this plate of platina, I now moisten it with a drop of water; and the question I wish to determine is, whether there is alkali in this clay, which I have washed so as to take all the soluble salts out of it; now I will make this part of the electric circuit—now I am decomposing it, and doing what I might do in a furnace by means of lime and other agents—and now you may see the development of alkali: here I should remark to you that electricity is a great chemical analyser, and resolves things into their elements in a wonderful way.

Amongst other peculiar properties belonging to clays, are the absorption of air, ammonia and nitric acid. Strong clay is used for a variety of useful purposes, and we have here a subject of great importance on which much might be said—draining, in which the application of clay for tiles, &c., is most convenient.

I have now concluded the task which your Lordship did me the honour to impose upon me. On all future occasions I shall be happy to assist your excellent society with any information which I may possess—and I need hardly say that this is a branch of science in which much remains to be effected.

At the conclusion of this and the preceding lecture, His Grace the Duke of Richmond, K.G., in a speech highly eulogistic of the abilities and kindness of the learned lecturer, proposed a vote of thanks to Professor Brande for the able and interesting address with which he had favoured the society. Philip Pusey, Esq., M.P., on each occasion seconded the votes, which were carried with acclamation.

THE TEMPLE OF MINERVA, OR THE PARTHENON, ATHENS

THE fine arts attained their greatest perfection in Greece during the period extending from the 80th to the 111th Olympiad, (*i. e.*) from the year 460, to the year 336 before Christ, which comprises the age of Pericles and Alexander; and to this period the most admirable masterpieces now in existence must undoubtedly be referred. Political events had long been preparing the way for this glorious advance. The Persian war, by the agitation it produced throughout the whole of Greece, had given an impulse and activity to the mind of men, which were the principal causes of this stupendous progress. Athens had been the grand theatre of the struggle, and consequently the operation of these causes was felt there in all its force. The successful issue of the war, by inflaming the nation, awakening it to a keen perception of its greatness, and inspiring it with a noble patriotic pride, raised its intellectual faculties still higher, and led to those astonishing improvements in art, particularly in Attica, which, as we learn from Herodotus (lib. v. cap. 78), began to appear in the fourth year of the 67th Olympiad.

Athens had the honour of producing Cimon and Pericles, at an epoch when its glory, power, and revenues, had reached their utmost limit.

[1] We are indebted to the conductors of the illustrated work on *Ancient and Modern Architecture*, published by Messrs. Didot, for permission to insert the above interesting paper. It will afford a favourable specimen of the manner in which the work is got up, and will, we hope, justify the high terms of approbation which we have felt it our duty to express in relation to this valuable work.—ED. C. E. & A. JOUR.

An abuse of power and breach of trust, which may perhaps appear venial in the eyes of the artist and antiquarian, who contemplate the beautiful specimens of art produced thereby, farther facilitated the execution of almost numberless monuments, which started up, as if by magic, to make ancient Athens the most wonderful city in the world, and a school for architects and sculptors through all succeeding ages.

The various states, when freed from the Persian rule, had formed a league to carry on the war against the great king; the chiefs of Attica were empowered to fix the contingent of each state; and, as proposed by Aristides, this contingent φορος, was at first very moderate, the total amount not exceeding 460 talents, or 100,000*l*. Such was the first contribution under the superintendence, 'Ηγεμονια of Athens. This treasure was originally deposited in the isle of Delos, inhabited by priests only, and secured from all danger of spoliation by its sacred character. Subsequently, when the power and ambition of Athens had increased, and a disposition to abuse them had sprung up, the tributes were augmented, and Athens ultimately succeeded in obtaining posession of the treasure, which, under Pericles, was raised to 1200 talents, and was, as we shall show hereafter, deposited in the opisthodome of the Temple of Minerva. This treasure was gradually increased by usurpations, and its guardians devoted the greater part of it, first to works of public utility, and afterwards to objects of art, or merely of luxury; a fact which explains the possibility of the immense works executed under the administrations of Cimon and Pericles. But, by thus flattering the national vanity in devoting the war subsidies to the embellishment of Athens, Pericles aroused the enmity of nearly all the other Grecian states, and prepared a reaction, which ended in the ruin of his country. A profound philosopher, a skilful orator, endowed with a mind bold in conception and fertile in expedients, with a noble and majestic exterior which had procured him the surname of 'Ολυμπιος, Pericles joined to these brilliant qualities an enlightened taste for the arts, of which he gave good proof in selecting Phidias to superintend all the works he caused to be executed. Of these works the most remarkable in every respect is the monument to which the present notice is devoted.

In the middle of the Acropolis, or citadel of Athens, stood a temple dedicated to Minerva, and called the Parthenon, either in homage to the chastity of the goddess, or because it had been consecrated to her by the daughters of Erechtheus, frequently designated by the name of Παρθένοι virgins (Hesychius). It was also called 'Εκατόμπεδον, on account of its extent, which was 100 feet in front, and not on every side, as some authors have supposed. We know that after Xerxes had ravaged the country of the Phocians, and vainly endeavoured to pillage the Temple of Delphi, he entered Attica, razed Athens to the ground, and destroyed all the temples by fire, without even excepting that of Minerva, which was the oldest in the city, and the most revered by the Athenians. Some traces of this last have been discovered recently. Among the ruins burnt in the 75th Olympiad (450 before Christ), have been discovered a number of tiles, antefixes of burnt clay, small bronzes, an immense quantity of lead pencils, which were no doubt used by the architects to draw on marble, and several colour-pots containing blue and red, which were used to paint certain parts of the architectural ornaments.

The new temple built by Pericles was placed on the highest point of the Acropolis, and is the first object that strikes the eye from whatever side Athens is approached, and is visible from the very entrance of the Gulf of Ægina. Under the direction of Phidias, the two cleverest architects of the day, Ictynus and Callicrates, were employed to erect the Parthenon.

The Parthenon subsisted many centuries almost uninjured; the Christians converted it into a church, and when the Turks became masters of Athens, either from indifference or forgetfulness, they left it untouched, except that some of the inhabitants occasionally carried away a piece of marble to make lime. Spon and Wheeler, during their stay in Attica, had the pleasure of seeing it entire in 1676. Not long after, Athens was besieged by the proveditor, Morosini, who was subsequently Doge, and Field-Marshal Count de Kœnigsmarck, a Swede, who commanded the Venetians, then at war with Turkey. The Turks had converted the Parthenon into a powder-magazine, which was fired by a bomb on the 28th September 1687, and the broken pavement still shows where the destructive missile fell. The explosion cut the temple into two parts, as it were; the whole eastern side of the cella, five columns of the portico, all the internal constructions of the cella, eight columns of the northern row of the peristyle, six of the southern, and all the sculptures belonging to these several parts of the edifice, were either shattered to atoms or thrown down. The eastern pediment, too, must have suffered considerably in its sculptures, though its architecture was not injured; but, to judge from the state of the ruins, it would appear that it had been seriously damaged previous to the event of 1687, probably at the time when it was converted into a Greek church. Morosini's desire to enrich his country with the spoils of this superb structure, contributed still more to its ruin: he determined on removing the statue of Minerva, with her car and horses, from the pediment; but owing to some awkwardness or inattention on the part of the workmen, these *chefs d'œuvres* were thrown down and broken into a thousand pieces.

The Parthenon is built entirely of white marble, dug out of Mount Pentelicus, in the immediate neighbourhood. The temple is Doric, octostylar, peripterous, and uncovered. Its length, measured on the top of the steps that support it, is 114 ft.; its width, 51 ft. The respective proportion of the two principal dimensions is very remarkable. The sides have seventeen columns, and the ends eight only,—less than half, an arrangement which seems to have been generally observed by the Greeks; we find it again in the Temple of Theseus, which has six columns at the ends and thirteen at the sides; and also in the temples of Pæstum. The Temple of Jupiter Olympius was in the same proportion, being, according to Pausanius, 95 ft. by 230 ft. The Romans made their temples much shorter.

The length of the cella outside, not including the pilasters that project at each end, is 78 ft. 6 in.; the width 35 ft. 2 in. The interior is divided into two parts, of unequal side; the largest is the temple, or ναος; the other, which was entered from the back front, was the opisthodome. The position of this temple with respect to the points of the compass, gave rise to an error which is not yet entirely removed, notwithstanding all that architects and antiquarians have written for that purpose. It was long believed that the front of the Parthenon, as is the case with most other temples, was turned towards the west, and in fact it is the western front that faces the entrance to the Acropolis by the propylea; but here lies the difficulty. It is at this end that we find the smaller division of the cella, which the partizans of the common custom have been pleased to call a vestibule, or πρoναος. But if we admit this, where shall we find the opisthodome, which all ancient authors are unanimous in placing in the back part of the temple? It must therefore be acknowledged that, contrary to the usual practice, the front was turned to the east, and we shall give further proofs of this when we come to speak of the sculptures on the pediments. Round the temple, as we have already said, there runs a peristyle composed of forty-six columns, eight on each front, and seventeen along the sides. We are indebted to Mr. Travers for one important remark: all the columns lean towards the interior of the temple, so that those at the angles have a double inclination, in order to oppose a greater force to the pressure of the edifice. The jointing of the blocks that form them is so well executed, that it requires close examination to discover it, the interstice being scarcely so thick as the finest thread; and the same perfection is observable throughout. The columns have no base, but stand upon three very high steps, which form a stylobate for the whole edifice. The height of the columns, including the capital, is 34 ft. 2 in.; their diameter is 3 ft.; those at the angles being rather larger, their diameter is nearly 1½ in. more.

The capital is very plain, and has no astragal, its place being supplied by an indenture which crosses the fluting without stopping it. The capital is joined to the shaft by four listels; the plinth has no talon; as that moulding would have had a paltry appearance in such a severe style of architecture. The total height of the capital is 2 ft. 2½ in.; *i. e.* 13 inches for the echines and listels, and 13½ in. for the plinth.

The columns are fluted with sharp edges throughout their whole height; but to make the fluting appear still deeper by the effect of light and shade, it is not cut in segments of a circle, which would have permitted the light to fall equally on every part of the concavity; but it is made flat at bottom, so that the sides, rising abruptly, cause a deeper shadow. This fluting does not, as in most Greek temples, run up directly, and at right angles, to the listels of the capital; it is more in the Roman style, except that in the Parthenon, instead of terminating, as in Roman architecture, by a semicircle, they end in a kind of elliptical arc.

The columns support an entablature 10 ft. 10½ in. in height, no less admirable for the beauty of the marble with which it is ornamented, than for the masculine character that prevails in its profiles. The face of the tryglyph is exactly perpendicular to that of the architrave, a rule which Leroy thinks was followed at Athens till the reign of Augustus, when the Greeks, and the Romans after them, began to deviate from it, in making the face of the tryglyph slope to the architrave. The height of the tryglyphs of the Parthenon is 4 ft. 4½ in., and their width 2 ft. 9¼ in. It will be observed that here, as in all Greek Doric temples, the angle of the frieze is flanked by a tryglyph, whereas the Romans left the corner plain, and placed the tryglyph perpendicularly over the axis of the column.

There is one very singular peculiarity, which Messrs. Fuente and

Travers observed, first in the Parthenon, and afterwards found in all Greek temples, which is, that the stylobate does not present a line perfectly horizontal, but a curve slightly convex. The entablature follows the same curve, and its face forms a concave line on each side of the edifice; so that the angles are not absolutely right angles, but slightly acute. These dispositions were evidently intended to add to the solidity of the temple, by making its several parts tend to the pyramidal form, and by opposing a greater resistance about the centre of the great lines to the pressure from within.

Mr. Woods, though he acknowledges that the fronts are perfect, thinks that the sides are inferior to those of the Temple of Theseus. "Why," asks he, "should a continued colonnade, crowned by an upright entablature, require more slender proportions than one supporting a pediment? I cannot tell; but such seems to be the fact. Yet, as in the Parthenon, the height of the columns is very nearly $5\frac{1}{2}\frac{1}{4}$ diameters; and in the Theseum the height is only $5\frac{1}{2}\frac{5}{7}$ diameters: the difference seems too small to produce any sensible effect: but the intercolumniations in the Parthenon are only equal to about $1\frac{2}{3}$ diameters, whilst in the Theseum they are $1\frac{5}{8}$ diameters; and to this greater space is doubtless owing the lighter appearance of the latter."

The portico is double on each front of the Parthenon: and the reader will perhaps be surprised to hear that the columns of the second row, raised on two steps, are of less diameter than those of the portico, and do not all correspond exactly with their axis. These irregularities, which the theory of the art will not admit, are not perceptible in the execution, and contribute, on the contrary, to the general effect. These smaller columns, appearing to converge to a central point of view, give the peristyle the appearance of being deeper than it really is: whereas, had these columns been of the same diameter as those in the front, from their not being like them enveloped in a flood of light, they would have appeared heavy and massive. Their height, including the capital, is 35 ft.; diameter, 2 ft. 8 in. The entire height of the capital is 1 ft. 9½ in., of which the plinth occupies 11¼ in., leaving 10¼ in. for the echinus and listels, which are only three in number. The fluting of the shaft is here executed in segments of a circle. The internal arrangements of the temple were nearly the same as those of the basilicas built by the Romans at a later period. Spon and Wheeler found three sides standing of the gallery, and which was composed of two rows of orders, containing twenty-two columns. These columns have been all thrown down and destroyed; but their plan has been drawn, and sufficient elements of the lower order have been found to ascertain their dimensions. The shaft was 15 ft. 6 in. in length, and 2 ft. in diameter. The capital, composed of a plinth, an echinus, and three listels, was 12½ in. in height; the architrave 1 ft. 6 in.; and the tryglyph, 1 ft. 7½ in.: the width of the intercolumniation was, from axis to axis, 8 ft. 2⅝ in. It is worthy of remark that these columns, for about one-third of their height from the bottom (5 ft. 3 in.) have only a flat fluting, as at Pompeii; the rest of the shaft only is cleared out. These columns formed a portico of 7 ft. 6½ in. in width, round the hypæthron or open part of the temple; the hypæthron was 16 ft. wide, which gives 31 ft. 2 in. for the inside width of the temple; its length was 49 ft. 2½ in.

The temple was lighted by the door and the opening in the centre of the roof. When the Christians consecrated it to their worship, they made a window in the eastern end, and built a semicircular sanctuary. The Turks made scarcely any alteration. This apsis is now demolished to within three or four feet of the ground. In the part of the temple under the opening, and near the bottom, stood the pedestal of the famous Minerva, of which we shall soon have to speak. Part of the base of this pedestal is still visible; it was 10 ft. 10 in. square.

In the back part of the temple was the opisthodome, so long supposed to be a vestibule preceding the temple itself. Its width is the same as that of the temple, and its length 21 ft. 6 in., or nearly one-third of the cella.

By some inexplicable error, Stuart, Chandler, and others, have represented, both in their text and plans, that the opisthodome was supported by six columns, placed in two rows: there never were but four. M. Brönsted has so given them in his plan, and the fact has been recently proved by Messrs. Leake and Travers. One of the columns having been broken, the Turks erected in its place a square pillar of masonry, which, as well as the three columns, is now demolished. The latter, according to Stuart, were of the same dimensions as those of the smaller order in the peristyle.

In the opisthodome, besides the money proceeding from the public revenues, and the contributions of the Grecian cities, 1000 talents were always kept in reserve to meet unforeseen expenses of the state. At the beginning of the first Peloponnesian war (432 A. C.), when the power of Athens was at its height, 6000 talents (£1,296,000), according to the Abbé Barthelemy, and 9700 talents (above £2,120,000), according to M. R. Rochette, were deposited in the opisthodome. The names of all the debtors of the state were inscribed there; they were called Ἐγγεγραμμενοι εν τη Ἀκροπολει, and after the payment of their debts, Εξ Ἀκροπολεως εξαληλιμμενοι. Private individuals were accustomed to deposit sums of money there which they were afraid to keep at home; it was also the repository for offerings made to the goddess, Ἀναθηματα, or votive offerings, and valuable spoils taken from the Persians, part of which was the throne with silver feet, on which Xerxes sat to witness the battle of Salamis. Other trophies, shields taken from the enemy during the Median war, were suspended on the architrave outside the temple, and alternated with bronze inscriptions, if we may judge by the marks of the nails which held them. The two guardians of the treasure deposited in the opisthodome of the Parthenon, were Jupiter Σωτηρ, and Plutus, the god of riches, represented with wings, and, by an exception peculiar to this god, not deprived of sight.

At the present day it is impossible to doubt that the Greeks made use of painting in the decoration of their architecture; the labours of Hitturf, Raoul-Rochette, Letronne, and Brönsted, combined with recent researches representing the Doric temples of Greece and Sicily, have removed all uncertainty on the subject, and given positive confirmation to the assertion of Vitruvius (lib. iv. chap. ii. § 2) respecting the blue wax, *cera cærulea*, which he states to be the usual colour for tryglyphs; the metopes appear to have been generally red. We know, from the testimony of ancient authors, that all celebrated sculptors had a skilful painter at command, whom they employed to paint their works; the names of several of these artists have reached our own times. "There was not in all Greece," says M. Brösted, "a single temple of architectural pretensions which was not more or less coloured—that is to say, painted so as to contribute to the effect and rich aspect of the monument by the harmonious colour of the symmetrical parts, and especially the upper parts of the structure. There were three different kinds of painting: 1. The colour was applied like common paint, without any illusive effect, merely to set off the architecture—that is to say, to give relief to the dull and monotonous colour of the stone. 2. The colour was used to produce an illusion in certain parts of the construction—that is, to give an effect of light and shade, of projection and depression on a plane surface; in a word, to produce real paintings, and consequently to dispense with sculpture. 3. Lastly, the colour was used as a finish for the mouldings. In this case, the application of the colours being altogether subordinate to the laws of polychromatic sculpture, did not belong to architecture, only in so far as these works were connected with it from their being an indispensable decoration."

We will now proceed to examine the admirable works with which Phidias enriched the Parthenon. Five grand pieces of sculpture made this edifice the wonder of wonders; they were, the two pediments, the metopes, the frieze of the cella, and the statue of Minerva.

According to Pausanias, the pediment αετος of the front, represented the *Birth of Minerva*, and the pediment of the back the *Dispute between Minerva and Neptune*. Now those who had seen the western pediment uninjured, if not in its details at least in its principal parts, before the explosion of 1687, without pretending to examine the sculptures minutely, all agreed that it was the *Birth of Minerva*, or rather her *Presentation by Jupiter to the Gods of Olympus*. Ollier de Nointel, ambassador from France in 1674, was of the same opinion, but the sketches which he caused to be taken of the already mutilated figures of this pediment were quoted to support a misapprehension that they were intended to remove. Stuart first pointed out the mistake, and asserted that the west front was the back front, and represented the dispute of Neptune and Minerva, while the east front presented the birth of the goddess. M. Quatremère de Quincy adopted this opinion, and made it the text of a learned dissertation, in answer to the contrary opinion maintained by M. Barbié du Bocage, in his Atlas of Anacharsis; M. Brönsted coincides with M. Quatremère. The east front is composed of about 24 figures, detached and in full length, more or less colossal; four of them were horses. Of these groups, of which there still remained a dozen figures entire when Carrey executed his drawings, only 12 or 13 fragments are now left, and they are in the British Museum.

The western pediment, which represented the *Dispute of Minerva and Neptune*, was composed, according to appearances, of the same number of figures and horses. Carrey made drawings on the spot of 22 figures; nothing now remains of them but five fragments preserved in the British Museum. Two figures placed in a corner, which were easily recognised as intended for Adrian and his wife Sabina, appeared to Spon, Wheeler, and Leroy, sufficient to authorize the assertion that these pediments had been restored under that emperor. But the very style of the sculptures proves this to be a mistake, and it is much more probable that, by a kind of flattery, of which there are numerous known instances, these heads were substituted for others in the times of the Romans; however, if we may believe Plutarch, the monuments reared by Pericles did not need restoration when he wrote his histories.

The second series of the sculptures of the Parthenon was composed of the metopes which decorated the frieze outside. These metopes were 4 ft. 4½ in. high, and 4 ft. 2 in. broad, those near the angles being rather narrower. Their height being greater than the width, shows that the architect intended to make them appear square, notwithstanding the projection of the band of the architrave. The figures were in higher relief than those of the inner frieze of the portico, because they were intended to be viewed from a greater distance. The metopes were 92 in number. Many of them had escaped the ravages of time and men, when Lord Elgin, during his embassy at Constantinople in 1801, unfortunately obtained a firman of the Turkish government, which authorized him *to erect scaffolding round the old temple of the idols, to take plaster casts of the ornaments and figures*, and also *to remove the stones containing inscriptions, as well as the statues still existing.* It is said that it cost Lord Elgin £74,000 to obtain all the beautiful fragments that it was possible to carry to London. This barbarous speculation, however, was far from being profitable to his Lordship, as the whole collection was purchased by the British Museum in 1816 for £35,000; and one of his most illustrious fellow-countrymen, Lord Byron, seeing his name engraved on the Parthenon, wrote underneath, *Quod non fecerunt Gothi, Scotus fecit.* It is nevertheless true that Lord Elgin has acquired a celebrity that Erostrates might have envied.

Very different was the conduct of the French ambassador, M. Choiseul Gouffier, who caused all the plaster-casts, now in the Museum of the Louvre, to be taken, and only brought away a single metope, which had long been detached. This is the metope that was purchased for the Royal Museum for the sum of 25,000 f. (£1,000) in 1818, after the death of M. de Choiseul.

Fourteen metopes still remain in their places. Some fragments have been found in clearing away the rubbish round the Parthenon, which operation was superintended by M. Pittakis; 16 metopes have been taken away, 15 of which are in London and one in Paris: the others have been destroyed by time, or the explosion of 1687, and the only traces left of them are in Carrey's drawings. The metopes of London and Paris all belong to the southern side, which was the least injured, and they represent episodes in the battle of the Centaurs and Lapithæ; but other subjects were treated in those which remain or have disappeared. The metopes of the Parthenon have been published several times, especially by Stuart, Legrand, and Brönsted.

The most considerable fragment of sculpture now remaining is a part of the frieze placed under the soffit or ceiling of the peripteron, about 10 ft. from the ground. This frieze is 4 ft. 8 in. high, and was originally 524 ft. in length. M. Brönsted estimates the number of figures it contained to be 320, the varied groups of which represented the procession of the grand quinquennial festival of the Panathenea. These sculptures were in very low relief, which was admirably calculated to allow them to be seen from below, without drawing back, as their position under a rather narrow portico absolutely required. Stuart and Revett sketched a considerable part of what existed in their time (1751—53). A fragment, containing seven figures, was removed by M. de Choiseul, and is now in the Louvre. Lord Elgin, in his turn, took down a length of about 250 ft., and carried it to London. In this frieze the harness of the horse was of metal, and the holes in the stone, made by the cramps that fastened it on, are still perceptible. The frieze has been published several times, wholly or in part, by the same authors that we have already quoted for the metopes.

We must now return to the great masterpiece of Phidias—the famous statue of Minerva, which stood in the sanctuary, and of which unfortunately we know nothing but what we can learn from the descriptions given in Greek and Latin authors. This statue, which, according to Pliny's statement, was 26 cubits high (35 ft.), including the pedestal perhaps, was made of gold and ivory, and the gold ornaments were equal in weight to 44 talents (£120,000). This statue was raised in the temple in the first year of the 87th Olympiad (A.C. 430). After being pillaged of the gold by the tyrant Lychares, who stripped off its golden mantle, and put on a cloth one, saying that it would keep the goddess warmer, it appears to have been finally destroyed by the Goths under the command of Alaric. Such was the temple which has been justly reckoned the masterpiece of architecture by both ancients and moderns.

ONE OF THE CRAFT.

A singularly blustering address has been issued by the new Editor of a contemporary journal, wherein, not content with vaunting of what he himself intends to do—and he certainly has a very large field for improvement before him—he gives his readers to understand that until now, when he has taken it up, "the periodical literature of architecture" has been marked not only by deficiency of talent, but also by "lowness of style, coarseness of diction, and a kind of *anything-arian* conscience." What the last expression may be levelled at, it is not very easy to guess, because, whether they be upon matters of fact, or on matters of taste and critical opinion, architectural topics do not touch upon moral or religious questions. Some, indeed, have thought proper to mix up a good deal both of *sanctimoniousness* and of religious party spirit—that, too, of the most intolerant kind, when they have handled the subject of ecclesiastical architecture, or have denounced the Grecian, Roman and Italian styles as Pagan and anti-Christian; but then they have not so much addressed themselves to professional and architectural readers properly so called, as they have sought to ingratiate themselves with their own particular sect or coterie.

We certainly were not before aware that the periodical literature of architecture was at all more open to the charge of looseness of principle than periodical literature generally, or even by many degrees so much so. At the same time, it must be allowed that a change has of late years come over architectural discussion and criticism; but it is both a natural and an advantageous one. It is but natural that a greatly extended circle of readers should have caused this species of literature to assume a more popular tone, and this in turn has helped to extend that circle still more. If, therefore, this is what is meant by the reproachful term "lowness of style," we can only say that it is to the full as good as the serving up stale truisms and namby-pamby remarks in inflated pomposity of verbiage. At all events it would seem that the offensiveness complained of is confined to diction and style, for had the matter also of such writing been considered poor, puerile, and absurd, that defect would have been dwelt upon more forcibly than the other.

Our contemporary is pleased to talk somewhat mysteriously of "scandal in the literature of architecture;" and no doubt there has been something of the kind, and, strange to say, it has most shown itself where it was least of all to be expected—in the publications of some professional writers who have aspersed nearly all their architectural brethren as a body, accusing them now of want of even ordinary talent, and now again of want of principle and honesty. To no one are the profession less obliged for what has been said of them, than to Messrs. Pugin, Gwilt, and Bartholomew—and to the last, perhaps, the least. However, from henceforth, we presume such scandals are to be put a stop to.

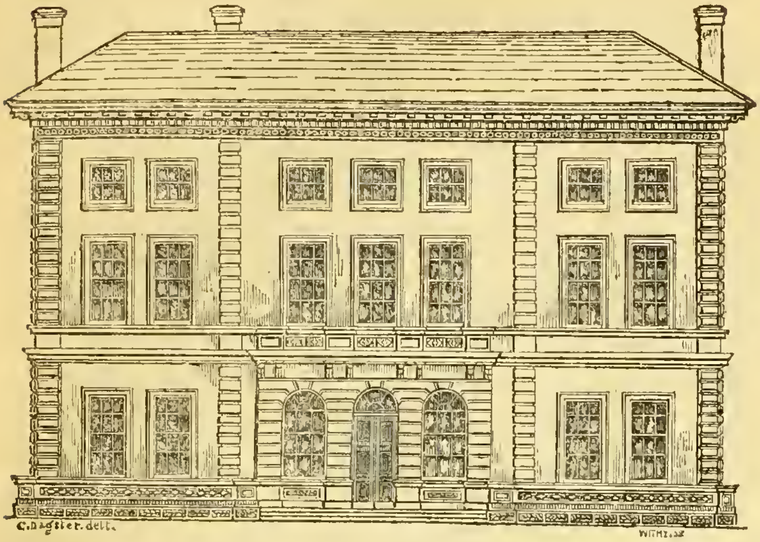
After no little bouncing, and some vapouring, too, about "the balance of justice hanging conspicuously over his columns," our contemporary takes up the submissive strain, imploring favours from authors and publishers, no doubt in order that they may be thrown into the said balance as "make-weight" on their side. It seems, therefore, after all, that his lofty independence may occasionally be jeoparded; and also that he trusts to the chapter of accidents, for being more fortunate than was his predecessor in obtaining the voluntary assistance of "high talent." However, he has shown himself discreet enough in one respect, since he has forborne complimenting that predecessor, or in any way referring to the past as satisfactory earnest for the future. His own style is by far more figurative than luminous; in fact, he sometimes wraps up his meaning in such very odd guise, that few will be able to make it out at all, for instance, where he talks of "baken-meats seasoned by a few gridirons!!" By "baken-meats," we suppose he means *pies;* but never before did we hear of "gridirons" being used as seasoning either for pies or anything else. Possibly this queer stuff may be intended as a specimen of "loftiness" of style; but then it soars so loftily that meaning is lost in the clouds. However, it is, at all events, funny and droll; and we therefore leave the "Swathed Horus"—as he chooses to call himself, "Infant of athletic promise," to do his doings as featly, and, above all, as "cleanly" as he can: only advising him to be more cautious for the future, and not to betray so much malevolence and arrogance towards all others who are engaged in the same cause as himself.

ROYAL ARSENAL, WOOLWICH.—Several powerful cranes are in progress of erection at this extensive department, made on the most approved principles, by Napier, the celebrated engineer. One capable of supporting 10 tons has been erected in the foundery, and the others on the wharf wall, for landing and embarking large guns shot and shells.

OBSERVATIONS ON ARCHITECTS AND ARCHITECTURE.

By Henry Fulton, M.D.

No. 5.



FEMALE TRAINING SCHOOL, TALBOT STREET, DUBLIN.
Scale 20 ft. to the inch.

The introduction of the Italian style is a novelty in the architecture of Ireland. It might be called the Farnese style, which as far as a bold unbroken cornice goes, is excellent. The edifice, of which a view is given, is newly finished; it is the design of Mr. Owen, the architect of the Board of Works, (the Woods and Forests of Ireland,) and does him considerable credit, and is intended for a model school. The unbroken cornice is very bold, perhaps a little too much so, as seen from immediately beneath; this is not the fault of the cornice, but of the site, as the building requires a larger space and wider street in front. I presume the architect was obliged to group the windows, and hence the necessity for the unmeaning tatooed pilasters which intervene. There is a kind of overlapping scale ornament, such as may be seen on the lately finished front of the London and Dublin Bank, in Dame Street, which would have had a better effect; and the tatooed quoins might also have been dispensed with.

Both on account of appearance and utility, it is desirable not to place chimneys at the ends of an edifice; any heat which is obtained from them might be serviceable in the centre, but here it is lost. The windows of the ground-floor might have had circular heads to make them correspond with the arches of the porch; still on the whole, we congratulate Mr. Owen on the production; and admire the omission of pediments and shoulders to the mouldings of the windows, an example of good taste which we hope to see followed.

II. In the last monthly number of this *Journal*, page 445, there is a very able article on the state of architecture; it goes at once to the root of the evil which impedes the progress of improvement. Were I a great potentate with plenary power, I would compel every architect in my dominions to read it; and if Mr. Gwilt were under my control, I would force him *nolens volens* to read it aloud in public: but alas, (for the nonce,) my authority is not so extensive, and I can only recommend its perusal.

The part of the paper I wish to call attention to, is that which treats of "the public and the profession," and the jealousy with which some, I am happy to say only *some*, of the latter (amongst whom Mr. Gwilt takes the lead) show in sneering at amateurs. I believe there is talent enough and taste enough, although it be latent in the profession to work out great things, and place the science where it ought to be, but where it is not, at the head of the fine arts; this will never be the case until such a pressure is applied from without as shall force the latent talent to show itself in practice; that is, until the public, who are the judges, shall be able to judge and require its development. If the public were well informed, I do not mean as to the mechanical part, but had their tastes and judgments improved and informed, would many of the edifices which have been erected in our day ever have had existence?

Sir William Chambers appears to have written his treatise in order to put down the "*gusto greco*" and give force in its stead to the *gusto Palladio*. Sir William was successful in his day, but his works shall not again be esteemed until the *gusto greco* shall again have been extinguished. I believe Mr. Hosking was the first to assert his want of faith in the infallibility of Palladio, and no disciple has come to the rescue. Even in Ireland, where Palladio reigned supreme, not a voice is now heard in his defence, although the Royal Institute of the architects of Ireland, in the inaugural address on the formation of the society, extolled the art as that which "Vitruvius taught and Palladio adorned," and we were even threatened with a course of lectures which were actually prepared, and were well known to be orations in praise of Palladio and his school, such as would have delighted Mr. Gwilt himself; but although these lectures and the drawings to illustrate them were all ready, they were not, and for aught I know, never will be delivered. The truth is, the star of Vincenza is on the wane.

III. Something must be done to raise up another and a better school. One naturally turns to the British Institute in expectation that they may be induced to do that *something*. Now, although I may come under the lash of Mr. Gwilt's pen, as "one of those idlers who had better mind their own business," yet I would wish in all humility, to give a few hints to the Institute on a subject of so much importance.

First, then, sue for a divorce from the Royal Academy, not indeed out of disrespect to the sister arts of painting and sculpture, or because you and I love them less, but because we love architecture more; and because the brilliant colouring of the one sister, and the poetic form of the other, quite throw the exhibition of architectural drawings into the shade, even if the hanging committee were disposed to give the best place in the rooms, and the consequence is, that few of the great body of the profession send drawings to the exhibition—few of those sent are exhibited—few of those exhibited are looked at—and still fewer are understood by the few who do see them. And, after all, although both Mr. Gwilt and myself might be able to see the beauty of an architectural drawing, and to realize in the mind's eye the effect which would be produced when constructed, yet many cannot, and others will not be at the trouble of giving it a thought at any time, and still less so when the eye is dazzled with the bright and varied hues of painting. I shall endeavour to point out a remedy for this in the third division.

Secondly, the Institute must get up an exhibition on their own account.

Thirdly, it is well known that the public in general are most profoundly ignorant of the nature of architectural drawings, and even of the subject itself, yet there is a method to teach them in spite of themselves, aye, and to instil into them a love of the art without their being aware of the why or the wherefore; it is by models, and when they fail the patient may be given up to the hopeless contemplation of such edifices as the palace at Whitehall, or the sentry box at the Horse-guards, or any other military post.

But of models, such as are to be desired, I have seen very few, and never a pleasing model of a modern edifice, nor indeed do I know any material out of which such a model can be formed, so as to give as good an idea of a perfect building as cork-wood does, of one which bears marks of the hand of time. I cannot speak of Sir John Soane's humbug collection, said to be given to the public, I mean humbug as far as the admission, or rather non-admission, of the public is concerned, for I never could get a peep at it. The models in cork which are in the Adelaide Gallery, in the Strand, are not well executed, nor do they appear to be on a scale. There is an artist at Rome, and another at Marseilles, who execute models of this description most beautifully, but they are worthless, except as toys, from being out of all due proportion, and as studies they would tend to corrupt, rather than improve, the taste. There is, or was some years ago, a collection of models in plaster to be seen in the Institute at Paris, but they are not worth the trouble of finding out the room in which they are kept. In the Museum at Naples there are some models in cork of part of the excavations at Pompeii, but as they are necessarily on a very small scale, they look more like toys than architectural works.

What I would propose is, that the British Institute of Architects should form a museum of models well executed, and all on the same scale, of all the buildings of antiquity of which we have accurate delineations, and also of all the modern ones of merit. As all the antiques are more or less dilapidated, cork-wood will answer admirably as a material: for the modern or restored works a premium should be offered for the discovery of a suitable material: or, perhaps, papier maché, to which the colour of Portland stone was given, might probably answer the purpose. The effect of wood painted is bad: the wood with which the Dutch, German, and Swiss toys are made would be much better, as it has something of the tone required. Such a collection, besides furnishing useful objects of study for the young architects, aye, and for the old ones too, would add to the interest of the annual exhibition of drawings, and tend with them to direct public taste into a proper channel.

By such means, and the aid of this independent *Journal, whose end is, to hold as 'twere the mirror up to art, to shew beauty her own feature, deformity her own image, and the very age and body of the time his form and pressure*, something may be done. The advantage of having an independent *Journal* as the reciprocal means of communication between the profession and the public is great, and I trust that the profession, so far from thinking themselves injured by contact with the public, may see that by having their own acquirements and the wants of the public reflected in such a mirror, they shall derive most benefit in proportion to the extent which the public may advance to in learning to form a correct judgment on the merits or demerits of an architectural design.

THOMSON'S TILTING APPARATUS FOR RAILWAY WAGONS.

For emptying Wagons at the termini of Railways, Shipping-places, &c., as used at the Magheramorne Lime-works, Ireland. By James Thomson, Esq., F.R.S.E., M.R.I.A., F.R.S.S.A., Civil Engineer, Glasgow. (Read before the Royal Scottish Society of Arts, the Honorary Silver Medal awarded, and reported in their Transactions.)

The apparatus may be generally described as consisting of three parts, viz.:—1st, The cast-iron brackets or quadrants for supporting the machine, *a a a*. 2d, The tilting-frame upon which the wagon is placed, *b b*. And, 3d, The malleable iron-swings for supporting the frame to the brackets, *c c*.

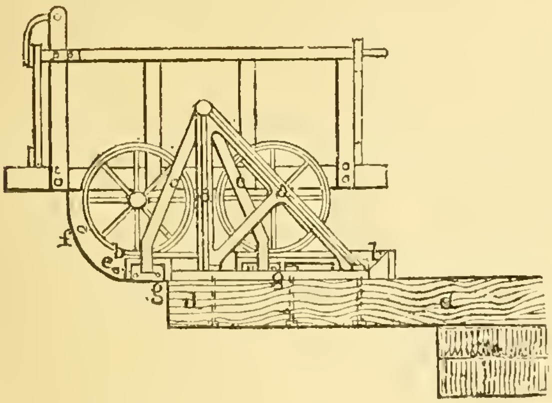


Fig. 1.

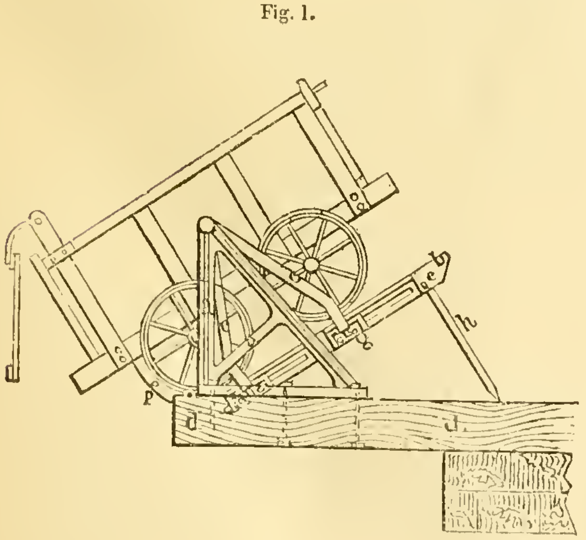

Fig. 2.

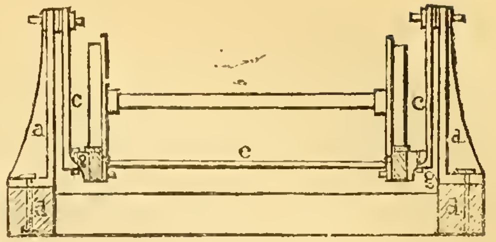

Fig. 3.

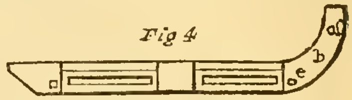
The supporting brackets *a a a*, are bolted to the wooden frame *d d*, of a moveable shipping platform, by means of which the apparatus is advanced at pleasure, and made to project beyond the wharf so as to discharge the wagon immediately over the hold of a vessel. The tilting-frame is formed of two cast-iron cheeks or sides, as shown in fig. 4, having in each two slots or grooves for attaching to the swings, and for adjustment of the apparatus. These sides of the



frame are connected together by two flat malleable iron-stays *e e*, as represented in fig. 3, with two bolts in each end, and a light round iron-stay *f*, at the curved ends. The swings are attached to the frame by means of snubs *g g*, which are bolted vertically to the lower ends of the swings, and horizontally to the sides of the frame, the bolts passing through the grooves or slots already mentioned, in which they are moveable—the upper ends of the swings work upon malleable iron journals fastened in the top of the cast-iron brackets. When the apparatus is properly adjusted (which is done by moving the tilting-frame forward or backward upon the swings by means of the adjusting slots), the wagon, on taking its position, should be so placed that its *centre of gravity may be slightly in advance of the point of suspension.*

The rails to the tilting-frame are laid with a gentle declivity, so that the wagon may be brought upon it with a slight impetus just sufficient to set the frame in motion—the wagon will then immediately fall into a position ready to discharge, as shown in fig. 2, when by a simple contrivance, which may be effected in various ways, the door of the wagon is opened from behind by a handle and connecting-rod communicating with the door latch, and the load discharged. While loaded, the position of the wagon will of itself remain the same, being in equilibrio; but immediately after it is discharged, and consequently the *centre of gravity thrown behind the point of suspension*, the tendency of the wagon is then to resume the horizontal position, which, however, it is prevented from doing, by means of the spur *h*, until completely emptied—the spur is then disengaged, and the wagon resumes its level position ready to be removed.

The whole operation of discharging a wagon (of whatever weight) is effected with perfect safety and facility in a few seconds, and one very important desideratum is supplied by this apparatus, viz.:—the practicability of *discharging wagons of different dimensions and different sized wheels upon the same tilting-frame.*

The advantages of the apparatus have been fully tested at the Magheramorne lime-works in Ireland, where they were first applied, and have since been in constant operation for the last three years, discharging wagons of three tons with 24-inch wheels, and wagons of only 20 cwt. and 20-inch wheels, with perfect facility and expedition —the cost of each apparatus not exceeding from 10*l.* to 11*l.* complete.

The Mersey and Irwell Navigation.—Late on Thursday, the 28th ult., or early on Friday morning, the lock on the river Irwell, at Barton, a little on this side of the place where the aqueduct on the Bridgewater canal is carried over the river, fell in. The lock is from 65 to 70 feet in length, and a great part of one side-wall near the top gate fell in, while about half the wall on the other side gave way. The top gate was entirely destroyed. The lock is an old one, and for the last two or three months has exhibited symptoms of giving way. The cause is said to be an unsafe foundation. The consequence of this accident, which fortunately was not attended with personal injury to any one, no vessel being in or near the lock at the time, will be the stoppage of the traffic on the navigation for a week or a fortnight. It is rather a curious circumstance that this should occur within three days of the time fixed for the transfer of the property in the entire navigation to Lord Francis Egerton, who, as we have already stated, is to take possession of the Mersey and Irwell Navigation on Monday the 1st of nuary.—*Manchester Guardian.*

AGRICULTURE AND ENGINEERING.

It has been well observed, that it is difficult to limit the range of professional studies, or the applications of professional knowledge. The ancients admitted this truth in all their pædagogic treatises. If Cicero and Quintilian laid down rules for the education of an orator, they urged the necessity for universal attainments, or a never ending pursuit of knowledge; if Vitruvius wished to produce a perfect architect, he laid down a category of studies and qualifications which men in these degenerate days would look at and fear to recognise. Without, however, requiring that a pleader should be a perfect mathematician, or an architect a good dancer and musician, we are not disinclined to recommend an ardent prosecution of study, and particularly of those sciences accessory to the practice of a profession, which widen the range of its application, and bring it in contact and harmony with other pursuits. We do not think the resident engineer of a railway the worse for being a good geologist, or the superintendent of an iron furnace for proficiency in chemisty; we believe, on the contrary, that they may find many useful occasions for the applications of such knowledge. It is with these views that we have looked with interest on the present position of agricultural science, the desire for a more efficient system of drainage, and the strong recommendations of a proper study of geology and chemistry; and here we pause and ask whether these are not circumstances which interest the engineer. Employed in the survey of an extensive estate, who so naturally would be the individual, not merely to ascertain its territorial limits but the nature and capabilities of its soils, subsoils, and mineral productions; to suggest the best system of drainage, of the supply of water, and of irrigation; to point out the best position for farm-steads, the most improved mode of construction, ventilation, and warming of the several buildings, the best means of preparing chemical manures, and the course to be adopted for the amelioration of the communications, means of conveyance, and implements; in fact, to make a report upon an estate and its capabilities.

When landowners come to consider what engineers have been already able to do for the improvement of estates, and of the country generally, we think there will be a natural disposition for their employment. All the great operations for the drainage of the country in the fens of Lincolnshire, Cambridgeshire, Bedfordshire, &c., have been executed under the direction of engineers, through whose means hundreds of thousands of acres have been rescued from the waste, and converted into corn-fields and pasture. Immense districts, moreover, have been reclaimed from the domains of the sea, or of rivers, by which the productive power of the country has been greatly increased. Such works as the embankment of the Nene, and others in the neighbourhood of the Wash, show what can be effected by well-conducted operations, and there are numbers and numbers of places on our coasts and on our river shores, where large additions might be made to the productive soil. Look at the estuaries on the Essex coast, the lagoons in the neighbourhood of Portsmouth, and on the Dorsetshire coast, the estuaries of the Dee, the Mersey, the Ribble, the Duddon, Morecambe Bay, and the Solway, not to speak of many equally favourable localities, but less known, and many of minor importance, but affording opportunities for profitable enterprise. All operations for the recovery of land, moreover must necessarily be attended with improvements of the drainage, of the water-courses, water communications, and places of shipment. The Lough Swilly and Lough Foyle embankments, now near complete, are very favourable examples of what may be done in the way of land recovery, and it is to be observed that in most cases land so recovered from the sea or from rivers is extremely productive, not being, as is vulgarly imagined, so much sand, but a fine alluvion. Partial engineering surveys of estates are common for mining purposes, but the greatest benefit would accrue from a general examination by well-informed engineers. The Dukes of Buccleuch and Sutherland, the Marquis of Bute, Earl of Burlington, and many other large proprietors avail themselves extensively of engineering science for the development of the capabilities of their estates, therein worthily following the example of the Great Duke of Bridgewater, for it is clear that the money spent under Brindley's direction in the improvement of the water communication, had of itself, at the same time, largely increased the mineral and agricultural value of the estates. The Duke of Buccleuch has laid out large sums on the improvement of the quarries and harbours on his estates, of which Granton pier is a splendid example. The Duke of Sutherland has for years been occupied in the systematic exploitation of his estates by the formation of adequate roads and harbours. The Marquis of Bute by his improvements at Cardiff, created a fine harbour, and immensely improved the value of his Welsh estates. In Inverness, the Earl of Burlington has for some years employed a gentleman of high scientific attainments, Mr. Jopling, the author of "Isometrical Perspective," as the superintendent of his slate and mineral works, who has greatly improved the roads and increased the produce of the property.

How many proprietors possess large estates, the resources of which are either unknown, or not adequately developed, where an improved road would bring a stone or slate quarry into work, where the finest brick or porcelain earth might be made available, where attention to the water courses would afford good mill sites, increase the produce of the estate by irrigation, improve its drainage, or perhaps, by very simple arrangements, convert a turbulent stream into a navigable river, enabling produce to be conveyed cheaply, and timber, materials, and manures to be introduced, and improving the access to markets. A simple bridge in a convenient place, may greatly facilitate communication between one farm and another, save time and labour of men and horses, and give better means for removing the produce. The deviation of roads, to avoid a hill or a vale, the most economical modes of constructing them all devolve on the engineer. In many cases the surface water is unfavourable to human or animal health, or insufficient for the uses of an establishment where the boring of an artesian-well may render the greatest benefit, and be the means of much pecuniary advantage. In fact, the opportunities are numerous in which a good engineering adviser can render important service to landed proprietors, and be the means of permanently improving his estates, and affording employment to the large numbers of the working classes dependent upon them, and for whom they may be unable to provide. In many cases where the means of improvement do not exist on the spot, the engineer will be able to find out in the neighbourhood, the course to be followed for adequate drainage, for improving the roads, or where the necessary mineral manures are to be found essential for the due development of an imperfect soil.

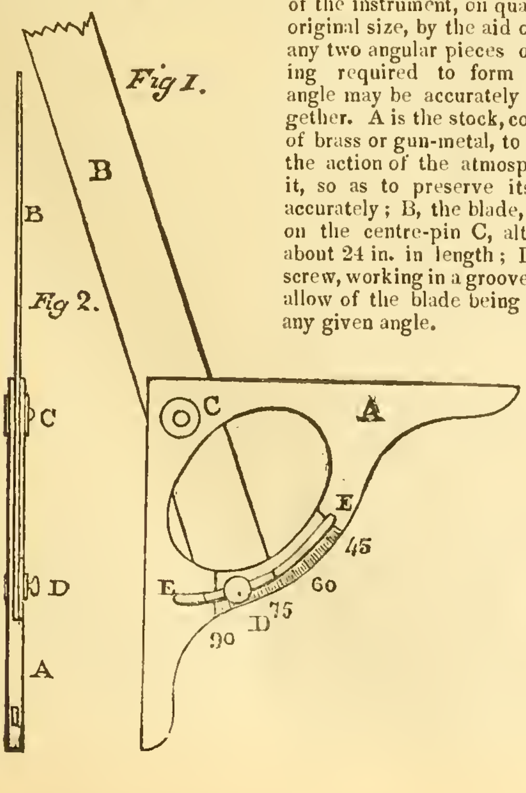
We believe, that in this respect, great scope exists, and it only wants the exertions of intelligent individuals to make this sphere of employment extensively available. While recommending this field of exertion, we must, at the same time observe, that a practical difficulty exists with regard to the uncertain nature of professional remuneration. It is too frequently the case that young members of the profession being called in, make charges after the rate of three, five, and seven guineas per day, being the charge of men in first-rate practice, a circumstance which has a material influence in deterring persons from calling in professional aid, or in inducing them, if they are to pay first rate fees, to make up their minds to have first-rate men, by which the junior practitioner is excluded. We would not in any way derogate from the dignity or adequate remuneration of the profession, but on every ground of propriety and policy we advocate moderate charges on the part of junior members. If experience be sought on the subject —what is the case with the bar and the medical profession?—the junior barrister gets a junior's fee, and works his way up to an independent practice. In the medical profession, however, there is a dignified scale of professional charges, on the guinea and half-guinea system, and every one who from professional standing cannot exact these charges, must submit to the derogatory and mischievous practice of sending in and charging medicines, or he must starve, or become an assistant for some years, which is much about the same thing; indeed, such is the mischievous system of remuneration in the medical profession, in consequence of young men not being allowed by etiquette to make moderate charges for visits, that a large part of the population are converted into medical paupers, as dispensary patients, &c., whereby we may fairly calculate that not less than a million a year is lost to the medical profession, being the sum which might be received from one million heads of families, small tradesmen, mechanics, and labourers. This sum would be adequate for the independent maintenance of five thousand junior medical men, and an efficient system would greatly raise the moral standard of the working classes, and get rid of the stain of medical pauperism, frequently the incipient stage of a demoralized career. Portrait painters have a wholesome system of political economy forced upon them, they know that it is of no use for John Scratchley to ask the terms of Sir Thomas Lawrence, but he must get up gradually as Sir Thomas Lawrence did. Lawrence, we believe, began at a shilling or half a crown; then his practice increased so much he was obliged to raise it to a crown, then half a guinea, a guinea, five guineas, till at last he did nothing under 250 guineas, and had more commissions than he could execute. People pay Sir William Follett a hundred guinea fee to induce him to give up a fifty guinea brief in their favour and such is the natural process, if a man be rising the public will raise his fees in the competition to ensure his assistance. We say again, then, let junior engineers, be moderate in their expectations, let them cultivate agricultural chemistry, geology of soils, and the practice of drainage, and there is a wide field open for their employment and exertion. At any rate we think we shall do good in directing attention this way, and we have, accordingly, not only made these few remarks, but in furtherance of the subject, published elsewhere the lectures by Professor Brande, on agricultural chemistry.

BEVELLING INSTRUMENT FOR JOINERS.

The Silver Isis Medal was presented to Mr. Thomas Quarm, 32, Wood Street, Princes Road, Lambeth, for *a Bevelling Instrument for Joiners.* (*Reported in the Transactions of the Society of Arts, London.*)

Mr. Quarm in his extensive practice in the finer parts of joinery, oft-times required a tool to answer the many purposes to which the one here explained may be applied. It will be found a valuable acquisition where any two angles when applied together are to form right angles. In a shop door the margins below the middle rail are at all times different from those above, which are required to form the sash. This causes the shoulder of the rail to be at a bevel, to meet the stile in the angle on the upper and lower edges of the rail, the angles on the reverse side of the door always varying to some extent; therefore, the angle of the shoulder would require to be different, as the case may require. By fixing the blade to the given angle, and by applying the reverse leg of the tool to the other piece, the line to cut to would be immediately given, so that, when applied together, they would be at right angles to each other as required, and, in the same way, the angles of the other side of the door would be given, therefore working with it with as much certainty as though the shoulders were square. Again, as all mitre squares hitherto constructed are subject to the change of atmosphere, and never correct, it would be a very unhandy tool if the blade were made of any length, answering only to one angle, if constructed with one leg only, however inaccurate the tool might be, the error would be increased two-fold when applied together. Both pieces would be fitted to the one leg in the present tool by moving the blade round to 45°, being so far as it will go; the fitting of one piece to one leg, and the other piece to the other leg, would, with certainty, form right angles when applied together; for, whatever might be the deficiency on the one side, would be made up on the other, if any. Again, by moving the blade in a straight line with the one leg, it will form right angles with the other, and may be used as a square in case of necessity. It will be found a very useful appendage to the drawing-board, to draw any given line to a certain angle required, without the assistance of a sector or scale; also as a bevel in isometrical and other perspective. The graduation beyond 45° is not continued, as any greater angle may be obtained on the reverse leg by going from right to left, instead of from left to right.

Description.—Fig. 1 shows a front view, and Fig. 2 a side view of the instrument, on quarter the original size, by the aid of which any two angular pieces of framing required to form a right angle may be accurately put together. A is the stock, composed of brass or gun-metal, to prevent the action of the atmosphere on it, so as to preserve its shape accurately; B, the blade, turning on the centre-pin C, altogether about 24 in. in length; D, a set screw, working in a groove E E, to allow of the blade being fixed at any given angle.



Fixed mitre-bevels, when made with one leg only, frequently vary from the angle of 45°, or half a right angle, so that when two pieces which have been set out by such a tool are applied together, their incorrectness is increased two-fold; whereas, in Mr. Quarm's tool, that difficulty is obviated by the use of the short end of the blade; for when the long end thereof is fixed at about 45°, whatever may be the variation in the angle set out by the longer portion of the blade, the two pieces when applied together will form a right angle. It will also be found accurate in setting out the shoulders of the diminished rail of sash-doors, and will likewise answer for a square, a common bevel, and a true mitre-bevel.

NEW ROMAN CATHOLIC CHURCH, "ST. GEORGE," AT LAMBETH.

This building, which is situated in Westminster bridge road, opposite the Blind Asylum and Bethlehem Hospital, is rapidly approaching completion. The foundation stone was laid in April, 1840, on which occasion the church was dedicated to St. George, the tutelar saint of England. It is the largest ecclesiastical edifice devoted to the Roman Catholic worship that has been constructed since the Reformation, when Henry VIII. destroyed and reduced the majority of the Catholic establishments. Its external dimensions are 250 ft. long by 84 ft. broad. The height of the tower at the west end at present is 60 ft., but when completed its extreme elevation will be 330 ft. above the ground level. The style of architecture throughout the building is the decorated Gothic. The tower is most substantially built with Caen stone dressings, its walls averaging nine feet in thickness. It contains a belfry with room for a peal of eight bells. On each side of the tower are double belfry windows, decorated with mitres, parapets, pinnacles, &c., and when funds shall admit, it is intended to ornament the walls with 100 statues of saints and martyrs. The tower will be surmounted by a steeple, built after the pattern of the magnificent spire of Salisbury Cathedral, and will be terminated by a large cross. The interior height of the church, from floor to ceiling, is 57 ft. The length of the nave in the clear is 160 ft., by 72 ft. broad; the chancel is 40 ft. long, by 26 ft broad. Over the entrance to the chancel is a richly carved oak screen, and a rood loft in the form of a cross, on each side of which will be placed statues of the blessed virgin and St. John. From either side of the rood loft ascends a spiral staircase, terminating externally in two turrets decorated with crockets, figures, and other ornamental work. Each turret is elevated 40 ft. above the ceiling. A carved stone pulpit will be placed at a short distance from the chancel screen. Adjoining the chancel, on each side, are two small chapels for altars, over which are to be placed stained glass windows. The chancel window is very large, measuring 30 ft. by 18 ft.; the mullions are of stone, with rich foliage; the interstices will be filled with stained glass of various colours, the subject is the root of Jesse, or genealogy of our Lord. It is the gift of the Earl of Shrewsbury, and will cost £500. Underneath will be placed the principal altar, which will be decorated with statues of saints and bishops. Another large window is placed in the tower opposite the chancel window, and is considered a fine specimen of the decorated style of architecture. The church contains in all 28 windows.

The roof is constructed of carved stained timber, which will be stencilled in various colours and devices. The mode in which the roof has been built is a modification of the manner anciently observed in the building of large edifices. Instead of covering the rafters of the ceiling with lath and plaster, to form a basis on which to construct the decorative work, as is usually done in modern buildings, the rafters themselves subserve ornamental purposes, by which means considerable expense is avoided, and beauty is combined with utility. The roof is supported by two rows of fluted stone pillars, consisting of eight in each row. The pillars are 18 ft. in height, and will be finished by capitals elaborately wrought in fine stone, carved in rich foliage, and connected one with another by small intercolumniations, in the form of arches, rising from the capitals to the rafters. The floor of the nave and aisles will be covered with red and blue Staffordshire tiles, each tile measuring six inches in the square. The chancel and side chapels are to be paved with encaustic tiles cast in different shapes and of various colours. At the south-west corner of the south aisle will be placed the large and richly ornamented baptismal font carved in Caen stone. The interior of the church is not obstructed by galleries; the only projections are the organ-loft and two small galleries for the choir over the two side doorways at the east end. No pews or closed seats will be allowed, but open benches will be placed down the aisles, constructed with low backs, so as to afford an unobstructed view of the interior. The seats will yield ample accommodation for 7,000 persons. The bare cost of erecting the building will be £20,000, but it is expected that a sum of £40,000 will be necessary to complete all the contemplated embellishments and improvements, including the tower and spire.

At the east end of the church is a large sacristy, and adjoining at the north east corner are cloisters, which connect the edifice with a presbytery, containing a spacious dining-room, and affording accommodation for several priests. Abutting on this is a convent for the Sisters of Mercy, and a school for 300 children. The convent is fitted up with kitchens, refectory, dormitories, a small chapel with a belfry, and will furnish an abode for 13 Sisters of Mercy; whose charity and kind offices will be distributed indiscriminately among the members of all religious denominations who may need assistance.

The convent, with its accompanying buildings, will cost £7,000. The architecture displayed in its construction is of a similar style to that used in the building of the church, only more subdued, and of a less expensive description. Several little turrets and spires are erected in various parts, which give it a very pleasing effect. The church and nunnery together stand upon an acre of ground, measuring 42,000 square feet. The entire edifice is built from the design of Mr. Pugin, and built by Mr. Myers, who, during the last ten years has been engaged in the construction of 37 churches.

The cathedral will be consecrated and opened for public worship in the autumn of the present year; but a considerable time must necessarily elapse before the great tower and spire shall be completed. The subscriptions towards this gigantic undertaking have, for the most part, been raised in the provinces through the exertions of the Rev. Mr. Doyle, who is the principal officiating priest. The Earl of Shrewsbury and the late Mr. Benjamin George Hodges have been the principal contributors. A considerable sum has also been subscribed by the poorer classes inhabiting the parish of St. George. The names of the King of Sardinia, the King of Bohemia, and other foreign potentates also figure largely in the list of contributors. A liberal donation is expected from Louis Philippe, who, during his stay in England, was a resident of St. George's parish. The Roman Catholic chapel in the London-road, as soon as the building is finished, will be converted into an hospital for the cure of cancer. The church is the largest structure in Great Britain that has been erected by voluntary subscriptions.

NOTES OF THE WEEK.

STRONG and urgent representations are being made to obtain a clear space at the east end of the Royal Exchange, efforts which we sincerely hope will succeed. If the houses on both sides of Finch-lane were removed, and those on the east side rebuilt as City offices, we believe no loss would be sustained by the corporation, while great public accommodation would be afforded. It would indeed be a shame that a public building of such importance should be spoiled for a trifle.

It is an item worth consideration in the progress of the age, that the lectures at the Royal Institution are to be considerably extended after Easter, so as to include a course on the Arts and Manufactures by Professor Cowper, and on Fresco and Decorative Painting, by Mr. Wilson, Director of the School of Design. It is by these compliances with the spirit of public improvement that the Royal Institution will maintain its high standing and achieve a position of permanent utility as a superior school of the useful and ornamental arts. The exertions to make it a school of scientific agriculture are equally commendable, but do not so properly come within the sphere of our observation.

The improvements at Eton College exhibit a commendable spirit of improvement, the attention to the sanatory arrangements is very laudable, inasmuch as it is very necessary. The drainage and ventilation are carefully looked to in all the arrangements, and a sanatorium for the sole use of the students has been established at Eton Wick, a mile off. Among the new buildings is a range of three large houses in the Elizabethan style, two of which are completed, opposite to the principal entrance of the college. A large hexagonal hall for a mathematical school and lectures is also nearly completed. The new lodge and gateway at the end of the Long Walk Wall is the subject of some criticism, but with its small octagon turret makes a handsome addition.

At Orleansville, in Algiers, a beautiful antique marble bust in fine preservation, has been discovered. Other excavations are going on there.

The bronze statue of Molière was this week placed on its marble pedestal on the fountain at the end of the Rue de Richelieu, at Paris.—The Council General of the Seine has determined on publishing the ancient works, manuscripts, accounts, &c., which it possesses relative to the customs of Paris, particularly the curious book of Trades of Boyleau.—M. Marochetti has just finished his equestrian statue of Napoleon. It is said that it will surpass all his former works.—The hotel Pontalba, next to the English Embassy, and one of the most magnificent private residences in Paris, has just been completed, it is by M. Visconti in the style of the interior court of the Louvre, constructed by Perrault.

A new hospital of 600 beds is to be erected at Paris, for the northern districts, in the Clos St. Lazare, the plans are by M. Gauthier.

The church of St. Severin, at Paris, one of the finest, is being completely restored, and in particular its curious tower. Some new sculpture is much admired, and particularly a Descent from the Cross. The new church of St. Vincent de Paul, at Paris, is making much progress, and will be completed by the 15th June. The whole of the external works are completed.

We are sorry to learn that the Hotel of the Minister of Foreign Affairs at Athens has been burned, and that an attempt was made to set fire to the Hall of the National Assembly, which fortunately did not succeed.

The postmasters on the Orleans, Rouen and Strasburg roads have sent in a complaint to the French ministry of the losses they have sustained from the railways, and the impossibility of carrying on their contracts. The ministry have promised them some relief in the ensuing session.

It is again reported that the Upper Silesian Railway is to be connected with the Austrian lines, and that the necessary arrangements have been made by the two governments.

In some excavations on the Augsburg and Donauwerth Railway works, a most interesting discovery has been made of tombs of the first four centuries of our era, belonging to the Celts, Romans and Germans.

A house has been built at Lyons in the Edinburgh style of twelve stories on the side of a hill. It is looked upon as a kind of giant.

A new church is to be built at Berlin, by voluntary contributions, in the Exercier Platz.

A new bath is to be erected at Bagneres de Luchon, by the town council, at a cost of £18,000. It is to be worthy of comparison with the buildings at the German Brunnen.

On the archæology of public monuments a course has been opened in the military school of St. Cyr. This might be well imitated in England, but we have nothing of the kind, not even in our Royal Academy of Arts.

INSTITUTION OF CIVIL ENGINEERS.—SESSION 1844.

January 9.—The PRESIDENT in the Chair.

THE first meeting of the season was held on Tuesday evening 9th instant. During the recess several alterations have been made in the rooms of the Society: along the sides of the gallery have been placed some handsome cast iron open work shelves, and brackets cast and presented by Messrs. Ransome and May of Ipswich, for supporting a series of busts of eminent engineers, and scientific men. The theatre which was formerly oppressively hot, and but dimly lighted, has now two gas lights placed near the ceiling which throw a powerful light into all parts of the room. The products of combustion are carried off by the open-jointed telescopic tubes which have been applied by Professor Faraday to lighthouse lanterns, and were described by him at a meeting of the Institution last year. This system of lighting and ventilation, which was, we understand designed by Mr. Manby, the secretary, appeared to be perfectly under control, and was very satisfactory in its effects.

The following papers were read.

1. By Mr. JOHN STOREY, descriptive of *a combination of Cast and Wrought Iron used in some Bridges on the line of the Bishop Auckland & Weardale Railway*. A general review of the usual construction and expense of occupation bridges of brick, stone, timber, and cast iron was given, showing their defects. In order to obviate these objections the author has introduced combined trussed beams of cast and wrought iron, which he contended might be advantageously adopted, and that bridges could be thus constructed at a less cost than those of stone, brick, or even of timber. The structure described consisted of longitudinal segmental girders of cast iron, resting on masonry abutments: a system of wrought iron tie trussing was applied, and struts were placed where requisite, to receive the pressure: when more than one principal truss was necessary, they were connected by transverse braces, and distance pieces of cast iron: sockets being cast upon the girders to receive the timber joists upon which Dantzic timber planking was spiked. The communication was accompanied by five drawings, illustrating in detail the various modes of construction treated of, with estimates of the expense as compared with ordinary bridges of similar spans, whence it appeared that the cost of the former was much less than that of the latter.

2. By CAPTAIN W. S. MOORSOM, Assoc. Inst. C.E., descriptive of *a Cast Iron Bridge over the Avon, near Tewkesbury, on the line of the Birmingham and Gloucester Railway*. The principal novelty of this work, which was proposed, and its execution superintended by Mr. Ward of Falmouth, is the mode of constructing the two piers, which were externally of cast iron in the form of caissons, each weighing about 28 tons; the plates composing each caisson were put together on a platform erected upon piles over the site of the pier, the bottom of the river being levelled by a scoop dredger, the caisson was lowered, and some clay being thrown around the exterior, a joint was formed so nearly water-tight, that two small pumps drained it in six hours. The foundation being thus excavated to the requisite depth, the caisson, which sank as the excavation proceeded, was filled with concrete and masonry; cap plates were then fixed for supporting eight pillars with an entablature, to which was attached one end of the segmental arches 57 ft. span, with a versed sine of 5 ft. 2 in. There were three of these arches, each formed of six ribs of cast iron, and two such piers as have been described, the land abutments being of stone-work joining the embankment of the railway. It was stated that this mode of construction was found to be more economical in that peculiar situation than the usual method of fixing timber coffer-dams, and building the piers within them; the total cost of the bridge being only £10,192, and the navigation of the river was not interrupted during the progress of the work. The paper was illustrated by eighteen remarkably well-executed drawings by Mr. Butterton.

3. A paper by Mr. G. W. HEMANS, Grad. Inst. C.E., descriptive of *a Wrought Iron Lattice Bridge erected across the line of the Dublin and Drogheda Railway* was then read. This bridge, which in construction is similar to the wooden lattice bridges of America,[1] only substituting wrought iron for timber, is situated about three miles from Dublin over an excavation of 36 feet in depth; its span is 84 feet in the clear, and the two lattice beams are set parallel to each other, resting at either end on plain stone

[1] [The original inventor of the lattice bridge, was the late Mr. Smart, of Westminster Bridge Wharf, Lambeth, who many years since took out letters patent for the principle.—EDITOR.]

abutments built in the slope. These beams are 10 ft. in depth, and are formed by a series of flat iron bars $2\frac{1}{2}$ in. wide by $\frac{3}{8}$ in. thick crossing one another at an angle of 45°; at 5 ft. 6 in. above the bottom edge, transverse bearers of angle iron are fixed similar to those now used for supporting the decks of iron steam vessels, and upon those the planking for the roadway is fastened. The account of the mode of construction, and of the raising and fixing the lattice beams, by Messrs. Perry of Dublin the contractors, was given in detail, and the author stated that, although it was expected that considerable deflection would occur, which was provided for by forming the beams with a curve of 12 in. in the centre, they did not sink at all even when heavy weights passed over them. The total cost of the structure, including the masonry of the abutments was £510. It was stated that this bridge had been erected by Mr. Macneill, M .Inst. C. E. in order to test the soundness of this kind of structure before he applied it in a bridge of 240 ft. span to carry the Dublin and Drogheda Railway over a canal.

The meeting adjourned to January 16th instant, when it was announced that the Annual Meeting would be held for the election of the council and officers.

ARCHITECTURE.

Report of a Course of Lectures delivered by Professor Cockerell, *at the Royal Academy.*

(Specially reported for this Journal.)

Lecture I.

Mr. President—The fine arts, whether they are regarded as an intellectual gratification intimately connected with mental advancement, or as the noblest recreation of which our nature is capable, should always be a subject of the highest importance amongst a polished and civilized community; and the Professor, however arduous and responsible his duties may be, will hail with satisfaction the returning season of his labours as a public and private benefit, so far as he may have it in his power, to illustrate his art by sound argument and profitable suggestions: and, as a true lover of his art, will rejoice in a candid discussion of its principles, regarding such discussion as a whetstone, whereby truth may be elicited and maintained. But the art especially which I so badly represent, demands, as a peculiarly learned art, the guidance of that experience which may point out the sources of its constitution, call into exercise the reasoning faculties, and engender a deep interest in its behalf.

Under the blessings of peace, architecture assumes peculiar interest. We may daily see the happy effects arising from the encouraging sentiment of emulation; expressions of regard for architecture have become almost universal; and we can scarcely look into the public prints without discovering some evidence of this fact; parliament for the first time has promoted such works, and has given a stimulus to them, which only patronage can give to the higher works of art.

The saying of the painter Barry, that he lived a century too soon, appears to be verified in the success which has crowned the exertions of his able successor in name; and the lambent flame which this academy has kept alive through good and evil report, seems now to shine forth with greater lustre. How great then should be our endeavours to qualify ourselves for this improved state of things!

The study of the fine arts is, as has been truly stated, the study of the "true and beautiful in nature." This science engaged the attention of Plato, Aristotle, Socrates, and the ancient philosophers; the fine arts have long been studied in the universities on the Continent; and it is now, I trust, becoming general in this country. The London University has already commenced; and Oxford and Cambridge will no doubt follow. An illustrious member of Oxford, (Mr. Gracewell,) in a remarkable paper published a few weeks ago, recommends a union between literature and the fine arts, and remarks that the fine arts being founded on the unchanging moral and intellectual nature of man, admit of being taught as dogmatically as the principles of any other science. In this respect they are unlike the useful arts; but when the useful arts have procured us the necessaries of life, the fine arts are found equally essential to enjoyment. Apollo and the Muses are only gifts to such a state of society, whilst they tend to check the progress of avarice, pride, and the other vices which follow in their train.

The arts will hail the proposition of Mr. Gracewell. Such a system, and in the hands of scholars, will go far to establish a respect for those branches of learning, and by thus uniting the elegancies of literature with those of art, each will illustrate the other; and by this means employment and amusement will be found for a large portion of society, who but for such a unity would regard the arts as toils.

The union of literature is obviously essential to the fine arts, and it has been ever so since the days of Socrates. The Grecian arts excelled through this circumstance. Many of Jocko's inventions were taken from the suggestions of the poet; so with Raphael and Reynolds and others, in whose works the suggestions of the poet may clearly be traced. Reynolds no doubt derived many ideas from conversation with Burke, Johnson, and other *literari* of the day. But whilst we leave to far more accomplished scholars the discussion of the fine arts, we have practical studies which we must endeavour to obtain and understand as the means of acquiring that greatest of all blessings, sound judgment.

We know, that like good taste and virtue, sound judgment depends not upon argument, syllogism, or sophistry, but must be cultivated by a beautiful and dispassionate revision of the best specimens of art. Philosophical discussions upon the sublime and beautiful will always be valuable as one of the means of instruction; but the subject is so subtle that it is not to be circumscribed by language, however logical. It is after all to genius we must look for the exact adjustment of those qualities on which the beautiful depend. The artist may lay down incontrovertibly his principles of art, but their adoption in particular proportions may not always succeed. To the practical student only belong the scruples and the grains of proportion, and it is in labour only combined with genius that the philosopher's stone is to be found by the artist. (The Professor here referred to some works of art by Palladio and Peruzzi, to show that where to apply the great principle of order was peculiarly the province of the man of genius, and was only to be decided by him.)

The speculative part of the fine arts, without the assistance of manual operation, can never attain perfection. Each department of art is of sufficient importance to occupy the whole attention of one man, but it is essential in an art where so many details are involved, that the student should occasionally be awakened to an enlarged view of the subject, and it is for this purpose that I have in former lectures taken extended views of the history of our art, and directed your attention to the magnitude of its extent; for to know what has been done, is to know what can be done. Charles V. said well that a man who possessed many languages, became, in fact, multiplied into many individuals, and enjoyed in an increased degree the privilege of existence. And the same remark might be applied to the architectural historian, whose experience teaches him the peculiarities of different nations, and points out to him the propriety or otherwise of peculiar applications to particular circumstances.

We are thus led to consider the practice of the fine arts, as but another language by which the moral and political subjects of the day are modelled and expressed: and as the literature and language of one period are not applicable to another age, so is it with the practice of the fine arts. For instance, imagine the republication of the *Nuremburg Chronicle* of 1492, as the journal of science of the present day; or of the works of Gore, Spenser or Chaucer, for the entertainment of the readers at the West-end of the present day. To follow the same principle in the fine arts would be equally preposterous.

When Edward III was engaged in his palace at Westminster, he granted a precept to—it might be the president of that day—compelling him to press all the painters throughout the country to go and assist at 1*d.* a day. Now let us suppose an officer despatched by Her Majesty on a similar expedition—to procure painters at 1*d.* a day; what an amusing exhibition should we not have! What complaints! What paragraphs in the newspapers! What petitions to the Commons House of Parliament! Thus we find the practice ever varying, though the principles remain the same. We admire the works of Chaucer, Gore, and Spenser, but it is the intrinsic beauty of their poetry that we admire, and not the language in which it is dressed: so we should be as glad to receive a commission now as in King Edward's time, but it is the compulsion at 1*d.* a day that we should not like.

I have also in preceding lectures recommended the study of those repertories of the experiments of past ages, which whilst they improved the understanding, proved the consistency of those great principles on which our art is built. Through the means of literature we may discuss the utility of popular conceits, and we thus arrive at those things that have received the praise of succeeding ages. When we consider, for instance, that Vitruvius composed his rules upon the science of the Greeks, good sense would seem to inculcate a respect to such rules; but such respect has not been awarded to them: for myself, however, I can only say, that my daily experience enforces upon me the greatest respect for his authority.

The Pantheon at Rome is a systyle; now M. Souplot has presumed to depart from the practice, and has made his portico merely diastyle, and the consequence of this startling diversion is, that the portico is meagre and unsatisfactory. I cite this instance only as proving my position, that respect should be paid to the theories and precepts of great masters if they are found to coincide with common sense and good practice.

Last year, when the Parthenon was cleared of the ruins, and some of the columns were exposed, it was found that there was a gradual rising of the columns of the central flank, so that the flank formed the arc of a large circle, and not a straight line from east to west. And this is in accordance with the principles laid down by Vitruvius, for, he says, if they be set out level they will appear to have sunk. This rule, however, has not been followed out at the important national work of the church of La Madeleine at Paris, and elsewhere. Let us inquire now of experienced builders, and we shall find 500 who know not so much as the name of Vitruvius, who will tell you when you build a barn, "be sure to make the roof hog-backed, for if you set it out level, it will look as if it had fallen." So says Mr. Harvey, a most respectable builder of Ipswich, and indeed I have heard it from my youth upwards; and thus we find that theory and experience agree. The professor in every art, is well justified in repeating to his students, the advice he has given to them to follow the principles and precepts of great masters without hesitation; if the practice appear strange, still, hesitate not; when you have tested the principles by practice, you will find their advantage, and will learn from time the reverence they deserve.

In enforcing this principle, Pope beautifully observes:—

"You then whose judgment the right course would steer,
Know well each ancients' proper character;
His fable, subjects, scope in ev'ry page,
Religion, country, genius of his age."
"Thence form your judgment, thence your maxims bring,
And trace the Muses upwards to their spring."
"When first young Maro in his boundless mind,
A work to outlast immortal Rome design'd,
Perhaps he seem'd above the city's law,
And but from nature's fountains seem'd to draw:
But when t' examine ev'ry part he came,
Nature and Homer, were, he found, the same;
Convinc'd, amaz'd, he checks the bold design,
And rules as strict his labour'd work confine,
As if the Stagirite o'er-look'd each line.
Learn hence for ancient rules a just esteem,
To copy Nature, is to copy them."

By literature then, the student will discover the consistency of great principles in art, and the conformity evinced by all the best authorities, whilst he will detect the fallacies of many pretenders, and the filchings and borrowings of ambitious authors.

In my last course, I invited you to consider this matter attentively, and, above all, I enjoined you to avail yourselves of every opportunity of seeking the best works, and of recording your opinion of them, always under the conviction that success must depend upon yourselves. I have referred to those preceding lectures: 1st. Because they apply only to the practice of the fine arts as they present themselves to the eye and the understanding, in which department these studies are essential. 2nd. Because the mathematical principles of an art form but a part of our consideration, and 3rd. Because the limitation of these lectures prevents our going over those grounds again, and requires that we should take a new line every year to fill up the measure of their utility. But I must remind you that though the lectures of this institution are unavoidably limited, that deficiency is greatly diminished by the liberality of other institutions. I refer more particularly to the London University and King's College, where the accomplished Professors give lectures almost weekly upon all the arts and sciences. You must be led to practice these arts before experience can be gained. Genius is a gift; and invention, nature only can bestow on us; but, be it remembered, that taste is the offspring of learning and a just education, and is always more or less within our power.

Let us now consider for a moment the present state of our art, and what is going on in this country. The actual state of architectural taste in Europe is remarkable. Since the revival of learning in the 15th century, the supremacy of Greece and Rome was readily admitted. Dryden and Pope had promulgated those laws which were regarded as the standard of good taste, all seemed settled, and no one ventured to doubt the prevailing sentiments, and the pursuit of taste in the best circles had acquired the utmost popularity. This was sustained by the writers of the middle and last century, but gradually lost its ascendancy before the great convulsions and political struggles which disturbed the empire at the end of the last century. Universal scepticism was raised upon all heretofore received doctrines; the test of reason was applied to every pursuit, and some artists whose critical works have had an effect upon our art, applied the doctrines of Bentham and the utilitarians. M. Duront, a respectable lecturer for many years at the Polytechnic Institution at Paris, refers all the problems of architecture to utility. He says there are no absurd rules of proportion that can be generally applied, because every building must differ in its wants; all features of which the use is not apparent, he proscribes. He abandons the base of a column as superfluous, when a column is built upon a column; for says he "has it not been proved that the base is not necessary for strength;" he proscribes all ornament in the structure, and recommends nothing that is not required to produce convenience, solidity, salubrity, regularity, and simplicity. Such were the doctrines that affected our art, as well as the political and social world during those years, which brought us to that startling simplicity from which we have now happily revolted. Heresies and latitudinarian views are as dangerous as the utilitarian doctrines. The student doubts if there be any fixed principles, and sighs for something which may satisfy that inborn desire of the mind for some standard of excellence to which he may refer.

It was extremely natural, on the recovery of Europe from the desolation of war in 1814, that we should deplore our sad departure from the rules of the fine arts, which were formerly in general acceptation. Long unused to that refined criticism, which experience can only arrive at, no wonder that we should fail to distinguish the good from the bad in former models, and should seize all that was presented to us. Like the youthful appetite, which swallows voraciously whatever has the semblance of nourishment, the artistic mind of Europe, during the last 30 years, has been wholly occupied in digesting those materials, and there is scarcely a school which has not been canvassed, criticised, and reproduced. This is on the wane, and Europe's mind is bent on asserting its own right to think and act for itself. To study departed excellence too intimately only extinguishes natural genius, and we become copyists, sinking under the errors of those we copy. We become mannerists instead of originalists. If there be no originality there can be no improvement; if no deviation from existing models, there can be no progression: whilst, to be original, is to escape from bondage, and at least to acquire the possibility of being superior. To these reflections may follow the inquiry, "But if we cease to follow existing models, how shall we find that exceeding skill which we do find?" This is a question I cannot pretend to answer, other than by saying that when you have a work to invent, you should put away all former notions; be animated only by the wants and requirements of the building, the materials to be procured, and the *genus loci*. Then let your invention proceed upon a natural view of these elements, without servility to any existing model.

Pedantry and ignorance are the two great enemies to the progress of our work. The pedantry of this age in architecture, arises from a small idea of the importance of the art itself. It has not been deemed of that essential importance to the character of the state, in which it was formerly held. Before the all-engrossing importance of war, or other vast operations affecting society, pedantry takes flight.

We must qualify ourselves for our profession by study and experience. These courses once gone through, we must exercise our own genius. The great captain of our day has no doubt studied every military tactic from Sesostris to Vaubau, but he never for a moment thought of resorting to any of those tactics in the achievement of his glorious victories; his only thought was how to suit his means to the necessity, his materials to the case, and the *genus loci*—and then his operations proceeded.

On his side, your Professor has felt all the importance of his duty, in the deep conviction that, however humble the seed he may sow in good soil, it may grow into a great tree, whose branches may extend to distant lands. He must bear in mind that he is acting amongst the richest and most powerful people in the world; that England's sons cover not only this land, but the continents of America and Asia, with their works, which do homage to the superior education and skill of Britain. Often we may see the most magnificent works in those countries raised from some office in this metropolis—some individual who may have derived his instruction from Sir John Soane or Peter Nicholson, and have carried his experience, and the superior learning of this country, into the presence of the autocrats and potentates of foreign countries; thus verifying the words of the prophet, "Seest thou a man who delighteth in business, he shall stand before kings." England, indeed, is like a great hive, from which the bees swarm, and carry honey into other lands. Two remarkable instances occur to me of this fact. Mr. Ladrone, a pupil of my father's, sent me, some years ago, the plans of the capitol of Washington, which was built by him. M. Montferron, at that time a young man of no repute in Paris, is now architect to the Emperor of Russia, and is engaged in building the church of St. Isaac. This is a magnificent structure; the section of the portico is like St. Paul's, but it is made of iron, and is contracted for by Mr. Baird.

Your Professor, then, considering the great importance of his duties in this respect, must omit nothing which his own, or the experience of others, has taught him. To interest you, therefore, he endeavours to acquaint himself with the movements in those nations which are before us in the fine arts. It is on this account that he visited our neighbours in Paris last year, and those on the Rhine this year, because, with the nature of their habits, they are more addicted to follow the fine arts than ourselves. With the blessing of peace greater public works have been accomplished there than here, and there the most liberal patronage is bestowed upon all the followers of the fine arts, whilst this country labours under the incubus of a national debt.

I purpose, in the present course, to direct your attention to the fashionable architecture of the day, and to refer to the much discussed subject of church building. These fashionable buildings in a country arise from many remote causes, which it is difficult to recognize—such as the moral condition of the people, their habits and government, the poetical vein of thought which prevails, politics, religion, &c. And the fashions change greatly with the age. When I first entered the profession, the Egyptian architecture was esteemed the most beautiful. We are not so susceptible of *mode* here, as our Gallic neighbours; but in France there was not a chimney of that day that was not covered with hieroglyphics, or shaped like a mummy. After that the Indian architecture prevailed, and George IV. adopted it in his pavilion at Brighton. And so on.

Such fashions will ever prevail, and certain deference must be paid to them, but in this fashion, as in dress, the weakest will take the extremes, whilst the prudent will only show a certain degree of conformity to it. I would suggest to the students that it is always necessary to refer to what may be called the tributary streams of art, for aid and assistance—especially to our Universities. The example of the accomplished Master of Trinity College, Cambridge, has been followed by a society not inferior in zeal, and it has taken the science of church building under its especial protection, on which subject it promulgates laws from head-quarters with the greatest confidence; and we can have no stronger proof of the favour in which our art is held, than the success which has marked the progress of the Camden Society. These gentlemen have limited their views to one style of architecture, and admit none other worthy to be used in a Christian church. They shut out all the rest of the world from their privileges, and adopt the architecture of the 13th century as the best adapted to this holy subject of church building. We admire the singleness of these gentlemen, so far as it goes, and shall endeavour to revive this subject in order to give a fair view of the matter, but not for the purpose of retaliating on those gentlemen terms which have already driven from the society the Bishop of London, the Bishop of Armagh, Professor Willis, Professor Sedgwick, the Master of Trinity, and others; and the students will find in this renunciation of the doctrines of the Camden Society, the danger of relying on such authority.

ARCHITECTURE.

Lecture II. By Professor Cockerell.

(Specially reported for this Journal.)

The Professor, who intimated in his last lecture that it was his intention to refer more particularly to church architecture commenced by remarking that the intimate connexion of religion with their art, threw, as it were, a veil of sanctity over all their proceedings. The most illustrious professors of the art were remarkable for their piety; they were wont to have solemn masses, and to offer up prayers upon the commencement of any great undertaking. "Unless the Lord build the house," said they, "we labour but in vain." That Sir Christopher Wren was fully conscious of the sanctity of the undertaking in which he was engaged when building St. Paul's Cathedral, was clearly evinced by an order which he had exhibited over the building, prohibiting the use of oaths amongst the workmen upon pain of instant dismissal. It was indeed a fact, that whilst an acquaintance with many branches of learning induced to scepticism, the study of the true and beautiful led to piety.

It had unfortunately happened that hitherto we had had no original style of architecture suited to the ritual and formularies of the Protestant church. In the 16th century our churches were made copies of the then existing Popish churches, and these forms had been perpetuated up to this very day. The time, however, would shortly come when Protestant churches should have a style of their own more suited to their worship, and more lovely than the mother whence they sprung. "*Mater pulchra, filia pulchrior.*"

The commissioners appointed in the reign of Queen Anne to inquire into the matter of church architecture had succeeded in leaving some beautiful specimens of their taste, but they spent upon eleven churches what was meant to serve fifty, and otherwise did not perform their duty as could have been wished. Such an enormous outlay and such a departure from duty thereby involved could not have occurred in France, where the government took such matters under their special cognizance and protection, for the Institute would at once have been consulted, who would have reported to the Ecclesiastical Commissioners the course most proper for them to pursue. In our country it was a most melancholy fact that whilst other subjects of far less importance constantly received the supervision of the state, such matters as these were entirely left to chance—to the accident of learned men, or otherwise, who might preside at the time. The consequence of such a system was the perpetuation of enormous heresies in art.

Since the 16th century then, the form of the papal temple had been retained, and the basilica of the western world had been retained with it; and how deeply rooted was the feeling in favour of the basilica, might be imagined from the fact that almost all the churches of the present day were in that form.

The Camden Society had decided upon the pointed style of architecture of the 13th and 15th centuries, as the best adapted to Christian churches. That that style exceeded many others in boldness of design, it was not to be denied, but that it excelled in suitableness to the ritual, was a very questionable point which it would be desirable to discuss; and, in doing so hereafter, he should direct the attention of the students to the plan and distribution rather than to the elevation; to the fundamental system of the structure appealing to the understanding, rather than to superficial forms appealing only to the eye. The Camden Society seemed to catch at that which was gratifying to the eye, whilst they passed over the more important details which recommended themselves to the understanding. The amateur generally, indeed, understood by architecture, the elevation only, but the intelligent architect regarded the disposition and the plan as the two bases of his work.

The forms of churches employed by Constantine were four. 1, The basilica; 2, The circular; 3, The octagonal; 4, The square or oblong. There were 18 basilicas in Rome, and St. Augustine introduced that form into this country in the year 596.

The second form was employed by St. Helena, the mother of Constantine, who was a native of York. That form was probably adopted from the tomb which she built at the holy sepulchre, and was in pretty general use until the dissolution, in 1312, of the Knights Templars' body, who employed that form in imitation of [the sepulchre of Christ, which they were appointed to guard. The octagonal form was also employed by Constantine, in Antioch, of which the church in Aix-la-Chapelle, by Charlemagne, was no doubt a copy; and this form was admirably adapted for the purpose of separating the male and female worshippers, as was then customary. Its adaptation to our ritual was well exemplified in the church of St. Dunstan, in Fleet Street, by Mr. Shaw.

The Fourth form, a square, like the basilica, was divided into three parts, having a nave and two aisles, and the centre of the nave was surmounted by a dome. This form was called *indronicâ formâ.* It was remarkably well suited to the protestant ritual. It was still employed in the Greek church, sometimes tetrastyle, and there were also a great many of that form in Germany. The four columns supporting the dome were, according to some writers, symbolical of the four evangelists. It was customary to run up these domes to a very great height; Eusebius says of Constantine, "*ad summam altitudinem, erexit, &c.*" Two principal types now contended for the pre-eminence, the Basilica, and the Byzantine, or vertical type. The Byzantine appeared best suited to us: as in the Byzantine style, we required galleries; but our ritual did not require the long nave and aisles through which the Roman Catholic was accustomed to view the Host. Pillars were an obstruction to the ritual of our church, and the fewer the pillars the better. With regard to the exterior, in his opinion, a large dome on the centre of the church, with smaller domes clustered around, afforded a very beautiful view. Our own church of St. Stephen, Walbrook, was a remarkable specimen of the beautiful grouping of domes, but it was unfortunately almost entirely hid from the gaze by the buildings with which it was surrounded.

The fact of the Russian churches being generally built after the Byzantine type furnished another reason in favour of that form, for the Russians were early converted to Christianity by missionaries from Constantinople, where the Byzantine form prevailed.

A glorious opportunity was offered by the Fire of London for suiting the temples of Christians to the uses and rubrics of our church. The matter was entrusted to the learned Archbishop Sancroft and Bishop Compton,—than whom, perhaps, no better qualified persons could have been found,—and aided by the immortal Wren, they left some beautiful models, as a living testimony of the genius with which they were inspired. One great reproach, which must adhere to Wren, was his modesty, which prevented his giving publicity to the principles by which he was guided in the execution of his works; had he left behind him any principles upon which he himself acted, they would most assuredly be regarded as canons by the students of the present day.

The learned Professor concluded his lecture by referring to church nomenclature. He thought that the cardinal virtues and graces might well be applied as the names of churches. The ecclesiologist appeared to be hard pushed for names, when he recommended such a one as St. John Pantiana, which, says the *Ecclesiologist*, "Though an uncommon, is a very beautiful name." If euphony were all that was cared for, it would be easy enough to find plenty of pretty names; but he thought something more should be aimed at than a mere pleasing sound.

[We had hoped to have afforded our readers much gratification by publishing the lectures of Professor Cockerell on this highly interesting subject at full length, as we did in our last number with his first lecture. Professor Cockerell has, however, intimated to our reporter that it is not his desire to have his lecture fully reported, and has given him to understand, that an attempt at a *verbatim* report in future would cause his exclusion altogether from the course. We are consequently enabled this week to do no more than present our readers with a very faint outline of the Professor's second lecture; and as that gentleman does not object to the publication of a brief abstract, we shall, with his kind permission, publish his remaining lectures in that form. We very much regret that we shall thus be precluded from presenting to the public his very admirable expositions of the art which he so ably represents.—Ed. C. E. & A. Jour.]

ILAM HALL.

Sir—There should be no occasion for making this inquiry, as the information should have been supplied by the account which induces me to seek further particulars relative to what appears to be a superior specimen of its kind. Ilam Hall, Derbyshire, the seat of Mr. Watts Russell, is said to have been erected "a few years ago," and to be remarkable for the "happy unison of both exterior and interior magnificence" displayed in it; the entrance hall and armoury being "finished off" in oriental magnificence. Nevertheless, there is nothing further said to bear out such character, nor are we told who was the architect of so superior a work, although his name might very well have been mentioned, notwithstanding the "want of space," which seems to be the never failing excuse for withholding matters of positive information, perhaps at the very same time that the writer is evidently ekeing out his paragraphs with more twaddle or fustian—as is the case when we are told that "what renders the charm still greater, is the perfect feeling of domestic comfort which remains unsullied by the grandeur which surrounds us." The idea of being "unsullied by grandeur," is certainly a new one. What description there is of the mansion is given only in a coarse and vilely drawn lithograph, which, however, serves to show that the structure is chiefly in the Elizabethan style, unusually picturesque in outline and in the grouping of its parts. Beyond this, nothing is to be made out, all besides being left to the imagination—to be shaped out for themselves by those who can perceive what beauties of detail and execution such a subject is capable of.

I would, therefore, fain elicit from some one of your readers, should any of them have visited the building—or from the architect himself, should this meet his eye, a more satisfactory and intelligible account of it. For anonymousness in architecture no reasonable motive of any kind can be assigned; certainly not, where a building would reflect credit upon the name of its author. Even the paltry lithograph view above-mentioned has the name of the *artist* boldly stuck at one corner of it; therefore, *he* is evidently neither ashamed of his handy-work, nor at all loth to receive whatever fame it may bring him.

I remain,

Yours, &c.,

Inquirer.

THE JOINT RAILWAY TERMINUS, LONDON BRIDGE.

Sir—Observing a paragraph in page 454 of the *Journal* for January, professing to correct the statement in the *Journal* for December last, describing the works of the new joint railway station at London Bridge, the object of which appears to be to produce the impression that the design for the façade building did not emanate from the writer, I rely on your high sense of justice and impartiality for the insertion of the following particulars, which will explain the circumstances under which the design was produced, and remove any misconception which might arise from the ambiguous wording of the paragraph I allude to.

Soon after the commencement of the proceedings, Mr. Roberts became seriously indisposed, and was laid up for several weeks, just at a time when it was extremely important that the plan and elevation of the façade building should be definitely settled, in order that the substructure works then executing by the Greenwich company should not be delayed, and should be adapted to receive that portion of the superstructure of the façade building, hereafter to be raised upon it; and on this account it was, as well as on account of the deficiency of accommodation in Mr. Robert's original plan, that I was directed in the preparation of an entirely new plan, laid out on the principle of providing distinct waiting rooms for first and second class passengers, which of course involved the necessity for a new elevation for the façade, which I was also directed to prepare, in composing which, however, I was left entirely free as to the choice of style and mode of treatment, being confined only as to the height of the building by an agreement previously existing with St. Thomas's Hospital. It was considered desirable that the design should also comprise the new booking offices of the Greenwich Railway company, so as to form when completed one uniform elevation, and on presenting it to Mr. George Smith, (the architect to that company,) it was readily adopted by him as to its distinctive features, and subsequently with the addition of the campanile, designed by me, and a slight increase in the height of the principal building, (which it was afterwards discovered could be obtained,) the design was finally approved by the boards of the joint station committee, and of the Greenwich Railway company; and it was not until some time after this that Mr. Roberts was sufficiently recovered to resume his official duties.

With respect to the details, which it is stated in page 454 "were left more immediately under the direction of Mr. Roberts," it is true that by his particular desire the fret in the lower frieze was introduced, square balusters used instead of round, the centre console under the balconies, and the vases upon them left out, and rustic quoin stones added to the south angle of the parcels office; with these exceptions every detail has been executed as originally designed by me. Under the circumstances it was to be expected that opportunities for alteration would be sought for; whether these alterations are also improvements may perhaps admit of question, and I have mentioned them that your readers may form a correct opinion as to their extent and value; but if the original conception of an architectural design, and of its details as actually executed, can confer a propriety in it, I think there can be but one opinion as to whom that propriety in the present instance rightfully belongs.

I am, Sir,
Your very obedient servant,
Thomas Turner.

13, *Judd Place East, New Road,*
January 11th, 1844.

SIR JOSHUA REYNOLDS.

Sir—On the 26th of December, it was asserted by the *Times*, in a review of Sir David Wilkie's life, "*That Edmund Burke touched up, if he did not write, the best of Sir Joshua's Academy discourses.*" I knew the folly of this exploded suspicion, and I wrote a temperate letter to the *Times* stating the origin of the injustice, and the reasons to conclude there was no foundation for it. The *Times* announced "*they saw no reason for publishing Mr. Haydon's letter.*" Now there was every reason for doing so, because it was an unjust accusation, and it was the duty of the editor to publish the reasons against it. Owing entirely to the ignorance of the nation as to the degree of intellect required to be a great painter at the time this calumny was first started, do I principally attribute that it was so innocently believed, for what was the foundation of it? The insinuation that Reynolds was imperfectly educated and could not have written so well.

It is well known there existed about 50 or 60 years ago, a writer, under the anonymous name of Antony Pasquin, who used to obtain money by threatening disclosures: he got hold of two or three letters of Reynolds', which he asserted Sir Joshua wrote to a lady from Minorca, during his voyage to Italy, and that the spelling was bad: on this discovery the suspicion is founded, not considering that if the letters were genuine, spelling badly was no evidence of not being able to think originally, for many of the greatest men of the last century were very bad spellers. Sir Joshua candidly alluded to the suspicion of being helped by his friends, but he denied it positively, yet acknowledging he had benefitted by their conversation, for says he in his papers published by Malone, "the observations they make on poetry and philosophy I applied to our art, with what success I leave you to conclude."

Reynolds' love of truth was proverbial, and if this had not been the real fact he would have scorned the affirmation. Malone says he was asked "if the discourses were not found in the hand-writing of other people after Sir Joshua's death;" he replies, "none whatever," and four he found warm from the brain in his own hand. Malone concludes, "I am as fully persuaded the discourses were wholly composed by Sir Joshua, as I am certain at this moment I am employing my pen in vindication of his fame." Reynolds affirms he wrote his own discourses. Pasquin insinuates he did not. The evidence then rests on the relative credibility of two men, and which ought the world to believe? Pasquin, who was hunted from society, as a literary assassin, and died from a beating he got from an exasperated man of honour, or Reynolds, whose whole life was devoted to integrity and a virtuous employment, whose word was his bond, who died regretted by society, and was followed to the grave by the most distinguished men of the day! The question must not be asked, it is an insult. "Few eminent artists have written well," says the critic; this is not justly stated—few artists have written at all: but those who have, have written well, viz., Apelles and Euphranor, Michael Angelo and Leonardo, Rubens and Reynolds, were all eminent, and have all written well.

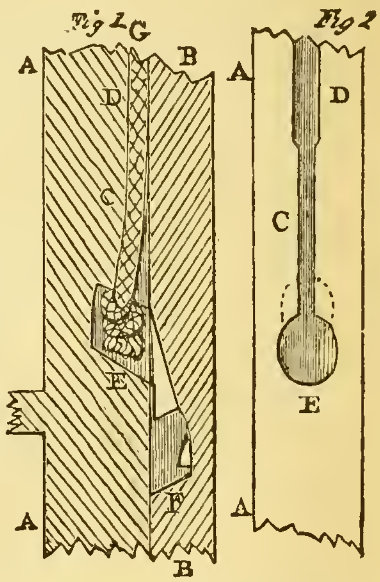
To conclude, it is not too much to say, Burke could not have written the discourse, the style is so pure, nor could Johnson. The style is an emblem of Reynolds' own nature, modest, calm, unaffected, and beautiful; they were the deductions of his own mind, and written by his own hand, and it was not just of the *Times* so to assault the illustrious dead and then refuse his justification.

B. R. Haydon.

London, Jan. 11th, 1844.

SASH-SUSPENDER.

For which the Silver Isis Medal of the Society of Arts, London, was presented to Mr. Jabez Osborn, and reported in their Transactions.



The ordinary mode of hanging window-sashes is by nailing the suspension ropes to the sides of the sash, which practice is very inconvenient when it becomes necessary to remove the sash from its frame, either for the purpose of repairing or cleaning it; both the woodwork of the sash and the line itself are destroyed by the nails, if the sash is frequently removed for either purpose. Mr. Osborn's plan entirely obviates these objections.

Fig. 1 is a section of part of a sash A A and frame B B, in which it slides as usual. Fig. 2 is a side view of the sash.

When the sash is in use, the line D C is attached to it by a knot in the end of the line being inserted in a hole sloping upwards, as at E, but when it is required to move the sash from its frame, the line D C is let into a groove in the frame, and the knob placed in an aperture F (fig. 1) similar to the aperture in the sash.

THE CONCILIATION HALL, DUBLIN.

Sir—Having read the "Observations on Architects and Architecture," by Dr. Fulton, in the *Journal* for the present month, I beg to correct an error relative to the above fabric into which he has fallen. Although I am quite ready to bear testimony to the justice of the *strictures* he has passed on the "offspring of a Martin," still I wonder how a person of such good taste as the Doctor, could commence without *nausea* to *operate* on so illegitimate *a subject for dissection:* or waste his time *analysing a mass* of incongruities such as every one was prepared for who had heard of the *undertaker* to whom the *laying out of the body*, and the construction and decoration of the *shell* were entrusted.

There was not any competition invited, and consequently no "committee of selection" appointed to decide on the merits of a design, or the fairness of an estimate, (the contractor in this case being the architect,) the Mecænases of the Corn Exchange deeming such things unimportant, when *neglected genius* was to be encouraged, and one of the fraternity advanced; such noble minded disinterestedness is worthy of the men who aspire to create a "national school of art," however the policy of insulting the whole profession may be questioned. For myself, I had every hope that the *contractor and architect* for the Conciliation Hall would prove worthy of his patrons, and fully realise the expectations they had formed of his abilities, and no doubt when the union is repealed, they will find in the *veteran undertaker* a person every way qualified to *undertake* the high office of "Surveyor-General of Public Works for the Kingdom of Ireland."

G. D.

Milford, Jan. 13*th*, 1844.

PACIFIC STEAM NAVIGATION.

Mr. Wheelwright's *Report on Steam Navigation in the Pacific, with an Account of the Coal Mines of Chile and Panama.*—1843.

If a proof were wanting of the extended nature of our steam navigation and commercial interests, it would readily be found in the prominent subjects of discussion at this moment, in connexion with transatlantic and West Indian steam navigation, and the communication with the Red Sea, India, the Brazilian coasts, and the Pacific. At the same time that our operations are thus extended, it is to be regretted that they are not equally profitable, from circumstances which we shall perhaps, ourselves, be called upon to discuss and consider on a subsequent occasion. It is further to be regretted, at the same time, that it presents a curious feature in the history of the subject, that a violent and injurious paper warfare is going on between the projectors and the companies. As if it were not sufficient to have a contest between Mr. MacQueen and the Royal Mail Steam Packet Company, Mr. Waghorn and the Peninsular and Oriental, Mr. Heathorn and the Bahia, we have a new element of discord in the controversy between Mr. Wheelwright and the Pacific Steam Navigation Company, of which the pamphlet now under consideration is the opening protocol. We need scarcely say that we view such a combination of disturbing circumstances with sincere pain for the result; on whichever side the victory may be, it is sure to be to the injury of both combatants. Wars of all kinds are active processes of destruction, whether fought on the reeking battle field, or with the less sanguinary but atrabilarious weapons of pen and ink, and, under present circumstances, property is depreciated to a fearful extent. Of the four companies named, the shares of all are miserably below their real value, and nearly unsaleable, while a general distrust as to investment in this class of property is being gradually diffused.

The *casus belli*, in the present instance, is a simple one, and requires but to be stated to be thoroughly understood, and, in succinctly stating it, we believe we shall be doing much more good than if we recapitulated the invectives and innendoes with which Mr. Wheelwright's book is charged. Mr. Wheelwright is a fine specimen of the merchant captain, of that class to whose energies, to whose industry, and to whose researches this country is largely indebted for the extension of its commerce and naval supremacy—employed for many years in the Pacific, the desire of introducing steam navigation on the coasts of the Spanish American countries, and of establishing an active communication with this country, took strong possession of him. For a long while he laboured assiduously in this cause, and by dint of great exertion, he succeeded in obtaining from the various governments extensive and valuable privileges conditional on his carrying his plan into effect. This preliminary step taken, of preparing the local interest, Mr. Wheelwright came to this country at a most unfavourable period for such a mission, every class of enterprise and industry suffering under the severest and apparently most hopeless depression. Ultimately, however, Mr. Wheelwright succeeded in inducing some of the influential merchants connected with the Royal Mail Steam Packet Company, and with South American commerce, to take up the plan, and, in 1838, a Board of Directors was formed. At the same time, among Mr. Wheelwright's own connexion in Liverpool and Glasgow, a large number of shares was taken. After various delays in October, 1839, a contract was entered into for two steamers to be built in London, and to be named the *Chile* and *Peru*. In 1840 a royal charter was obtained limiting the responsibility of the shareholders to the amount of the shares. By this time (the end of 1840) the period was approaching, at which the privileges granted by the local governments would have expired, and it became necessary to send Mr. Wheelwright to the Pacific to obtain their renewal, and prepare for the reception of the steamers. In this mission he succeeded, and before the end of 1840, the two steamers arrived at their destinations. Here two new difficulties arose, the Royal Mail Steam Company's vessel was removed from the Chagres station, so that the Panama traffic was virtually cut off, while from the hurried manner in which the *Peru* and *Chile* were sent out, adequate measures could not be taken for the supply of coals. One cargo of 600 tons of new Welsh coal, turned out a complete failure, and injured the machinery considerably. Captain Wheelwright was here again thrown upon his resources, and set about obtaining coal from the coast. After vainly trying the rivers Maule, Laraquita, and Valdiera, Mr. Wheelwright began working the mines of Talcahuano, which he had already explored in 1834. Of these mines he obtained a lease, and soon raised large supplies of serviceable coal, of which nearly 5000 tons have since been taken at an expense of about 15*s*. per ton, while "shafts have been sunk to the depth of more than 100 ft.; machinery for raising the coal has been made, workshops built, coal screens and coal carts provided; a mole 300 ft. long constructed; a railroad formed from the working shaft to the end of the mole; a breakwater erected for the protection of the mines; launches built to convey the coal on board; in fact, all the conveniences and material provided for the effectual keeping up and working the mines. And all these important advantages have been secured at an expense of only £2194, and under judicious arrangements a full and ample supply of coal may always be provided."

Having effected this, Mr. Wheelwright remained in superintendence of the affairs in the Pacific till the end of 1842, when, at the request of the Directors, he returned to England, in his way exploring the Isthmus of Panama, and the supply of coal there. Now, however, we come to the tragic part of the performance. Hitherto we have had to laud Mr. Wheelwright's energy, industry and enterprise, the skill with which he combated obstacles and provided resources for the conduct of the undertaking. No men, however, are faultless, still less projectors, and Mr. Wheelwright, like too many of his brethren, had early in the enterprise involved himself in disputation. The school in which his energy and enterprise had been best cultivated, the merchant navy, is but a poor school for discipline, things are carried out upon too small a scale, and the relations are too simple to suggest the artificial expedients requisite in large undertakings, and where many individuals are concerned. Captain Wheelwright, while acting as superintendent of the company's affairs in the Pacific, thought only of the services he had performed in the suggestion of the undertaking and the formation of the company, and of the large stake he and his friends held in it. He felt a deep interest in it both personal and pecuniary, and while he assumed a high degree of authority to himself, he freely expressed his sentiments on the acts of the executive at home. He forgot that as superintendent he ceased to be a partner, and that instead of having to deal with mercantile co-partners, he was under the official superiority, not of Messrs. George Brown, J. R. Templeman, J. N. Daniel, &c., but of an abstract body, the Directors of the Pacific Steam Navigation Company, and on several occasions he indulged himself not only in insubordinate strictures on the conduct of the Directors in his correspondence with them, but also in his communications with his co-officials and third parties at home, shareholders in the company. No board, whether they had acted rightly or wrongly, could either consistently with their own dignity or with the interests of the company which they represented, submit to this, and they firmly but courteously called Mr. Wheelwright's attention to the subject, at the same time that they showed every confidence in Mr. Wheelwright's proceedings, and every disposition to allow him the legitimate exercise of his own discretion and responsibility, (p. 43, 40, &c.) A course like that pursued by Mr. Wheelwright was bad enough when carried on at a distance, but still worse when he came into personal contact with those over whom he seemed to consider that he rather held the superiority, than that he was bound to recognise it in them. He seems to have been totally incapable to discriminate between A & B and C & D, as private individuals and as abstract personages engaged in the management of the affairs of the company. Being at the same time totally ignorant of the mode of conducting public business, he was ever led into fresh difficulties, and ready to give and to take umbrage on the most trivial occasions. Thus it is one of his grievances, as stated by a partizan, that he was always politely requested to leave the boardroom while the directors were engaged in discussion, a course of proceeding which is well known to every one who has had experience in committee business, and at which it could be supposed that few officers of a company could take umbrage, and still fewer expose themselves by making it a ground of public complaint. However, Mr. Wheelwright's grievances did not end here, he brought plenty of others about his ears, which forced on the directors his dismissal.

As to Mr. Wheelwright's charges against the directors, they have been fully considered by them, and are not worth going into, neither should we do good by engaging in a controversy of the kind. We think Mr. Wheelwright and everybody else may very quietly dismiss them. We have every respect for Mr. Wheelwright's public services, and we have every wish for the success of the enterprise, and we have only alluded to the subject of this pamphlet in the hopes that some attention may be paid to the earnest expression of our desire that this crimination and recrimination may cease on each side. Mr. Wheelwright's services are great and ought to be remunerated, at the same time by his own act he has precluded his re-instatement in the active superintendence of the company's affairs. He cannot hope that he can succeed in displacing the London directors, supported as they are by so many influential capitalists and large holders, neither can they expect that Mr. Wheelwright can remain in opposition without great detriment to the credit of the company, and without a serious depreciation of the value of its shares. Let Mr. Wheelwright have compensation, either in the shape of an annuity for a short term of years, or of a per centage on the profits, when a certain dividend has been paid: let the bye laws excluding proxies be rescinded and two Liverpool directors elected on the board, and we believe a permanent settlement of all differences will be made, of the most beneficial result to all parties.

Having got rid of the controversial portions, we will now proceed to other points of more interest to our readers. Mr. Wheelwright, with great judgment and foresight, urged on the directors at an early period that the steamers should be built of iron, and the boilers of copper, and he gives satisfactory reasons for his recommendations. These were not at that time acceded to, for the merits of iron steamers on a large scale were not so firmly established as they are now; neither was the alleged superiority of copper boilers admitted. The directors were not therefore to blame in rejecting what they considered an experiment, in favour of the ordinary and established modes of construction; but we hope on future occasions they will profit by the arguments which Mr. Wheelwright so ably adduces in his reports. He also well observes,

"Nothing can be more desirable for the complete success of this company than the extension of the line to Panama. Our steam operations would then embrace a continuous coast from the latitude of 9° north, to the latitude of 37° south, a distance, including the sinuosities of the coast, of 3500 miles. To secure these necessary and vitally important advantages, two more steamers are required, one to make a monthly voyage between Lima and Panama, and the other to take the place of either steamer when repairs are necessary; it is utterly impossible to carry on economical steaming except by nursing the steamers and not over-working them; the old adage of "*a stitch in time*" is no where more applicable than to steam: procrastinating repairs is absolute ruin; however great may be our advantages in the mildness of the Pacific, and the very slight wear and tear to which we are exposed, unless these advantages can be sustained by having a steamer to take the place of either when necessary, it would be much better to abandon the enterprise altogether; any interruption of the line is a most serious evil to the inhabitants and ruinous in its consequences to the Company."

We can only regret that Mr. Wheelwright's partisans should have been those who at the recent meeting prevented the extension being carried into effect.

A point, with regard to which Mr. Wheelwright justly expresses great anxiety, is as to the passage of the isthmus at Panama, which he has surveyed, and the practicability of the route over which he has fully established, having on his return to England from Chagres, occupied only 24 hours in travelling by land and water from the Atlantic to the Pacific Ocean. We sincerely hope that this matter will not be lost sight of, but that it will be seriously taken up, and obtain every assistance from the government and the interests concerned.

This has become the more necessary, since we learn from recent Paris advices that M. Parella has been promoted to the rank of mining engineer, and appointed by the French government to sail immediately from Brest for the purpose of examining the isthmus of Panama, and ascertaining the practicability of a communication, by canal or otherwise, to Chagres.

WEALE'S QUARTERLY PAPERS.

Weale's Quarterly Papers on Engineering. Christmas, 1843. Part II. London, Weale, 1843.

The first volume of Mr. Weale's work is now completed, and we can sincerely say that not only does this fact give us great pleasure, but that we wish the series may be as extensive as it promises to be useful. The work supplies a desideratum in engineering literature, inasmuch as it affords provision for many valuable memoirs of great length, which could not otherwise be submitted to the public gaze, being in a Procrustean condition, as too long for our columns, and too short to admit of separate publication. Such is the treatise on the Dredging Machine, which would have been a hazardous experiment to have published separately, and yet here we have a laborious dissertation, with no less than ten copper-plates describing the minutest details.

The first article of the present part is by Mr. F. W. Simms, C.E., on setting out the widths of ground for the works of a railway or canal.

The next is a memoir by Mr. S. Hughes, C.E., of William Jessop, the engineer, being in continuation of the series, commenced in the first number, with memoirs of Brindley and Chapman. Thus engineering biography, a subject of considerable interest at the present moment, when the profession is rising in public estimation, is likely to receive great accessions, and to be put on a respectable footing. William Jessop, the son of one of Smeaton's assistants, was born at Plymouth, in 1745. At the age of sixteen, his father having died, he was left under the guardianship of Smeaton, whose pupil he became, and with whom he remained ten years. He was from that time (1772) employed on the improvements of the rivers Aire, Calder, Hebble, and Trent. About 1792 he was engaged on the Cranford Canal, the Nottingham Canal, the Loughborough & Leicester Canal, the Barnsley, and the Horncastle navigation, and the Ouse navigation. His great work, however, was the Grand Junction Canal. This was succeeded by the Grantham Canal, the Barnsley Canal, and the Great Ellesmere Canal. He was also employed on the Grand Canal, and other government works in Ireland. About the commencement of the present century, Jessop was called upon to take part in the dock establishments, and completed the City Ship Canal, and West India Docks, the first in London, and the Bristol Harbour improvements. It is curious, also, that at this time his attention was closely directed to the railway system, and which, under the form of tramroads, he had been much employed in extending to the mining districts of Derbyshire, Yorkshire, and Nottinghamshire. The Croydon and Wandsworth Surrey Tramway, the first in the metropolitan district, was also Jessop's work. With the Caledonian Canal Jessop was connected as consulting engineer. This great engineer died in 1814, after severe sufferings from paralysis. We should observe, that some controversy exists as to the engineership of the Ellesmere Canal; Telford, who acted as Jessop's assistant, having subsequently claimed for himself the sole merit. Mr. Hughes has entered into this question, and, we think, done justice to Jessop's claims. We are sorry to learn that in the compilation of this memoir, Mr. Hughes has received no assistance from the Messrs. Jessop, which is, we think, far from creditable to gentlemen of their high public standing.

The third paper is on the Dredging machine, in continuation and conclusion of an article published in the first part. It is as we have already said, copiously illustrated with copper-plate engravings.

The fourth paper is by Captain Vetch of the Royal Engineers, on the advantages of employing a framework of malleable iron in the construction of jetties and breakwaters. We shall leave the gallant captain to explain his system in his own words, but he has not certainly said enough to satisfy us as to the practicability of his plans.

"The mode of construction upon this project consists essentially in the application of upright rods of malleable iron, steadied and fixed in their places by passing them through apertures in two parallel and horizontal frames of flat iron, provided with corresponding orifices to receive them; the lower frames being placed about three feet above the low-water mark and the upper frame about three feet above the high-water mark, or at such other convenient distances apart as the circumstances of the case may demand. The horizontal frames may be conveniently constructed in short lengths, say of four feet each, and an additional piece of frame may be connected with the preceding one by round bolts passing through loops, forming so many moveable joints, that the frames may be the more easily raised, lowered, or adjusted to the required level, if from the settlement of the upright rods, they have swerved from their original horizontal position. The new lengths of frames having been bolted to the preceding ones, and retained in a horizontal position by diagonal stays, are ready to receive the upright rods, which are then to be dropped separately through the corresponding apertures of the frames, and each allowed to take its bearing separately by its own gravity, or by such farther pressure as may be deemed proper. When the rods have taken their bearing and settlement, a row of sloping rods have to be added to each side of the jetty, inclining inwards one foot in ten or twelve, to give lateral support; and at this state of the operation, it is proposed to key on to the rods the iron collars for the permanent support of the horizontal frames and the platform."

Obituary.—We have to announce, with regret, the demise of Mr. John P. Briggs, R.A., which took place on the 18th inst., about 5 o'clock, at his house in Bruton Street. Mr. Briggs was long a shining ornament to the profession of the fine arts, and his death will be esteemed a great loss by all the lovers of genius. Mr. Briggs had not been in town above a fortnight, after a tour of six months on the Continent. He has left two children of a tender age to lament his loss.

ON THE PREFERENCE DUE TO CUBICAL STANDARD MEASURES OF CAPACITY.

By T. N. Parker, Esq. A.M.

The pains which have been taken by Parliament, from time to time, to establish a uniformity of measures of capacity throughout the kingdom, have hitherto failed of producing the desired effect, and the greater the labour lost, the more unwillingness is shown for resuming the subject.

I have long entertained a belief, that a cubical standard measure might be advantageously substituted for the cylindrical, as the test of capacity; while cylindrical or vessels of any other form, should be continued, as at present, for common use: but a difficulty occurs in regard to the contents of a measure, which is to be multiplied and divided, into quarts, gallons, &c., without having to deal with any smaller parts than a cubical inch, and at the same time to preserve as nearly as possible, the like quantity in a gallon, bushel, &c. which has been customarily understood to be represented by such denominations. I, at length, luckily hit upon a cube of 4 inches for a quart, which is so near to the customary quantity as to be deserving of much consideration; it is remarkable that it did not sooner present itself, being so obvious, incapable of improvement or modification, as it must be entirely accepted, or entirely rejected.

The Winchester measure, 13 Will. 3, c. 5.		Gallon in cubical inches
Ale	..	282
Wine	..	231
Grain, &c.	..	268 8 tenths.
	3)	781 8 tenths.
Average	..	260 6 tenths.

By the 5 Geo. 4, c. 74, the imperial gallon is adopted, and described as containing 277 cubic inches, and a fraction of 274 parts in 1,000: but so repulsive is the task of approaching the mathematical impossibility of squaring a circle, that the following inaccuracies were found to exist in the Winchester standard measures in the Exchequer:—

		Cubic inches.
The gallon contained	..	270·4
If derived from the bushel	..	266·1
If derived from the quart	..	279·3
If derived from the pint	..	276·9[1]
	4)	1092·7
Average	..	273·1 tenth of an inch.

I shall next examine the difference between the Winchester and the Imperial measures, and I find that the Imperial bushel of 32 quarts contains 33 quarts of the Winchester, and an insignificant fraction of a cubical inch.

The increase in the imperial measure, as compared with the Winchester measure, is equal to 1½ farthing in every shilling, or 3⅛ per cent. And the decrease between the Winchester measure, and the proposed cubical measure, is 2¼ farthings in every shilling, or $4\frac{1}{16}$ per cent.; the cubical measure being that much smaller than the Winchester. But I contend, that the facility of ascertaining the accuracy of the cubical measures by a common rule of a few inches in length would be a very great advantage to all consumers, and more particularly to the poorer and less educated classes.

Lastly, I will endeavour further to explain the advantages of the proposed cubical standard measures.

	sides. in.		in.		depths. in.		contents. cub. in.	shapes.
Quarter pint ..	2	×	2	×	2	=	8	cube.
Half pint ..	4	×	2	×	2	=	16	double cube.
Pint	4	×	4	×	2	=	32	half cube.
Quart	4	×	4	×	4	=	64	cube.
Half gallon ..	8	×	4	×	4	=	128	double cube.
Gallon	8	×	8	×	4	=	256	half cube.
Peck	8	×	8	×	8	=	512	cube.
Half bushel ..	16	×	8	×	8	=	1024	double cube.
Bushel	16	×	16	×	8	=	2048	half cube.
Double bushel ..	16	×	16	×	16	=	4096	cube.

If a cylindrical vessel be required, equal to a given cube or square figure, multiply 1·1283791 by the side of the cube or square: take a cubical quart for instance;

1·1283791 × 4 (side of square) = 4·5135164 diameter of cylinder and the answer is 4·5 in. or 4½ in. for the diameter of the cylinder, so that a cylindrical vessel of 4 in. deep and 4½ in. diameter, is equal to a cub of 4 in., or sufficiently so for all practical uses, as a great measure.

By this rule the quarter pint would be 2in. deep by 2·2 in. diameter of cylinder, and the peck 8 in. deep by 9 in. diameter of cylinder. The standard measure of extension would in this case furnish copies in the shape of graduated rules, say of 8 in. or 9 in. in length, which might be marked also, with perforated points for the diameters of cylindrical vessels of the depths above mentioned.

In the year 1838, I distributed a brief sketch of suggestions on this subject, as an æronaut despatches his pilot baloon to see which way the wind blows, but the current was opposed to my views. I then published and distributed a pamphlet with little more success,[2] for the members of Parliament recollected the tiresome business of legislating on the imperial standard, and would not entertain the notion of another change, although the scheme was generally thought well of.

As a proof, that the introduction of the imperial measure does not tend to the uniformity of measures of capacity, I will quote the prices of grain from a respectable weekly provincial paper, dated 15th November, 1843, relating to four markets in the same county, and one market in the principal town of a neighbouring county: the same paper having been taken up as the latest published, and the only provincial paper which comes regularly to my hands. In this, wheat is taken at 75lbs. per bushel in all the five cases; oats at 225lbs. per bag in two cases, 50lbs. per bushel in one case, and not mentioned in the other two; beans 235lbs. per bag; peas 225 lbs. per bag, the two latter being mentioned only in one case each. But the point best applying to my argument is, that barley is in the five cases quoted at 38 quarts to the strike or bushel, and malt is only once mentioned, and then for the imperial bushel. So that the malsters buy barley at 38 quarts of Winchester measure, considerably greater than the imperial bushel, at which malt is sold as quoted in the said paper. There is therefore a disadvantage to the consumer in the proportion of 38 to 32, besides the outcast in the malting process of about 10 per cent. minus the proportion of 32 to 33 being the difference between the Winchester quart and the imperial quart. Taking the whole of these quotations together we must arrive at the conclusion, that the attempt to establish the imperial measure, is but a retrograde movement towards the uniformity of measures of capacity; which might with more probability be accomplished by the very simple system of cubical standard measuses of capacity, the advantages of which I have endeavoured to describe. Malt is often sold, I believe, at the old fashioned customary measure, the same as barley, of 38 quarts to the bushel.

20th November, Sweeney Hall.

[1] This was taken a few years ago, from some document of good authority, and I believe it was from a report of a committee of the House of Commons.

[2] Sold by Richard Baynes, 28, Paternoster Row, prices 2*d*. and 6*d*.

A FEW REMARKS ON DECORATIVE ARCHITECTURE.

Much as architecture has been valued, studied, and understood in this country, the application of the true principles of the art to internal ornament has been despised, or at least neglected. The plumber, painter, paper-hanger have taken the place of artists, and of architects—patterns and colours have vied with each other in absurdity and ugliness; and even when beauty, either by skill or by chance, has been obtained, it has been arrived at without reference to the general character of the building, and however beautiful, pains, because it is incongruous. When the mere shell of a building, whether public or private, has been erected, when the exterior has been constructed and ornamented, the architect's task is far, very far, from being finished.

Buildings, of whatever character or nature, were meant to be inhabited, and the solemnity of a church, the grandeur of a hall, or the ease and comfort of a private house, must be obtained by internal arrangement, and the glory, the beauty of the edifice should be adapted rather to the select few, the private circle, than meretriciously hung out to the indiscriminating gaze of the gaping multitude.

Nothing can be worse than the present system—a house is finished—Gothic windows or classical pilasters supplied *ad libitum*, and the architect pockets his 5 per cent., and sends a neat paragraph round to the papers to say that "it is to the skill and taste of our talented townsman, Mr. Pecksniff, that we are indebted for this elegant ornament to our rapidly improving town." Then in rush the tradesmen—a marble chimney piece of the severe classic style, a fender of decidedly Brummagem Gothic—and indescribable paper—and unaccountable curtain fixtures—mar the architect's designs, and martyrize the unhappy possessor, should he unfortunately possess an atom of artistical knowledge or an atom of artistical feeling; of what avail is it o an architect to endeavour to do justice to his patrons—to study his ground plan—to be harmonious in his proportions—choice in his cornices, if the lights and shadows he carefully designs are to be botched by a glaring paper—Grecian cornices, disgraced by surrounding Louis XIV papers, and the whole design to be left to the tender mercies of a lot of well-meaning but ignorant artificers? What are the profession about? What is the Institute doing? Will architects never combine together for their mutual assistance and the advancement of their profession, but spend their days in petty squabbles and low envy?

We have been led to these remarks by a recent visit to a house now in the hands of the decorator, No. 37, Westbourne Terrace, Paddington, and we hail this attempt as the dawning of a new era in decorative architecture, as a promise that, hereafter, grace and beauty shall not be confined to the palaces of the rich and powerful, but be diffused through all classes, till they gladden the home, and elevate the condition of the poorest among us. The house alluded to stands in a terrace, designed in a rich Italian style, with bold cornices, and rich columniated windows. The credit, we believe, of the design, is due to Mr. Nelson, and the evident care bestowed on the interior effects, and general ground plan, is a lesson that many of his brother professionals would do well to copy.

The walls of the back and front drawing rooms are painted in a dead ground, and relieved by raised gilt panels in the Louis XIV style, the interior panels are painted in oil, with little scenes of courtly and pastoral life, after the style of the refined and elegant Watteau. These are from the able pencil of Mr. Baines, the artist, and do him much credit in a walk of art that most artists *affect* to despise. We earnestly recommend all architects who have the real good of their profession at heart, to study and agitate this subject. Should they feel inclined to visit the house in question, they will, I am sure, meet a most obliging guide in Mr. Baines himself.

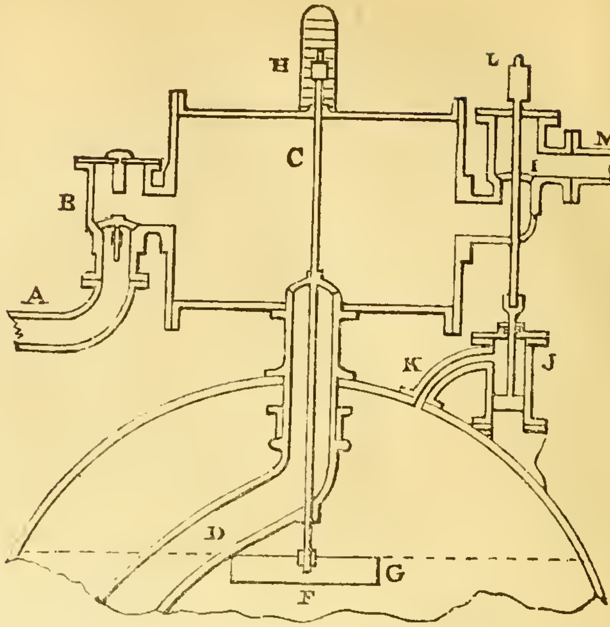
Westminster, January. A. H. Patterson.

FEEDING APPARATUS FOR HIGH PRESSURE BOILERS.

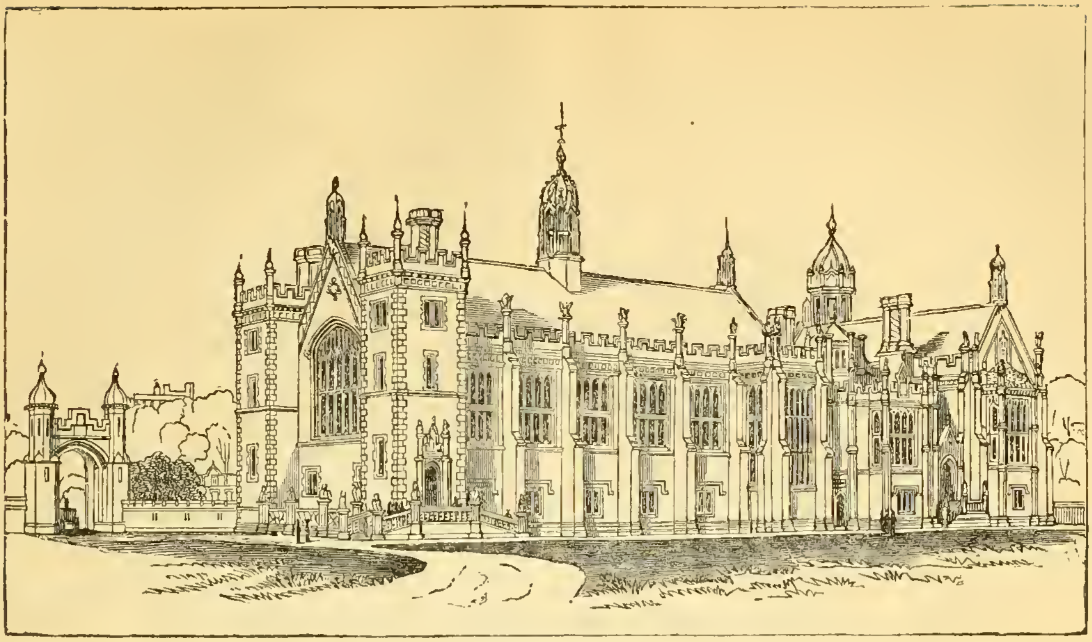
For which the Silver Medal of the Society of Arts, London, was presented to Mr. C. Grafton, of Dover Street, Chorlton-on-Medlock.

It is, I believe, an acknowledged fact, that the absence of any practical self-acting feeding apparatus for boilers in which high-pressure steam is employed, is a deficiency of a most serious nature. The deplorable consequences which may ensue from the neglect of those who have the care of such boilers, in keeping up the requisite supply of water (a neglect which I believe to have been the cause of three out of five of the steam-boiler explosions which have as yet taken place), the wasteful expenditure of fuel, and deterioration of the boiler, which must arise from irregular feeding, when the due level is not maintained equally during the period of working, are consequences of this deficiency so obvious as scarcely to need a comment. It is now a principle, recognised by the highest authorities, that the most economical engine is that in which the expansive property of steam is put forth to its fullest extent, by employing high-pressure steam in one of the ordinary condensing construction, and cutting it off at an early period of the stroke, which will of course neutralise the present system of feeding by means of a column of water; for, supposing that a pressure of 35 lb. on the square inch were employed, it would require a column of water 87 ft. 6 in. high to overcome such a resistance; recourse must then be had to hand-feeding, with all its disadvantages.

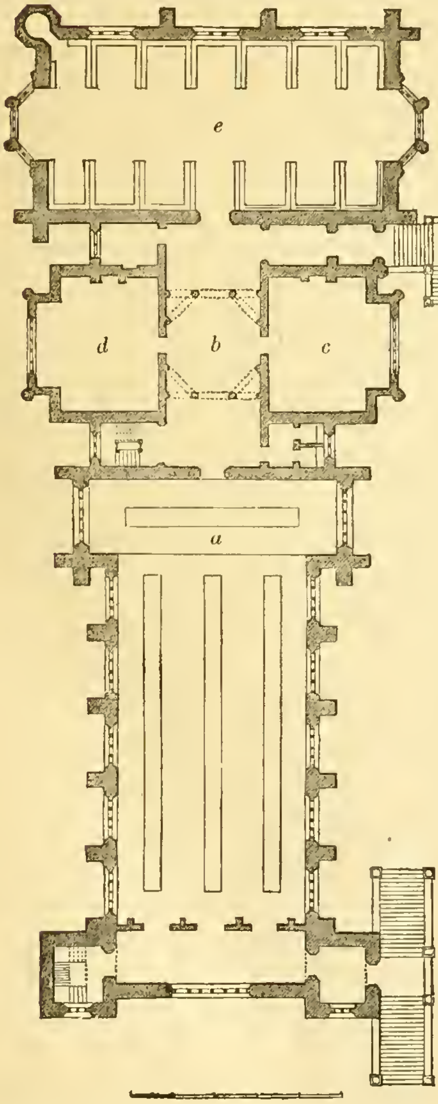
It has occurred to me that possibly a remedy for these evils might be found in the application of a plan which I have endeavoured to delineate in the accompanying section through the feed apparatus and part of an ordinary ten horse high-pressure boiler, mounted in the usual manner with steam nozzle, loaded safety-valve, man-hole, and additional safety-valve; but in place of the common feeding apparatus, I propose to lead the feed-pipe A, provided with a common conical valve at B, into a small tank C, placed immediately over the boiler, through the bottom of which the end of the internal feed-pipe D, fitted with a rising valve E, is introduced; the spindle of this valve is brought down, and passing through a small stuffing-box, is attached to a lever at F, which is loaded by means of a float G, buoyed up by the water in the boiler; a slight brass wire tapped into the stalk of the valve E, and passing through the top of the tank, shows, by means of an index-plate H, the position of the valve. On the opposite side of the tank I would place another valve I, the spindle of which would be attached to the rod of a small piston working in a cylinder J, open at bottom, and of equal area to the valve I, the top side of which is exposed to the steam-pressure of the boiler by means of a pipe K. This valve is also loaded with a slight weight L, and the water, after passing through it, escapes through the overflow-pipe M.



The action of this apparatus may be explained in the following manner:—Supposing the boiler at work with a pressure of 40 lb. on the square inch, I propose that the weight L should exert a pressure of 1½ lb. on each square inch of the valve I, which would be (supposing the valve to be 2½ in. diameter) 7·362 lb. on the whole, which, together with the pressure communicated by means of the pipe K, from the boiler to the piston of the cylinder J, would give a total load of 41·5 lb. on each square inch of the valve J. This pressure would soon be exerted by the force-pump of the engine; but when the water in the tank C, attained more than this pressure, the valve I would rise, and allow the water to escape down the overflow-pipe M. But supposing the level of the water to be lowered, the float G will descend with it, and, aided by the lever F, raise the valve E, and allow the water in the tank to force its way into the boiler till the requisite level is obtained, and the float again buoyed up till it closes the valve E, and the water escapes through the valve I; for, supposing the float G to weigh 4 lb., and the leverage (which might be increased, if necessary) to be as 9 to 1, you would then have a pressure of 7·33 lb. on each square inch of E; but this must be diminished by 1·5 lb., which is the extra weight on the valve I. This would give an *effective* pressure of 5·83 lb. on the square inch to raise the valve E; for it must be borne in mind that (as both these valves are of equal area) by this arrangement the pressure of steam in the boiler is exerted equally to raise the one and depress the other; and therefore, as soon as the equilibrium is disturbed by the descent of the float, consequent upon the diminished level of the water, the extra weight being overcome, the water will rush into the boiler with a force of 1·5 lb. on the square inch more than the actual steam pressure. This is supposing the water to fall entirely below the bottom of the float G, but it is obvious that it would, even with the leverage and adjustment I have given it, not require to fall more than an inch and a half before the valve would be raised, and by a judicious adjustment of the leverage, still greater nicety might be attained. (A small wire might be attached to the float and rise through the boiler, to close the valve E, by hand, if necessary.) It is upon the fact of the pressure upon both the valves E and I being constant, that I rely for success; for all the other schemes of whose existence I am aware have this defect, that the pressure from the boiler is variable, while the pressure from without is fixed; and even in boilers working with common low-pressure steam, that which is technically termed "boiling over," is often noticed when the steam becomes suddenly of a higher pressure than the feed-pipes were calculated to overcome, and the safety-valve is neglected. I have brought this proposition forward as applied to high-pressure boilers, but I am inclined to think that it might be applied with economy, as far as regards the prime cost, even in cases where the jack-head system is effective, as the cost of the extra valves and tank would certainly not be more than that of the great amount of piping required under the above-named system; and the inconvenience to which their height and position expose them, and the absolute necessity which must exist, whenever the pressure is increased, of adding to that height, would be done away with.



Lincoln's Inn Buildings.



50 feet.
Plan of Lincoln's Inn Buildings.

LINCOLN'S INN HALL AND LIBRARY.

This structure is fast approaching completion, having been laboured at night and day with all the vigour which its energetic architect and contractor could bring to bear. The buildings include a library, a dining hall, and a bencher's room, and are in what may be called the early domestic style of the sixteenth century, or reign of Henry VIII. They stand, as our readers are aware, on part of the site of Lincoln's Inn Garden, looking on Lincoln's Inn Fields, and form an important addition to this great inn of court, which hitherto has been rather in arrear in the matter of architecture. In compliance with the practice at the Temple, Gray's Inn, and Staples Inn, these buildings are in a medieval style, but which, in the present instance, does not accord with some of the other prominent edifices in Lincoln's Inn, nor with those in Lincoln's Inn Fields. If, too, Mr. Barry is to erect his New Courts of Law in Lincoln's Inn Fields, the New Hall will sadly put them out of countenance. We hope that now the benchers have begun, they will persevere and give Lincoln's Inn an architectural character, consistent with its legal standing and the many interesting historical and literary associations connected with it.

As much interest is attached to this structure at the present moment, it gives us great pleasure to avail ourselves of the accompanying engravings and description, for which we are indebted to the courtesy of the conductors of the *Companion to the Almanac*, and which afford a very comprehensive view of the design.

To begin with the dining-hall: at the south end, *a*, it greatly exceeds the present one in dimensions, that being only 75 ft. by 32 ft. whereas this is 120 ft. by 45 ft. and 64 ft. high, it is therefore considerably larger also than Middle Temple Hall, supposing the size of this last to be correctly stated at 100 ft. in length, and 40 ft. in width. One characteristic feature of this hall will be an open timber roof of oak; and all the windows will contain a great deal of stained glass emblazoned with the arms of members of the Inn. There will also be two bay windows at the upper or *dais* end of the hall. The vestibule, *b*, connecting the hall with the library and other rooms (*c*, the council-room, and *d*, the drawing-rooms, each 31×24 ft., exclusive of bay), will be lighted by a louvre lantern, which will also show itself conspicuously on the external roof. The library, which runs transversely to the rest of the plan, and therefore gives extent in another direction, is 80 ft. by 40 ft., and 35 ft. high, and will, like the hall, have an oaken open roof. On the ground-floor is a reading-room for the benchers, and various other rooms for the officers attached to the Society: and in the basement are a spacious kitchen and all other requisite domestic offices.

The exterior of the building is of red brick and stone, with an intermixture of darker-coloured bricks, and executed in a superior manner. Architectural effect will be extended both by the terraces connecting the structure itself with the gardens and by the adjoining entrance from Lincoln's-inn-fields.

We should have been better pleased had a more lively-looking material than the dark red brick have been used, as its peculiar hue, in the present instance, gives a very dingy and sombre appearance to the exterior.

The first stone was laid on the 20th of April last, so that the present advanced condition of the building shows the expedition which has been used, and which equally with the design, does great credit to Mr. Hardwick, its able architect.

NOTES OF THE WEEK.

Music has hitherto been more favoured than architecture, with regard to royal and princely professors. We have Prince Albert, Prince George of Hanover, Prince Poniatowski, and many others, entering themselves as candidates for musical honours, but they have not yet dabbled with architecture. This, however, is about to be remedied, and Berlin is to be decorated with a new cathedral, of which Herr Stieler is charged with the execution from ideas given by the King of Prussia. The contribution of notions is but a preliminary step, still we do not despair to see architecture more royal, if not more popular, occupying the pencils, and claiming the superintendence of the high and mighty after this great example. This building at Berlin is to rival those of King Lewis of Bavaria, and be one of the most magnificent in Germany. It is to be in the style of an Italian basilica, and enriched with all the adornments of painting and sculpture. In the vaults are to be interred the mortal remains of the members of the Prussian royal family, and the tombs of former members now scattered in different cities are to be removed to the new mausoleum. The cost of the edifice will not be less than 10,000,000 thalers, or £1,500,000.

The hotel of the minister of the navy at the Hague, has been unfortunately burned down.

The celebrated monastery of Saint Jerome, at Grenada, the supposed model of the Escurial, has suffered much from civil war, the recruits quartered in it at different times, recently, having wantonly destroyed many of the works of art.

The erection of monuments in France, to men of eminence, is making active progress, particularly in the provinces. Among other places the following are cited as having thus celebrated their illustrious great. Cambrai, Dijon, Meaux, Bordeaux, Perigueux, and Montbard, have monuments to Bossuet, Fenelon, Buffon, Montesquieu, and Montaigne; Chateau Thierry, La Fontaine; Laferte Milon, Racine; Caen, Malherbe; Clermont, Pascal; Rouen, Corneille; Paris, Moliere; Strasburg, Guttenburg; Havre, Bernardin de St. Pierre, and Casimir Delavigne; Marseille, Belsunce; Lyon, Jacquard; other cities Cuvier and Duguesclin. This is a great contrast to the state of affairs in England; while columns and monuments are awarded to generals, admirals, and statesmen, the only public memorials of men of literature and science, in the places of their birth, are, we believe, Dr. Johnson at Lichfield; Dr. Dalton, at Manchester; Watt and Tennant, at Glasgow; Bell, at Greenock; and Chatterton, at Bristol. Shakspeare, Milton, and Bacon, and all our great names, which are consigned to oblivion by those cities derive so much glory from their birth. London, with all its public monuments, has none to literary men, while more honour is paid to Shakspeare abroad than here, the king of Saxony having just placed a bronze statue of the great bard on the façade of the New Theatre at Dresden, something better than the affair at Drury Lane.

The Palais de l' Industrie, for the *exposition* of 1844, in the Champs Elysées, is getting on with rapidity. The construction of the canal and basin of La Villette, has greatly increased the prosperity of that quarter of Paris, and at the present moment a church, town-hall, and school, are being built. The French Minister of the Interior has commissioned M. David to execute two colossal figures for the tomb of Napoleon. A magnificent chapel to the Virgin, in the Byzantine style, richly decorated, has been completed in the church of St. Gervase, at Paris. The painted windows are by Messrs. Cousin and Pinaigrier, and the decorations and gilding by M. Delorme. A new illustrated monthly periodical, on a large scale, has been commenced at Paris, called the Revue Pittoresque. It contains articles and engravings by the first hands, and is published at the low price of 5*s*. a year.

The King of Bavaria, in the new year, has given the cross of the order of the Bavarian Crown to the artists Shnorr, Hess, and Schwanthaler.

An attempt is being made to bore for water at Calais, under the direction of M. Mulot, and the artesian well has already reached 300 metres, about 1000 ft. in depth. This is the extent to which the contractor was bound to go for £1440, and a new contract must be made to carry on the works further, and to save the expense already incurred. It is expected that water will be found at 400 yards, as the chalk, which has been reached, is becoming greyer and greyer, seeming to denote an approaching change to the green sand formation. The boring, down to 72 metres, was in gravel, sand, clay, and flint; then chalk mixed with flints; at 263 metres the whiteness of the chalk began to be affected, and at 277 metres it became grey.

The number of miles of railway open in Germany is about 249 German miles, or about 1160 English miles.

A fine deposit of asphalte has been discovered at Velder, five miles from Hanover. It is said to be 14 ft. thick, and only a few feet below the surface. It is said to be similar to the asphalte of Seyssel and the Val de Travers.

An eruption accompanied with flames and ashes, has taken place at Olopad in Sclavonia.

M. Dufrenoy and Elie de Beaumont, in their remarks accompanying their new geological map of France, make the following calculations as to the supply of coal in the rural countries of Europe. The coal district in this country forms about 5 per cent. of the superficies; in France only ½ per cent.; in Belgium 4 per cent. Italy, Greece and Turkey appear to be very badly off, as also Denmark, Sweden and Norway; Russia is also very inadequately supplied. Wurtemburg, Bavaria, Austria Proper, Moravia, the Tyrol, Styria and Illyria are deficient rather than otherwise with regard to coal. Hungary has some mines on the Danube. Bohemia is pretty well provided, as also Saxony and Poland; but Prussia is best off in its possessions in Silesia and at Sarrebruck. Spain and Portugal have some good basins towards the north, and the Asturian mines have excited a good deal of attention as affording the means of an export trade towards the south of France. The French basins are generally thin, poor and small; while the Newcastle basin covers 1,200,000 acres, the north basin, the greatest in France, extends over only 125,000 acres. As an instance of the rise of manufacturing towns where an abundant supply of coal is at hand, Decazeville in France, is cited, where 20 years ago there was only an old barn, and now there are 4000 people.

The *Vulcan*, an English iron vessel of 318 tons, excited much attention at Havre, for although of 318 tons register, and carrying 400 tons of coals, she draws only 11½ ft. water, and can pass all the difficult places of the Seine. She has carried her cargo up to Rouen. The advantages she possesses in her lightness of draught, arising from the material of which she is constructed, have powerfully impressed scientific and commercial men in France, and the result will be most probably a great extension of the coal export trade, and perhaps the creation of a new branch of trade in the supply of iron vessels. For river service ships of this material seem particularly well adapted, and as they are able to ascend the rivers, they are expected to save the expense and trouble of transhipment from lighters with regard to all bulky cargoes, as coal, corn, timber, &c.

A new iron steamer is being built at Ulm for the Austrian company, to navigate the Upper Danube, and to be called the *Danube*. The voyage between Linz and Ratisbon has already been reduced five hours in duration by the competition, and something more is expected.

The Austrian Lloyd's company have launched at Trieste their fourteenth steamer, the *Empress*, on the 22nd ultimo.

The French are now claiming screw propulsion as their invention, and the government have granted to M. Sauvage £100 as an indemnification for the experiments he has made on the subject during some years.

We are glad to see that a movement is being made at Edinburgh to provide baths for the working classes; we wish something were done here. London has peculiar advantages in its river, and abundant supply of water, yet neither the city corporation, the commissioners of Woods and Forests, nor any other authorities, have made any provision for establishments so necessary to the health of the population. The tides offer great facilities for easy supply and removal of water, and we hope the subject will not be forgotten in connexion with the proposed embankment of the river.

The subscription statue of Sir David Wilkie has been placed in the National Gallery, being the first honour of the kind awarded, though we trust by no means the last. The floor of the National Gallery is so weak that it has had to be secured under the pedestal of the statue, though it would naturally be supposed that such a building was intended for the reception of works of sculpture. The statue is by Mr. Joseph, and is a good though not a striking likeness of the celebrated painter.

At Newcastle there are two new banks in progress, and at Seaham Harbour the north dock is about to be enlarged, for which purpose the commissioners have advertised for tenders to remove 40,000 cubic yards of limestone, the estimated expenditure of which is £10,000. The works are under the superintendence of Lieutenant Usher, R.N., and Mr. Walker as engineer. A branch railway from the Newcastle and North Shields Railway is spoken of under the auspices of the directors. As to the high level bridges—1st. Mr. Green's is of wood; 2nd. Mr. Grainger's, of cast iron, raised on the piers of the present stone bridge; and 3rd. Mr. Dobson's, of cast iron for railway traffic, (the two first only for road traffic,) under the auspices of the Carlisle Railway. Mr. Green's is under the Brandling junction and Mr. Hudson's patronage, who ask the corporation of Newcastle to give the approaches and £5000, or make the footway as well as give the land for approaches. The common council reported in favour of the latter. In the plans deposited no details are given, except the height above low-water, and two piers would be in the river; borings are now making on the site of Mr. Green's bridge to ascertain the nature of the foundation.

Mr. Robert Hawthorn, C.E., of Newcastle, has patented a locomotive to work the steam expansively, by cutting it off at any portion of the stroke; it is said to reduce the quantity of coke one half, or half a pound per ton per mile, and to materially reduce the priming and coughing or puffing of the engine.

The Newcastle papers state that plans and estimates have been prepared with a view to introduce to public notice the utility and practicability of a tunnel under the river Wear, below the present ferry boat landing. They say that parties are willing to contract for the same, to be completed within six months from the commencement, and the projectors are very sanguine as to the undertaking proving one of a remunerating character.

Six iron vessels, as we stated in last week's number have been contracted for by the Government, of the same class as the *Locust* and the late *Lizard*, and are to be employed as dispatch boats, each to be fitted with engines of

150 H.P., on the side lever or beam principle, and with tubular boilers. Three of these boilers are in the hands of Messrs. Ditchburn & Mair of Blackwall, to be supplied with engines by Bolton, Watt & Co., by Penn & Son, and by Seaward, Capel & Co. Mr. Robert Napier, of Glasgow, is to build the other three, and also to supply the engines. One of the improvements to be introduced, is to have the coal boxes built as part of the vessel and perfectly water-tight, and also to have water-tight bulkheads.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.—Session 1844.

January 16.—The President in the Chair.

The Annual General Meeting of the Institution was held on Tuesday evening, when the usual report of the Council was read. It appeared that the progress of the Society was satisfactory, and the increase of members was equal to that of preceding years, but the amount of arrears of subscription was larger. The members were pressed to transmit papers for reading, for, as was justly stated, scientific societies can only be supported by useful and interesting communications, and by raising such discussions upon them, as are the distinguishing feature of the meetings of the Society of Engineers.

Memoirs of Professor Wallace of Edinburgh, of Mr. Buddle of Newcastle, and of several other deceased members were read.

Telford medals were presented to Messrs. F. W. Simms, W. Pole, and T. Oldham, for communications presented by them to the Institution.

Telford and Walker Premiums of Books were also presented to Messrs. D. Mackain, D. Bremner, D. S. Hope, R. Mallet, W. J. M. Rankine, W. L. Baker, S. C. Homersham, J. O. York, G. D. Bishopp, and G. B. W. Jackson, for their papers and drawings, which had been read and exhibited at the meetings during the past session.

Mr. J. Walker, the President, addressed the meeting upon the internal management of the Society, the election of His Royal Highness Prince Albert, as an honorary member, the valuable addition to the library presented by the Duke of Buccleuch, the course of study and practice most beneficial for young engineers, and the opportunity afforded by the Institution for coming advantageously before the world; he then, among other novel subjects connected with engineering, spoke of having lately visited the atmospheric railway near Dublin, and said, that without prognosticating as to the future, the experiments he witnessed appeared more promising than those with locomotive engines at a corresponding early period of their introduction upon railways.

He then gave a short notice of the connexion of Colonel Stoddart with the Institution as its honorary secretary, in the years 1834-5; alluding to the exertions now making by a committee of gentlemen under the direction of Captain Grover, for ascertaining the fate, and, if possible, of obtaining the release of both Colonel Stoddart and Captain Conolly, who, there was every reason to believe, were really still alive, although detained in a sort of captivity. In confirmation of this, Lieutenant Colonel Humfrey stated that Captain Grover had been informed by Lord Aberdeen, that authentic intelligence had been received from Constantinople, and from the British Consul at Trebizonde, to the effect, that some pilgrims recently arrived direct from Bokhara, had seen both Colonel Stoddart and Captain Conolly alive and at liberty, although strictly watched; that they were both employed in the military service of the Ameer, and that evidently they were restrained by some powerful reason from attempting to make their situation known, as it was not probable, otherwise, that two officers of such merit should allow themselves to be reported dead, and their names to be struck off the army list. The favourable reception of Dr. Woolff at the various places he had hitherto passed through was noticed, and a spirited subscription to the Stoddart and Conolly fund was immediately commenced among the members of the Institution, who all appeared anxious to aid in the restoration to his native country, of a gentleman who had, whilst connected with them, gained so many friends.

The ballot for the Council took place, when the following gentlemen were elected:—J. Walker, President; Messrs. W. Cubitt, B. Donkin, J. Field, and H. R. Palmer, Vice Presidents; W. S. Clark, F. Giles, G. Lowe, J. Miller, W. C. Mylne, J. M. Rendel, G. Rennie, R. Sibley, J. Simpson, J. Taylor, F. Braithwaite, and W. Cubitt, other members and associates of Council.

The following papers were announced to be read at the next meeting, on February 6, until which time the meeting adjourned:—

"Description of a water-wheel constructed by W. Fairbairn, Esq., and erected in Lombardy," by S. B. Moody, Assoc. Inst. C. E. "Description of a new chain bucket water-wheel," by J. Wight. "Description of Whitelaw's horizontal water-wheel," by J. Whitelaw. "Description of a water meter," by P. Carmichael.

BRISTOL AND WEST OF ENGLAND ARCHITECTURAL SOCIETY.

A general meeting of the members of this society was held on Tuesday evening, December 19, in the theatre of the Institution, Bristol, and was numerously attended.

The Ven. Archdeacon Thorp, on being called to the chair, observed, that the present meeting might be considered an anniversary meeting, as the report of what had been done by their society during the year would be read, as also the statement of their accounts. It was gratifying to find that the principles contended for by the society were rapidly gaining ground; although they had not at the present moment to report the formation of new societies, they had to congratulate the friends of the society on its making a steady progress; that there had been an increase of members, which was hardly to have been expected, after the novelty of the society had ceased to excite. The chairman alluded to the rule of this and similar societies, by which a member of one society was also a member of the other societies, and said that much benefit had been the result. In carrying out the principles of the society they were mainly endeavouring to promote the welfare of the Church. It was not merely for the sake of promoting the elegancies of art that they were concerned, but in all their proceedings they were anxious to bring all the aid that art or science could afford into the service of their church. It was peculiarly gratifying to him to observe that they were not looked upon any longer with suspicion by a large and influential body of gentlemen who were professionally devoted to architectural pursuits, but that instead of being deemed intruders into the profession, they were considered as amongst its ablest promoters. The principles of church architecture and restoration, for the encouragement of which the society was formed, were a very few years ago unknown or unacknowledged. Churches were built and restored, without considering who were the persons to be engaged in religious worship, or the manner of worship to be celebrated. The service of the church had not been in accordance with its ritual. But now a better state of things had obtained, and he confidently believed that many of the heart-burnings which prevailed in the church would be subdued in proportion as the church principles of architecture were more understood. Persons who were formerly greatly averse to this society, were now, after seeing its principles carried out, its friends. Distinctions between the worshippers in the church had been made where God never intended them to exist, and persons had been excluded from its service for whom the church was specially bound to provide. The austerity evinced by some to pews he had himself at one time thought too great, but he now thought the time was rapidly approaching when pews would altogether be abolished. Churches had been built without regard to the service to be performed in them,—rather for the worship of Mussulmans, Indians, or Egyptians than that of Christians. But now, after the numerous examples which had been set, it would not be deemed necessary to have pews fitted up with every convenience for domestic comfort, and persons instead of being driven to dissent, would find the internal accommodation of the church consistent with its ritual. The Venerable Archdeacon concluded a long and able address by observing that the interest of that and kindred societies were favourably progressing, and that great practical beneficial results had been effected, and instanced the church of St. Sepulchre, at Cambridge, which, instead of being a place not fit for a pig-stye, was likely to be one of the most beautiful churches in the kingdom.

The Rev. J. R. Woodford, the secretary, then read the report, which stated that they had concurred in several undertakings which seemed calculated to advance the end the society had in view—the restoration of the ecclesiastical edifices in the diocese, and the prevention of the introduction of architectural improprieties in the new buildings which were rising around them. They had forwarded a memorial to the Commissioners for Building additional Chapels and Churches, with reference to certain objectionable points in their rules, viz., the introduction of galleries, the toleration of pews, and the position and materials of the font. The committee had been active in promoting the circulation of *The Bristol Archæological Magazine*, as it was believed the wider its circulation, the greater degree of usefulness would be obtained. The committee had undertaken the restoration of the south porch of Slimbridge church. A grant of money had been made towards the repairs of the tower of Bitton church. A font, of the Norman period, had been erected under the superintendence of the committee, in All Saints' church, in this city, the cost of which was defrayed by the vicar. The report concluded by recommending four gentlemen for election as vice-presidents.

The Rev. Eccles Carter read a paper on "*The Church of Slimbridge*," situated 11 miles from Gloucester, on the left side of the road from Bristol to that city. The church is an object of interest to travellers from its lofty and very graceful spire, which rises amidst the dense foliage of that flat but fertile vale. Its more peculiar beauties are, however, concentrated in the interior. The edifice, in its pristine and perfect state, for completeness of plan, elegance of proportion, and elaborate execution of general design, could scarcely have been second to any of its own style and date. The church is said in the history of the county to have been dedicated to St. John the Evangelist, but there is no tradition or commemoration whatever of this fact. The church consists of a chancel, 32 ft. 9 in. by 16 ft. 3 in.; nave, 60 ft. by 18 ft. 3 in.; tower at west end, 11 ft. 10 in. square; north and south aisle, 57 ft. 9 in. by 13 ft. 2 in.; south porch, 7 ft. 9 in.; vestry, on the north side of the chancel, 9 ft 10 in. by 11 ft. 1 in. The church does not stand due east, but is rather to the south of east. The east window consists of three lights, decorated. In the centre light is a shield of richly stained glass, bearing the arms of the Berkeley family. The chancel is elevated one step; two altar steps run the whole width of the chancel. As there was formerly a chantry dedicated to St. Katherine, it is supposed that the place now used as a vestry was also a chapel dedicated to that saint. There are five piers carrying four arches on either side of the nave. The clerestory is about 40ft. high, containing four windows. The pulpit, of carved oak, stands in the interior of the second pier, on the north side of the nave. The whole of the nave and aisles are pewed with large square deal pews to the height of 4 ft. 9 in. There are some good encaustic tiles scattered over the pavement, but the patterns are broken by grave-stones. The font, of lead, is close to the western arch; it bears the date of 1640. The height of the tower is about 84 ft.; out of it rises the spire to the height of 75 ft., which is particularly graceful and slender, its chief beauty arising from its being set so very straight from the base. The whole of the interior of this beautiful church was formerly covered with white and yellow wash; the window jambs and mullions had been broken away, and repaired with plaster; the pier arches and caps were so thickly coated with plaster that it was impossible to guess what might be contained under it. The mullions, &c., of the windows in the chancel have, however, been restored in the best possible way, the splay and sash of the east window being cased with freestone instead of mortar and wash. The wash and plaster have also been removed from nearly all the piers, caps, and pier arches. Two large pews of 6 ft. 7 in. by 6 ft. 3 in. and 5 ft. 4 in. high. on each side of the chancel, have been removed, and are being replaced by two stalls. The expense of these restorations, amounting to 70*l.*, has been defrayed by the rector, with the exception of 5*l.* from the rural dean, and 5*l.* from the farmers of the parish. The south porch had been restored through the generosity of the Bristol and West of England Architectural Society. Speaking of gilding in the church, the paper continued—" If symbolism is to retain its full force, the present is not the time for painting and gilding our churches. At a time when the church, if not peculiarly under the harrows, is just emerging from a worse condition, it would seem that, however much we are bound to use every endeavour to extend her circuit and take care that she goes in solemn and costly attire, yet the time is not come when we may clothe her in that joyous and triumphant garb which we fully trust awaits her, fully wrought with gold purified in the fire of affliction." The rev. gentleman, in conclusion, said, that the cost of the proposed farther restoration of the church was estimated at £2,000.

An interesting conversation ensued upon various subjects connected with the church architecture, in which the chairman observed that a work was in course of publication for determining the direction in which churches were built. It was frequently observed that churches were not built due east, which had been accounted for by supposing that respect had been had to the point of the sun's rising on the festival of the saint to whom the church was dedicated. The *Orientator* was accompanied by a calendar, by which the sun's rising on the festival days could readily be ascertained. The venerable chairman also observed that much more good would ultimately be effected by building one church at a cost of £20,000, than four at £5,000 each, inasmuch as men's minds would be called to the due distinction and honour which ought to be given to a building dedicated to the service of God.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

January 8.—C. Barry, Esq., R.A., V.P., in the chair.

A communication was read from W. M. Higgins, Esq., " *On the recent restoration of the spire of St. Stephen, at Vienna.*"—It proceeded to state, that the ancient church of St. Stephen is supposed to have been founded, in the year 1144, by Heinrich Jasomirgott, afterwards the first Duke of Austria, one of the twenty-three children of Agneseus, to whom the Klosternenburgh owes its foundation. The church seems to have been several times injured by fire, and, in 1519, by severe earthquakes, which did great injury to the buildings in Vienna and the vicinity, and on these occasions to have been partly rebuilt, and much enlarged. The tower, as built, or restored, in 1519, in process of time, deviated out of the perpendicular to a considerable extent. An iron bar was carried through it as an axis for the support of the spire, which, having a considerable tendency to vibrate, might be considered as an element of destruction, rather than of strength; consequently the thin wall of the lower portion of the spire was reduced almost to a ruin, and at length became in such a dangerous condition, as to require rebuilding. The removal of the old spire was commenced in August, 1839, and in the following spring all the condemned part had been removed. The mode of construction adopted in the restoration, was novel and ingenious; the slight masonry of the spire being supported by means of a framing of vertical iron ribs fastened, at their lower extremities, to a cast iron plate or base, and united to each other at intervals by horizontal rings of rolled iron. These rings are made to project from the inner surface, so as to admit of a person ascending, with the assistance of ladders, to the top of the spire. All the wrought and rolled iron employed in the construction of this iron skeleton, the weight of which was only 123 cwt., was prepared in the government works at Neuberg, in Styria. The cast-iron plates or rings were furnished from the government iron works at Marie-zell. In the autumn of 1842, when the whole of the masonry of the spire had been completed, the upper portion, consisting entirely of iron work, was fixed. This also was attached to a strong cast-iron circular plate, similar in construction to that below. This portion of the framing, with the other iron work employed in the spire, weighed about 80 cwt., so that the entire weight of iron was about 203 cwt. The new portion of the spire was connected to the old by means of an arrangement of iron work, very appropriately called " anchor fastenings." The portion of the spire restored, (viz., from the gallery of the tower to the top of the cross) is about 182 ft., the cost thereof being about 130,000 gulden, of which sum 15,500 gulden were expended in taking down the old spire, and in the construction of the necessary scaffolding. Objections have been raised, at Vienna, to the extensive use of wrought iron in the reconstruction, from an apprehension of injury arising from the dilatation of the metal under changes of temperature; it appears, however, from careful experiments made, that the expansion of a bar of wrought iron 40 ft. in length, under an alteration of 40° Reaumur, is not more than three lines, even in a horizontal position, and would be less in a vertical position, in consequence of the pressure of the upper parts on the lower; and the opposite effect would increase with the diminution of temperature, the effect being still less when a number of pieces are united, forming a system (as in the iron work of the spire), than when the same length is in a single piece. It further appears, that Bolinger, the mechanical engineer, found the dilation of one of the iron ribs, between the temperature of summer and winter, to be only one line, and that of the iron framework, when completed and exposed to the direct rays of the sun before it was covered by the masonry, to be imperceptible.

At the next Meeting, on Monday Evening, the 22nd instant, the following papers will be read:—" A description of the new bridge over the River Moine, at Clisson, near Nantes," by William Bromet, Esq. M.D., F.S.A. " Some observations on the Church of St. Peter and St. Paul, at Kettering, in Northamptonshire, by Mr. R. W. Billings, Associate.

ON BRONZE FOR STATUES.

By Captain Charles Hoffman, of the Prussian Artillery.

(Translated for the Civil Engineer and Architect's Journal from the Berlin Gewerbeblatt.)

Bronze should be of a good colour, and yellowish red is preferred: it should be capable of being wrought with the file and the chisel; it should have the fluidity requisite for filling perfectly all the cavities of the mould, and producing an exact impression, and it should be capable of taking patina or a green colour by the application of a mordant. The first quality is best obtained in those alloys of tin and copper in which the tin is in a proportion of from 15 to 6 per cent, the red colour of the compound, and its tenacity increasing in inverse proportion to the quantity of tin contained. But all the combinations of copper and tin are formed by the mechanical mixture of anterior combinations of copper and tin, of which one containing exactly 61⅔ per cent. of copper, and 38⅓ per cent. of tin, is distinguished by a bluish tint and crystalline fracture, and possesses considerable hardness; whilst the other contains nearly 95⅓ per cent. of copper and 4⅔ per cent. of tin, and has a bright yellow colour tinged with red, and presenting a close grain, on fracture, a rough surface, and much tenacity. The first combination, which is the harder, contains exactly 3 atoms of copper and 1 of tin, and the second 30 to 40 atoms of copper to 1 of tin. These two combinations may be considered as representing hardness and tenacity, the due development of which properties of cohesion can only exist as the combination is uniform throughout the mass, an effect difficult to be produced in pieces of bronze very dissimilar, and cooling with a different degree of rapidity. These reasons form a considerable objection to the use of copper-tin bronze for statuary founding, besides which, although a sufficient proportion of tin will give fluidity so as to fill the mould well, such an alloy is bad for the chisel, flying off in little bits, which prevents the work from looking well; neither do these alloys present a good patina.

The capability of being wrought by file and chisel is afforded by copper-zinc alloy, provided the zinc does not exceed 25 per cent. nor fall below 5 per cent.; but it is often obstinate to handle, and yet is not hard enough in delicate parts to withstand the action of chiselling. The colours are a yellowish red, verging often to a citron yellow. Some of these alloys are very fluid, but do not fill the mould well, to effect that, 50 or 58⅓ per cent. of zinc must be introduced, but which alloys are hard and brittle under the chisel. Copper-zinc, therefore, is not a good alloy, but zinc added to copper is susceptible of a good patina.

Profitting by these several properties, Professor Hoffman has made some experiments to obtain a good statuary bronze, and recommends the alloys ranging between the two following cases.

1st. To produce the reddest bronze.

88¾ copper-zinc (7 atoms copper, 1 atom zinc.)
11¼ copper-tin (3 atoms copper, 1 atom tin.)
———
100

2nd. A cheap bronze with a bright yellow colour almost golden.

93½ copper-zinc (2 atoms copper, 1 atom zinc.)
6½ copper-tin (3 atoms copper, 1 atom tin.)
———
100

The combinations between these two, Captain Hoffman ranges in five classes, possessing various properties.

REGISTER OF NEW PATENTS.

UNDER this head we propose to give abstracts of the specifications of all the most important patents as they are enrolled. For this purpose we shall feel obliged if patentees will favour us with abstracts of their patents, immediately after their enrolment. If any additional information be required as to any patent, the same may be obtained by applying to MR. LAXTON at the Office of this *Journal*.

STANDING RIGGING FOR SHIPS.

JAMES JOHN GREERS, of Woolwich, Surgeon, for "*Improvements in apparatus for securing, or fixing, standing rigging, and chains, and other tackle.*"—Granted July 1; Enrolled January 1.

THIS invention of certain improvements for fixing standing rigging, chains, and other tackle, relates first to an improved lanyard, and consists in the application of a screw with a right and left handed thread, each of which are made to fit into a boss, having a hook at the outer end, for affixing the same to certain parts of the rigging: it will therefore be seen, that, on giving motion to the screw, which is effected by means of a tommy, or spanner, which is made to fit on a boss, or enlarged part formed in the centre of the screw, the two bosses will be simultaneously drawn together or separated, so as to slacken or tighten the parts of rigging to which they may be attached at pleasure.

The second part of the invention relates to a hook which is constructed at the lower part where the curve takes place, with a hinge joint; the two parts of the hook thus formed, when affixed to the rigging, are secured by a cord or "mousing." These improvements, with respect to the screw lanyard, are stated to be preferable to the present mode of securing rigging, for this reason, that they can be slackened or tightened in any weather without impeding the vessel's course, and in the application of the above to vessels of war, the inventor presumes that, on account of the cylindrical form of the screw lanyard, a shot would glide off, and thereby preserve the shroud, whereas, by the present mode of constructing them, the lanyard would be cut, and the shroud disengaged, and thus cause danger and inconvenience to those working the ship. Lastly, the hook, which may be used in connexion with the screw lanyard, for securing the shrouds, being secured by the mousing, may, in case of sudden storm, or where it is necessary to cut away the masts and rigging, be disengaged at a moment's warning, by simply cutting the cord or mousing, which will allow the hook to fly open.

The inventor claims, first, the mode of working a double screw into two separate boxes bored out to receive the screw, and applying the same to standing rigging. Secondly, the exclusive manufacture of a hook or hooks with a joint or hinge, and the privilege of attaching such hook to chains or standing rigging.

FLATTENING GLASS.

JAMES HARTLEY, of Wear Glass Works, Sunderland, Glass manufacturer, for "*Improvements in the manufacture of glass.*"—Granted July 6; enrolled January 6, 1844.

THE present mode of flattening cylinders of glass, appears, from the specification to be defective, inasmuch as the heat of the cylinder to be flattened is the greatest on that side next the flattening stone, which side of the cylinder, being towards the fire, becomes highly heated, in consequence of which, such side will flatten, whilst the other side, being comparatively little heated, will retain much of its stiffness; the first part of this invention, therefore, consists in the application of a rotary stone of about 10 in. diameter, which is fixed at the right of the flattening stone, in the position where the cylinders are usually put before being moved to the flattening stone: on the under surface of the rotary stone is an axis which is caused to rotate in suitable bearings, so that the workman may readily turn round the stone with the cylinder of glass upon it, so that the heat of the glass can be kept equal on all sides. The patentee, in the second part of his improvements, states that some difficulty is experienced in getting a cylinder of glass, after it has been cut open, flat upon the stone, in consequence of the air which is between the flattening stone and the glass; to obviate this, Mr. Hartley perforates the flattening stone with a number of small holes, about ⅛ of an inch in diameter, which allows the air to escape from underneath the plate of glass; it is possible that a stone so perforated would mark the face of glass, but where such plate is to be ground and polished it is of no consequence, as the marks would be removed by the operation of grinding. The third part of the invention relates to certain improvements in the bed or table upon which plate glass is ground; the mode hitherto employed has been, to form a bed of plaster of Paris; in place of this, a bed is formed by a sheet or sheets of india rubber cut about ⅜ of an inch in thickness, and of a size dependent upon the plate to be ground; owing to the adhesive quality of india rubber, the plate of glass will be found to adhere very firmly during the process of grinding and polishing.

Lastly, in the manufacture of crown glass, it is well known, that just before introducing the glass into the flashing furnace, the nose of the glass is heated in a furnace constructed at one side, and which is called the nose-hole; the air which causes the rush of vapours through the nose hole, is introduced below the fuel; by which means the draft causes a dust and certain vapours to pass this nose-hole, which is found to be prejudicial to the glass; the mode of obviating this is by constructing air tubes which proceed from the outside of the glass house; by these tubes air is conducted to the furnace, and allowed to enter in streams at the sides, or front, and above, to the fuel, which entirely obviates the defect above referred to. The claims are for the improvement in the flattening kiln capable of rotating; for successively receiving the cylinders of glass to be flattened before they are moved on the flattening stone. Second, the application of a perforated flattening stone. Third, the use of india rubber for the purpose above described. Fourth, the peculiar mode of constructing a furnace for heating the nose of crown glass before introducing the same into the flashing furnace.

METALLIC ROOFS AND JOISTS.

JAMES BRYDELL, Junior, of Oakfarm iron works, near Dudley, Staffordshire, Iron master, for "*Improvements in the manufacture of metallic roofs and joists and improvements in joining sheets or plates of metal for various purposes.*"—Granted July 6; Enrolled January 6.

THE mode of constructing metallic roofs, according to the first part of this invention, is as follows; the rafters are made with a groove along the upper edge; and the plates forming the covering, which are of a rectangular form, are bent down at the sides, so as to form a right angle with the surface; one end of each of the plates is also bent down in like manner, and the other end bent upwards, so that when the plates are put together, the lower end or that bent downwards, laps over the upper end of the plate adjoining, the end of which is bent upwards, the lateral edges of each of the plates fitting into the grooves formed in the rafters, into which they are secured by means of wedges, the space between the plates is then filled with asphalte: another mode is by forming a groove in the rafters as described, and also in the stretchers, which, on being put together, form a rectangular or oblong groove, the edges of the plate in this case are bent one way, and made to fit the rectangular groove; the plates in this case are secured by wedges, and the water prevented passing through the joints by filling the space with asphalte.

The second part of the invention relates to a mode of joining metallic battens or laths; in this case the rafters are formed with a mortice on the upper edge, and the ends of the battens so constructed as to fit in the same, which are to be constructed as above described. The third improvement consists in forming the rafters partly of wood, and partly of iron; this is also effected by forming a groove in the edge of the rafter, which is afterwards to be filled with wood, so that the laths or battens, when tiles are to be employed, may be nailed to the rafters.

Fourth, and lastly, this part of the invention relates to a mode of welding iron plates, and bars of iron together; for this purpose the patentee erects a pair of rollers close to the mouth of the furnace; the plates intended to be welded may be affixed together by a lap joint, or a bar of iron may be placed upon the plates so as to cover the joint. The plates are then to be secured by means of rivets or clamps, and placed in the furnace; the rollers are so constructed that the top roller is capable of being raised, so that the workman can put a pair of tongs between, for the purpose of taking hold of the plate; when the plates have got to a welding heat, they are withdrawn, and one end placed between the rollers, which on being set in motion, will draw the plates from the furnace, and the parts will be welded together by the pressure. When it is required to strengthen a plate of iron, a number of small pieces may be placed upon the surface in various devices, and the plate heated and welded as above described.

The inventor claims first, the mode of constructing metallic roofs by employing iron rafters with grooves and metal plates turned at their edges. Second, the mode of making metallic roofs by applying iron rafters with grooves for receiving iron laths. Third, the mode of constructing wrought iron rafters and joists with grooves for wood. Fourth, the mode of joining plates or sheets of iron, by causing them to be welded by means of the pressure of rollers.

RECTILINEAR INTO ROTATORY MOTION.

JAMES BOOTH, of Liverpool, clerk, and doctor of laws, for "*Certain improvements in the means of converting rectilinear into rotatory motion, and of converting rotatory into rectilinear motion.*"—Granted July 6; enrolled Jan. 6.

THE specification, after referring to the various mechanical arrangements which have been employed for the above purpose, proceeds to state that it is a well known mathematical principle that if a right line of fixed length is in motion, and its ends move in two right lines that are at right angles to each other, the centre or middle point of such right line will describe a circle, whose diameter is equal to the length of the given right line; let A B, fig. 1, be the right line, and C D, E F be right lines, at right angles to each other, and O the middle point of A B; then if the extremities move alternately on the lines C D, E F, the point O will describe a circle, whose centre is I, and diameter A B; it is from the above principle that the inventor bases his invention, which is as follows. Fig. 2, is a sectional elevation; A A is a framework of iron, supported by pillars B B, C is the cylinder of an engine, D the piston rod, attached to a cross head, each end of which passes through a slide *d*, made to work freely in the grooves or openings E E, of the framework A A. Fig. 3 is a view of the framework A A, showing the arrangement of parts for converting the rotatory into a rectilinear, and the rectilinear into a rotatory motion. G is the main or crank shaft, H the crank, and I a connecting or coupling, one end of which is attached to the slide *d*, working in the vertical groove, the other end being connected to a slide working in the horizontal groove E, and the centre or middle point connected to the outer end of the crank H. It will be evident, that on motion being imparted to the piston rod, the extreme ends of the connecting link (or slides) will move in a horizontal and vertical direction, which combined movements will give a rotatory motion to the crank shaft. It is perhaps worthy of notice, that if the cranks (there being two) be placed in opposite directions, or in a line with each other, the shafts to which they are affixed will revolve in opposite directions. Mr. Booth claims the conversion of alternate rectilinear motion into continuous rotatory motion, and *vice versa*, by the combined action of the ordinary working cranks, in connexion with arms or sliding cranks, the ends of which are caused to move in grooves at right angles to each other, as described.

Fig. 1.

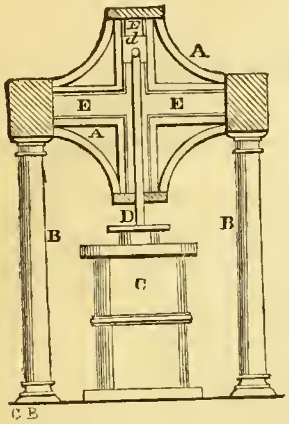

Fig. 3.

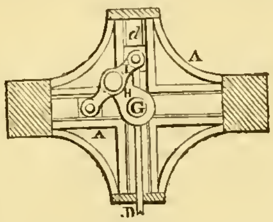


IMPROVEMENTS IN PROPELLING.

James Joseph Brunet, of Limehouse, Middlesex, Esq., for "*Improvements in propelling*."—Granted July 6; enrolled Jan. 6.

The first part of this invention relates to an improved paddle wheel, the float boards of which can be forced outwards, or drawn in, or reefed or unreefed as may be desired. This improved wheel is constructed with two float boards to each arm of the wheel, one placed at the front side of each of the arms, and the other at the back, and attached together by means of a diagonal arm, so that the floats are in two different places, but so situated with respect to each other, that the inner edge of one coincides with the outer edge of the other; in place of bolting the floats to the arms of the wheel, they are so constructed as to be disengaged from the arms, or in other words, to be locked and unlocked, with respect to the arms, at pleasure; this is effected by means of two wheels, one of which the patentee terms the compression wheel, and the other the reefing wheel; these wheels are made to turn freely on the shaft of the paddle wheel, and have motion given them by means of an arrangement of gearing and a winch; to each pair of float boards is attached, by means of a pin joint, one end of a diagonal arm, the other being attached, in like manner, to the periphery of the reefing wheel, which, in being put in motion by the aforesaid gearing and winch, the floats will be drawn towards the axis of the wheel, and the same will be unlocked, or disengaged, from the arms of the wheel.

The second part of the invention consists in another modification of the above, the difference being that the floats are placed further apart, as in the ordinary paddle wheel, and in a line, or some circular plane with each other, at equal distances from the axis; in this case, each alternate float only is connected to the reefing wheel, and is capable of being reefed and unreefed, the other being bolted to the arm of the wheel. The inventor claims the reefing and unreefing of floats of paddle wheels by the combined action of reefing wheels and connecting rods.

The third part of these improvements consists in a mode of propelling vessels without the aid of paddle wheels, or other external propelling machinery. This is effected by causing a continuous stream of water to be drawn through a number of openings, either at the bow or sides of the vessel, and then ejecting or forcing the same through a number of openings at the stern of the vessel, whereby a retractive force is obtained, which propels the vessel forward. For this purpose a steam engine of sufficient power is employed to work a three-throw crank, which gives motion to three pumps that inject and eject the water in a continuous stream, thereby propelling the vessel forward.

The last part of the improvements consists in a new mode of connecting and disconnecting the cranks of the paddle shafts of steam vessels, and the cranks of the engine; this is effected as follows:—A piece of iron of the form of a washer, having a portion of its circumference, equal to the diameter of the hole, cut out, is affixed to the end of the crank of the paddle-wheel shaft by means of bolts; the opening in the above is in a lateral direction and of sufficient size to receive the end of the "toe-pin," or crank-pin, which pin is fixed to the crank of the engine shaft in the ordinary manner; the mode of securing the end of the crank-pin into the opening of the piece of iron bolted on the crank of the paddle shaft, is by a strong iron ring, which in the first place is passed over the crank-pin, and the ends of the two cranks brought together, so that the end of the crank-pin passes into the opening of the piece of iron, and is there held by slipping back the ring, and passing it over the aforesaid piece of iron bolted to the crank of the paddle-wheel shaft. The patentee claims the mode of propelling a vessel by causing water to flow from the outside into and through pipes, and to be ejected continuously through orifices placed near the stern, by means of two or more pumps.

Lastly, the mode of connecting and disconnecting the crank of the paddle wheel shaft to the crank of the steam engine shaft.

PORTABLE ROOF.

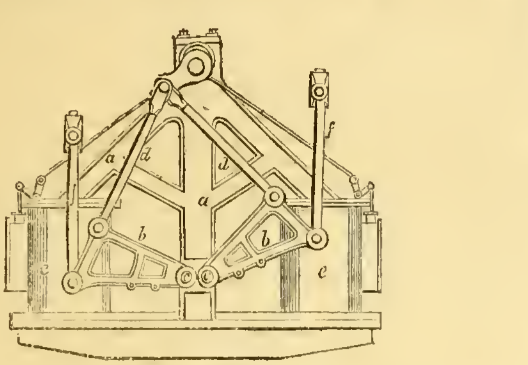
George Parsons, of West Lambrook, near South Petherton, Somersetshire, gentleman, for an "*Improved portable roof for agricultural and for other purposes*."—Granted July 6th; Enrolled January 6th.

The portable roof, as described in the first part of the specification, consists of an iron boss or socket, having a collar at each end; in the circumference of one of the collars there is a number of mortices for receiving the upper ends of the rafters, the lower ends being attached to a suitable framework of a circular form, supported by the lower part of the socket; the roof so constructed is made to slide over a pole made in the form of a screw, by nailing or otherwise fastening thereon a number of segments of metal, which, when joined together, are of a spiral form; the screw pole so constructed is made to pass freely through the socket, within which is an antifriction roller that rests upon the plate or plates of metal forming the screw: it will be seen that this description of roof can be easily removed, as it is only required to provide a block or pedestal having a hole in the top for receiving the screw pole and keeping the same in a vertical position; and in order to raise or lower a roof in constructing or removing a hay rick, so as to protect it from the weather, it is only necessary to give a rotary motion to the roof, and the same will be raised or lowered as may be required. Another description of roof, which is of an oblong form, is supported by two poles, but in place of raising and lowering the roof as above described, at each end of the roof there is a pulley, each pulley being provided with a ratchet wheel: round one of the pullies there is a rope or chain, which passes in a horizontal direction to the pole adjoining, and over a guide pulley to the top of the pole, where it passes over another guide pulley to the top of the other pole, and from thence in like manner once round the other pulley at the opposite end of the roof; thus by giving motion to the axis of each of the pulleys by means of a winch, the roof can be raised or lowered at pleasure. Another mode of supporting and raising the roof, is effected by boring a number of holes in each pole and passing pins through, upon which the ends of the roof are made to rest. The patentee claims, first, the arrangement of a roof formed round a sliding socket capable of being moved up and down at pleasure, on a pole. Second, the peculiar method of raising and lowering a roof, first by a spiral worm and antifriction roller in the socket; and, secondly, by a ratchet wheel and pulley. He also claims the application of a gauge rod, which is fixed to the lower collar of the socket of the roof first described, which gauge is capable of being moved round independently of the roof, for the purpose of regulating the diameter of the hay rack about to be constructed.

IMPROVEMENTS IN STEAM ENGINES.

Jacob Samuda, of Southwark Bridge Iron works, Surrey, Engineer, for "*Improvements in the construction of steam engines, particularly applicable to the purposes of steam navigation.*"—Granted July 10, 1843; Enrolled January 10, 1844.

The first improvement consists in a novel construction of the steam engine, whereby the cylinders are placed almost over the keel of the boat; the steam cylinder, piston rod, cross head, and side rods, are of the ordinary construction, but in place of the side lever beams, Mr. Samuda employs a lever of a triangular form moving upon centres, which gives motion to the connecting rod; the cylinders of this engine are not exactly in a line with each other but a little sideways, and in an opposite direction to each other, so that the connecting rods may work close to each other, but if it is desirable to have the cylinders in the same line, it can be effected by cranking one of the connecting rods, so as to receive the other: the following sketch, which is an elevation of the engine with one side removed, will serve to illustrate more clearly the novel construction of the same; *a a*, is the framework of the engine, *b, b* two iron triangles working on centres *c, c*, fixed to the framework; *d, d* the connecting rods, the lower ends of which are connected to the ends of the triangle by pin joints, and the upper ends to the single crank pin; *e, e*, the cylinders, *f, f*, the side rods connected at one end to the cross head of the piston, and at the other end to the triangle by a pin joint as shown by the drawing.



The second part of these improvements consists in a modification of the above, but in place of one cylinder being employed at each end of the frame, there are two cylinders placed abreast of one another; in this case there are four air pumps employed which are worked from the cross head, but if preferred one only may be employed, which may be placed in the centre of the frame and worked from the crank shaft; the condensers are underneath the bed plate of the engine. The cylinders in the third part of these improvements are elevated upon brackets cast or otherwise fixed to the framework, so that the pistons descend and are connected to the ends of the triangles by short links; the eccentrics in this case are fixed one on each shaft, and the crank pins are connected by a link, so that the engines in case of an accident, can be worked independently of each other. The fourth part of these improvements shows the application of the above to vessels moved by submarine propellers. Some idea may be formed of this part by inverting the annexed sketch. In this case the triangles are placed above the main shaft, which latter passes through the stern of the vessel, and upon it is fixed a drum having arms of plate iron made in a spiral form, so as to have the effect of forcing a very solid body of water through, the reaction of which has the effect of propelling the vessel. Fifth improvement consists in the arrangement of two vibrating cylinders inclined at an angle of 45 degrees, and an open topped air-pump placed between them, all of which are worked from one crank pin. Sixth improvement relates to a mode of working the exhaust valves of steam engines, the steam valves being constructed in the usual way. For this purpose, two segments of metal sufficiently long to cover the exhaust passages are made to fit the inner circumference of the cylinder; these segments of metal, which are connected together by a rod, are actuated by the motion of the piston, that is to say, when the piston has nearly finished its upward stroke it comes in contact with the segment at the top of the cylinder, and closes the exhaust way at the top, and opens that at the bottom, and *vice versa*. The seventh relates to a mode of regulating the expansion valves of steam engines and so as to cut off the steam at any point of the stroke; each expansion valve is worked by a cam or eccentric having a boss cast on one side, and bored out so as to fit the crank shaft and work loosely upon it through the circumference of the boss, and about one third or fourth of the way round is made a slot; a hoop is then bored out to fit nicely upon the boss of the eccentric, and through the circumference of this hoop is made a spiral slot; a pin is then passed through the slots of the hoop and eccentric, and is fixed into a hole formed in the circumference of the shaft; the hoop it should be observed, is prevented turning round upon the boss of the eccentric by means of keys; it will therefore be seen that on moving the hoop endwise, which is effected by a bell-cranked lever actuated by a screw, that the eccentric will be turned round upon the shaft, whereby the expansion valves can be regulated so as to cut off the steam at any required part of the stroke.

The eighth and last improvement is for a mode of constructing a governor for regulating the discharge of the saturated brine from the boilers; to effect this a valve box is made in the discharge pipe, having a conical valve, on the spindle of which there is a helical spring which acts against a collar formed on the end of the spindle, so as to raise the valve and thereby increase the size of the aperture; the action of the steam and brine upon the base of the cone, will of course have the effect of closing the aperture by forcing into it the apex of the cone, and the same will be regulated according to the pressure of steam in the boiler.

STONE SAWING MACHINERY.

William Hutchison, of Ivy-bridge Lane, Strand, Middlesex, marble merchant, for "*improvements in machinery for cutting or sawing marble and other stones.*"—Granted July 13, 1843; enrolled January 13, 1844.

This improvement consists in the application of a saw guide, or frame fixed above the block of marble or stone to be cut, whereby the sawing of stone is rendered very easy, and capable of being done by any man or boy of sufficient strength to move the saw frame.

The saw guide consists of two pieces of timber parallel to each other and a few inches apart; these timbers or guide are placed above the stone, and supported at each end by transverse pieces, which pieces are capable, by means of screws, of being raised or lowered at pleasure. At each end of the saw frame (which may be of the ordinary construction) there are two anti-friction rollers which work between the guides, and serve to keep the saw frame in a vertical position; in addition to the screws above referred to for raising the pieces of timber that support the ends of the guide frame, there are also screws for moving and adjusting the said guide frame laterally, by means of which the saw can be set to any part of the face of the block of marble or stone when it is required to cut it into slabs, and the guide frame by the arrangements above described, can also be set to any required height. Another improvement in this apparatus is in the application of a weight for bearing up the saw frame, so that the sand and water may get freely under and pass the blade of the saw; for this purpose a pulley, capable of adjusting itself to the position of the saw frame, is suspended from a bar affixed to the roof of the building; a rope, having a counterbalance weight at one end, is passed over the pulley, and attached to the frame of the saw, which will have the effect of supporting the same as may be required. The claims are for the mode of guiding saws worked by hand by means of guides, together with the moving of the guides laterally or vertically by means of screws; also the application of the anti-friction rollers, and lastly, the mode of suspending a pulley that moves with the saw guide.

STEAM PROPELLING MACHINERY.

Joseph Maudslay, of Lambeth, Surrey, engineer, for "*Improvements in machinery used for propelling vessels by steam power.*"—Granted July 13, 1843; enrolled January 13, 1844.

The first part of these improvements relates to a mode of transmitting power from one shaft to another, for the purpose of driving or giving motion to a submarine propeller. The main or crank shaft in this case is in a line with the keel of the vessel; on the end of the shaft (which may be prolonged to any convenient distance towards the stern of the vessel) there is a drum, having a number of grooves in its periphery. On the end of the propelling shaft, which is placed below and parallel with the crank shaft, there is another drum of smaller diameter having a like number of grooves formed in its periphery; these drums are keyed on their respective shafts in such manner with regard to position, that the grooves in one of the drums are opposite the spaces of the other drum: the mode of transmitting motion from the drum of the crank shaft to that of the propelling shaft, is by a rope which circulates with repeated convolutions around the two drums. The rope in the first place is passed over the drum of the crank shaft at one end, it is then conducted by means of two guide pulleys to the opposite end of the drum, and made to pass under the drum of the propelling shaft into that groove nearest the end of the drum; it is then passed over and under the two drums until it reaches the opposite end, at which place the two ends of the rope are spliced together. Between the two drums there is another pulley fixed on the end of a moveable lever, actuated by a screw; the object of this apparatus is to tighten the rope when required, which is effected by causing the pulley to press against the rope. The patentee claims the improvement in machinery for propelling vessels by steam power, which consists in the application of an endless rope or ropes circulating with repeated convolutions around grooved drums, for the purpose of transmitting motion from one drum to another. The second improvement consists in the application of a revolving propeller having two, three or more oblique vanes, and also in the application of two rudders in place of one, which rudders are placed behind the revolving propeller, as seen in the accompanying diagram. Fig. 1 is a side elevation of a portion of a vessel, showing one of the rudders and the revolving propeller. Fig. 2, an end view of the same: *a a*, is the revolving propeller fixed upon the end of the shaft *b*, which passes through the stern of the vessel, as shown by dotted lines. The propelling shaft receives its motion from the

Fig. 1.

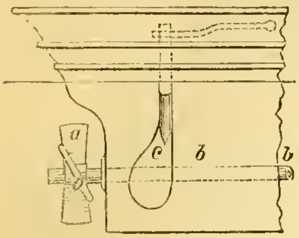


Fig. 2.

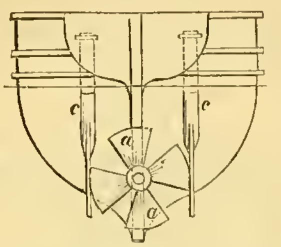

crank shaft of the engine in the manner above described, or the same may be driven by spur wheels: *c, c*, are the two rudders, the situation of which will be seen by the drawing. Mr. Maudslay claims for this part of the invention the improvement in machinery described for propelling vessels, which consists in the application of any revolving propeller by oblique action, being situated behind or abaft the stern post of the vessel, and substituting for the ordinary rudder two rudders, when such rudders are used in combination with the revolving propeller.

STREET CLEANING APPARATUS.

Stephen Geary, of Hamilton Place, King's Cross, Middlesex, Architect, and Civil Engineer, for "*Improvements in machinery, or apparatus, for clearing, cleansing, watering, or wholly or partially covering with sand, or other materials, roads, streets, or ways; and which machinery is also applicable to other similar purposes.*—Granted July 13, 1843; Enrolled January 13, 1844.

The machine, as described in the first part of the specification, consists of a large drum or cylindrical case of wood, or other material, mounted in a frame running upon two wheels; to one of these wheels is fixed a spur wheel, which takes into and drives a wheel keyed on the end of a horizontal shaft, which passes through the centre of the machine; upon this shaft, and within the machine or cylinder, there are keyed two wheels, or circular pieces of wood, having notches or openings in the periphery, which receive the ends of two or more pieces of wood or metal, which are denominated the "stock;" between these pieces of wood or metal, the brushes or brooms, formed of any suitable material, such as "birch, cane or whalebone," (or scrapers of wood or iron), are secured by means of screws or rivets. It will, therefore, be seen, that on motion being given to the machine, a rotary motion will be imparted to the axis, upon which is keyed the circular pieces of wood, and the brushes (which may be arranged in consecutive order, or alternately with scrapers, or scrapers alone may be employed) are caused to act against the surface of the ground, whereby any accumulation of dirt will be removed by the brushes, which are in close contact with the internal surface of the cylinder, and the same will be conducted by the brushes or scrapers, and deposited into a receiver formed within the machine, and from which it can be removed through an opening formed for that purpose. The claim is for the construction and application of revolving brushes or brooms when acting against a fixed curved surface, or portion of a cylinder, with which they are in close contact, for the purpose above described.

The drawings show another modification of the machine above described, in which the receptacle for the dirt, in place of being within the machine, is placed in front; in this case the receiver may be placed on a pair of wheels, and so constructed as to be detached from the machine itself. Another part of these improvements relates to the application of certain parts to the machine first described, whereby the said machine may be rendered available for the purpose of watering the streets or roads, when the machine is not required for the purpose of removing dirt or soil. In order to convert the aforesaid machine into a watering machine, it will be necessary, in the first place, to throw the wheels out of gear and remove a portion of the brushes. The reservoir, in this case, is constructed with openings at the lower part, to which are attached the branch pipes, provided with a valve or stop cock, and delivery pipe, which is perforated in like manner to those in ordinary use. The next step is to fill the reservoir with water, when the machine is fit for use, and can be employed for the purpose of watering streets, roads, or ways. The claim is for the general combination and arrangement of parts constituting a machine for the purpose above described.

Another part of these improvements relates to the application and arrangement of certain parts to the above mentioned machine, whereby it may be employed for the purpose of distributing sand or other material, over and upon the surface of roads, so as to afford a better foothold for horses, and also more secure for pedestrians. Presuming the machine last above described to be employed for this purpose, it will be necessary to remove the pipes, &c., and the reservoir, which is constructed with a flange, has another portion affixed to it by means of bolts, which, when put together, form a circular reservoir, with an opening at the lower part for the delivery of sand, or other material, which is regulated by a slide or hopper. The patentee does not claim any of the separate parts of the machine above described, except so far as the same may be employed in the general combination and arrangement of parts constituting a machine or apparatus for the purpose above described.

PROCESS FOR OBTAINING AMMONIA AND CYANOGEN.

Richard Laming, of Radley's Hotel, New Bridge Street, Blackfriars, gentleman, for "*Improvements in the purification and application of ammonia to obtain certain products.*"—Granted July 13, 1843; enrolled January 13, 1844.

In order to obtain ammonia according to the first part of this invention, sufficiently pure for the arts, the patentee employs a solution of muriate of lime and gas water, as follows: a sufficient quantity of muriate of lime in solution is mixed with gas water, in order to convert the ammonia which is present into muriate of ammonia; the carbonate of lime is then separated, and the remaining solution boiled for an hour, and then left to cool; it is afterwards mixed with a sufficient quantity of hydrated oxide of iron to combine with all its sulphuretted hydrogen, and secondly with sufficient lime to saturate the muriatic acid which is present, after which the solution may be distilled, when the ammonia will be found in the water in a tolerably pure state. The second part of these improvements is the application of ammonia to the production of cyanogen, so as to make prussic or hydrocyanic acid the primary result, and at a price so low as to admit of its application to the economical production of the cyanurets, ferrocyanurets, and hydrocyanates. Generally the process is as follows: the inventor provides an iron cylindrical retort about 1 ft. 6 in. diameter and 8 ft. long; this cylinder, which is lined with fire bricks, and filled with pieces of charcoal, is set vertically in a furnace, and brought to a red heat; ammonia in the form of vapour, with certain other substances, which do not prevent the desired result, is introduced by a pipe near one end of the retort. In its passage the ammonia is deprived of part of its constituent hydrogen, while the remaining part, together with its nitrogen, combines with carbon to form prussic or hydrocyanic acid, which finally escapes from the heated vessel in the form of vapour, mixed with other matters, amongst which will be some of that substance in an undecomposed state. The prussic acid vapour thus obtained may be condensed in water, for subsequently making the compounds of cyanogen and for other purposes, or it may be brought at once into communication with the several substances with which it, or its constituent cyanogen, is to be combined; for instance, it may be received into water containing certain metallic oxides, with which it will make the corresponding metallic cyanurets or hydrocyanates, &c. The patentee claims the making of prussic or hydrocyanic acid by the re-action at a red heat of any convenient form of carbon and ammonia, by whatever means such re-action is established: also the use of prussic acid so made for saturating and dissolving bases; and thus giving existence to cyanurets and hydrocyanates, and for other purposes, to which prussic acid is or may be usefully applicable.

Condensation of Carbonic Acid by Charcoal.—The cells of wood charcoal have a diameter of about 1-2400th of an inch, and if a cubic inch consisted entirely of cells, their united surface would amount to 100 square feet. By experiment it can be shown that the cells constitute five-eighths of the whole cubic contents of the charcoal, and, allowing for the space occupied by the charcoal, the actual surface of the cells will be about 73 square feet. When charcoal is plunged into carbonic acid gas, it absorbs into its cells no less than 56 times their cubic contents at the ordinary temperature and pressure, and, consequently, the gas is condensed to 56 atmospheres. But according to the experiments of Addams, carbonic acid liquifies under a pressure of 36·7 atmospheres, and we are hence compelled to conclude that above one-third of the carbonic acid which is condensed on the walls of the cells is in the liquid state.—*Mitscherlich.*

THE PHILOSOPHY OF DESERT FORMATIONS.

No. 5.

Were the love of learning to be revived among the Arabians, and did their philosophers turn their particular attention to the modern science of geology, their opinions and theories, suited to the phenomena before them, would be peculiar to themselves, and such as embrace a system of oceanic deposits alone, excluding many of the phenomena now so familiar to even the unlearned reader: instead of describing a succession of catastrophes, so strikingly manifest in many of the formations of Europe, their ideas would be confined to the extreme simplicity of the desert strata, and to those changes which have taken place in fossil bodies and fossil beds, and by which changes, dependent upon climate and position, the mineral kingdom is produced: and could they not avail themselves of modern discoveries, facts which speak for themselves, requiring no interpretation, their ideas would be narrowed to the days of Woodward and others, and their theories would be equally ridiculous. On the other hand, did modern geologists take the trouble of visiting and exploring these lands, submitting with resignation and cheerfulness to the necessary privations and dangers attending these journeyings, there is little doubt but great changes would take place in their respective theories: they would undoubtedly learn and unlearn much.

In the preceding chapter I have confined my observations to oceanic fossil formations, and in these are naturally included all desert soils; but, inasmuch as the mineral kingdom is extensively developed in these wastes, it becomes necessary, in order to explain with perspicuity and simplicity the phenomena of nature, to enter into more minute details of the causes of effects manifest in the creation of rocks, stones, earths, and metalline bodies. The multitude of fossils found in all parts of the earth, arranged in groups and families, forming in many instances entire strata, and generally disseminated over the surface or in the interior beds, attest to the wonderful changes which this planetary body has undergone during the revolutions of Time. Exclusive of the magnificent fossil formations of the deserts, which are very often some hundreds of feet in thickness, and which, in fact, compose the entire strata, every portion of the earth exhibits the like phenomena of oceanic and mineral formations; the chalk deposits, extending over a great portion of the British isles, northern France, Germany, Denmark, Sweden and Russia, as also in North America, however dissimilar in their lithological composition, agree in their character of oceanic organic bodies; and such may be said of the oolite and shell limestones. On searching into the lower strata, we invariably find fossil bodies analogous to those now forming beneath the waters, or but recently abstracted from them, and so perfect is their state of preservation, that we are enabled not only to identify the genera or order to which they belong, but also to discover the sequence of events and the manifold influences under which they were produced; we distinguish in the Ichthyosauri, ammonites, echini, clumps of coral, and families of shell fish, the once living occupants of quiet seas and tropical heat, which must have lived and propagated their kind in those places where we now find them; and as Cuvier truly remarks, they are found in elevations far above the level of the ocean, and in places where the sea could not have been conveyed by any existing cause. They are not only included in loose sand, but are often embedded in the hardest stones. Every country, every continent, every island of any size, exhibits the same phenomena. To what other conclusions, therefore, can we come, but that the most elevated parts of the earth were once covered by the waters, that those vast chalk and oolite deposits, hills of carbonate of lime, and valleys of oceanic marl, owe their origin to oceanic organic bodies? The varied phenomena also testify, that, although by changes of the earth's axis of rotation, some portions of these elevated lands have been again, and perhaps again submerged, the general appearance of the earth testifies to the operation of very slow causes of effects manifest, as well as to the gradual but universal decrease of the waters. The earths produced by atmospheric influences, although wonderful to contemplate in their variety and extent, are as nothing compared to the oceanic formations, to the existence of which the former owe their origin and many of their peculiar properties; with the exception of several varieties of schist and basalt, the bulk of aggregate, and in general the entire mass of rocks forming the prominent features of the earth, are exclusively oceanic, and most of the mineral bodies included in the carboniferous beds are produced by oceanic influences.

The protean powers of nature are strikingly manifest in the changes which take place from the living body to the mineral compound, the same species of shell fish is seen under a variety of forms: it resolves into marl or chalk, it silicifies as flint, it is identified in limestone or shell marble, it sometimes consists of several distinct minerals, thus chalk and flint often form separate parts of an echinite, and in Derbyshire, chalk, calcareous spar, bitumen and quartz, are frequently incorporated in the same shell; many of the after changes are still more beautiful: thus some are converted into Egyptian jasper, others into amethyst quartz, chalcedony, or carnelion. It is only when we follow the order of these changes, and become acquainted with the laws which govern and direct them, that we are enabled to form a correct idea of their extent and importance in nature: thus many of the chalk and oolite formations, and the limestones, have no appearance of organic remains left, in consequence of the general decomposition of the fossil bodies of which they are composed; but the material of these bodies is left as an undeniable record of their previous existence, as sure and certain as the comminuted particles of land vegetation, termed earth, denote the previous existence of terrestrial vegetable earth; and in corroboration of these facts, the same slow but certain changes are continually taking place before our eyes, until they are lost sight of in crystalline bodies.

Did this earth exist merely by decay and re-production, the phenomena of nature would similate to the causes in action, the rocks would moulder into sands and pebbles, and the terrestrial and oceanic matters would be so intimately blended together as to defy classification: but, is such the case? the oceanic earths, consisting of varieties of sands, marls and calcareous matters, limestone rocks, and siliceous bodies, are throughout the by far greater portion of the earth of unmixed qualities; thus vegetable earths are not found in the vast desert beds of the earth, nor does alumina enter into their composition, until such time as they become blended with terrestrial earths, or exposed to long atmospheric action: the syenites, porphyries, basalts, &c., simply siliceous bodies composing these oceanic tracks, are peculiar to them, and peculiar to their respective localities: the carboniferous formations bear an analogy to the formations of Europe and America which have not been intruded upon, by herbaceous plants and other organic products of dry earth: every portion of their soils is the product of organic action, or of action resulting therefrom: every stone is a group of fossil organic bodies, the body or fragment of a body of some inhabitant of the deep: the sands in their primary state principally consist of the comminuted particles of mollusca, but the shelly texture soon disappears after exposure to atmospheric influence: the animal oils have become mineralized, and either preserve their quality as naphtha, or they enter into combination with other substances, and thus disappear partially or wholly from the view. In all, and through all, we acknowledge the fossil kingdom as the basis of, and the proximate cause of the production of numerous mineral bodies.

The deserts of Persia are exceedingly extensive, and according to Chaudin, not more than one-tenth part of that country was cultivatible in his time. On the east of the Tigris a considerable desert commences, pervaded by the river Ahwaz, and extending to the north of Shuster, about 140 miles in length and 80 in breadth. The great Saline desert, including the great desert of Kerman, is about 700 miles long by a medial breadth of 200 miles; attached to this is the desert of Mekran. This immense area, extending 200 miles, is impregnated with nitre and other salts, which taint the neighbouring lakes and rivers. The whole country is distinguished for its deficiency of rivers, and a multitude of rocky mountains without vegetation. The soil of the plains is in general stony, sandy, barren, and everywhere so dry, that if it be not watered, it produces nothing, not even grass: even the clays on the banks of the Euphrates are strongly impregnated with muriate of soda. Separated from the great desert of Kerman, and bounded by mountain ranges and the Indian Ocean, are other extensive deserts of Baloochistan. The great desert of Zaharah stretches from the shores of the Atlantic to the confines of Egypt, including a space of 2500 miles in length and 700 in breadth, the whole of which, except a few insulated spots of comparative fertility, are sterile and desolate, consisting of barren plains, shifting sands, and ranges of hills composed of that peculiar class of rocks common to oceanic deposits, and sometimes wholly composed of rock salt. Its borders towards the Atlantic present in many places a succession of sea beaches, the table land rising upwards of 20 feet above the present level of high water. All the great deserts of the earth are most unquestionably ocean beds whence the waters have gradually receded, or otherwise have been suddenly thrown off by changes in the earth's plane of position, occasioning local or general catastrophe; where they have gradually retired, is evidenced by immense deposits of muriate of soda covering the surface of valleys, and forming hills of considerable magnitude, as well as entire strata disposed beneath the surface: on the other hand, their sudden retiring is denoted by the violence done to the elevated strata, and by the peculiarity of the valleys, which exhibit by strong water lines the rapid retreat of the ocean waters. Most deserts have their peculiarities thus the deserts of Lybia, Syria, Cobi, Hindostan and Persia, are noted for their sands; the Suez and Nubian, and Arabian deserts, for their saline and fossil beds, some of the Persian deserts, the desert of Ava, and others, for their immense quantities of naphtha, petroleum or mineral pitch; all of them abound with fossils, of species analagous to those now inhabiting the bordering seas, with petrifactions in which many species of fish may be distinguished, commingled with natron, the sulphates, and muriates, gypsum, limestone, magnesia, ocean marl, and other peculiar products, which denote oceanic origin: such is the general composition and character of the exterior beds, and such it appears to be beneath the surface, so far as the discoveries of man extend. Even the rocks of syenite, basalt, porphyry, sandstone and limestone, partake of the same nature, and from the simplicity of their components, and the total absence of potash and other peculiar products of terrestrial vegetables, must be exclusively assigned to the ocean. In and throughout the whole, the coral formations are exceedingly extensive, passing by a variety of transitions into rocks and earths, and silicified stones, and in the latter state lying loosely spread over the valleys, resembling in appearance, and being often mistaken for trunks of trees.

"The Arabian Desert," says Niebuhr, "bears every mark of having recently been a part of the bed of the ocean; and its little elevation above the sea would require but a small rise of its waters to restore this desolate track to its former condition. Its subsoil like that of the deserts is a grey clay, with a large proportion of sand intermixed with marine exuviæ, extending to a great distance from the sea. It contains large strata of muriate of soda, which in some places rise up in hills of considerable elevation. Its gentle and uniform slope towards the sea seems to indicate that it has gradually emerged from the ocean, which is still receding from it." The advance of the land upon the Gulf of Persia is exceeding great; indeed Charles T. Bell calculates it to be more than 280 miles since the last catastrophe, and there is certainly every reason to suppose that the whole extent of the great salt desert was at no very distant period covered by the waters of the Gulf, everything upon and beneath its surface demonstrating oceanic origin. The great salt plain at the head of the Red Sea is of like composition with the surrounding deserts, and in the days of the early kings of Egypt, must have been entirely covered by the ocean waters, and indeed the whole of the Suez, Egyptian, Syrian, Lybian, Mesopotamian, and Nubian Deserts bear incontestible evidence of their marine nature; the elevated plateau being almost wholly calcareous, or consisting of extensive fossil formations, and beds of salt. The soils of Syria, Palestine, and a great portion of Turkey in Asia, are of fossil formation, the greater portion of which is still uncovered, and unaffected by terrestrial vegetable matters. Syria abounds with salt lakes, and the soil of Palestine is so impregnated with bitter acrid salts and sulphur, as to render it wholly unfit for cultivation, even the waters of the river Jordan during the dry season, are brackish and unwholesome, flowing through hills of ocean marl of the consistence of clay: in fact, divested of its historical reminiscences, Palestine, composed of barren mountains and numerous deserts, is, considered as one whole, far from being favourable to the happiness or increase of the human race, depending entirely upon the rise of its rivers and periodical rains for its agricultural produce, and in periods of drought, which often occur, it too often suffers the triple scourge of famine, pestilence, and plague. Nor can we forget the Dead Sea, which is disposed in a valley of salt and mineral pitch: the hills by which it is surrounded are chiefly calcareous and abounding with fossils. Passing eastward over the great desert of Bockhara towards the Persian Gulf, we find the sea retreating from Baloochistan on the one side, where a great sandy desert is formed, and from Cutch on the other side; the great run being one vast sandy flat, containing immense quantities of muriate of soda, and covering a surface of 7000 square miles; but, however extensive, it is comparatively insignificant compared to the great desert with which it is united, embracing the important provinces of Agmere and Rajpootana. The drying off of inland seas is also an undeniable fact; thus the communications between the Caspian and the Black Sea, and the Red Sea and the Mediterranean, have been broken up, and the land is still encroaching upon the waters to a vast extent. One of the deserts of the Caubul territory is about 400 miles in length, and composed of sand hills and indurated clay.

Besides the acrid or saline deserts which more immediately embrace the rainless regions situate within the tropical band, there are other immense tracks of waste and unproductive soil termed STEPPES. The Steppe of the Dnieper comprehends a vast plain between the Dnieper and the Bogue, of a dry and sandy quality, containing many salt lakes and salt plots. The Steppe of the Don and Volga, comprehends all the space between the Don, the Volga, and the Kuban: it is a very large acrid steppe, containing several salt lakes and salt plots, and abundance of sulphur. Within the confines of this steppe is what is called the Kuman Steppe, in which lie the salt lakes of Astrakan, several bitter lakes and warm springs, having every appearance of being a dried up sea: this being rendered more probable by the appearance of the flat shores of the Caspian and Azof Seas, the shallowness of their coasts, the low situation of the Steppe, and the nature of its compounds. The Steppe of the Volga and Ural, called the Kalmuck Steppe, consists of a far stretching ridge of sandstones, extending from the middle of the mountains to the Caspian, and of the vast extent of plain on either side of these mountains: its constituents evidence its having been the bottom of a sea, rock salt and salt lakes being thickly diffused over the whole plains. Other Steppes there are stretching towards the north, and partially or wholly waste.

In South America there are also very extensive steppes consisting of beds of sand, saline deposits, and other products of sea water, by which they are rendered barren and desolate, there being only a few acrid plants and scrub wood dotting their surface. The slight elevation of the Llanos, of Varinos, and the Caraceas; the Bosques and forests of the Amazon; and the Pampas of Buenos Ayres, make it appear that the waters of the Atlantic formerly covered this great extent of land; forming immense gulfs in the dry land, reaching the base of the Andes.

The nature of the changes produced in the oceanic earths depends on the nature of the local affections to which these earths are subjected; thus, for instance, in Arabia Felix, the salts, phosphates, carbonates, and sulphates, being produced, remain unchanged from age to age: but on the Abyssinian side of the Red Sea, a distance of only a few leagues, in consequence of the abundance of rains, the salts and other volatile and vaporous products, which are inimical to life, are washed into the bowels of the earth, and are thus united with compounds composing the lower strata, or in their union with each other, form neutral bodies: at the same time, the shells of mollusca either decompose, or gradually indurating, separate in their parts, and pass by transition into stones and pebbles. The decomposed masses of carbonate of lime unite as rock, and the earth soon becomes covered with coarse grasses and scrub wood, to be replaced by the acacia and eventually by trees of a nobler growth, more complicated, and of a higher order of development. Animal species and genera no sooner find their food covering the new made soil than they repair to it, and propagate in their generations, and very often the locality has both animals and vegetables peculiar to itself. In whatever part of the world we view nature, in production and reproduction, the very determinate effects of local influences are strikingly manifest in the production of organic and inorganic bodies.

Removed from the influences of terrestrial matters, produced by the animal and vegetable orders, genera and species are eventually produced, and as a necessary consequence, various compounds and fossil and mineral formations are generated. The young oceanic earth rests in its own strength, and the changes which take place in the various depositions of matter are wholly governed by local influences. In those parts of the earth where the heat is excessive, and the rains seldom or never fall, nature slumbers for ages in organic production, confining her operations to the mineral kingdom, or if genera, orders, and species, of animals and vegetables are developed, they are such as are conformable to the sterility of the soil, being in the simplicity of organical structure; thus the land is desert, ever presenting the like monotonous view to the traveller, who treads interminable plains of sand, intersected with groups and chains of hills equally barren and unproductive, abounding with noxious exhalations, poisonous gases, bitter salts, and sulphur, all around speaking of imperfection, the organic body decomposing, and the mineral body forming: of the beauty and variety common to a more favourable soil and climate, nothing is to be found but a few crystalline bodies of comparatively little value; not one spark of animal life appears to cheer the dreary scene. In this desert sterile state the earth reposes, free from the continued action and addition of accumulating matters producing in other localities: but even in regions the most forbidding and destructive to organic creatures, nature acts unceasingly in creating mineral bodies and mineral beds from the fossil soils spreading forth on every side; the cast off clothing of mollusca and fishes, preserved from decomposition, in the re-combination of their atomic structure, become things of other name and nature; the beds of the valleys become covered with petrifactions, the sands sparkle with crystalline or efflorescing salts, the decomposed masses of commingled oceanic matter are converted into gypsum, alabaster, marble, sandstone and other species of rock, and a degree of order takes place where confusion and disunion previously revelled triumphant. The periods necessarily required to effect these multitudious changes depend entirely upon association and climate: excess of dry heat, or excess of moisture alike militating against the development of terrestrial organic bodies. When incessant dry heat acts upon the thirsty soil, it oxidates all bodies of a calcareous nature, and causes the coral reef, and the beds of shell fish, to decompose in dry friable masses, and in this state they remain, until by the agency of water, the disintegrated masses are united as one consolidated or crystalline body. Where the rains are unfrequent, and in many extensive regions they are seldom or never known to fall, here nature sleeps over the creation of living creatures, and the scanty vegetation consists of those few plants which love a hot dry climate and an acrid soil, while here and there, in more favoured spots, may be observed a few miserable acacias standing as guides to wandering Arabs, or as signs of a well of wretched brackish water being within the reach of the expiring wanderer: of the animal creation there are none, save a few vultures, kites, and ravens, which flit rapidly over the burning waste, or follow in the wake of the expiring camel, as though conscious of its approaching death. No living form could possibly exist in some of these regions, there being no springs of water, no shelter from the continuous vertical heat, no form of food, animal or vegetable; the soil throughout is alike inimical to the development, sustenance, and propagation of living species. Such are the characteristics of the African and Asiatic deserts, and of the numerous islands of the Red Sea, and wherever these lands are disposed in the rainless regions, there they continue barren and desolate from generation to generation, preserving there their characteristic traits, by which their origin and nature has been handed down from generation to generation, extending over a period far beyond the records of man, and being evidently produced ages before man was a denizen of the earth.

(To be continued.)

CEMETERIES.

Report on the Sanitary Condition of the Labouring Population of Great Britain. A Supplementary Report on the Practice of Interment in Towns.—By Edwin Chadwick, Esq., London, 1843.

On the Laying out, Planting, and Managing Cemeteries.—By J. C. Loudon. London: Longman, 1843.

In no one thing has the march of intellect more fully shown itself, and under the most favourable auspices, than in the strong public feeling which has been growing up of late years, in favour of improving the health of towns by scientific and enlightened administration. Many circumstances have favoured this, the remarks of staticians, the operation of the Registration Act in particular, which by giving the elements for local comparison, showed incontestably to what an extent population is affected by unfavourable circumstances. It might formerly be matter of opinion how far drainage, or the adequate supply of water could influence health, and knowledge and intelligence were kept at bay with the assertion, that the results were but matter of opinion, and that one man's opinion, *i. e.* the ignorant man's opinion, was as good as another's. It is now, however, very different, and we can point to regions of the metropolis, where, by defective administration, the life of the labouring population is abridged to a fearful extent, while in others better cared for, a higher standard of vitality is to be recognised. At the same time the problem of vitality is better understood, its moral and economical bearings have been detected and elucidated, and the fearful consequences of ignorance and neglect clearly eliminated. It is undeniably ascertained that the operations of unfavourable external circumstances is not merely to doom to death so many per cent. of the population, but to strike down the experienced and able-bodied adult, to throw widows and children pauper burdens on the public funds, and to increase the population with an excess of helpless infants; for in an unhealthy and abnormal population, the increase of that population is not checked by misery and death, but it is a natural law, as it were, that the void created by the extinction of the adult should be filled, and how filled?—not by an adult necessarily—not by an individual educated in some way, useful to society, and able to earn his livelihood, but by the infant, who must for years be fostered and maintained from the common stock. This is an awful punishment upon ignorance and inattention, one which, in its operation leaves no class unscathed; the poor man sees the scythe indeed, but the rich does not escape its edge. The fevers generated by a close population invade the habitations of the wealthy, while the poor rates, enormously increased, become a burden on their purses. These are facts, which, if humanity could be silent, if religion were to be stifled and its dictates disowned, would still force a remedy from the most selfish and most obtuse. The labours of the Commission of Sanitary Inquiry have disclosed the most appalling facts as the consequence of evil, while they have, on the other hand, as clearly shown the immediate and permanent good which results from intelligent and well directed measures. In these inquiries the public is deeply interested, but the architect or engineer is not less interested, it being his professional duty to be acquainted with the evils, and to be able to apply the remedies. It has not, however, been the case that the members of these professions have been active in such investigations, and it will in the end certainly result, that if they do not take care, they will have no part in the subsequent measures that may be adopted. The medical profession have taken a much more prominent part, and particularly the medical officers of unions, in communicating the results of their experience, and it might be said that the parochial medical officers form a corps well organized for the acquisition of information. It must not, however, be forgotten that the surveyors of highways, and the surveyors of sewers are not less local officers, possessing local experience, and being able to bring a large amount of practical knowledge to bear on the state of the arrangements for securing public health. We cannot however say that they have come forward to do so; with a few exceptions, no professional name occurs. We see, indeed, the names of Mr. Mills and Mr. Roe, of the Finsbury Division of Sewers, quoted by Mr. Chadwick, and we are pleased to see, by the exertions of Mr. Sopwith in the Newcastle Committee of Inquiry, that he has effectually shown what the practical and scientific experience of an enlightened man can do. We call the attention of professional men most strongly to this fact, that it is important for them to be on the alert, and that unless they do exert themselves and show their competency as public servants, they will be superseded by the medical men, and passed over in the Boards of Health, which will no doubt ultimately be formed. A strong public feeling has been manifested with regard to sanitary measures, the government has felt itself called upon to do something, and permanent arrangements will no doubt speedily be made. It has been for some time a matter of regret to us, that no step has been taken by professional men, as a body, to interfere in these measures, though it is naturally to be accounted for, the Institute of Architects occupying itself solely with artistic subjects, and the Institute of Engineers with the details of science, and neither of them having time or scope for the discussion of professional etiquettes or professional interests, at the same time that many events of great importance have recently occurred where the intervention of an organized body would have been of the highest benefit. Indeed a great many of the subjects entertained by the Metropolitan Improvement Society are purely professional in their bearings, while there is no opportunity of discussing or protecting professional interests. With regard to the Building and Drainage Acts, the want of this organization was strongly felt, and also with regard to the contemplated survey of London, the protection of private interests is left to isolated efforts. We cannot doubt that a centralization must take place of the Metropolitan Sewers and Pavings Boards, and any legislative enactment for the purpose will require to be closely watched. Under these circumstances we think it would be of the greatest benefit if an Association of Architects, Engineers, and Surveyors, were formed, not for the discussion of matters of art or science, which are already adequately provided for, but for the protection of professional interests, and we earnestly recommend that some step should be immediately taken.

The report of Mr. Chadwick is supplementary to that on the sanitary condition of the labouring classes generally, and is more particularly directed to the practice of interment in towns. It is one of the finest documents of the kind which has ever been laid before the public, characterized by elevated and enlightened views, a liberal and kindly disposition, and far-seeing policy. It takes up many subjects of the highest interest, particularly in connexion with the general laws of mortality, and which we regret that the special tendencies of our publication prevent us from investigating. On the subject of interments it is full and precise, and discloses a multitude of most striking facts, which cannot be without their influence on the legislature. Through a work so abounding in details we must proceed cautiously, and, however careful we may be, we must omit much matter of interest, and much evidence of value, but we shall endeavour to give a succinct view of the contents of the report.

Mr. Chadwick shows fully the nocuousness of the emanations from human remains, and he very ably combats the negative evidence of Parent Duchatelet and other physiologists, who had been relied upon as authorities to the contrary. On this point Mr. Roe and Mr. Mills gave evidence, that where the sewers come in contact with church yards, the exudation is most offensive, (St. Pancras for instance) and that whatever precautions are taken, exudations to a certain extent pass through the brickwork of the sewers. Evidence to the bad effect of the drainage of churchyards on wells, was also given by Mr. Roe. This latter effect is well known.

"In consequence of various investigations in France, a law was passed prohibiting the opening of wells within 100 metres of any place of burial; but this distance is now stated to be insufficient for deep wells, which have been found on examination to be polluted at a distance of from 150 to 200 metres. In some parts of Germany, the opening of wells nearer than 300 feet has been prohibited."

The production of deleterious gases from the decomposing bodies is fully proved, particularly by Professor Leigh of Manchester. Mr. Chadwick next proceeds to show, that as the labouring classes reside chiefly in one room, the most injurious effects, both moral and physical, result from retaining the corpse among the living. When coming to consider the economical results of an excess of interments, Mr. Chadwick observes:—

"If the proportion of deaths to the population in the Whitechapel union were reduced to the proportion of deaths to the population in Herefordshire, then, instead of 2,307 burials, there would only be 1,305 burials per annum; and if the cost of the remaining burials were reduced 50 per cent. of the average present cost, then the saving of funeral expenses to the Whitechapel district would be at the rate of more than £23,000, or nearly 3*l.* per house on the inhabited houses of the district; about half that sum being deemed sufficient to defray the expense of the proposed structural improvements. The funeral expenses in the parish of Hackney on the proportion of burials amongst them, are at the rate of 5*s.* 2*d.* per head on the living population. Were the burials in Liverpool reduced to the same proportion, 1 in 56 instead of 1 in 30, at the rate of expenses for funerals in London, nearly £50,000 per annum would be saved to the population of Liverpool, being more than sufficient to enable them to pay 30 years' annual instalments, the principal and interest, at five per cent., of a sum of £845,065 sterling for structural arrangements."

It is very clearly shown that the present parochial establishments are very inefficient, and that any system founded on parochial administration may be liable to great objections, as to which we fully concur. The report before us also proves the growing disposition among all classes of the public, to prefer interment in the great cemeteries in preference to the intra-urban churchyards, and that the labouring classes are disposed to make considerable sacrifices to insure this object. The objection to churchyard interment seems to become stronger every day, and even family vaults are frequently abandoned by wealthy individuals. Mr. Chadwick, advocates as part of an improved system of interment, an inspection of the body by a competent medical officer of health and the deposit of the body immediately after the supposed death, in what may be called a dead-chamber, where constant attention shall be given to see if any signs of life are manifested, and by which great advantages will accrue to the living. He proposes, also, the performance of the funeral rites by a public establishment, so that the services of religion may be more efficiently administered both to rich and poor, accompanied by the singing of anthems, and the assistance of a full choir. This is a feature which we cannot omit, for we feel assured that by cultivating the higher feelings we are rendering the public mind more susceptible in matters, of art, refining the manners, and developing the kindly emotions of the heart. We will not repeat the hackneyed quotation as to the emollient influence of the liberal arts, but we know no case in which their solemn and religious influence would be better and more permanently felt, than in connexion with the last offices to the dead. The chanting of the choir, the devont ministering of the clergy, the orderly attendance of the assistants, will be most touching in the presence of the beauties of nature, and the apt memorials of art, amid which the relics of the dead are entombed. A feeling of holiness and solemnity, softened by the external influence of surrounding objects, cannot but fail to soothe the mourner, and beneficially impress the visitant and spectator in communion with the departed dead. A wide field, under such circumstances, exists for the exhibition of a refined and chastened taste, for not merely is there the general disposition of the ground and buildings, which can afford but restricted occupation, but every tomb admits of a careful and original treatment, with a due regard to the sanctity of the place, and the noble impressions to be produced. Such opportunities are to be courted, for the occupation of the English architect is too restricted; instead of being able, like the artist of old, to display his taste in many small works, affording him daily and hourly occasions for its cultivation, he erects only a few large buildings, and those perhaps stereotyped in their details. The field of taste, like the field of agriculture, must be constantly and carefully cultivated; the fallow shows unprofitable husbandry, and he whose taste in leisure hours is occupied in worthy pursuits, can scarcely fail to show himself at least respectable on great occasions. Neither can the studies here recommended be injurious; it is not frittering the mind in detail and minutiæ, but it is the laudable exercise of the great principles of art. The narrow-minded copyist may busy himself on a sepulchral memorial, marring the ideas of his predecessors, and producing nothing of his own but his errors; but a noble and simple conception in a small work will not detract from the highest genius. Indeed, it is now beginning to be recognized that the sphere of the architect's labours is more extensive; in the dwelling it is his business to design the ornaments, and take care that the furniture and accessories agree in character with the style of the building itself. We look, therefore, with pleasure to the opportunities which are now likely to be afforded, and the more so as the works will be exhibited to the public gaze, not like the secluded examination given to a private dwelling, while the architect will be brought into competition with the sculptor, the painter, and the enlightened amateur, and will be led to the study of the higher attributes of art, now too much neglected or conducted upon a false basis. We are aware that at present our cemeteries have much that is meretricious, but we know no better mode of correcting this than by elevating the tone of public feeling with regard to the practice of interment. We may observe, too, that Mr. Chadwick recommends that some of the metropolitan cemeteries should be on the banks of the Thames, affording economical conveyance for the poorer classes, and the means of great funeral pomp on what the poets have called "the silent highway." Those who recollect the grand funeral procession of Nelson, will bear testimony to the solemnity and grandeur which may be ensured in such scenes.

Mr. Chadwick is of course an advocate for interment in the free soil, and a higher tone of public feeling seems to prevail as to this practice. If we reflect on the associations attached to the burial places of great men, our impressions are not confined to the sight of the tomb, but they extend to the surrounding soil; the tomb of Virgil sanctifies the country around, though the bones have long since mingled with their native earth; the tombs of the kings in the valley near Jerusalem bring their votaries from afar, though many centuries ago their ashes must have faded; the Holy Sepulchre has been the veneration of ages, though only serving as the tomb of a day. So, too, the memory of Napoleon, although his remains have been exhumed, still brings pilgrims to St. Helena, for it is not the mortal relics that we venerate, but those efforts of intellect which illumine the world in all ages, and bring us from our distant homes to pay tribute to the memorials of genius, which it has consecrated to itself in the cradle, its residence, or its last long home. Incorporation with the soil of a holy and consecrated place, must surely then be more to be sought than fruitless expedients to evade the common lot, which honour not the dead, and are injurious to the living. The state of the public feeling, too, on this point, materially affects the cemeterial arrangements to be made on any comprehensive scale. In another point of view we are happy to bring the opinion of Mr. Chadwick in evidence to illustrate the moral influence of improved arrangements.

"The great moral force, and the consolation to the dying, and the incentive to public spirit whilst living, derivable from the natural regulations of a public cemetery, is almost entirely lost in this country, except in the few cases where public monuments are provided in the cathedrals. In the metropolis it would be very difficult to find the graves of persons of minor fame who have advanced or adorned any branch of civil or military service, or have distinguished themselves in any art or science. Yet there are few occupations which could not furnish examples for pleasurable contemplation to the living who are engaged in them, and claim honour from the public. The humblest class of artisans would feel consolation and honour in interment in the same cemetery with Brindley, with Crompton, or with Murdoch, the artisan who assisted and carried out the conceptions of Watt; or with Emerson, or with Simpson, the hand-loom weaver, who became professor of mathematics at Woolwich; or with Ferguson, the shepherd's son; or with Dollond, the improver of telescopes, whose earliest years were spent at a loom in Spitalfields; or with others who "have risen from the wheelbarrow," and done honour to the country, and individually gained public attention from the ranks of privates; such, for example, as John Sykes, Nelson's cockswain, an old and faithful follower, who twice saved the life of his admiral by parrying the blows that were aimed at him, and at last actually interposed his own person to meet the blow of an enemy's sabre, which he could not by any other means avert, and who survived the dangerous wound he received in this act of heroic attachment. The greater part of the means of honour and moral influence on the living generation derivable from the example of the meritorious dead of every class, is at present, in the larger towns, cast away in obscure grave-yards and offensive charnels. The artisans who are now associated in communities, which have from their beneficent objects a claim to public regard, might, if they chose it, have their spaces set apart for the members of their own occupation, and whilst they derive interest from association with each other, they would also derive consolation from accommodation within the same precincts as the more public and illustrious dead."

In considering this subject, the praiseworthy labours of the great Wren could not pass unnoticed, who in his report on the re-building of London, reprobated all interment in churches, and advocated the foundation of cemeteries outside the town. Mr. Chadwick, resuming this idea, calculates that the annual saving to the inhabitants of the metropolis, by a comprehensive system for the interment of the dead, would be no less than £374,743, and we do not think he has overrated the amount. This saving, he shows, if applied to remedying the sanitary arrangements of the metropolis, would fully effect it, and relieve the public from a large amount of poor-rates, increase the labouring power of the population, and extend the duration of life, health and strength. Mr. Chadwick then proceeds to propound his plan, which is, that the practice of interment should be placed under government direction, the structural arrangements being confided to the Commissioners of Woods and Forests. The present practice of burying in towns to be entirely abolished. The expenses of national cemeteries to be raised by loans bearing interest, the repayment of the principal and interest being spread over a period of 30 years, and charged on the several interments. Compensation is also to be given from this fund to the new cemeteries, which it is recommended should be purchased, and in some cases retained for the purpose of interment. The general economical result, it is very clearly shown, would be the reduction of burial charges to at least one half of the existing amount.

With regard to the choice of ground for cemeteries the report observes—

"The progress of the decay of the body is various, according to the nature of the soil and the surrounding agencies. Clayey soils are antiseptic; they retain the gases, as explained by Mr. Leigh; they exclude the external atmosphere, and are also liable to the inconvenience of becoming deeply fissured in hot weather, and then allowing the escape of the emanations which have been retained in a highly concentrated state. Loamy, ferruginous, and aluminous soils, moor earth, and bog, are unfavourable to decomposition; sandy, marly, and calcareous soils are favourable to it. Water, at a low temperature, has the tendency, as already explained, to promote only a languid decomposition, which sometimes produces adipocire in bodies: a high and dry temperature tends to produce the consistency and permanency of mummies. A temperature of from 65° Fahrenheit and upwards, and a moist atmosphere, is the most favourable to decomposition. The remains of the young decompose more rapidly than those of the old, females than males, the fat than the lean. The remains of children decompose very rapidly. On opening the graves of children at a period of six or seven years, the bodies have been found decomposed, not even the bones remaining, whilst the bodies of the adults were but little affected. The process of decomposition is also affected by the disease by which the death was occasioned. The process is delayed by the make of some sort of coffins. The extreme variations of the process under such circumstances as those above recited, is from a few months to 30 years or half a century. Bones often last for centuries."

"Attention to these circumstances by qualified persons in Germany has led to different regulations of the depth of graves at different ages. At Stuttgart the different depths are as follows:—For bodies of persons under 8 years, 3 ft. 9 in.; 8 to 10 years, 4 ft. 7 in.; 10 to 14 years, 5 ft. 7 in.; adult, 6 ft. 7 in. At the Glasshutte, in the Erzgebirge, the depths are as follows:—Under 8 years, 3 ft. 8 in.; 8 to 14 years, 4 ft. 7 in.; adults, 5 ft. At Frankfort the average depth prescribed for graves is 5 ft. 7 in.; at Munich, 6 ft. 6 in.; in France, 4 ft. 10 in. to 6 ft.; in Austria, 6 ft. 2 in., if lime be used."

We should observe, indeed, that the views of Mr. Chadwick, with regard to the laws regulating the duration of life, are most valuable and original, but being out of the immediate range of our occupations, we are unable to discuss them. The doctrines illustrating the effect of good accommodation upon health and disease, are also enforced by the example of the four provinces of Ireland, where the proportion of mud cabins is found to indicate the lowest average of life.

We have now to consider the mode of administration pointed out, and we feel bound at once to give in our accession as to the necessity of a comprehensive plan, and the ineligibility of parochial management. We do not, however, like in this or any other case to give up the principle of popular control, one of the oldest and dearest in our constitution, and a disposition to abrogate which, and to advocate centralization, has too frequently manifested itself of late years, and too readily met with public acquiescence. The evils of parochial jobbing and sectarian bigotry, we should be foremost in attacking; but we do not think the only resource is administration by a government board, certainly not in the metropolis and the large towns. We think a municipal administration would fully meet the circumstances, would ensure efficient control, and be free from the evils of the parochial system. It is true that a municipal body does not exist for the metropolis, and that the Woods and Forests has been made a kind of nurse-tender in many cases, while attempts to give regular municipal institutions have been evaded by the government; but we see no difficulty in providing for the present case, which must also be considered in reference to future legislation, as to the Sewer and Paving Commissions. Although apathy may exist as to the administration of cemeteries, yet surely professional men would not like such an example brought forward on the occasion of the centralization of the Sewers Commissions for instance, and the whole matter coolly handed over to the Woods and Forests; yet it is evident that such case must be met not merely on its own grounds, but with reference to a general principle. The question is, whether the principle of government administration, not recognized with regard to metropolitan roads, paving and sewers, is to become predominant, and the whole profession be placed under the rule of Her Majesty's Commissioners of Woods and Forests and Land Revenue.

OBSTA PRINCIPIO.

THE CONSERVATIVE CLUB.

Architects, Sydney Smirke and George Basevi, Jun.

(With an Engraving on Steel, Plate I.)

Club architecture is a new class, which has sprung up of late years, and which forms an important feature of the Pall Mall district. It may be divided into two classes, the classic school, to which the earlier specimens belong, and the Italian school, in which Mr. Barry led the way by the erection of the Travellers' Club. Year after year has gone on adding to the magnificence of these structures, and we hope not without a beneficial influence on the taste of the architects concerned. The artists, who have chiefly exerted themselves in this department, have been four, the two Smirkes, Decimus Burton, and Barry, each of whom has contributed at least two specimens. In the Athenæum Club Mr. Burton introduced the novel feature of an extended sculptured frieze, which, although not original, yet being a copy of that from the Parthenon at Athens, preserved among the Elgin marbles, is an ingenious and appropriate adaptation. Mr. Barry took the next step, by adopting the Italian style for the Travellers' Club, the old garden front of which has been justly admired for its chasteness, and which, even in its altered form, has not lost its character. Mr. Sydney Smirke's Oxford and Cambridge Club was a happy attempt to produce effect by sculptural decoration, the emblematic panels giving dignity and elegance to the façade, at the same time that they indicate the classes to whom the edifice is devoted. The Reform Club sank in the shade all its competitors, rising in giant majesty over the surrounding edifices. The taste which presided in the distribution of its details, and in its internal decorations, has been ably commented upon by some of the contributors to our columns, though the effect of the grand front is in some degree marred, by the fatal necessity of the interior arrangements, so that on the Pall Mall side it looks too windowy, having indeed symmetry, but affording little relief to the eye. In the side elevation, the grouping of the windows avoids this monotonous appearance. It was felt, however, that the erection of the Reform Club had thrown its neighbours into insignificance, particularly the Carlton Club, and the necessity of a new conservative club soon became evident, and resulted in the erection of the edifice of which the engraving is now before us. We have felt that these edifices have strong claims on our readerss, on the one hand as affording many useful studies, and on the other, as illustrating the practice of some of the most eminent men, and the progress of what we may call social architecture, an acquaintance with which in its highest forms, is of great value to our metropolitan and provincial brethren, in the erection of clubhouses, chambers of commerce, newsrooms, literary institutions, &c. We have accordingly given elevations of the Reform Club, (Vol. III, pp. 144, 336,) Oxford and Cambridge University, (Vol. I, p. 15,) Club Chambers Association, (Vol. II, p. 319,) with the present article, that of the Conservative Club. Plans of the same buildings will also be found in our volumes, Reform Club, (Vol. III, p. 109,) Oxford and Cambridge Club, (Vol. I, p. 59,) and Club Chambers, (Vol. II, p. 319.) A section of the Reform Club, and details of the windows, cornicione, &c., are given in our third volume, (pp. 336, 409,) making altogether about fifteen plates and engravings, which we have appropriated to this subject.

The Conservative Club is the joint work of Mr. Sydney Smirke and Mr. George Basevi, Jun., and is placed on the west side of St. James' Street, near the Palace. As a rival to the Reform Club it has one of the largest façades, as the annexed table will show.

The front of the Conservative Club consists of two stories or orders, the lower rusticated and without columns, except at each wing, as described below. The upper story is Corinthian, and consists of entire, but attached columns and pilasters upon the usual podium, and having the entablature surmounted by a balustrade. In the intercolumniations are windows with enriched dressings and pediments. Over the windows and ranging with the capitals of the columns, is a frieze of carved foliage, for the most part of classical character, but having the Imperial Crown, encircled by an oak wreath, occasionally introduced. The front is of uniform height, but the wings are slightly advanced. In each wing the lower order is Roman Doric, that on the left contains the porch entrance, deeply receding, with groups of columns and pilasters on either side. In the right wing the leading features are uniform with the porch, but instead of an entrance is a bow window, which was introduced as essential, in the opinion of some members of the club, to the morning room, affording the loungers a view of Pall Mall and St. James's Street. The whole front is of Caen stone, and with the rest of the building has been carried up in about six months, the foundations having been commenced in the middle of June, and the whole clubhouse being now roofed in, with much of the interior plastering far advanced. The contractors are bound to complete the building by the end of the present year.

	Built.	Architect.	Lgth. of Front. feet.	Height. feet.
University Club	1822-6	Wilkins & Gandy	76	..
Union Club	1825-7	Sir R. Smirke	65	57

Athenæum	1829	D. Burton	76	..
Travellers'	1831	Barry	74	50
Carlton	1835-6	Sir R. Smirke	90	..
Oxford & Cambridge	1836-7	Sydney Smirke	93*	57
Reform	1837	Barry	120†	68
Do. with side entrance	....	....	135	..
Club Chambers	1839	D. Burton	76	55
Conservative	1843-4	S. Smirke, G. Basevi	117	69

* The length of this is elsewhere given as 87 feet.
† According to some authorities the length without the entrance to the dormitory, is 117 feet.

It will be recollected that Mr. Sydney Smirke was one of those who sent in designs for the Reform Club, (Vol. I, p. 67,) when he proposed a building with a grand tetrastyle portico. Mr. Barry's design was then preferred, but on the present occasion Mr. Sydney Smirke, conjointly with Mr. Basevi, has had the opportunity of exhibiting his talents on one of the finest sites in London, and he has well availed himself of it. Difference of opinion will exist with regard to the merits of the Conservative Club, but at any rate the design is not hackneyed, while the grandeur of the edifice cannot be denied. It now forms the most prominent feature in St. James's Street, and the half view from the front of the Palace is very good. A difficulty existed in the shelving nature of the ground, but that has well been mastered by the able architects.

OBSERVATIONS ON GWILT'S ENCYCLOPÆDIA OF ARCHITECTURE.

By Henry Fulton, M.D.

This work, although reviewed in former numbers of this *Journal* by an abler and more experienced pen than that which now takes up the subject, is by no means exhausted. Our author says in his preface, that his object has been to impart to the *student* all the knowledge indispensable for the exercise of his profession, but should the perusal of it serve to form, guide, or correct the taste even of the *mere amateur*, he will not consider that he has laboured in vain. A work which could effect all this is much to be desired, but as far as the book before us is concerned, it is to be feared that the attempt is a failure. The fact alone of professing to treat of no architects or their works, subsequent to the end of the 18th century, renders this an incomplete encyclopædia for publication in the middle of the 19th, and the reason given for the omission is "the fear of coming into contact with cotemporaries and their connexions, which if not dangerous and fearful, might be unpleasant." But let not the reader suppose that these sentiments, be they right or erroneous, at all embarrass our author, either in relation to himself or others, whenever he pleases to deviate from it, for, in page 726 he tells us of "the execrable mass of absurdity to which the government who sanctioned it have facetiously given the name of National Gallery." And in what he calls "a catalogue of the principal and most useful works to the student of architecture," we find the name of our author recorded eight times. To do him justice, he mentions the name of Wilkins also in this catalogue, as the author of the Antiquities of Magna Græcia; to be sure Mr. Gwilt in some measure takes this work out of the list of the "most useful works to the student of architecture," for he adds to it, "an ill-drawn work," and that too, without making almost any special observations in praise or dispraise of any of the other productions mentioned in the catalogue.

But although Mr. Gwilt gives us his own name, and that of his works eight times, yet no mention is made of Hosking's Treatise on Architecture and Building; no doubt this was out of sincere regard to Mr. Hosking, for if mentioned at all, he would have been forced to add as a pendant, *an ill written work!* But although he had done all this, that treatise must be read and esteemed even when students shall spring up "who know not Joseph," and in the meantime "the mere amateur" will find it better calculated to "form, guide, and correct," his taste than even Mr. Gwilt's Encyclopædia. If Mr. Gwilt had desired to leave out all mention of the "ill drawn work," he might have substituted *Rovine Della citta di Pesto. Di P. Paoli,* fol. Rome, 1784. This, and another work omitted, I happen to have, viz. *Pincturæ Antiq. Cryptarum Rom. et Sepulcri Nasonum.* A. J. P. Bellorio et Mich. Ang. Causseo, fol. Rom. 1750. I could mention the names of 32 other works omitted, and which are in the library of the Royal Dublin Society, many of them of merit. Mr. Loudon's *Architectural Magazine* is named, but the *Civil Engineer & Architect's Journal* is not; were it worth the trouble of the search, no doubt the moving cause of the high honour conferred on the Magazine might be found to consist in the merits of some review of Mr. Gwilt's publications. I trust that this article alone may procure insertion for the *Journal* in the next edition of the Encyclopædia.

We shall now proceed to some of the other chapters. That on the Architecture of Russia is both defective and erroneous. From what I have already written on that barbarous country, it cannot be supposed that I now enter the lists, in opposition to our author, as a panegyrist, such as Dr. Grenville, but in justice, I must admit the public edifices and street architecture of St. Petersburgh, and the private palaces of Moscow, are in better taste than those of London. Mr. Gwilt knows of no Russian architect of the 18th century; but as he speaks of the "church of our Lady of Kevan," meaning, I suppose, that of Casan or Kasan, he ought to have told us that it was erected from the designs of Woronikin, a Russian architect; but he tells us "that on account of its columns it has obtained more celebrity than it will acquire for the beauty of its composition." Woronikin took St. Peter's at Rome for his model, but instead of falling into the error of its architects, made the Kasan of the same order throughout; the colonnade in front having 150 Corinthian columns; the cornice of the wings ranges horizontally with that of the portico, which gives it a great advantage over St. Peters; nor has he made part of the colonnade at right angles to the portico as in St. Peter's, but semicircular throughout, so that its ground plan may be described without a diagram by representing it as the curve of an arch, the portico forming as it were a dipping key stone. The interior, in which both workmanship and material do justice to a magnificent design, is not dishonoured by a comparison with St. Peter's or our own St. Paul's. I regret that I cannot describe the St. Isaac lately finished in the Russian capital and said to excel any other church in the world.

Mr. Gwilt mentions, "Ivan IV. as a great patron of the arts:" if he means the Czar Ivan Vasilovitch, which from the date given I presume he does, he was Ivan II., and his patronage of the arts can scarcely be extolled as "great," if by that he means desirable for the artists themselves, for having procured an unfortunate Italian to erect the church of St. Vasil at Moscow in 1538, he put out his eyes lest he might be able to erect any other building as *great* or greater elsewhere. This church, which contains 20 chapels of nearly equal size under the same roof, is not of great dimension, and is entirely in the Tartar style.

The chapter on the art in China is neither satisfactory nor laudatory. I regret that I did not see it with the eye even of a "mere amateur," or I should be better able to set Mr. Gwilt right; still the impression left is favourable, and I may say without praising it too highly, that its ornamental details are better than those of the style called that of Louis Quatorze, and as good as many of the Gothic. I trust we shall soon, either by some native or foreign artist, be made better acquainted with its details.

Our author, quoting from Sir William Chambers, says that the shops form the fronts of the dwelling-houses. This is not so, and I doubt if it were the case when Sir William was in Canton, for there, as in all the cities of the East, even in Russia, the shops are for the most part in open bazaars, quite detached from the dwelling-houses. In ground plan the dwelling houses in China present a striking similarity to those of Pompeii, and like them have no opening to the streets except doors. Again, in the ground plan of the temples, particularly that of Honan, we have almost a copy of those of Egypt; we need not be surprised at this latter circumstance, when we know that an intercourse must have been kept up between the two countries at a very remote period, as is proved by Chinese vases having Chinese characters on them, which can be understood in the present day, being found in the mummy tombs of Egypt.

Mr. Gwilt only mentions the large circular openings, which I believe are peculiar to Chinese architecture. There is scarcely a house or pleasure ground in which they are not introduced, forming open doorways and windows from six to eight feet in diameter. The effect of them in our own country would be very good, where, as in gardens and pleasure grounds, the doorway is not required to be closed.

In the chapter on the pointed style, a view is given of the west front of the Duomo at Milan, which is not correct. It would appear from it that the doorway is a circular arch springing from two columns, and above it there appears to be a kind of pointed arch also placed on two columns; whereas these, as also eight of the other openings at their sides, have segmental and triangular pediments with the centre of the horizontal cornice broken away. This breaking away of the cornice forms a principal feature in the erection called York stairs, London, and of which Mr. Gwilt favours us with a view and the following eulogium, page 207, "York stairs, another of his (Inigo Jones) examples, exhibits a pureness and propriety of character which appear afterwards unappreciated by his successors, with Wren at their head." Alas, Sir Christopher, is it come to this? and from a Palladian—*et tu, Brute*. But although our Encyclopædist is severe, he is not consistent, for at page 745 he tells us "that no pediment should be tolerated composed otherwise than of two raking unbroken and one horizontal unbroken cornice."

The description of the Duomo, which accompanies the plate, is not very lucid, at least to a "mere amateur;" he says, "In the third story from the bottom" (very precise) "a painted" (?) "window, separated by three mullions, is introduced. The rest" (?) "of the façade is vertically divided by buttresses into five parts, &c."

I have given one example of unsophisticated contradiction. We shall now have another of a different complexion, made with so much caution, so much acumen and foresight, that it would almost appear he had provided for the enjoyment of the literary sin, and at the same time secured a retreat in case of an indictment being framed against it. The safety valve shall here be given in italics:—page 57, "In all imitations of that" (Greek) "style, its" (arch) "introduction produces discord which no skill can render agreeable to the educated eye. Attempts have been made by the modern German architects to introduce the use of the arch with Greek forms; but they have been all signal failures, and that because it is incapable of amalgamation with the solemn majesty and purity of Greek composition. *Before such blending can be accomplished with success, the nature of pure Greek architecture must be changed.*" Now the whole of this was written as a kick at the German school, which he never omits giving when opportunity serves—but to the contradiction, page 718, "an arcade or series of arches is perhaps one of the most beautiful objects attached to the buildings of a city which architecture affords." No doubt can be entertained of the nature of these arcades, which when not in German hands find so much favour in Mr. Gwilt's eyes; they are neither arcades without columns nor yet Gothic compositions, but the pseudo Greek arcades, of which he gives a number of examples from Vignola, Palladio and Chambers. No doubt our author will say that the style is successfully changed by the Italians but not by the Germans before the addition of the arches. On one occasion an eminent architect, knowing I was only a "mere amateur," kindly offered to show me a *Greek dome* of his own designing: of course he knew better, but he did not think that I did; however, on my expressing a doubt of the Greeks having known anything about domes, his reply, though not so terse, was tantamount to what Mr. Gwilt might give on the present occasion. "*Nous avons changé tout cela.*"

It would be too *german* to our author's antipathies not to admit that his work has some merit, and that in 1053 pages the reader may find much information, which can only be gleaned from a more extended surface elsewhere. The ground plan (if we may so speak) is well arranged, and has the advantage of some ground plans in leaving plenty of room for improvement in the filling up. The application of a highly condensing power to literary effusions, except in the actual process of elimination, is bad; it ought to be applied to the ore in the author's head, and not to the metal in the printer's form. The type is too small for continuous reading, and three volumes might be given to the binder instead of one. And this arrangement would be of advantage to the "mere amateur," as the principal part of the second book on mathematics can be learned more fully elsewhere.

Having concluded, at least for the present, the notice on the Encyclopædia, which is given with all the modesty and hesitation of a first appearance in the character of a reviewer, the writer feels called on to say a few words in defence of giving his name to what he writes. That it may be well in most cases for writers in the miscellaneous periodical press of the day, to write anonymously, is readily conceded; but no necessity calls for it in a respectable professional journal, where all who contribute should have but one object in view—the advancement of science. A name, although (as in the present instance) it may have no intrinsic merit attached to it, yet encourages some to read and others to write.

LORD ROSSE'S TELESCOPE.

At a meeting of the Belfast Natural History Society, the steps by which difficulties were overcome in making the speculum, were explained by Mr. Stevelly in detail, under the following heads:—

Metal for the Speculum.—The metallic alloy for the speculum consists of four atoms or chemical combining proportionals of copper to one of tin, or by weight 126·4 copper to 58·9 tin. This alloy, which is a true chemical compound, is of a brilliant white lustre, has a specific gravity of 8·811; a twelfth of a cubic foot, or 144 cubic inches of it, weighing, therefore, a little over $45\frac{3}{4}$ lb. avoirdupois, or to allow for all waste when casting, 50 lb., which is the rule by which Lord Rosse estimates the weight of metal he requires. This alloy is nearly as hard as steel, and yet is almost as brittle as sealing wax. Of this most unpromising material Lord Rosse has cast, ground, and has ready for polishing, a circular mass 6 ft. in diameter, $5\frac{1}{4}$ inches thick, and weighing upwards of three tons, with a surface perfectly free from crack or flaw, and quite homogeneous. The next head is

Casting.—On the first castings having flown into pieces, finding that the fragments no longer fitted each other in their former places, he perceived that they had been in a state of violent strain arising from the cooling and setting of the outer parts, while the inner parts, yet fluid, were also largely expanded by the heat; this, and the porous surface, led him by many stages and trials to the remedy, which is simple and complete. The bottom of the mould is made of a ring of bar iron, packed full of slips of iron hoops set on their edges, which lie in parallel chords of the ring. These, though packed very tightly together, and so closely fitting that the melted metal cannot run between them, yet allow any air that is carried down to the bottom of the mould when the metal is cast in, to pass out through the interstices. After the ring is packed, it is secured in a lathe, and the face, which is to be the bottom of the mould, turned true to the convex shape to fit the concave speculum required. It is then placed flat on the ground by spirit levels (between the furnace in which the metal is melted, and the annealing oven), and the mould completed at the side with sand, in the way practised by founders, but left open at top. The metal is then melted in cast iron crucibles; wrought iron would be corroded by the speculum metal, and injure its properties, while fire clay crucibles will not answer. Unless the crucibles be cast with their bottoms downward, they will be porous, and the melted alloy will run through their fine pores. When the metal is melted, and still much too hot to pour, the crucibles are brought by a crane, and set firmly, each in a strong hoop iron cradle, which turns on gudgeons, and so arranged round the mould that when the handles of the cradles are depressed, they pour out their molten mass direct into the mould. An oxide forms rapidly on the surface of the metal while too hot—this is as rapidly reduced back to the metallic state by constantly stirring it with a pine rod; as the temperature sinks, the instant this reduction of the oxide begins to cease, is seized on as the proper moment for pouring. The liquid mass descends with a few fiery splashes, and after waving back and forward for a few seconds, the surface becomes still. The setting process begins at the hoop-iron bottom, where a thin film first sets—the process extends upwards in horizontal layers and at length the top, though red, becomes fixed in form; the mass is then as tough as melting glass, and being turned out of the mould upon a proper truck, with the face upwards, is drawn into the oven to undergo the process of

Annealing, or very slow cooling. Here it is built up into the oven, previously heated red-hot, and fire is kept up under the floor of the oven for some days; the under fire-places are then stopped, and all left for weeks to cool down to the temperature of the air. The six feet speculum was left here sixteen weeks. Here the particles of the alloy slowly arrange themselves into the arrangement in which the aggregating forces are in equilibrium, or natural and equal antagonist tension. When the oven is opened, the speculum is removed to the workshop, to undergo the process of

Grinding, which process was illustrated by working a model. In the workshop it is placed on a circular table, in a cistern filled with water, of temperature, say 55° Fahrenheit, with the face to be ground upwards. The circular table is turned round by the motion of the grinding-engine. But first, the edge is made truly cylindrical by being surrounded by many pieces of deal board set in an iron ring pressing against the edge; emery being introduced as it turns round, soon grinds it cylindrical; it is then placed in the box in which it is to be used; here it is firmly secured by a ring of iron brought to embrace, firmly yet gently, its now truly cylindrical edge. The box and speculum, with the face to be ground placed upwards, is now again placed on the circular table in the cistern of water. Emery and water being placed upon it, the grinding disk is laid on, which is a cast iron plate turned at one surface to the shape to fit the speculum when ground, and grooved on that surface with many annular grooves concentric with the plate, and with many straight grooves running across at right angles to each other. The back of this grinding plate is ribbed with six or eight radial ribs, to give it stiffness. This plate sits rather loosely in a ring of iron a little larger in diameter, which is driven back and forward by the motion of the steam-engine. This ring has two motions, longitudinal and transverse. The engine causes it to make $24\frac{1}{2}$ strokes for one turn of the speculum on its axis under the grinding disk, about 80 strokes taking place in a minute; the length of this stroke is one-third of the diameter of the speculum. The motion is produced by an eccentric pin. The transverse stroke takes place 1·72 times for each turn of the speculum, and its extent is, at the centre of the speculum, $\frac{27}{100}$ of the diameter of the speculum; it is produced by an eccentric fork. A fourth motion takes place by the grinding disk, while for an instant free of the ring, at the turn of the eccentrics, being carried round a little by the speculum, on which it is then lying as it were free; this causes it to turn once for about 15 turns of the speculum. Emery and water being constantly supplied, the surfaces of the grinding disk and speculum in a few hours grind each other truly spherical, whatever be their original defects of form. The process is finished, when, upon drawing off the grinding disk with one steady long pull, the surface of the speculum is left everywhere uniformly covered with the fine emery arranged in uniform lines, parallel to the line in which the disk was drawn off. A slight polish being now given to the speculum, its focal length is tested by a very simple process. The floors of the loft above the workshop, in the tower of the castle, contain trap-doors, which are now opened, and a mast crected on the top of the tower, which carries at its top a short cross-arm, to the under surface of which a watch-dial is fastened, the face of the dial looking down on the speculum, now directly under it, and at a distance of 97 ft. A temporary eye-piece erected in the upper floor of the tower, soon finds the place of the faint and still imperfect image of the watch-dial, the proper place of which is a matter of simple calculation, if the speculum be ground to the expected focus. If it be found incorrect, the grinding disk is rendered a little more flat, or a little more convex, and the grinding process is renewed, and so on, until the spherical face of the speculum is given its proper length of radius. When this is accomplished, the brilliant reflecting surface, and true form for producing a good image, is given to the speculum by the final process of

Polishing.—In this, two matters require attention, the polishing powder and the surface of the polisher. The powder used by Lord Rosse is not putty or oxide of tin, as used by Newton and his followers, but red oxide of iron procured by precipitation from green vitriol or sulphate of iron by water of ammonia; this is to be heated carefully in an iron crucible, for it has a tendency to take fire, and thus run many particles into one, and render the polishing powder too coarse. The surface of the polisher used by Newton was pitch in a very thin layer. Instead of pitch, which Lord Rosse found too full of gritty impurities, he uses resin tempered with spirit of turpentine. A large quantity of resin being melted, the spirit of turpentine is poured in, and well mixed and incorporated (about a fifth by weight suffices.) The proper temper is known by taking up a little on an iron rod, and putting it into the water until it acquires the temperature, say of 55° Fahrenheit. Then if the thumb nail make a slight but decided impression, it is rightly tempered; if not, more resin or more spirit of turpentine is added, until the proper temper is attained. The tempered resin is now divided into two parcels: to the one parcel a fourth part (by weight) of wheaten flour is added to give it tenacity and diminish its adhesiveness. This is incorporated by stirring until it becomes clear. To the other parcel an equal weight of resin is added, which makes it very hard. Upon this, when cooled to 55°, the nail will scarcely make an impression. The grinding disk, with its spherical surface turned upwards, is now heated by fire underneath, and the resin rendered tenacious by flour laid on with a brush in a thin even coat about, 150° Fahrenheit. This coat and the grinding disk are then allowed to cool down to about 100° Fahrenheit, when a thin coat of hard tempered resin is laid on as evenly and thin as possible. The smooth ground concave speculum is now covered with a creamy coat of the fine polishing powder and water, and the warm polishing surface turned down upon it at about 80° Fahrenheit, when it soon takes the form of the speculum as in a mould; care must be taken not to put on the polishing plate too hot for fear of cracking the speculum, which the interposed creamy polishing powder helps to protect; nor too cold, else it will not take the proper figure. The grinding engine now gives the same motions to the polishing plate as before, but its weight is much diminished by counterpoising it. The soft tenacious coat below, and the grooves on the surface of the grinding disk, permit the proper lateral expansion, while the hard outer coating retains its form, and holds firmly embedded the particles of polishing powder. The polishing now proceeds rapidly, and as soon as what is technically called the black polish is attained, the defining power is judged of by examining the minute divisions of the image of the watch dial under an eye-piece of high power. The true form is known to be given as the polishing proceeds, if the focal length slowly increases in a tabulated proportion to the time. The six foot speculum it is expected will be finished after six hours' polishing.

NOTES OF THE WEEK.

The Wilkie statue in the National Gallery has been the subject of much interest and much discussion, and very different opinions have been expressed as to its merits, according to the standard by which it has been judged. It is the same with Chantrey's horse in Trafalgar Square; those who look to precedent and consider prancing horses as legitimate, condemn it as tame; those who maintain that it is unnatural to have a fixed statue in a prancing attitude, praise the artist's skill in preserving propriety, at the same time that the vigour and life-like character of the animal is so well expressed. Mr. Joseph has represented Wilkie as a young man in the act of sketching on his tablets some vivid idea which has struck him. An objection to the expression of the countenance has been found in the fact that it does not give strongly enough the national harsh features which the painter possessed, and Mr. Joseph has softened down. How far it is legitimate to do this, will, of course, be decided agreeably to the different views different parties entertain. Wilkie being represented standing by the trunk of a tree and draped in a cloak, is considered by some as improper, as if the artist could not as well be represented pursuing his labours in the open air as in his studio, while it is not unnatural to imagine him struck by one of those peasant groups, which he has transferred to canvass. The whole figure and its details have been minutely scanned, and even the way in which the crayon is held has been the subject of criticism. Neither has the place in which the statue is put between without its commentators, its location among the umbrella takers awakening the ire of some. For our own part, we must confess that it appears in some degree derogatory that the artist should be kept waiting at the porch, instead of being admitted to the cella of the temple of art; but, alas! such are the sad necessities of that unfortunate building, the National Gallery. If, indeed, the ground-floor could not without props support the weight of a statue, how could the safety of the upper stories be jeopardized. It is lamentable that every year brings to light fresh defects in connexion with this ill-conceived structure. Taking the statue of Wilkie as a whole, and allowing for the necessities of its position, we are much pleased with it. The merit of Mr. Joseph cannot be contested, though a difference of opinion may exist as to details of treatment, and as to the fact of the statue being erected, and we are glad to take it with all its defects, as a first offering to men of art in the national building. If Wilkie is to be honoured, surely others cannot be neglected, and we hail, therefore, with pleasure the prospect of a proper commemoration of ancient individuals. If statues are awarded to painters and sculptors, the honour of architecture cannot be forgotten, and we hope to see the day when Wren, Inigo Jones, and Chambers will receive due homage.

The public works, which have been brought forward recently, seem almost without exception to have met with strong support, and there is every probability of a great number of new railways being authorized in the ensuing session. This will be a most seasonable relief to professional men, whose employment has been so seriously interfered with by the restrictive legislative enactments.

The basins for the fountains in Trafalgar Square have been asphalted. The contract for paving the whole of the square has been taken by the Bastenne Bitumen Company, who will proceed immediately to lay down their composition.

We are sorry to see that the foundations for the buildings in 'Change Alley, or rather Freeman's Court, are being proceeded with.

A new Concert Hall has been opened at Rotterdam from the designs of Mr. W. N. Rose.

The painter Ferdinand Deurer died at Munich on the 9th, aged 67. The lithographer Piloty died in the same city on the 15th. He was one of the oldest lithographers, having begun in 1808.

The new English steamer for the Main Steam Navigation Company arrived at Frankfort on the 9th. She made the passage in two hours less than the old boats.

The first steam towing boat for the Company of the Palatinate has been launched at Strasburg.

The works for the rebuilding of Hamburg get on well. At the end of December, the bridges in the Gorttwiete, the Steintwiete, and of the Exchange were finished, and in use. The quay on the Monkedamm is in active progress. The bridges over the Kastenschleuse and the Resendamm are begun.

At the last meeting of the magistrates for Middlesex on the 18th instant, Mr. George Legg was elected district surveyor for the united parishes of St. Andrew, Holborn, St. George the Martyr, and the Liberty of the Rolls.

The Assize Court at Cambridge, designed by Wyatt and Brandon, is to be decorated by a series of four colossal statues of Law, Power, Justice, and Mercy.

The Eastern Counties' contract for the Northern and Eastern extension is, we understand, signed at about £12,000 a mile, for everything. Grissell and Peto are the contractors.

Another large hotel, 150 feet larger than the present, will be begun at Folkestone in the course of next month.

Mr. Macqueen has brought out a voluminous pamphlet, which we have had the good fortune to see, in which he enters most fully into the details of the management or rather mismanagement of the Royal Mail Steam Navigation Company. It is certain to make a great sensation, and we shall take an early opportunity of entering into the subject. Mr. Macqueen's vindication of himself seems complete; as to his inculpation of other parties, that must be matter of investigation.

Another large work has been published at the expense of the Pope on the Etruscan Museum Gregorianum; it is in two volumes, and contains upwards of 200 plates.

Of *Durand's Parallèle*—one, however, not quite so well planned as it might have been—a new edition has lately been brought out at Brussels, containing a great many additional, and also several unedited subjects. Among them are La Madeleine, Notre Dame de Lorette, L'Ecole des Beaux Arts, Le Palais du Quai d'Orsay, and several other recent monuments of Paris: further, the University at Ghent, the Palace of the Grand-Duke Michael at St. Petersburg, the Royal Palace at Stockholm, some buildings in Germany, the Royal Palace at Naples, and that at Madrid. Among them all, however, there is not a single example of any of the numerous buildings erected in England and Scotland within the present century. It would therefore seem that our architecture is not held in greater esteem on the Continent, than foreign architecture is by some here at home. Or possibly, the omission may not so much have been intentional as occasioned by the difficulty of obtaining authentic materials for the purpose. In other countries, those who have done most and best, have published their own designs—at least have contributed some of their principal ones to collections of the kind; but such practice, we regret to say, does not prevail among the architects of this country. Even could such reserve be imputed to humility, it would be a more strange than satisfactory excuse. Rather, we fear, must it be attributed to indifference on the one hand, and an illaudable economy on the other. Profit, indeed, could hardly be promised them, therefore, if there be no higher inducement than that of bringing out works of the kind, we have no reason to expect them; yet surely those—and some there are—who have accumulated wealth by a long and prosperous career, could well afford to renounce all ideas of profit, and even to abide by a certain loss. There is another reason—a most valid and cogent one, but we will leave it to the sagacity of our readers to find out, it being one that will hardly be confessed to.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

January 22.—T. L. Donaldson, Esq., in the chair.

Several donations were announced, and among others a rubbing of a brass intended to be erected in the country as a sepulchral mural monument. —As the impression was a very effective one, Mr. G. Godwin, jun., inquired whether any particular process had been used to obtain it?—Mr. Cox said it was done with the common heel ball, but as the brass was not fixed, the heel ball could be used more freely, and a sharper impression obtained. He hoped it would be seen, by the specimen before them, how very effective this mode of celebrating the departed was, and that it would not be without its effect in influencing the revival of this neglected branch of art.

The Chairman concurred in this wish, and observed that the practice of consecrating painted glass windows as monumental memorials of departed friends was now becoming prevalent, and was also worthy of praise.

Mr. Poynter then made some remarks on a plan and section of the transept of Minchinhampton church, in Gloucestershire, presented by Messrs. Foster & Son, of Bristol. The transept was, he said, a very curious one of the 14th century, and it was most remarkable that the roof, although supported by stone joists, was built as if it were of timber. The transept was not large, being 29 ft. long and 15 ft. wide, and the roof was carried by six stone ribs; the height to the crown of the arch being 32 ft. The appearance was very irregular, the windows also being narrow. The roof was originally covered with slabs of stone, but is now tiled.

The next paper read was by Dr. Brömett describing a bridge over the Moine, at Clisson, near Nantes, in Brittany. The river here runs in a deep ravine, and is a rapid, unnavigable stream, formerly crossed by a bridge at the bottom of the hollow made for purposes of fortification, as difficult of access as possible. The present construction is not so properly a bridge as a viaduct, and consists of 15 arches with two large abutments, being 106 metres (348 ft.) in length. The abutments rest on a coarse granitic foundation, but the structure itself is of a fine white granite, and the stones of large size, well jointed with fine white mortar. The foundations are six feet below the bed of the river, the height from the bed of the river to the springing of the arches 33 ft. and the total height from the foundation to the top of the parapet 61 ft. The total width at the top is 30 ft. 3 in. at the widest part. The viaduct is placed at right angles to the stream. The chief peculiarity of its construction is, that the piers are pierced with the pointed arch intersecting the cylindrical intrados of the main arches in the direction of the length of the viaduct, so that the roadway rests on a groined vault, which, seen from the abutments, have the appearance of the aisle of a Gothic cathedral. The same principle is adopted in the bridge of St. Maxence, built by the celebrated Peyronnet, about 70 years ago. The Clisson viaduct was completed in 1842, but it was opened for traffic a year or two before.

Mr. Billings proceeded to make some remarks on the Church of St. Peter and St. Paul, at Kettering, in Northamptonshire. As Mr. Billing's illustrations of his subject were principally sketched by himself at the moment, and describing minute points, we regret that we cannot follow him through his whole subject, as to many of those details great interest is attached. He described the Northamptonshire district as being characterised by churches with lofty towers and spires, and stunted bodies. At the same time, they are invaluable as studies at the present moment, as the cost of them is entirely within the means devoted to church building. There was an early church at Kettering, on the plan of which the present church was built, in the 15th century, all the remains of the old church being destroyed, except the chancel and the north doorway of the church. It so happened that the new building was first begun on a different line, and the tower at the west end being the first part of it, it was built at a very different angle from the rest of the building, so that the tower looks completely atwist. Ultimately, however, the church was built on the old foundations, but in the perpendicular style. The porch, also, was another anomalous appendage, for to suit the entrance to the church-yard, that is also atwist; indeed the tower and spire are at 15° angle in one direction, and the porch about as much in another direction. There was a curious thing with regard to the tower, and it appeared as if in that case, as in some others, it had been intended that the tower should have been isolated. The tower was finished on the inside with buttresses and ornaments, so as to afford a view of it from the interior. "This shows," said Mr. Billings, "that the old architects sometimes made mistakes as well as we do, by putting more work than is necessary." This remark caused much amusement. He proceeded to say, that the plan of the church was a square of 64 ft., and contrary to the usual proportion allotted to aisles, the church was so divided that it might be said to have three equal aisles. There being five compartments on each side of the nave, there were twelve piers, which, if the symbolists were right, would stand for the twelve apostles. At Harrow it was a very interesting circumstance, that with twelve compartments, each niche was occupied with the statue of an apostle. He then described the columns, the caps of which were, in his opinion, very beautiful. As to the roof, there was nothing remarkable in that, except the blunders committed in its design and construction, and particularly with regard to the great beams, which were not long enough to reach from wall to wall, and consequently they rested on a piece of timber at each end, and were supported by two most bungling struts and knees. The doorway at Kettering he notices as very pretty, and a window, in the chancel, as curious; one of the windows in the clerestory he considered as perfect. There was also an instance, in a chapel of a late date, in which the pointed arch was nearly lost in a circle, and for his own part he was strongly inclined to believe, that had not the progress of architecture been arrested, the tendency was to a revival of the ancient round arch style of architecture. The plan of the spire and tower he considered as the most extraordinary portion of the whole building; the tower being a square within which diagonals had been drawn, and the angles of these being cut off, an octagon remained, which represented the base of the spire. The question of entasis or swelling of the spire, which created great interest, Mr. Billings said he had minutely examined, and measured Kettering spire, and there was no sign of it; it was formed by right lines. At Stamford he had been told there was an entasis on one of the spires, but, on examining it, attentively, he found the appearance merely arose from the spire being formed of two lines at a different angle. He did not, however, mean to deny that bulging might exist, though the bulging was in most cases done purposely. The introduction of rain pipes at Kettering instead of gurgoyles, he considered as one of the oldest instances. In answer to a question from the Chair, Mr. Billings said the materials were of lead.—The Chairman remarked, that it was not unusual to find old rain pipes of that material.—Mr. Billings said he was aware of that, and particularly in domestic building. There had been paintings, he said, at Kettering, usually called fresco, but which, in reality, were distemper. Among others was a Saint Christopher, with brilliant azure breeches, decorated with gold stars. Having concluded his remarks on Kettering, Mr. Billings made some remark on the book he had published on the subject, and, in order to prevent speculators subsequently bringing out the work at half-price, to the annoyance of subscribers, he had brought the work out at half price in the first instance.

The Chairman, after passing a vote of thanks to Mr. Billings, and paying a great many compliments to him, proceeded to assert, that he had seen a church in Northamptonshire, where there were very old pews, and that the use of pews was an established practice of the ancient church in this country.

Mr. Billings, on the other hand, said, all the spires in Northamptonshire had been built by the protestants, which caused much laughter, and also that all the pews had been built by them.

The Chairman contested this.

Mr. Poynter, in reference to entasis, said, there was a decided case of a curved line in a spire at Newark, though, in most cases, the appearance arose from the spire being made on distinct lines. He had recognized as many as three distinct lines.

Mr. Billings said, that in St. Mary Redcliffe, Bristol, there were two distinct lines observable.

This subject being concluded, the Chairman called the attention of the members to a subject generally interesting to the profession. They were, perhaps, aware, that the Westminster Division of Sewers had determined to extend their staff by the appointment of a new assistant surveyor, and new clerk of the works. They had advertised, and they had determined on putting certain questions to the candidates, to ascertain their competency, which questions he had prepared in conjunction with Mr. Walker, Pres. Inst. C. E., and Mr. Gwilt, Surveyor of the Surrey Commission; 33 candidates appeared, but on the questions being put to them, and three hours being assigned as the time to write out the answers, several of them immediately retired. Ultimately, six candidates were selected, who were considered the best, and not one surveyor or architect was among them; they were all engineers. This struck him most forcibly, and he felt himself disappointed. He urged, therefore, on the younger members of the profession, the necessity of keeping pace with the tide of knowledge, and the spirit of the times, or they would be undoubtedly outstripped by the engineers. It was indispensable for them to acquire the higher branches of knowledge; it could no longer be considered that mathematics was unnecessary, or natural philosophy, physics, or geology, nor any department of practical knowledge. They would find, too, in their own profession, several brilliant instances of acquirement: as mathematicians, Mr. Gwilt, and Mr. Newman, had procured the admiration even of engineers; neither must it be supposed that the engineers had carried off all the honours. Mr. Walker, it was true, held several appointments, but Mr. Gwilt, Mr. Newman and Mr. Ianson, were all architects. The profession must, however, exert itself, many valuable appointments would be open to competition, for success in which, interest could no longer be looked to, but they must depend on their own merits. They might rely upon it, that they must not be below the age, nay, they must not be merely equal to the age, but they must be in advance of the age, if they wished to maintain that position, which, as architects, they ought to hold in the public estimation. Mr. Donaldson then proceeded to read several of the questions, which all related to practical points with which it is requisite candidates should be acquainted, as, the nature of the different cements, the mode of constructing sewers, shoring houses, &c.

The meeting then adjourned to Monday, February 6.

THE ROYAL SCOTTISH SOCIETY OF ARTS.

January 8.—GEO. BUCHANAN, Esq., F.R.S.E., Vice-President in the chair.

The following communications were made:—

1. *On the Comparative Value of different kinds of Parrot Coal for yielding Gas*, &c. By ANDREW FYFE, M.D., F.R.S.E. In this paper the author laid before the Society the results of experiments which he had undertaken, with the view of ascertaining the comparative illuminating power of gas from different kinds of parrot coal; and also, whether gas is altered in its quality by its transit through the street pipes. The coals used were those from Lesmahagow, Monkland, Knightswood, and Skaterig, in the west of Scotland; Torryburn and Wemyss, in Fifeshire; and those from the Marquis of Lothian's, from Dryden and Arniston, in the neighbourhood of Edinburgh—being, in all, ten varieties. Taking the average of the different trials, the comparative illuminating power of the gases, as ascertained by the usual tests, was as follows:—For equal consumpts of gas—Skaterig, 1; Knightswood, 1; Marquis of Lothian's (B), 1·76; Torryburn, 1·8; Marquis of Lothian's (A), 1·9; Lesmahagow (F), 2; Lesmahagow (D), 2·48; Monkland, 2·5; Arniston, 2·9; Wemyss, 3. The coals above-mentioned were found to yield different quantities of gas, and, taking this into consideration, along with the difference in the illuminating power, the comparative value of the coals for yielding gas, without having any reference to the other products, such as the ammoniacal liquor, the naphtha, &c., was—Knightswood, 1; Skaterig, 1·12; Marquis of Lothian's (B), 1·8; Marquis of Lothian's (A), 2·1; Lesmahagow (F), 2·2; Torryhurn, 2·2; Monkland, 2·8; Wemyss, 3·4; Arniston, 3·4; Lesmahagow (D), 3·5. The second object of inquiry was to ascertain whether the gas is affected in its quality by passing through the pipes to the place of consumption. For this purpose the illuminating power of gas in different towns was tried at the manufactory, and at the greatest distance to which it was conveyed. At the Edinburgh works the gas was found, by a particular test, to indicate an illuminating power, as 13·16; at the distance of a mile it was 14. In other trials, the distance from the works being three miles, the results were as 13·5 and 12·5; in others, as 14 and 14. Similar results were obtained in other towns. In one place, at the distance of six miles from the manufactory, they were as 14·75 and 14·25. From these and other experiments, Dr. Fyfe concluded, that if there is any diminution in the illuminating power of gas when carried to a distance from the gas-works, it is so very trifling as to be altogether unworthy of notice.

2. *Description and Drawing of an Improved Apparatus for Levelling small Theodolites.* By Mr. JOHN SANG, land-surveyor, Kirkaldy. The apparatus exhibited is an elegant addition to the theodolite, and renders the instrument much more easily and quickly adjusted to the level, one hand being only needed in place of two, and, when once brought to the level in one direction, requiring no second adjustment, from the disturbing influence of the other screws at right angles, which render the usual method so tedious and troublesome. The apparatus was not only invented, but constructed in so perfect a manner by Mr. Sang, that it elicited praise from opticians who were present. Referred to a committee.

3. *Model and Description of an Improved Double-acting Cross-cut Saw.* By Mr. ROBERT DICK, wood-forester, Scone.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM DECEMBER 28, 1843, TO JANUARY 23, 1844.

Six Months allowed for Enrolment, unless otherwise expressed.

Richard Archibald Brooman, of the Patent Office, 166, Fleet Street, London, gent., for "*Improvements in figure weaving machinery.* (A communication.)—Sealed December 28.

Thomas Murray Gladstone, of Swan Garden Iron Works, Wolverhampton, iron master, for "*Improvements in machines for cutting or shearing iron or other metals, which improvements are applicable to other like purposes.*" Dec. 28.

George Benjamin Thorneycroft, of Wolverhampton, iron master, for "*A machine for rolling, squeezing, or compressing puddled balls of iron, and also for crushing or grinding other substances.*" Dec. 28.

Robert Noyes Elven, of Southampton Street, Camberwell, shoemaker, for *Improvements in the manufacture of boots, shoes, galoshes, and clogs, which improvements are applicable to the manufacture of leather hose and buckets.*" Dec. 28.

Henry Lowcock, of Westerland, Devon, yeoman, for "*Improvements in ploughs.*" Dec. 28.

Edward Budd, of Swansea, Glamorgan, copper merchant, and William Morgan of the same place, refiner of copper, for "*Improvements in treating or reducing of copper ores, and in the construction of furnaces for treating such ores, part of which improvements are applicable to other ores.*" Dec. 28.

George Gwynne, of Regent Street, gent., and George Fergusson Wilson, of Belmont, Vauxhall, gent., for "*improvements in the manufacture of candles, and in treating fatty and oily matters, to obtain products for the manufacture of candles and other uses.*" Dec. 28.

James Champion, of Salford, Lancaster, machinist, and Thomas Marsden, of the same place, machine-maker, for "*improvements in drawing and spinning cotton and other fibrous substances.*" Dec. 28.

Alexander Denoon, of Adams Court, Broad Street, London, merchant, for "*improvements in the mode of making carbonate of soda.*" Jan. 1.

Alexander Denoon, of Adams Court, Broad Street, London, merchant, for "*improvements in the mode of making muriate of ammonia.*" Jan. 1.

William Longmaid, of Plymouth, Devon, accountant, for "*an improvement in the manufacture of copper, tin, zinc, and peroxide of iron.*" Jan. 1.

John Hinks, George Wells, and Joseph Finnemore, all of Birmingham, Warwick, metallic penmakers, for "*improvements in the manufacture of metallic pens, and in machines for manufacturing metallic pens.*" Jan. 4.

William Wright, of Duke Street, St. James's, Middlesex, surgeon, for "*improvements in rendering leather skins or hides impervious to wet, more flexible, and more durable.*" Jan. 11.

Laurence Hill, jun., of Glasgow, civil engineer, for "*improvements in machinery for manufacturing shoes for horses and animals.*" (A communication.)—Jan. 11.

William Hale, of Woolwich, Kent, engineer, for "*improvements in rockets.*" Jan. 11.

Robert Foulerton, of the Jamaica coffee-house, Cornhill, London, master mariner, for "*improved machinery for moving vessels, and other floating apparatus.*" Jan. 13.

Anthony Movillon de Glimes, of Panton Street, Haymarket, gentlemen, for "*improvements in apparatus for propelling vessels on water, and also in machinery capable of communicating manual power to work the same, which machinery is also applicable to raising heavy bodies, and exerting power for various other purposes.*" Jan 13.

Henry Bessemer, of Baxter House, St. Pancras, engineer, for "*a new pigment or paint, and the method of preparing the same, part of which method is also applicable to the preparing and treating of oils, turpentine, varnishes, and gold size, when employed to fix metallic powders, and metal leaf, or as a means of protecting the same.*" Jan. 13.

James Lindley, of Cranbourne Street, Middlesex, gent., for "*improvements in coffins.*" Jan. 16.

Thomas Aspinwall, of Bishopsgate Church-yard, Esq., for "*an improved cannon, formed either of wrought iron, or steel, or wrought iron and steel combined, and also instruments and machinery used in making, and method of making the said cannon.*" Jan. 16.

Charles Cameron, of Liverpool, chemist, for "*improvements in extinguishing fires in buildings.*" Jan. 16.

Benjamin Cheverton, of Pratt Street, Camden Town, sculptor in ivory, for "*improvements in machinery for cutting wood and other materials.*" Jan. 16.

William Edward Newton, of Chancery Lane, civil engineer, for "*improvements in machinery or apparatus for facilitating the tracing and copying of designs, drawings, and etchings of all kinds, either of the original size or upon an enlarged or reduced scale.*" (A communication.)—Jan. 16.

William Watson, jun., of Leeds, manufacturing chemist, for "*improvements in the manufacture of sulphate, muriate, and other salts of ammonia.*" Jan. 16.

William Nichol, of Edinburgh, printer, for "*improvements in lithographic, and other printing presses.*" Jan. 16.

John Fielding Empson, of Birmingham, manufacturer, for "*improvements in the construction and manufacture of buttons, and other fastenings for dress.*" Jan. 16.

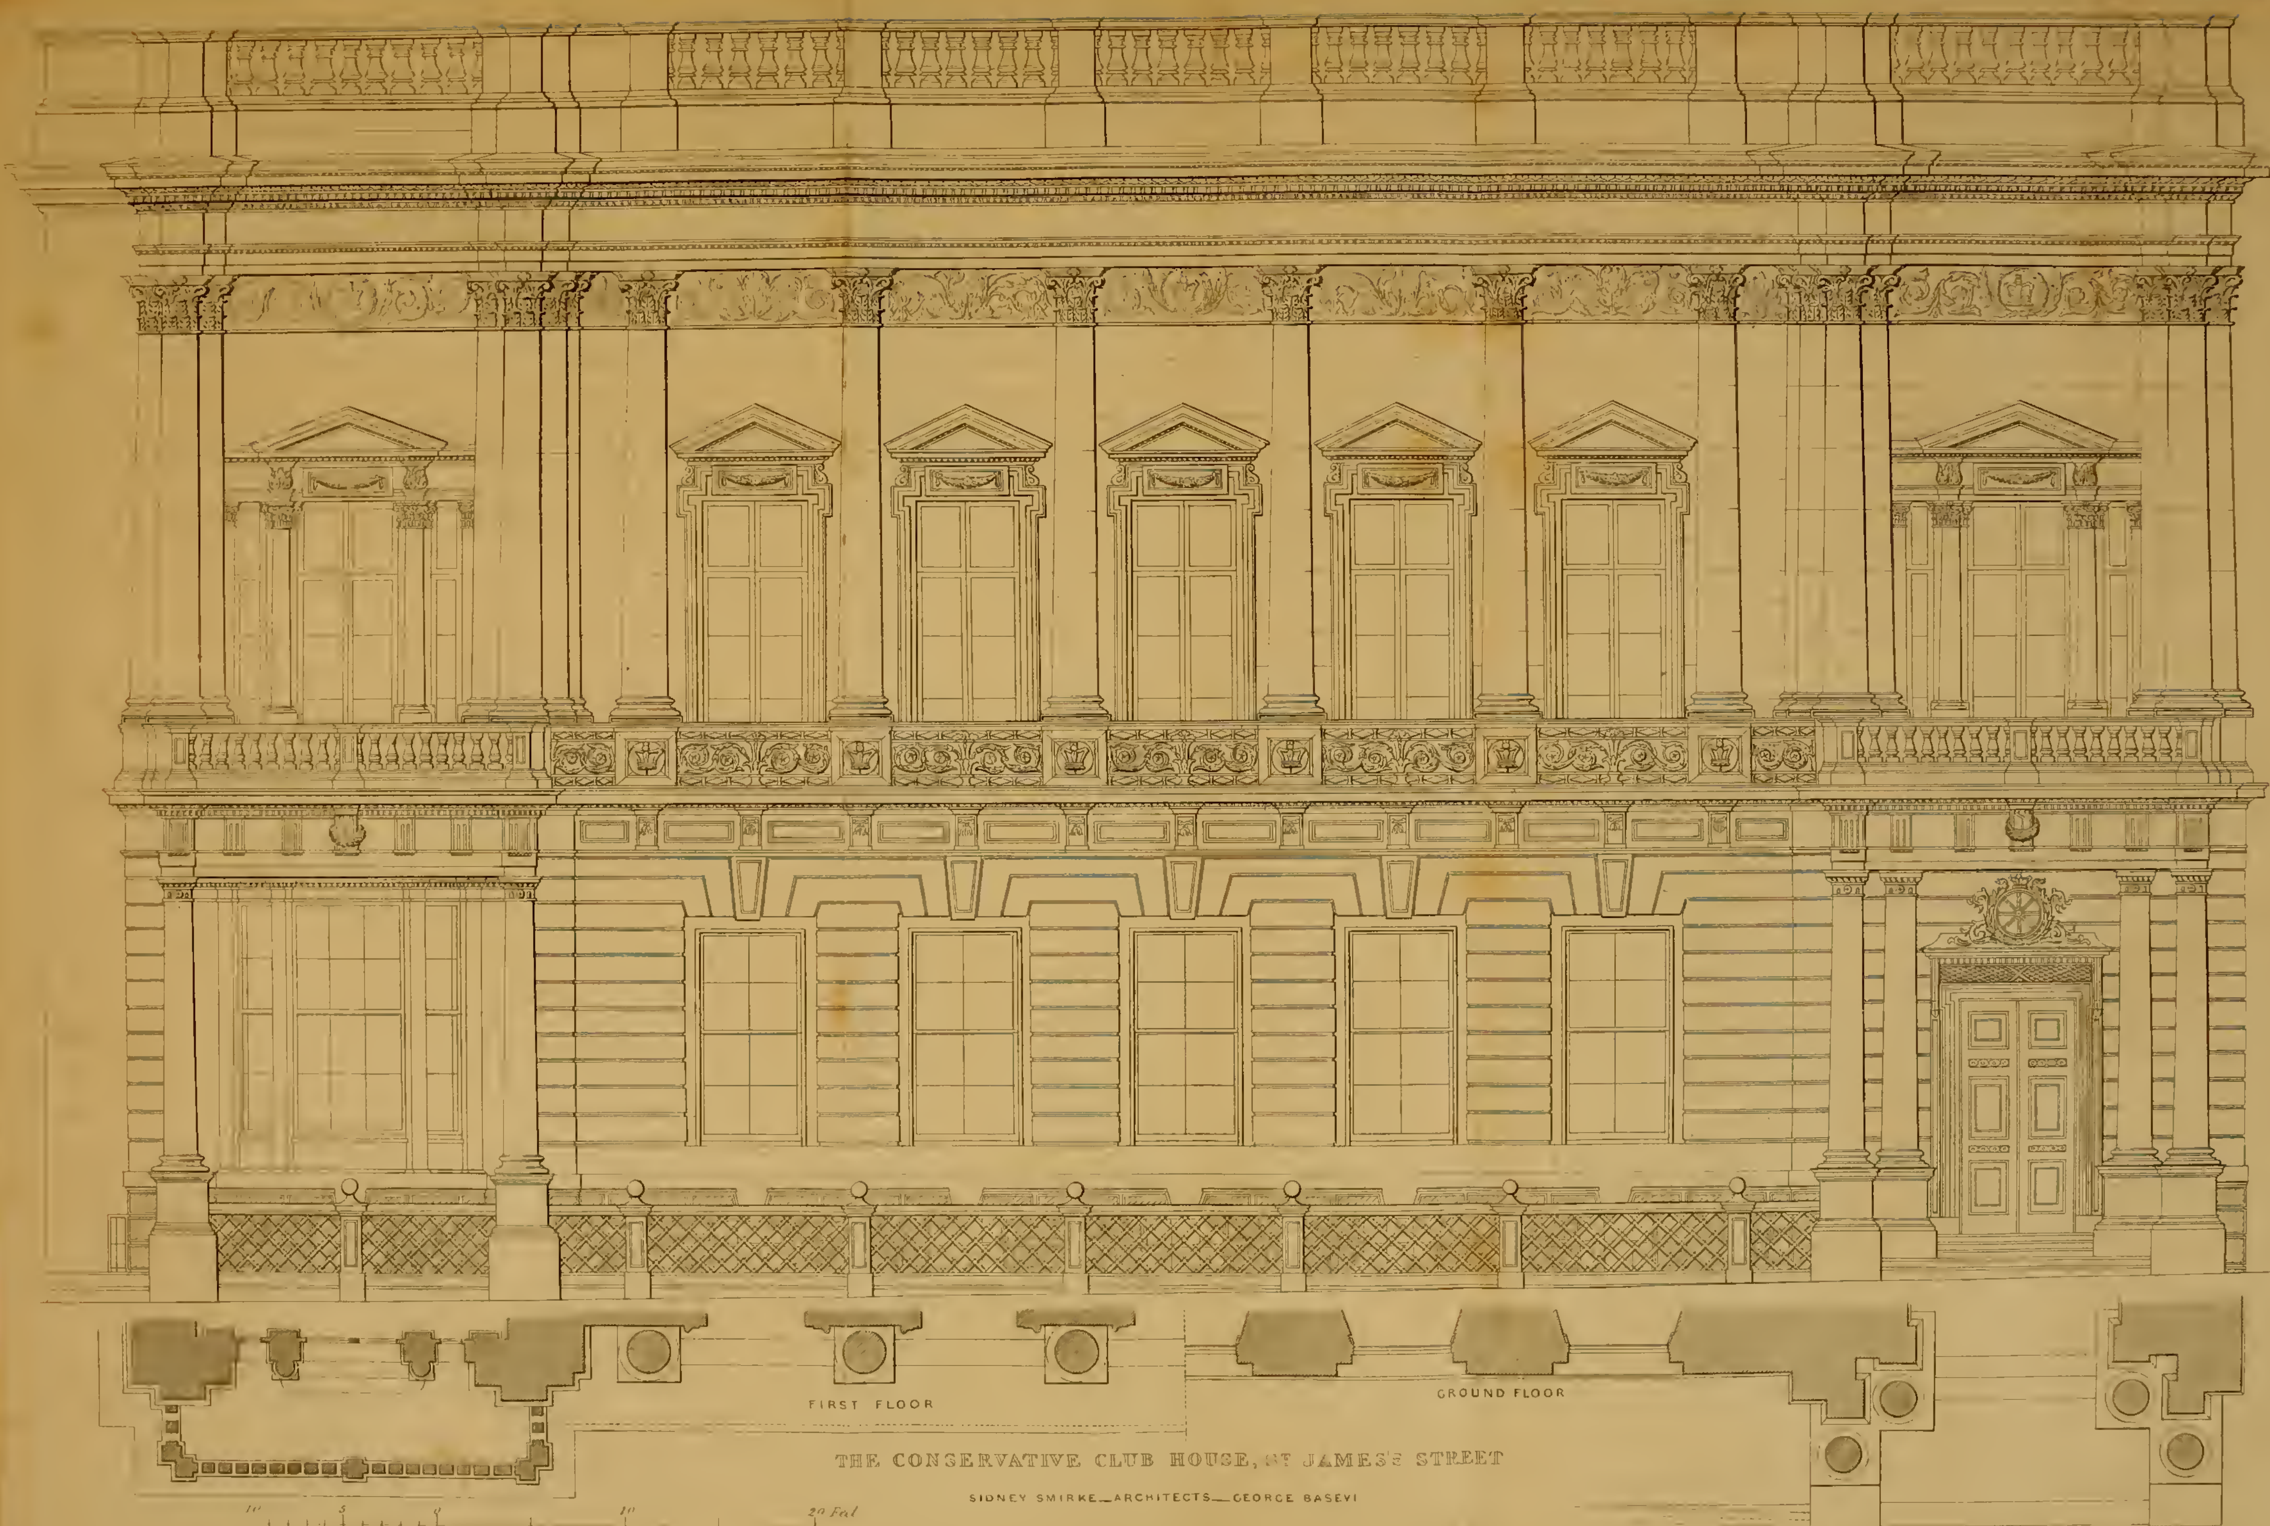
William Basford, of Burslem, Stafford, brick and tile manufacturer, for "*improvements in the mode of manufacturing bricks, tiles, quarries, and certain other articles made or composed of brick, earth, and of burning and firing the same, and certain articles of pottery and earthenware.*" Jan. 23.

Claude Francois Jules Petit, of Regent Street, merchant, for "*improvements in fastenings for gloves.*" (A communication.)—Jan. 23.

Samuel Wright, of Shelton, in the Staffordshire Potteries, for "*a manufacture of ornamental tiles, bricks, and quarries for floor pavements, and other purposes.* (Being an extension of former letters patent for the term of seven years, from the 26th instant.)

Thomas Nash, of Paul's Cray, Kent, paper manufacturer, for "*improvements in the machinery for the manufacture of paper.*" Jan. 23.

Henry Davies, of Norbury, Stafford, engineer, for "*improvements in the construction of vessels for conveying goods or passengers on water, also certain improved arrangements of machinery fo recommunicating motion to such vessels.*" Jan. 25.



THE CONSERVATIVE CLUB HOUSE, ST JAMES'S STREET

SIDNEY SMIRKE — ARCHITECTS — GEORGE BASEVI

Engraved by H. Banks for the Civil Engineer & Architect's Journal Feb. 1844

WATSON'S PATENT IMPROVEMENTS IN DRAINING.

The serious difficulties which railways have had to contend with, particularly in the vicinity of the metropolis where there are deep cuttings in the London clay, in consequence of the continued slipping or rather sliding of the banks, mainly owing to the filtration of the surface water or the springs percolating through the substrata, induced Mr. Watson to turn his attention to the evil, to see how far it might best be corrected, and that with economy. For this purpose he invented iron drain pipes with conical perforations, the smaller end of the cone being on the outside, and the base or larger end inside; or instead of holes the pipes are sometimes made with slits, having a small aperture on the outside of the pipe enlarging towards the inside; by thus making the outer apertures smaller than the inside, they do not become clogged up. These pipes are shown in the annexed figures A, B, C & D; they are cast in lengths of 4 ft. each, and 3 in. diameter, for which the charge is 4*s.* 6*d.* each, they are also made in pottery from 4 in. to 12 in. diameter. It is not to the pipes only that Mr. Watson, directed his attention, but likewise to their insertion in the banks, without being obliged to cut a deep trench; this he contrives to do by a boring machine that he has invented for the purpose, and which we shall describe in our next number. By the aid of this machine, the pipes are easily and cheaply inserted in the clay or other soil, as shown in the annexed engraving of a cutting.

Another advantage offered by this patent is the ventilation that is procured in the works to which it is applied, and which will preserve building materials and consolidate earthwork. The borings are to extend not merely through the masonry, but some distance in the solid earth. As mortar will not harden if kept from the air, the importance of admitting air within masses of brickwork will be readily acknowledged. It may here be remarked, that holes bored for drainage, without the insertion of pipes, soon become choked and useless.

These pipes have lately been introduced for draining the back of the retaining wall in the cutting of the London and Birmingham Railway, between Euston Square and Camden Town, and also on the Croydon Railway.

Mr. Hughes of Bunhill Row will be happy to give any explanation as to the cost of inserting the pipes either by his own men, or he will instruct others.

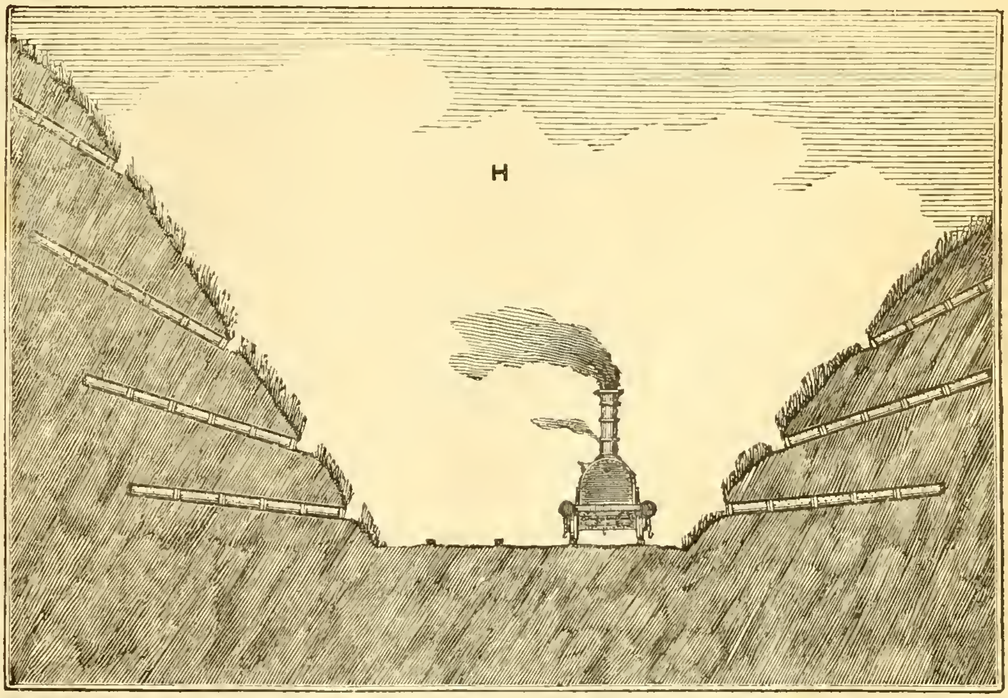

Fig. 2.—Drain Pipes in Open Cutting.

THE DRAINAGE OF THE COUNTRY.

By W. Mullingar Higgins, Esq., C.E., &c., formerly Professor of Experimental Philosophy at Guy's Hospital.

During the next three or four years there will probably be such an opportunity of improving the internal resources of the country, as has never before occurred. It is generally understood that the Government intends to introduce, during the next session of Parliament, a general measure, which will, probably, embrace the sewage of towns and the drainage of the land. That such a measure, wisely planned and carried out with skill, will be an invaluable boon to the nation, every one admits; but it may be doubted whether the public is at all aware of the extent of its value, and perhaps not many of its most sanguine promoters. The health of the population in towns, and the improvement of cultivated lands, are the two results which are generally acknowledged; but the effect of a good system of drainage will be scarcely less beneficial to the internal navigation of the country, than to the agricultural condition of the lands which are now, or may be brought into a state of cultivation. This view of the subject is so important, that a few remarks may not be inappropriate in the present state of the question.

There are numerous rivers in this country which would be of immense value to the districts through which they flow if they were navigable, and would become competitors with the railways for the carriage of merchandize, and the transit of passengers. Many of these have been at former periods large and deep rivers, and have carried vessels of considerable burthen. By great ignorance, or want of attention, and small temporary expenditures, natural causes, which man ought not only to control but to render subservient to the accomplishment of his objects, have, in various ways, so changed their former condition, that they are not only altogether useless for navigation, but are scarcely sufficient channels for the drainage of the country through which they lazily flow. As soon as the commercial wants of some town situated on or near their banks demand a rapid and commodious transit by sea, an engineer is required to give his opinion as to the method of improving the river; dredgings and embankments are immediately commenced, and the streams which had before only tended to the destruction of the channels, are made to assist in their excavation. The difficulty and expense which attend these local improvements, are only known to those who have been engaged in conducting or performing them. And after the expenditure of millions in various parts of this country, during the present century, the good which has been effected is confined to a few districts, and is not appreciated, if in any degree felt, by the country at large.

Should a general plan of drainage be adopted, there will be an opportunity of improving, and perhaps rendering sufficiently navigable, every river in the kingdom. They are the natural and proper channels by which all the waters that fall on the surface of the island should be conducted to the sea. In the present state of the country, these waters are allowed to lie upon cultivated lands, to be evaporated by the heat of the sun, or to collect in low lands, forming bogs and marshes. But, carry them by a perfect system of drains into the rivers, and with a little assistance they will deepen the channels, and improve the outfalls.

It is not my intention, at present, to enlarge upon this subject, as I may, at some future time, offer a few suggestions upon the manner in which this drainage, as a national measure, should be performed, and take a more enlarged view of the benefits that may be obtained. The importance of the measure, however, will entirely depend upon well devised plans and careful execution. The subject is one almost unknown to a large number of engineers, and there is no work in the language which treats the subject systematically. My attention has been many years directed to this and similar pursuits, but although I could mention many admirable reports delivered by British engineers during the last two centuries, in which the great principles of drainage are fully enforced for particular localities, I do not know of any paper containing so excellent a practical view of the subject as is given in one chapter of Gughelmini's work on rivers. I have, therefore, been induced to offer a translation of it. The Italians still look to the writings of this great man as authorities on all questions relating to the motion of water, and although in some particulars he has erred in judgment, the credit given to him by his countrymen can scarcely be denied by us, notwithstanding the advance that has been made in both the theory and practice of hydraulic engineering. It is at present uncertain to whom may be intrusted the works necessary for carrying out the intentions of the Government, but I have no hesitation in saying that a careful study of the following paper, considered in connexion with the works which have been performed in this country, particularly in the Fens, may be the means of preventing many errors that would be fatal to the success of the plans, in the ever varying conditions of the districts in which the improvements are to be made. It is with the view of assisting those who may be thus employed, and the agriculturists who are attempting to secure the effectual drainage of their particular districts, that I have made the following translation.

Beside the large rivers, which have their origin in high mountains, and the torrents which, although they are not fed by springs, have also their birth in mountainous districts, there are channels which carry rain water only, and these commence in the plains. They have seldom if ever been formed by nature alone, but by the art of man, who, to drain his fields and render his ground fit for cultivation, has excavated ditches, into which the rain water immediately flows, and these uniting with others, are finally discharged into a common bed, formed by manual labour, and called a drain,[1] or by other names, according to the custom of the country, and such drains have their own proper names, in the same manner as rivers. Most of these drains are public property, because the right of introducing the rain water into them is common to many, and by their channels the united waters flow towards their outlet. It happens, however, that some fields have no need of the public drain to keep them dry, and these are they which are contiguous to rivers properly embanked, into which, by means of private ditches, their waters are introduced; but these do not need any explanation, as they are but few, and nature herself teaches the mode of managing them.

The declivity of plains is generally so small, and the surface so unequal, that it is not possible for the rain water, unless it moves with great impetuosity, to run off from the high to the low lands, and leave the fields in a state of perfect cultivation, particularly in the time of spring and summer, when the grasses greatly impede its discharge. It is true that the waters are ultimately united in low places, and leave the higher free, but it is also true that for this end a long time is necessary, during which the earth, imbibing an excess of moisture, becomes barren; and as there are in the plains, low places shut up on all sides by more lofty grounds, the water is collected in them, and not being able to escape, necessarily forms a marsh or bog, as frequently occurs in countries unoccupied or neglected by man. This has made it necessary for civilized nations to cause all the plains to be connected by excavated ditches, and to direct the outlet of these ditches to the places where experience has proved they may find basins or continued low grounds, and along these to excavate a capacious canal to receive the atmospheric water from the drains of the country. From this artifice arose the drainage of all the provinces, which have been brought into a fertile state, but they can only be kept in that condition by the preservation of the first excavations.

These drains have their termination, either in neighbouring rivers, in marshes, in ponds, or in the sea. Those that discharge themselves into rivers can serve only those fields that are at least higher than their beds, if temporary, or than the lowest surface of their waters if permanent. The mouths of drains, where they discharge themselves into a river, may be either open or closed. Those only can have their mouths free, that is open at all times, which have their beds higher, or at least as high, as the greatest flood of the river, for otherwise, if the river be turbid, regurgitation through the drain would stop it with deposits, and close the outfall; hence it is that only higher grounds can be drained by open conduits in rivers. But if these channels are embanked, (a certain evidence that the flood rises over the surface of the country,) it will not be possible to have the mouth always open, but some mechanical arrangements will be necessary to prevent the floods of the river from being introduced into them, and that the rain waters, if there are any, should be retained either in them, or in the ditches of the fields, until after the flood has subsided, when the impediments at the mouth may be removed, and the water discharged.

Many artifices have been adopted to prevent the regurgitation of rivers in drains; but this is not the place to speak of them: they may be seen in Baratteri's "Architettura dell'Acque," part 1, lib. 8, cap. 19. The most common are the before mentioned. We should, however, in these cases, carefully observe the conditions of the districts, which give occasion for as many rules.

1. If the lands which are to be drained by a channel, furnished with a gate, are on the same horizontal plane, it is not necessary that the sides of the conduit should be embanked; because when the gate is closed the water is unable to overflow any one part, or if through too great an abundance it should overflow a part, it will distribute itself equally over all the country, an effect embankments could not prevent, which are therefore of no utility; but if the inundation of the country should not be prevented, (in case the gate should break, an accident very rare,) other cautions will be demanded.

[1] Scolo, fossa di scolo, condotto, tratturo, discursorio, o in altra maniera.

2. If the country should decline towards the mouth, as it commonly does, it will be necessary that the banks of the drain towards the outlet should be so much elevated as to equal the height of the highest part, or the water that flows down will overflow and cause inundations. Hence it is

3. That the districts which have a great declivity on the surface cannot have drains with gates, without overflowing the low lands when they are closed; and therefore in such a case we ought

4. To separate the drains of the high lands (as far, at least, as the highest flood of the river) from those of the lower grounds, and to make the former discharge by an open mouth, enclosed with banks sufficiently high to support the regurgitation of the river, while the latter may be provided with a gate and banks if necessary, in the manner above named. It is true that if the water of the open drain should not run in such abundance as to prevent the regurgitation of the high waters, during the freshes, a deposit will be formed, and there may be so small a quantity of water in the drain, that it has not sufficient power to remove the impediments when they are formed: in this case new and repeated excavations will be required.

5. The flood gate may be closed when the river is swollen, until the water in the drain shall be raised to the same level, and then it may be opened to discharge such additional water as may flow into the drain; in this way the regurgitation of the flood will be prevented, and the water that comes afterwards into the drain, will be discharged without inundating the country.

6. The low grounds may be drained by the use of flood-gates either in rivers or in the channel above named, but more easily by the former than by the latter, because the water of the river is lower than that of the drain, and also because the deposit which is formed in the channel cannot be produced in the river, in which the fall must consequently be greater.

The drains which fall into marshes, stagnant waters, and similar places, have generally an open discharge, and the reason is, because the difference between the highest and lowest surface of the water in the marshes is, for the most part, not so great as to require the application of a flood-gate (which is difficult to manage) to prevent regurgitation; and especially as the fields which are to be drained into them are higher than the surface of the marshes, and it is from the fields that the water comes which swells them; besides which, on deposit is to be feared from the regurgitation of the waters. Sometimes, however, the country has so little declivity in those parts contiguous to the marsh, that remaining dry, the great part of the year, in consequence of its elevation, it only spreads the waters at the time of floods. Under such circumstances it may be useful to defend the higher ground by surrounding it with banks, so that the water of the marshes increasing, may not overflow it, and at such times to arrest the rain-water in the fields, which, when the surface of the water in the marshes begins to fall, may be discharged into it by one or more cuttings in the bank. Such localities cannot be brought into a state of perfect cultivation, being by nature marshy, but they must be kept for pasture or meadows to which the dampness of the soil is useful. When marshes are occasionally much flooded, as, for example, when rivers enter them, or when rivers overflow their banks, flood-gates may be used at the mouth of the drains, but before they are introduced, it is necessary to consider the duration of the floods, the state of the country, and other similar questions, for upon these their usefulness depends.

Those channels which have an immediate discharge into the sea, must be differently treated according to their circumstances. The rise and fall of the tides, and the swell produced by winds, is sometimes productive of damage, and sometimes of advantage to the mouths of the drains. Every one knows that the sea forms its own banks, and throws up mounds of gravel upon the shore. The height of these defends the interior low grounds from inundation, which would otherwise be the result in time of storm, and sometimes also at the time of the usual high tides. These beaches must be cut to form an outlet, but the openings must, at the same time, be protected by strong banks, in order that when the water of a stormy sea introduces itself into the drain, it may not spread into the back country, and overflow it for ever, as has sometimes happened in low grounds. Therefore not to run such a risk, they are usually provided with strong gates, which being shut when the sea is high, keep it within its ordinary limits, and being opened when it is low, give a free discharge to the water that was retained during their closure. In some drains, however, which, on account of their length, or for some other reason, carry a large quantity of water at all times, and are equal to small rivers, it may happen that gates are not necessary, the continued flow of the water of the drain being sufficient to keep back the water of the sea; nor are they necessary in those places where the country rises as it recedes from the shore. By comparing the elevation of the sea when tempestuous with the level of the country, it is easy to determine what drains require gates, and what kind of banks should be employed. There are some drains which have outlets so large and deep that they form small harbours, and give shelter to vessels of moderate size. This may be occasioned by the natural depth of the sea in that situation, by the abundance of the water in the drain, or by the position of the shore; it may arise from the direction of the mouth being such that it is not exposed to those impetuous winds which, in tempest, drive sand or beach to the coast, or from the great rise and fall of the sea; or it may be occasioned by the operation of other causes, which prevent the formation of a deposit, and promote excavation, but which cannot be described without a particular examination of the place. On the contrary, the outlets of some other drains are closed when certain winds blow, and these drains must either be diverted and discharged in other places, or the water must be penned up so that it may enter the sea with velocity, and remove the deposit formed at its mouth.

In drains not large enough to have a good outlet, it is especially necessary that they should be sufficient to carry all the surface water of the country, and that they should not overflow their banks. It must, therefore, be borne in mind, that as they have, under ordinary circumstances, a comparatively small quantity of water, they must, when the stream is turbid, have a considerable fall before they can establish their beds. In a plain of little declivity the bed would be elevated above the level of the country, and the drain be rendered incapable of receiving the surface waters. In streams of this kind it is useless to expect any excavation, but it is, on the other hand, necessary to form the channel by manual labour, and prepare the course the waters should have to their discharge.

We must then be careful that the channels shall be excavated sufficiently deep to receive the water in great abundance, so that it may not be raised above the plane of the country, and, if possible, not within the drains that run into them. In addition to this, every excavation is superfluous, as, for the drainage of the land, it is enough that the private drains should remain dry after the fall of rain. Such benefits, however, cannot be obtained in low places with any amount of excavation; for, the bed being horizontal at a lower level than the place of its reception, where the mouth of the conduit ought to be, if greater excavations were made, they would only serve to produce a greater regurgitation, or to cause an eddy; besides which, when the excavations are deeper, a greater width is required, which would, in such a case, be a waste of ground, without a corresponding utility. It is true, that in the excavation of these channels it is better that they should be made too large than too small, for, although the drains of the country carry only limpid waters, they must always hold some earthy compounds brought from the surface of the cultivated land, particularly at the time of heavy rains, or, if from nothing else, from the washing and breaking down of the banks of the conduit, and therefore, the water having but little velocity, in consequence of the little declivity of the bed, as well as the small quantity of water, the earthy matters being deposited, must raise the channel. The water of the drain being raised by the elevation of the bed, the surface waters of the country can no longer have a free discharge: hence it is, that the greater the excavation, so much the longer will it be before the bed is raised to that height at which further deposition will become injurious; but, on the contrary, if the first excavation be too small, the defect will be immediately felt, and will continually increase. Hence it is, that the drains not being able to maintain a free discharge, and being necessarily obstructed by the inevitable accidents above mentioned (besides many others which ignorance permits, and malice creates) repeated excavations are required, which must, as the occasion demands, be done according to established rules."

OCEAN STEAM NAVIGATION.

Mr. Macqueen's *Reply to the Chairman and Directors of the Royal Mail Steam Packet Company.* London: Blackwood, 1844.

On a recent occasion, we expressed our regret that the condition of oceanic steam navigation is so unfavourable, and that dissensions exist which so seriously impede the extension of this important branch of commerce, and deteriorate the property of shareholders. Considered in a commercial point of view, ocean steam navigation affords the means of acquiring for this country, an extensive transit trade, if not the monopoly of it. We well know for how long a period the supremacy of Dutch commerce was maintained from such sources, and how, in the present day, we are deprived of any share of the transit trade, and beaten out of the market by the Americans, and other rivals; this, too, must necessarily continue, so long as the cost of materials for a vessel, and the cost of her stores, are so dear in this country, and cheap and abundant elsewhere. If we have not only to bring timber from the Baltic, but to pay a heavy duty on it, it is evident that shipowners on the Baltic can undersell us, so too, if our shipbuilders and mariners are paid higher wages, and if the stores of the ship are more costly here than in America or elsewhere. If, however, we can change these conditions, it is evident that the preponderance must be on our side, and steam navigation affords us the means of doing this. Iron for ship building and machinery is indigenous, not imported, and is cheapest here; the skill of our workmen is able to defy foreign competition; we are exporters of steamers, and machinery; this country is rich in the possession of the best coal, with which we largely supply other countries; our enginemen receive higher wages abroad than they do here. Thus we are able to build and to work steam ships cheaper than any other people, while the cultivation of this branch of trade will develop our own resources, largely increase the workings of our iron and coal mines, invigorate our manufacturing and mercantile industry, and give employment to large numbers of the population. On these grounds we feel the deeper interest in the subject, and we urge it on our readers as worthy of their most serious consideration and co-operation.

The present time is also most favourable for making a movement in advance; the part taken in the navigation of the wide seas by other countries, is very small. France is engaged in the Mediterranean and Levant lines, and also in the East Spanish; in the north, the Russian line is the only one of her connexions worth mentioning. Her most serious effort, however, is in connexion with the West Indies, though we do not anticipate such serious damage from a mercantile business carried on by naval officers, and, of all naval officers, Frenchmen. Austria has taken part in the Levant and Black Sea trades, and requires watching. The operations in the Baltic are comparatively of little importance. The Anglo-Americans are principally occupied with the navigation of their own rivers and coasts, and would still be so, had not the neglect of the Royal Mail Steam Navigation Company invited them into the West Indies. While little has been done by others, we have done much. We hold the chief part of the steam navigation in the northern seas from Christiania to St. Malo; also on the Iberian coasts, and in the line to Egypt. We have the Transatlantic routes to Boston, New York, and the West Indies, the traffic of the coasts of Brazil, Chili and Peru, and that of the East Indies.

If, however, such are our opportunities, we have been far from profiting by them as we might have done; though large profits have attended good management, the most serious depression has been the general result. Misconduct and rashness have been among the causes tending to this catastrophe, while many unfavourable circumstances have aggravated the casualties naturally attendant upon new enterprises, neither have there been wanting the distractions which cabals, rivalry, enmity, and revenge, infallibly produce. The loss of property and the loss of confidence have been very great, but we believe the period of adversity has now passed by, and that such evils as remain, readily admit of correction. The Liverpool and Boston line of packets has done its duty regularly, and given good proofs of what may be done by careful and well intentioned administration. The Great Western Steam Navigation Company have suffered most severely, both by their own misfortunes, and the success of their rivals. The unhappy loss of the President, and the unfavourable state of the money market, impeded them in their endeavours to recruit their force, while the line to Boston, supported by a government grant, has been able to cut down their prices, without any efficient means of competition. It is very evident that the traffic to the United States admits of unlimited extension, when rapidity of transit, frequency of communication, and lowness of price, are brought to bear, as in time they will be and must be. The Great Britain is a powerful means to this end, but when the time comes that the passage can be made weekly, with a duration of only ten or twelve days, and a cost of as many pounds, the traffic must be immense. Hitherto, neither to the United States, nor to the East or West Indies, has any adequate accommodation been afforded for second class passengers who, of course, form the bulk of the contributable population. Of the fatality which has attended steam navigation in the West Indies, we will speak presently, and the subject of Pacific steam navigation we have already fully discussed. In no case, however, can we see any grounds for despondency; adversity tends to increase its own evils, as good fortune ministers to its own further success. With the extension of steam navigation, and its conduct on enlightened principles, all the evils that now afflict it will cease, and it will, we hope, become as it ought to be, one of the great arms of national strength, and a powerful contributor to the national wealth.

The scheme for West India steam navigation was undoubtedly one of the most magnificent ever submitted to the English public, its very vastness appalled common minds; like the creation of a Frankenstein, it struck terror into those to whom its movements were entrusted. The original plan has been freely blamed—its projector has been assailed, and all the evils and mischiefs which have blasted the concern have been charged upon his head; yet surely that can have been no insane project, which the most cautious merchants pledged themselves to support with their wealth, which the experience and scrutinizing examinations of the Admiralty and its officers approved, and towards which, with small objection, the several bodies of the legislature voted a large and burthensome grant. The plan was great, it is true, but it was simple—entailing large outlay, but economical, because comprehensive—and ensuring a great profit, by leaving no source of traffic untouched. The long connexion of Mr. Macqueen, its projector, with the West Indies, and the prominent part which he had taken for the advocacy of particular interests, did not blind him in the views he adopted, but both he and the government of the day considered the plan as the means of binding together our own colonial interests, and securing the trade of the other West India possessions; while a route opened across the Isthmus of Panama, gave us access to new markets in the Pacific, the intercourse with our chief customers in the southern slave states of America was made more direct, and our communication with the Brazils, a great consumer of our produce, efficiently provided for by a branch line. This plan has received not merely the momentary approval of the Admiralty functionaries of the day, but it has been stamped with the approbation of the French government, who appreciating the immense advantages which it would give to this country, have started a rival line of their own, arranged on the same principle, and calculated, if well conducted, seriously to injure our interests in that quarter. We do not think, then, that Mr. Macqueen is to be rashly condemned for consequences which deviation from his plan has mainly contributed to produce.

It so happened, as it too often does, that the very support which the plan met with, was a fertile cause of misfortune; nothing apparently could be more fortunate than the strong support of the Admiralty and the West Indian interest, nothing, in fact, was more prejudicial. At an early period, intrigues took place among the members of the direction, to limit the operations to our colonies, by which the communication with the Havannah, and Mexico, New Orleans, and the countries on the Mexican Gulf, was to be sacrificed for petty islands, many of them more burthensome than they are productive. This was very specious, and colonial men readily adopted it, but a subsection also declared itself for sacrificing even the colonies genera ly to Barbadoes, and this party ultimately succeeded in carrying the day, so that Barbadoes has the advantage of several days post before the other colonies. This alone would have been sufficient to unhinge the plan, but out of compliment to the Admiralty, naval officers were generally appointed to the vessels, and a naval system of uniform and administration adopted, and as navy men were bitterly opposed to giving up the packet system, and have been constantly endeavouring to get the company knocked up, and the whole matter taken into the hands of Government, it was not to be wondered at that the scheme was burked by the parties engaged in carrying it out. Insolence towards passengers, neglect of duty, refusal to comply with customs and quarantine regulations, or to receive goods and passengers, were common occurrences, while the loss and grounding of vessels, intoxication and insubordinations were not rare. Intrigues were also set afloat by some of the leading officers of the Company, to supplant others, and there can be little doubt, that not the least among the misfortunes of the company, have resulted from the success of these cabals. Thus with an incompetent staff at home, treachery among the officers and agents abroad, a new administration at the Admiralty, the intrigues of the colonial party, the attempts of the naval party to knock up the concern, and of a colonial party to depreciate its value, and buy it into their own hands at a low price, operations began, and such a series of disasters has been the result as no common ability could stem, and which the exertions of the Directors, men of large capital and great talent, could not prevent. As a consequence of the intrigues Mr. Macqueen resigned his appointment in the company, and all the misfortunes being attributed to him, he has been obliged, in his own defence, to enter upon explanations of his conduct, while he has also become an assailant, whose incessant attacks have greatly depreciated the concern. This we regret, as he is himself largely interested in the company, both morally and pecuniarily, and his co-operation with the directors would go far to arrest the downward course of the concern. What is wanted is peace, and a gradual return to the original plan, the correctness of which every day's experience tends to establish.

The pamphlet now before us goes largely into the controversy between Mr. Macqueen and his opponents, but into the minutiæ of that it is not our province to enter. On the engineering department he charges many instances of neglect.

On the 30th of April, last year, it is said :—

"The account you heard about the *Teviot*, one of the Royal Mail Steam packets, having nearly sunk in the Southampton water, is perfectly correct. It is a well known fact here. The circumstances were these :—the engineers, on leaving work, left one of the sea cocks open, and some hours after, it was discovered that the ship was settling by the head from 1ft. 6in. to 2ft. On examination the cause was discovered, but so difficult was it to get at the cock, that one of the engineers got a bed or bag, or something of the kind, to stop the water until she was pumped out, and the ensign was hoisted union down, which is a signal of distress, or to indicate a want of assistance, which was sent from the *Severn*, and one of the Havre steam vessels stopped to render assistance."

Also that the *Severn* took fire on the voyage from Bristol to Southampton, owing to the construction of her boilers and furnaces. These have been strongly denied by the secretary of the company, but the evidence adduced by Mr. Macqueen has not been disproved. To the mismanagement, Captain Chappell, the Secretary, bears testimony in a circular addressed to the captains :—

"One ship proceeded from St. Thomas to Havana, through the old Bahama channel, finding no difficulty whatever in the navigation, whilst another passed to the south of Cuba, thereby extending her voyage unnecessarily between 300 and 400 miles, burning away above 60 tons of coals that could have been saved, and creating two days' delay on the passage, as well as further detention at Havana to replace the fuel thus unnecessarily consumed.

"Coals have in many cases been taken on board at a most objectionable expense, in places where the company have no depôts, and where no absolute necessity existed to ship coals, such as at Tobago, Charleston, and Curaçoa. In other instances more coal was taken from the depôts than was required, such as at St. Thomas, where the stock being short, one ship took much more than she wanted, leaving none for the next ship."

Also Mr. Macqueen says :—

"Several of the officers and crews at the outset would, however, lend no assistance to coal, and the manner in which the steamers had been constructed, with spar decks, is unfavourable for coaling rapidly, and the delay thus occasioned is increased by the coal-funnels being too narrow to admit the coals quickly. At the coal depôts these defects were much complained of, and which are attributable to the ignorance or carelessness of Captain Chappell, Marine Superintendent, when these were originally constructed. The existence of all these defects tended to produce delay, delay to produce confusion, and both to bring the great undertaking at the very outset into disrepute."

CONDUCTING AND ABSORBING POWER OF BUILDING MATERIALS.

New Experiments on Building Materials. By John Hutchinson, M.R.C.S. London: Taylor & Walton.

This small work embodies the results of the writer's long and laborious researches communicated to the Chemical Society. His attention was directed to the subject in connexion with the relative conducting power of building materials, as influencing the construction of penitentiaries, hospitals, union houses, &c. The compositions used for the purpose of experiment were obtained by permission from the Model Prison. From the degree of labour bestowed on this work, and with the knowledge that it is about as easy to make a right experiment as a wrong one, we are bound to presume that Mr. Hutchinson is right in his conclusions. It should be also observed, that he has most fully and carefully described the materials used, and the methods of experiment resorted to, so that any source of error, if existing, can be immediately detected. Of the labour, as we have said, there is abundant evidence. Such a work rests entirely on its own merits, and it is difficult to give an idea of the value of that which depends upon its merits as a whole, without republishing the entire work. We have, however, availed ourselves of two tables with Mr. Hutchinson's remarks and observations which by professional readers will be viewed with great interest, as they clearly show, at a glance, the conducting and absorbing power of most of the materials used in building.

There are in the work nine tables. The first gives the whole matters necessary to work out the calculation of specific heats of equal bulks and equal weights. The second table shows the times of passage as to velocity, through the various substances. The third exhibits the time consumed in the passage of heat. The fourth the resistance to the passage of heat outwards. The fifth the conducting power or velocity for the transmission of heat, corrected for specific heat, referred to the conducting power of fir wood as 100, and slate as 100. The sixth exhibits the conducting power during four different intensities of heat. The seventh the times of cooling in air. The eighth the quantity of heat conveyed outwards in air by different substances, compared with fir wood as 100, and with slate as 100. The ninth (shown below as No. 1) illustrates the gradation of conducting power. The tenth is also extracted as No. 2.

Table I.

Gradation of Conducting Power referred to Fir Wood as 100, *and to Slate as* 100, *in heating, and the rate of Cooling in air referred to Fir Wood as* 100, *to Slate as* 100, *the lowest Conducting Power, the lowest rate of Cooling, the lowest Specific Heat by Weight and Bulk, and lowest Specific Gravity placed first in each column.*

Conducting Power. Substances.	Referred to Fir Wood.	Referred to Slate.	Cooling. Substances.	Fir as 100.	Slate as 100.	Specific Heat. Substances.	Equal Weights.	Specific Heat. Substances.	Equal Bulks.	Substances.	Specific Gravity.

PRACTICAL DEDUCTIONS.

Want of space will not allow me to point out the numerous subjects of practical utility to be derived from the whole series of experiments hitherto detailed for the benefit of architects, engineers, and builders, but I will venture to fill up the remaining sheet with a few deductions that appear most prominent.

Asphalte stands as the best composition for resisting moisture; it is a slow conductor of heat, and hence is well adapted for flooring, as in cells of prisons, where economy of heat and dryness, the most important advantages are obtained. Slate will be seen to stand as a very dry substance, but from its quick conducting power (Table I.) it is very unfavourable to flooring where warmth is required; but when the one property is sought for and not the other, as preventing the ascent of moisture up the walls of houses, it is well calculated to be useful by forming a layer in the wall a few inches above the ground. The absorbing power of common brick appears very great, being more than one-fifth of its own weight; whereas Mann and Co.'s Stucco paint cement is not greater than $\frac{1}{31}$ of its own weight, and hence more than six times better adapted to resist moisture than brick, therefore the advantage to be derived by covering brick houses in exposed situations with this substance is considerable, while Roman cement resists moisture even worse than brick. I wish it to be borne in mind that I only speak of this stucco as regards its power of resisting the transmission of water, being the only property of it which I have examined.

Keene's cement and plaster of Paris stand as the warmest substances, therefore are well adapted to line rooms with, while hair and lime is a remarkably quick conductor, and therefore a cold substance for that purpose. I would also draw attention to the fact, that plaster and sand and plaster of Paris (particularly the latter) are admirably calculated to resist the action of fire, while we know, on the other hand, that lath and plaster is about the most combustible material in a house. I can most confidently recommend plaster of Paris and plaster and sand to be employed in surrounding iron chests, or other places which contain valuable property, intended to be protected from fire. If an iron chest be surrounded with six or eight inches in thickness of this substance, I believe it will perfectly preserve papers, &c., from any destroying heat in the midst of the burning of our ordinary dwelling houses. I may also point out that Yorkshire flag stone is a very quick conductor, and therefore ill adapted for warm flooring; also that lead which forms the covering of roofs is a remarkably quick conductor, and therefore a great waste of heat is experienced where such covering exists; hence the third back rooms on ground floors in our London houses are found to be so cold; a vast quantity of heat escapes through the leaden roof, and through three of the surrounding walls, which are generally external, and so thin as to allow of a free escape of heat. Such places should be lined with slow conductors if warmth is sought for. Touching the practical utility of the specific heat experiments, I may point out, that fire brick absorbs a great quantity of heat, and therefore is well adapted to form the backs of our fire grates, whereas, with iron backs, there is an enormous waste of fuel and heat, at the same time the fire requires constant stirring, and a quick supply of coal to keep it in; yet, curious to remark, we never enter a house, even of the highest order, where iron backs to fire grates are not universally to be seen, while, a back formed of a composition, as that of fire brick, which can be as easily moulded into any desirable shape, would both save fuel, thoroughly warm any apartment, require less stirring, and not go out so soon.

With regard to the specimens of wood I have examined, it is worth observing that Maulmein teak absorbs much less water than oak wood, in the proportion of 82 to 224, being nearly one-third less; and as the density of woods in their ordinary state bears a strict relation to their porosity or proportion of air within their pores, connecting with this, the fact that iron, protected from contact with the atmosphere and water (being compounds of oxygen) the better it is preserved, may very possibly be the reason assignable for the truth why iron is preserved considerably longer in Maulmien teak than in oak; the relation of absorption of water with the teak and oak (omitting the decimals) is as 82 of the former to 224 of the latter. The density of all these specimens of wood is here calculated from the state in which they naturally exist, that is, as dry as could be obtained, yet containing an unknown quantity of air and moisture. Mr. Parnell observes "when wood, rendered perfectly dry by the aid of heat, is exposed at common temperatures to the atmosphere in its ordinary state of humidity, it re-absorbs a certain proportion of water, varying accordingly to the compactness of the wood, and to the quantity of deliquescent saline matters present." In reference to these two assigned reasons that govern the absorption of water by woods, I would draw attention again to the Maulmien teak in comparison with the beech wood; the relative specific gravity or density of the former to the latter is as 7442 to 7498, being very nearly equal, yet the absorbing power of the two is very different, being in the proportion of 82 to 185. These facts render it incumbent on me to recommend it to the attention of ship-builders.

By Table II. it will be observed that the two kinds of flag stone, termed Shetland and Caithness, absorb very little moisture; having been previously informed of this property, I was desirous of examining them, and certainly they maintain the character determined from the observation of practical men. Their conducting power for heat I had not an opportunity of calculating, but if I might venture an opinion, I suspect they would range like Yorkshire flag stone; if so, they are quick conductors, or cold materials for flaging rooms were warmth is required; nevertheless, they will be found as valuable materials for arresting the ascent of moisture in the walls of houses, and speaking from memory I believe the Caithness flag has thus been employed in the north of England with great success.

The Carrara marbles mentioned are those generally employed in constructing mantle-pieces; it is curious to observe, though their density is the same, yet the harder specimen absorbed more than twice as much water as the softer marble.

Portland stone, Bath stone, and the stones employed in erecting the new Houses of Parliament, may be considered as spongy materials for absorbing water; their relative conducting power may be referred to in the first column in Table I. It will also be seen that Napoleon marble is a warmer material than common brick. I mention this to correct the general opinion that brick is a slow conductor, and therefore a greater thickness of that material should be used in forming the walls of our houses; hence it is that the brick walls so often neither afford protection from the cold of winter nor the heat of summer.

It will be observed that the specific heats have been compared with water as 1, therefore, if we reflect upon the capacity of water for absorbing heat, it very much exceeds all the substances with which it is compared. Water, therefore, becomes a reservoir for heat upon the surface of the globe; islands being surrounded by this reservoir, are preserved of a more equable temperature than main lands.

In reference to the conducting power of malm and stock brick, it will be seen that stock brick is placed twelfth in the scale, and malm brick the sixteenth; it is, therefore, so much colder as a shield from the weather. From this circumstance I would remark, that when this brick (malm) is used to case a building (as is now commonly done) the walls should be constructed proportionably thicker, or we render the house so much colder. The absorbing power also of this brick for heat is very low, being placed third in the scale in Table I. (third column), therefore we may conclude that malm brick is more a substance to please the eye for building than useful as a protection against the escape of heat, and what applies to the escape of heat will bear a similar relation to the protection against the cold of our climate.

It is curious to observe how low in the scale hair and lime is placed, both as to conduction and capacity for heat. If lead were omitted from the Table it would stand nearly as the quickest conductor and the lowest specific heat, proving that the compound is ill-adapted to line our rooms as far as concerns the preservation of heat. The best property of Roman cement, from these tables, certainly appears to be that of its slow conducting power, and therefore it is much better adapted to encase brick houses than malm brick, and as far as regards their relative absorbing power for moisture, the difference is not very great, being in the relation of (omitting the decimals) 133 of the former to 116 of the latter.

AN IMPROVED WATER METER.

Invented by Mr. ALEXANDER MITCHELL, Watch & Clock Maker, Glasgow; described by JAMES THOMSON, Esq., F.R.S.E., M.R.I.A., F.R.S.S.A., Civil Engineer, Glasgow.

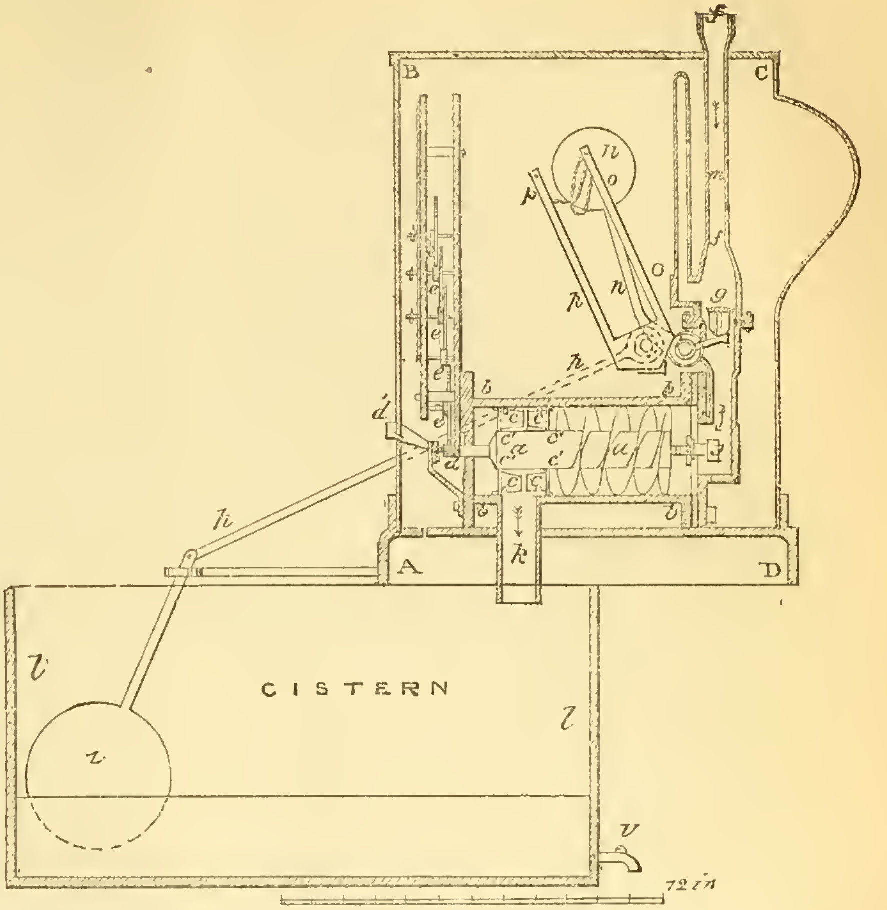
(Read before the Royal Scottish Society, 12th December, 1842, and reported in their Transactions.)

THE action of the meter, referring to the annexed figure, may be described as follows:—

The supply-pipe *f f* being connected to the water main by a coupling, &c., in the usual way, the water flows through the valve *g*, and passing into the cylinder *h h h h* at *j*, is discharged by the pipe *k* into the receiving cistern *l l*, from which the water is drawn off by a stop-cock *l'*.

Upon one end of the axis or spindle of the screw *a a* is fitted a pinion *d*, working into the train of wheels *e e e*, so arranged as to indicate the quantities of water discharged either in gallons or cubic feet, similar to the index of gas meters—the whole being set in motion by the flow of water through the cylinder acting upon and causing to revolve the Archimedean screw enclosed within it. To prevent the screw from being driven forward by the water, and in order to reduce the friction to a minimum, the end of the axis at *d* has a hard steel point inserted, which works in a cock or pottance fitted outside, and enclosed in an oil box, supplied with oil through the filter *d'*.

In order to render the indications of the meter uniformly correct, under different heads or pressures of water, the following very ingenious method of adjustment is adopted:—Upon the axis of the screw are fixed four thin brass wings or leaves *c c c c*, each moving upon a separate hinge or pivot *c'*, fixed at right angles to the axis, with screw nuts upon the end of each pivot, by means of which the wings can be maintained open or shut at pleasure, and so lessen or increase the discharge of water at each revolution of the screw. The lower pair of wings in the drawing are represented slightly open. With this power of adjustment, it is very easy to regulate the quantity of water discharged under different pressures, so as to correspond exactly with the index and train of wheels, which can best be ascertained by trial upon setting up the meter, say by a measurement of 20 gallons, and opening or closing the fly leaves, to bring the *quantity measured and the index to correspond.*



REFERENCE TO ENGRAVING.—A B C D, outer case of thin cast iron for enclosing the apparatus shown in section. *a a* Archimedean screw working in the cylinder *b b*. *c c* thin brass wings or flies, with adjusting screws for regulating the motion of the screw. *d* pinion upon the end of the screw-spindle or axis. *e e e* train of wheels set in motion by the pinion *d*, to indicate the quantity passed through the cylinder, closed in with a glass front. *f* supply pipe. *g* valve worked by the lever *h h*, connected to the ball-float at *i*. *h h* lever for opening and shutting the valve *g*. *k* discharge pipe flowing into the cistern *l l*. *m* air vessel to prevent injuring the pipe on opening and shutting of the valve. *n n* lever, with lead to retain the valve open or shut. *o o* and *p p* arms fixed upon the end of the lever *h h*, and attached with chains to the lead weight *n*.

It will be evident that the quantities of water passing through a metre, upon this principle, would be correctly indicated down to that quantity requisite to overcome the friction of the screw, below which amount, however, the water would pass through the cylinder without affecting the index, and consequently without being registered. Although the quantity thus passing would not be considerable in a well-constructed meter, Mr. Mitchell has recently introduced an improvement which completely obviates this objection, and renders the indications correct under any circumstances, and down to the smallest quantity.

This is accomplished by means of the conical valve cock *g*, which is so constructed as to act instantaneously, and so keep the supply either flowing at the full bore, or suddenly shut off, when the cistern is full. The opening and shutting of this valve is effected in the following manner:—To the end of the lever *h h*, which works upon a journal, and is raised or depressed by the ball-float *i*, are attached the two arms *p p* and *o o*. As the water in the cistern rises, these arms are carried forward without acting, however, upon the valve, until one of the chains, connecting them with the lever and lead-weight *n n*, is upon the stretch. At this point the lever and weight are upon a balance, so that the least further rise of water in the cistern carries it suddenly over, and allows the valve *g* to close. A reverse motion takes place on the fall of the cistern water, the action of the other arm and chain *p p* opening the valve, which a small catch retains in its place against the force of the supply water. To prevent any injury to the pipes from the sudden action of the valve, an air-vessel *m* is attached to the supply-pipe immediately above the position of the valve.

The introduction of this improvement, which prevents the possibility of water passing unregistered through the cylinder, renders this description of meter very perfect, and capable of indicating accurately the smallest as well as the largest quantities. From the small cost, too, at which they can be manufactured, it is to be hoped they will soon be brought into general use, *and substituted for the present unequal mode of water assessment upon house rent.*

REPORT OF COMMITTEE.—Your Committee having met with Mr. Mitchell, and having again heard his explanations, and carefully examined the water-meter submitted to them, came to the following conclusions:—1. That as far as they can judge, this meter may be considered sufficiently accurate to form a fair measure between water companies and their customers. 2. That its construction is simple, and well devised for permanent practical use, being little subject to derangement from the wear of its parts. 3. That its rate of registration being susceptible of easy adjustment, either in plus or minus degree, and its actual delivery, during certain portions of time, being always ascertainable by the consumer, its use may be adopted with confidence, as being alike equitable to the suppliers and the consumers.

GEOLOGY IN CONNEXION WITH ARCHITECTURE.

On the importance of geological studies in connexion with the practice of architecture, with notice of experiments on the resistance to crushing and fracture, and on the absorbent qualities of the principal building stones of Ireland. By George Wilkinson, Esq. Read at the Geological Society of Dublin, 10th of January, 1844.

In bringing before the Geological Society the results of some experiments made on the principal building stones of Ireland, it is, I conceive, necessary to offer some general remarks on the advantages to be derived therefrom; advantages, in my opinion, so very general, that to look at the result of experiments in a merely mechanical and professional point of view, would be confining the subject within too narrow limits. It ought to be a just matter of surprise that, at this advanced age of scientific investigation, the subject of practical geology in all its important bearings should have occupied so little attention; and that where there appears a desire for ameliorating the condition of the people of this country, particularly by promoting employment in ways calculated to develop its natural resources, persons should overlook what is capable of being accomplished through the medium of well directed experiments in this interesting and valuable science. To present the importance of practical geology in a familiar way, I would call your attention to the large proportion of people who are daily engaged in operations on the rocks in the country, either in dislodging or separating from their native beds those portions required for the varied purposes of building operations, or in conveying to the localities where they are required, and in shaping them for the different purposes to which they are to be applied, and thus calling to aid all the useful arts of the country, giving extensive employment to labourers, mechanics, and tradesmen, as well as to the scientific and learned professions of engineers, architects, artists, and others.

Most persons are more or less interested in the construction of their habitations, and I may say, all see the advantages of public structures, and appreciate the importance of bridges, canals, and other public and private buildings, and probably see in them the progress of civilization, and the benefit and dignity they confer on a country; but few, and very few, know anything of the materials employed in their construction, which too often present themselves to their minds only as a heap of stones and mortar. If we look to the early history of the most ancient nations, we find that the art of building has attended the first advance of civilization; and the use of worked stone has succeeded to caves in rocks, and the rude wicker or earth work of their common and early structures; but the conversion of stone to the increasing artificial wants of society was necessarily consequent on the advance of the mechanical arts before it could be shaped and applied. How interesting are the first though rude efforts displaying practical geology! The bold and noble monuments of the early ages show the natural vigour of the human mind, untutored in the mechanical skill and art of later times. The stupendous monolithal structures, and those early sepulchral monuments, known as cromlechs, cairns, and moats, which abound throughout Western Europe, were doubtless the work of a people, who, taking nature for their guide, by prodigious labour, raised and put together, and frequently conveyed to great distances, for the erection of their monuments, the immense stones which, detached from their native beds, were distributed over the surface of the country. Most of those stones are of the primary and crystalline class of rocks, which, from their hardness, have resisted the violence of that disturbing power which removed them from their mass, and afford us a good knowledge of their enduring quality. Moreover, the originality and boldness of their application, resulted from minds familiar with nature's works and untaught in the arts, which in after ages, accomplished by skill and the use of smaller sized materials, what the early ages, unskilled in building, could alone express by the magnitude of the stones.

Let us consider the more advanced history of the principal nations of the earth, and we shall find that geology, which term I may here use to express the converted rocks, has received great consideration. The architects and sculptors of Greece and Rome knew the qualities of their materials, and if we may judge from ancient writers and existing remains, gave considerable attention to them, abounding as those countries did in good materials. In the writings of Vitruvius on Roman architecture, the most particular rules are laid down with regard to the selection and use of building stones, and the cements employed with them. How important are the results of their influence on society! If Egypt, Greece, and Rome, had had their principal structures of a perishable material, what would we not have lost? What interest would we now feel in those countries; or how could we have derived the great advantages which have flowed from them? Good materials, and a right knowledge in using them, have, however, produced a different result; and again, what do not those countries owe to the durability of their structures, conceived, as they have been, in a noble spirit. Without them, Rome of the present day would be unvisited by the countless thousands whose wealth now enriches her; without her buildings the classic shores of Greece would less of European sympathy; nor would the dusky inhabitants of Egypt occupy such interesting ground but from the remains of the stupendous and imperishable monuments of her past history. Our own kingdom also possesses proud memorials in the enduring monuments of the middle ages, Those connecting links with the past and present, afford us noble examples of the religious zeal and skill of our forefathers; whilst the perseverance which has been displayed in accomplishing their erection, is much calculated to stimulate us to bold designs. These indelible landmarks of his early home, the traveller finds deeply implanted in his mind, and it is difficult for us to estimate their effect on society, in the attachment they cause to our laws and institutions. Nor do those venerated and bold structures fail to excite a powerful feeling in the inhabitants of the new world, who, though born in a distant land, contemplate with pride and fervent admiration the works of their progenitors. But the edifices of centuries past, many of which, even in their dismantled state, have withstood the destructive violence of the elements, will yet outlive very many of the most costly structures of the present day; and until a very recent period, so comparatively few were the buildings calculated to endure to any distant period, that future ages, judging by our public structures, will look upon the people of the present time as a degenerated race, and in the erections of centuries back will contemplate the finest and most durable monuments of architectural skill.

Many persons may say that a durability sufficient for the age is all that is necessary, and that posterity, which has done nothing for them, may act for itself. This, however, even in a narrow practical and economic point of view is most erroneous, for the constructive arrangement of the ancient buildings is less costly than in those of the modern period, and from their simplicity and the right use of the materials employed, they are more sound and durable edifices. In the buildings of the present day the simplicity of early structures has been lost sight of; a laboured mass of cut stone being more appreciated by the public than outline of design, and harmony of effect. We see in the ancient structures a homogeneous construction—the use of timber as supports under masonry is avoided; where openings or projections occur stone arches or other stone supports are employed, and a much more general use of stone, for various purposes, prevails, than at the present day; and in them we have models of constructive arrangement which we may profitably imitate. Many of the old buildings are so constructed that when dismantled of their roofs and their floors, they return almost to the state of the original rock, perhaps as a mass of limestone, for the stones may be lime, the sand may be that of limestone, and the lime burnt from the same rock. Such is frequently the case; thus, the mortar being good, becomes hardened by age, and more approaches the nature of stone; for it is said by an intelligent and scientific Frenchman who has given much attention to cements, that it requires 1,000 years to make mortar really good. Without doubting that a few years are sufficient to produce good mortar, it might be stated that the mortar of the Egyptian Pyramids, now supposed to be nearly 4,000 years old, is still in a good state of preservation. Structures so constructed become like a solid mass of rock; and that this is the case, the explosions made by Cromwell, in the 17th century, have very well shown, for the remains of some of the old castles, of which portions have been disturbed, appear almost imperishable. The sound and enduring state of some of the ruins, the original forms of which are still perfect, enable us fairly to state that a right use of the rocks of the earth has been capable of producing such a solid mass, that many may now, in their skeleton shapes, fairly be called architectural fossils; and they afford to the practical, as organic remains do to the scientific geologist, valuable studies in determining the character of the rocks to which they belong.

To the antiquarian, also, the study of geology affords much information, for the use of certain rocks, and the mode of working them, determine, to a considerable extent, the chronological date of the building in which they occur. It was a peculiar custom of the Normans and Anglo-Normans, to make use of none but the sandstones or oolites, similar to those with which they had become familiar in their own country, and in the round towers, and early ecclesiastical structures, erected under the influence of the Christians familiar with the Norman or Lombardic architecture, we rarely find anything but sandstones employed in the dressed masonry. With the Normans or Lombards (under which name I may include the northern nations who established themselves on the decline of the Roman power, and perfected from the last and worst models of the eastern and western Roman empires that peculiar architecture known to us as Norman, in which circular arches are the peculiar characteristic,) it was the practice to make their doorways the most enriched portions of their structures, and from being more elaborated or worked than any other part, they are commonly executed in a different kind of material, sandstones of variable quality having been generally used; and it is a peculiar fact, that an instance in which limestone occurs for dressed work or for doorways is very rare. Being familiar with the kind of materials employed in most of these structures, I do not recollect one in which the ordinary limestone rock has been so used.

It is not until a late period of the Norman architecture in Ireland that limestone has been employed. In the large limestone tract of the west of Galway and Mayo, where are the ruins of Cong and Ballintubber, in the later

Norman and transition styles of architecture, a light coloured easy-working limestone has been obtained from some distance, while the lime-stone of the locality, which is now preferred to any other material, and is conveyed to distant places for use, has been avoided excepting for the erection of the unwrought faces of the common walls. After the period in which these buildings were erected, limestone appears gradually to have come into general use in all parts, and now the directly opposite custom prevails, limestone being commonly used in sandstone districts; and I have known masons when employed in working sandstone to which they have been unaccustomed, to complain of stiffness and swelling of the arms for some days occasioned by the toughness of the stone, so different to the brittle rebounding effect of the limestone. It is most probable that the brittle nature of the limestone, in the working of which the Normans were not skilled, rendering it difficult to shape into mouldings after the masonry was built, as was commonly their custom, may have operated against its use. Those interesting structures, the round towers, on which so much that is evidently erroneous has been written, appear from their architectural and constructive peculiarities to be decidedly after the early Norman style of architecture. These edifices, of which Ireland has just reason to be proud, display to the practical geologist most interesting models of simple constructive arrangement, erected as they are with various kinds of rocks, including granite, slate, sandstone, and limestone, and which are almost always the stones of the locality, excepting in the superior dressed work of the doorways. Many antiquarian works of a recent period show very mistaken ideas as to the nature of the materials with which these early buildings have been constructed, and, therefore, draw erroneous conclusions. A very slight acquaintance with practical geology, and nothing more than this society, from their collections, will be able to afford, will tend to correct such errors; and it is most likely that such statements as those of Colonel Morris, in his work on the round towers, (in which he determines the red sandstone of some of these structures in the south to be Roman brick, and deduces from this certain conclusions regarding their origin,) will not be repeated.

There is one more feature connected with antiquarian research, upon which I should wish to remark, viz., the peculiarity of some of the earliest Norman architecture of this country. The architecture of the Normans in every country in which it was introduced (though preserving all the general characteristics of its early originals,) differs in details. It clearly continued to be the style of architecture in Ireland much later than in England, and extended over a much longer period than in other countries, owing, doubtless, to the peculiar and remote position of Ireland, at the western limits of Europe. It also frequently differs considerably from the Norman architecture of England; but it is in the early examples that the most distinctive details occur: and here a peculiarity is devolved, for which practical geology affords a ready and satisfactory reason, for the very hard nature of the stone has induced a different kind of ornament, and in several of the early examples we find the most elaborate execution on almost square columns, or rather jambs and architraves, quite at variance with the bold and deep cuttings so common in the Norman style. Nor is such a result other than should be expected, for they must have been deprived in those early ages of the facility of obtaining softer stones. It was the practice of the Normans at an early period to supply stones even to England, where soft oolitic stones abounded in many parts; and when at a later period intercourse with Ireland improved, we find that the stones of Normandy were brought to this country, and are to be met with in many of the ecclesiastical buildings, more particularly on the eastern coast.

It may be said that the study of the different properties of the rocks of the country, as regards their fitness for building operations, relates more particularly to professional investigation—that matters of this kind should be confined to the meetings of civil engineers and architects; and that the Geological Society is constituted for scientific investigation of the theory of geological phenomena connected with the structure of the earth's surface, and for the study of the successive changes it has undergone in arriving at its present state. To such an objection I would remark that, however interesting the pursuit of such a science may be in its theory, and however calculated to elevate the mind by reflecting on the wonderful architecture of our earth, and the vast changes its surface has undergone in becoming suitable for the habitation of the human family, we shall yet stand far short of obtaining all the advantages to be derived from this noble study if we confine ourselves merely to the theory. Owing to the neglect of the study of this science, designs are often prepared by architects and engineers, to whom is intrusted the expenditure of very considerable sums, without sufficient regard to the geology of the locality, the inquiry being confined to the question of cost, as to the nearest place from whence materials required to carry out a particular design may be obtained. It has frequently happened that stone has been brought from a great distance at considerable expense, when rocks of an equal, or of superior quality abound in the vicinity, with regard to which an acquaintance with this science might have reasonably afforded information. Numerous instances of such occurrences have come under my own observation within these last few years, where, either from sinking wells, or in making excavations of other kinds, or by chance trials for stones, there have been unexpectedly discovered, at very great advantage in outlay and frequent benefit to the contractors, some very valuable quarries; in illustration of which I may mention a particular instance with which I am familiar, in the discovery of a valuable working limestone quarry in the vicinity of a nobleman's mansion, which, if earlier known would, I am informed by the contractor, have saved him upwards of £1000 in the expense of procuring stones, which he had to convey a distance of many miles, and which were of an inferior quality to those which could have been obtained on the spot. If the science of geology were made practically useful, such occurrences would be rare, and in time would be altogether avoided.

The professional man is often deterred from the study of geology by the difficulty of mastering the technicalities, if I may so term them, of the science; and the theoretical geologist on the other hand is unable to appreciate the wants of the other; but acting together, the result would be mutually beneficial. The practical man would acquire the theory of the science with much greater facility; the theoretical geologist defining the geographical outline of the principal rock formations, and by the existence of fossils, and by recorded facts, determining where similar formations may or may not be expected to prevail; the professional member would obtain specimens of the different stones for experiment and chemical analysis, which in the yet imperfect state of geological science would most probably induce new theories in regard to many rocks, where the gradation from one mineral character to another is almost imperceptible. The peculiar stratification or dividing joints of the rocks are also features for profitable investigation. If we examine the various kinds we find great differences to exist in the size and shape of the masses into which they are subdivided; and in the same kinds of rocks we discover a subdivision peculiar to certain depths or other influences. In all, however, we recognize the wonderful contrivance of the Almighty in adapting the surface rocks of the earth to the want of industrious man. The greater portion of these rocks (the result of sedimentary deposition in water, of which the traces are still evident) occur in layers or thin beds, so separated from each other as to admit of being easily raised; others, with beds of soft clay, or other matter interposed; and, in the rocks of the primary or igneous classes, among which are included granites, basalt, &c., and which, occurring in large masses, would otherwise frequently be unconvertible, we observe the wise provision of nature in traversing them with joints or cleavages influenced by some prevailing law of crystallization or polarization, not as yet, perhaps, sufficiently accounted for. In the more solid masses, in which are included some of the limestone as well as other rocks, from the effect of internal heat, great pressure and other causes, the stratified form has disappeared; while the same cause which has obliterated the earlier divisions has itself produced others; and in some instances so shattered is the upper portion of the rocks that the practical builder altogether avoids them, although the removal of some feet from the surface would frequently disclose a most valuable material. Hence the advantage of scientific investigation and recorded facts. At the present time the want of a society combining practical and theoretical inquiries cannot, I think, but be manifest to all who contemplate the ordinary edifices of the present day. A better acquaintance with geology, or what is the same thing, a better knowledge of the rocks of the country, is essential to the production of edifices which will vie with those of past ages in durability, and harmonious adaptation of design to the locality. And it is, I conceive, only by correcting the public mind, and by giving assurance from experimental results and established facts, that a beneficial change can be effected.

Nor is the pursuit of this science unimportant as regards the *commerce* of the country. Let us look to the article of slates. At the present time there are several good quarries working, among which I may mention Killaloe, Valentia, and one more recently opened with great spirit by Mr. Synge in the county of Wicklow (the slates from which resemble those from the Bangor quarries); yet, such is the state of public opinion with regard to the native slates as to preclude their general use; and because at one period, in their early working, the slates of this country were very inferior to those now produced, the prejudice arose, and still continues, and no effort has been made to show by experimental inquiry, that Ireland contains slate quarries more than sufficient to supply all her wants; and yet thousands of pounds are annually going out of the country *in a direction from which there is no reciprocal trade*. I feel persuaded that it only requires the assurance which would result from well directed efforts of the Geological Society to cause, in a very short period, the annual expenditure of several thousands of pounds in the country in raising a native material, by extending the use of it, which money now unnecessarily goes to Wales; and there is this circumstance attending an increased demand, that the quality and economy of raising the slates will be improved. I may speak from experience on this subject, having used native slates in many instances; but from the little encouragement given, and from the prejudice still remaining, though the cause is chiefly gone, the proprietors have to struggle with many disadvantages in effecting a sale against their long established competitors who have a trade in the Welch slates. In more than one instance the native slates have been partly placed on buildings, in which I was concerned, and to satisfy prejudiced objections, it was expedient to have them removed, although the same slates have been used elsewhere. At Killaloe, where a few years back there was a rude surfaced mountain in which only goats or very poor cattle browsed, there are now, owing to the slate rock which prevails there, many hundred men daily employed. At Valentia not less than 200 are in daily work, and probably half that number at Mr. Synge's in Wicklow. The importance of the encouragement of such a trade is therefore manifest; for a regular trade of this kind, with all its minor ramifications, is much more beneficial to a country than the mere temporary employment on public works, which, creating a temporary excitement, occasionally works more mischief in the end than otherwise. At present the proprietor of the Valentia quarries, who works them chiefly for sawn flags, finds his principal market in London, while articles of this kind required for Ireland are obtained out of the country.

A similar remark may be made with regard to bricks. Good clay is abundant in the country, and good bricks are made in some parts, and might be made in many others; but from the frequent indifference as to the purchase of good materials, there is, in many cases, great carelessness in their manufacture. If, however, samples of bricks, and particulars of the clay, were collected, and the result of experiments made known, the good articles would be encouraged, and the making of many of the perishable ones of the present day, which are dear at the cost of carriage, would greatly decrease, and the buildings of the country would thereby be improved. Again, there is a strong prejudice against native bricks, which are really good. In illustration of this, I may mention a case connected with the manufacture of fire bricks at Dungannon, which are of excellent quality, and remarkably well made from the clay of the coal district, like those of Staffordshire; but the public, not knowing if they were really good, prefer buying the English fire-brick. Their sale is, however, now, or was, some little time since, considerable; but it arose from an ingenious, and scarcely to be condemned trick of the maker, who stamped the word Stourbridge on his bricks, and they then had a ready sale as good Staffordshire brick.

Before entering into the details of the experiments on the stones now before you, I would beg to advert to the important light in which the study of practical, or economic geology, is now viewed in the sister country, in confirmation of the remarks which I have made. Previously to the building of the new houses of parliament, a commission consisting of geologists (accompanied by the architect of the building) was appointed to investigate the various qualities of the different convertible building stones of the country. The result of their experiments has now been published in the parliamentary papers, (and this *Journal*, Vol. IV.) and has been received with the greatest satisfaction. It has also had the important effect of originating a museum of economic geology, for displaying the properties of the different stones of the country, in order that practical information on the various materials, with the characters which experiment and observation of the present state of those materials used in ancient structures supply, may prevent the continuance of the very numerous failures which have attended the use of many stones employed in different parts of the country, and which, being of inferior quality, have brought to speedy ruin many noble and interesting buildings. The institution referred to is now supported at the expense of government, and is under the direction of the distinguished geologist Sir H. De la Beche: connected therewith is a curator, and a laboratory for an analytical chemist, by whom experiments are made on various rocks, and who affords, at a fixed charge, any information required relative to the various properties of rocks for building, mining, or agricultural operations. I recently had an opportunity of visiting this museum, but found less really useful information for the architect and practical builder than I expected. It, however, contains most valuable and interesting collections of models, illustrative of the strata of the earth, the working of mines, and the minerals themselves in their several progressive stages from the mine to the manufactured article. From the constitution of the institution, at present, however, in its infancy, it does not appear to me to represent the spirit of a department in which the minds of those most interested in building operations are engaged; and from the contrary opinion with reference to the Dublin Geological Society, combining as it does scientific and practical geologists under its most intelligent and zealous curator, I augur that with perseverance most useful and interesting results will flow from their labours.

Reverting to the more practical consideration of the subject, we find that the altered circumstances in the advanced civilisation of the present age, now occasion the much greater use of the more convertible building stones, and so variable are the different kinds of rocks in the degrees of hardness and facility of conversion, in their colour and their relative durability, that a knowledge of these properties is now almost indispensable to the economical erection of the structures of the present day, as well as for the designing any building, in which the bold simplicity and spirit of the ancient structures is to be embodied; and hence the value of experiments and recorded observation on the defective materials which ancient and more modern buildings present, and without which expensive practical experience, and frequent failures will alone teach. The importance of attention to the good quality of the building stones will be evident by reference to buildings in Dublin, and to the already decaying nature of much of the granite in the Four Courts, and portions of many other structures; and I may mention that it is but a few years since, the necessity arose for restoring with new masonry the walls of the extensive building of Trinity College Library and the walls of the cathedral structures of Christ Church, and St. Patrick, in the old buttresses of which latter buildings the effects of perishable stone may now be seen.

EXPERIMENTS.

The experiments which I have now to bring before the Society have been made on nearly 600 specimens of the principal stones of Ireland, which I have from time to time in various ways collected together, and obtained chiefly through the kindness of different parties, by whom they have been presented to me, and among others I may mention the managers or proprietors of the several slate quarries. I shall divide these experiments into three classes, viz.: —1st, Absortion when immersed; 2d, Resistance to fracture, or bearing strength; 3d, Weight necessary to crush these stones.—1st. The results of the weight of water imbibed on immersion are very interesting, and disclose some important facts. The size of the stones immersed was 14in. long by 3in. square, one half of which specimens are now in the possession of the society. There were placed on their ends in 16in. of water, and were uniformly immersed for 88 hours, having been brought to a dry state before immersion, by being kept some time in a room at the ordinary temperature of domestic apartments. They were carefully weighed before and after the immersion. (It would be impossible to give in detail the results of these very numerous and extremely valuable experiments, and it will only be in our power to notice the averages given by Mr. Wilkinson). Of the six principal varieties of rock, viz:—Limestone, sandstone, granite, basalt, and slates, the following are the results:—Ordinary limestone of Ireland—average weight per cubic foot in a dry state (53 different experiments) 170lb., least weight 159lb.; greatest 180lb.; average absorption ½lb.; least absorption nothing; greatest ditto ½lb. The chalk limestone of Antrim weighs 160lb. to the cubic foot, and absorbs 3lb. of water. The impure shaly calp limestone weighs 160lb., and absorbs from 1lb. to 4lb. of water per cubic foot. Sandstone average weight per cubic foot (from 38 specimens) 145lb.; least weight 123lb.; greatest ditto 170lb. The absorption varies from nothing to upwards of 10lb., being exceedingly variable; the average being 5½lb. Granite average weight per cubic foot 170lb.; extreme weight 176lb.; least weight 143lb. The Newry and Kingstown granite absorb ¾lb.; Carlow from 1½ to 2lb.; Glenties (Donegal, between granite and gneiss) 4lb. Basalt average weight per cubic foot 178; extreme weight 181lb.; least ditto 171lb.; absorption is less than ¼lb. to the cubic foot. Clay roofing slate average weight of cubic foot 177lb.; extreme weight 179lb.; least ditto 174lb.; absorption from nothing to less than ¼lb. Soft clay slate from near Bantry absorbed about 2lb. In these experiments the weight of the stone and the absorption have been determined by direct weighing, and not by taking the specific gravity. The latter mode would probably give the most exact result; but from the small size of the specimens which would be operated on, and from the variation in density, which is evident in different parts of the stones here experimented on, and which is common to most rocks, I think that the result would frequently not approximate closer than that derived from direct weighing in larger masses. For particular scientific investigation the specific gravity is doubtless desirable, but for practical purposes the weight of the stone and its absorption ascertained in its ordinary state, is, I conceive, all that is useful or necessary for practical consideration. The limestones, it will be seen, are among the least absorbent of the rocks, and being the most abundantly used as a building material, it is obvious, that if good mortar be used in a proper manner in the external pointing, any weather may be resisted in almost any situation, without the use of perishable rough cast or costly cement. Buildings, however, carried up in wet seasons, in which the external mortar is not allowed to become hard, or where it becomes injured by frost, cannot resist the weather, but with good mortar pointing inserted between the stones from which the old joints have been raked out, I feel satisfied from experience and from the result of cases to which I could refer, that no material is more secure than these non-absorbent limestones. There is a popular error with regard to limestone, which is very generally considered to be a stone that will not keep out the weather; its very non-absorbent quality is, however, the cause of this idea, the stone condensing in the interior of the rooms the moisture of the air. Sandstone and limestone, when properly used together, owing to their different properties, make the best work; the absorbent quality of the sandstones keeping the interior face of the walls dry, and the exterior of limestone resisting the weather. I believe it is doubted if mortar will itself resist the weather; that it will, however, when it is carefully and properly applied, I feel a strong conviction, resulting from experiment, practice, and observation. And I may here remark what is calculated to strengthen the opinion, viz.: the state of some of the external mortar in the old castles and other ruins, where the plastered surface, after weeks of wet weather and heavy rain, if struck with a hammer, will commonly show a dry dust very close to the surface. It is therefore, not the fault of limestone that wet penetrates buildings, and it is frequently incurring unnecessary expense to avoid it on that account, for in most cases it is the fault of the mortar joints and not of the stone; and those portions of a building erected with the ordinary cut stone of the present day, are frequently likely to be the least dry part of the structure, owing to the generally imperfect mortar joints. The absorbent stones, such as the ordinary clay slates, and common earthy sandstones, are not likely to resist the severe weather in exposed aspects without some external protection.

The second series of experiments relate to the strength of the different kinds of stone employed to bear superincumbent weights, or applied in various ways, in which their resistance to fracture is the point to be considered. [Mr. Wilkinson here exhibited a diagram, which showed in a familiar way the results of the experiments. Slabs of the different classes of stones were represented of equal size and length, and a height of wall shown resting on them, varying with the bearing power of the different stones, the average, extreme, and least, bearing of all being given. The very great difference at once showed the importance which belonged to experiments of this kind, and how failures, which frequently result from their improper use, might be avoided, and how far their strength might be depended on, in applying them in any way different from that which they have been commonly and locally applied.] Mr. W. continued—I may here remark that the experiments have been very carefully made, and the test has been applied by a powerful but well-adjusted lever, the arrangement of our talented and scientific member, Mr. Mallet, by whose kindness I have been allowed to use it. The result of the average of many experiments is shown in the diagram, and the lines above and below represent the extreme weak stones, and the extreme strong stones of each class. From this it will be seen that the strongest stones in resisting fracture are the slate rocks. Some of these are stronger when the pressure is applied on the edges of the laminæ of cleavage than when applied on the faces. The basalts are next in strength, then the limestone, the granite, and the sandstones. Fortunately for construction, that stone which is the strongest is that which supplies the materials in the most useful forms for those portions of a building in which such strength is required. I have no doubt that the Valentia slate rock will ultimately come into very much more general use, and that the quarry will be of a considerable value; stones can be raised from it nearly 30 ft. long, 4 ft. or 5 ft. wide, and from 6 in. to 12 in. thick, and it is probable the use of this material will effect a considerable change in many parts of the interior constructive arrangement of buildings. Such are the convenient sizes and strength of the stone that it would without any intermediate bearings or support make the floor or ceiling of the room in which the Society is at present assembled, the ends merely resting on the side walls. It can also be easily wrought. The sandstones are the least satisfactory, and require great caution in using them in any important constructive arrangement. The only instance, among several hundred stone staircases, in which I have encountered any failure from the fracture of the stones has been at Lisburn, where several of the stone steps fractured close to the wall; being a geometrial staircase the failure of one broke the others. Now, in looking to the results of the experiments we find a satisfactory explanation, because the stone here used is the weakest of the whole; and though the stone quarries at Scrabo contain some really good and useful material, the quality of it varies so much as to make it necessary to exercise great caution in its use. By recording failures of this kind, however, much future inconvenience would be avoided.

The third series of experiments was to ascertain the pressure required to crush cubes of one inch sides. The second diagram represented by the difference in the heights of the walling over columns of the same size, but supposed to be of the different kinds of stone, their relative strength, the columns being considered as the stones on which the pressure was exerted. The order of strength in this case differs from that ascertained in the experiments on fracture, as shown in the first diagram. When subjected to crushing, the basalts proved the strongest, the limestones, and successively the slates and sandstones; the quality of the latter is exceeding variable, and show the great advantages to be derived from recorded facts. Of the different varieties of the limestones, some of the largely crystalline stones, and the compact hard calp, are the strongest. The light coloured crystalline stones of Ardbraccan, and those around Cork, are among the weakest. The Connemara white marble, or primary limestone, is the strongest of all the limestones I have yet met with. Among the strongest sandstones are the red rocks of the south, and the hard quartzy grits of the north-west of Ireland. Among the weakest are those of the county Down quarries, and the sandstones in Antrim and around Clonmel, and some of the coarse quartose sandstones of Donegal. Of the slates, those from Valentia, as proved by several experiments, resist less pressure than those of Killaloe, and those from Mr. Synge's quarries in Wicklow are about intermediate. Of the granites I have given no comparitive results, not having yet completed sufficient experiments to enable satisfactory conclusions to be drawn. I may mention, however, that, from several trials, the results do not give granite any superiority over many of the stones in ordinary use.

From the foregoing experiments, which I apprehend to be sufficiently numerous to allow of some general practical conclusions, it is clear that relation generally exist between the weight and degree of absorption of stones, the lightest being the most absorbent, and the heaviest the least so; but this relation is not constantly uniform, and in some varies considerably, as might reasonably be expected. Nor is it probable that, however carefully the stones might be weighed, either under an exhausted receiver of an air pump, or in any other way, that any results would be obtained, differing much from the conclusion here arrived at. Nor is there any uniform relation between the same kind of stones when used in different ways; for, used as a column, or in any other position where a weight would be exerted to crush it, the basalts, as shown by the foregoing experiments, may exceed all others, and yet occupy an inferior position in the scale when applied to support a weight over an opening, or as an architrave resting on columns (the peculiarity of mineral character rendering one stone better for one purpose than another) as the particles of the stone are differently acted on; and although this may be at variance with a commonly received opinion, I have full confidence in the general result of the present experiments which are very decided, and I believe much more numerous than any others of the kind which have been made. And however close the relation may be, which would appear from other experiments to exist between the crushing and fracturing strength of similar bodies, it is very clear to my mind that this law does not extend to stones, which, as aggregated or compound bodies, may be expected to differ much in experimental results from those which are simple. In conclusion, I trust that these experiments will be received by the Society as incipient attempts to establish some positive data in this neglected but important branch of their study, and hope that they may be the same means of inducing others, better qualified, to pursue the subject.

NOTES OF THE WEEK.

It was with great regret we learned that the Council of the School of Design had succumbed to the clamours of interested parties, and given up the class of wood engraving for females. The strong remonstrances of the press have, however, procured its restoration. The necessity of providing suitable employment for females would alone entitle any proposition for effecting this to favourable attention, from motives of common humanity. Then, too, it should be considered, that it is perfectly legitimate to give elementary instruction in any branch of the fine arts. We never heard of sculptors inveighing against the Royal Academy, or architects against any of the numerous public institutions for giving instruction in their art. The elementary processes may indeed be taught, but genius and refined taste cannot so well be communicated. Just imagine Landseer, Maclise and Westmacott applying to the Government for the prohibition of all public schools of art, what a lamentable spectacle would it present. If the School of Design can invent any process for making young girls first-rate engravers, we say so much the better, let them do it; but if, as we believe, they cannot communicate inspiration, but only create mechanical skill, we say again so much the better, for it will tend to reduce the price of inferior works, which now have to be paid for at high rates without any adequate cause. The remuneration of first-rate talent instead of being reduced by this measure is much more likely to be increased, while much good will be done by reducing the price of merely mechanical performances, and providing suitable employment for many females. It is ridiculous to assert that a common diagram engraved on wood is a work of art, and is to be paid for as an artistic production.

The Society of Arts has had a legacy left to it of £5000, and University College receives £14,000 under Mr. Brundrith's legacy.

We were amused to learn that a Theatre Royal has been erected in New Zealand, which although of slight materials, is illuminated with gas.

A fine statue of the Queen has been erected on the top of the grand portico of the Royal Institution at Edinburgh. It is from the chisel of Mr. Steele, and has attracted much admiration. The height of the pedestal and statue is 18ft., and the Queen is represented with a diadem, and in her robes of state, holding the orb in her right hand, and in a sitting posture. It is esteemed a very fine ornament to Edinburgh.

The 8th and 9th of April are the days named for sending in works of art to the Royal Academy for the ensuing exhibition.

M. Jacques, a French sculptor in Russia, has met with a great misfortune in the destruction by fire of his model for a colossal statue of the Neva, by which the labours of four years were lost.

Signor Lanzaruslo of Rome, has, it is said, discovered the means of fixing on lithographic stone, daguerréotype impressions. He has presented to the Pope several plates of the public buildings of Rome.

It is said, that Mr. Clegg is going to Berlin for the purpose of laying down an atmospheric railway from Berlin to Charlottenburg.

The monument raised by public subscription to the Prince of Condé, in France is finished. It is by M. Fauginet, sculptor, and M. Leveil, architect, and consists of a column and a cross of marble, 40ft. high. The base is decorated with statuary.

Overbeck is at Rome at work on a picture for one of the churches of Lubeck, his native place, and for which he is to receive 1000 ducats.

The palace at Baden is to be decorated with stained glass, by Dr. Stantz, of Berne, a celebrated artist, and with paintings by Gotzenberger, illustrative of the history of the district.

Among the engineering works recently published at Naples are the following:—"Monticelli, Sulla origine delle acque del Sebeto, 1840." "F. Abate, delle acque publiche della citta di Napoli, 1840." "L. Cangiano, sulle a. p. potabile di N. 1843," and also on artesian wells, 1842. It is now determined that a boring shall take place for an artesian well at Naples. The supply of water to that city is very bad, but the expense of obtaining it has hitherto prevented any effective measure.

The Emperor of Austria has determined on erecting a new Imperial Library at Vienna. The new building will also provide for the imperial collections of natural history and antiquities. It is hoped that this will give an occasion for the employment of Austrian painters in decoration on a large scale.

A great many new lines of railway have been brought forward during the week, and the best prospects of employment for engineers during the ensuing season are formed.

A very splendid new hotel has been built on the site of the ancient Ducal Palace of Bragnaza, in the centre of Lisbon, and is to be placed under the admirable management of Madame de Belem, who will immediately remove to it her entire establishment.

REGISTER OF NEW PATENTS.

Under this head we propose to give abstracts of the specifications of all the most important patents as they are enrolled, If any additional information be required as to any patent, the same may be obtained by applying to Mr. LAXTON at the Office of this JOURNAL.

IMPROVED WATER CLOSETS.

Henry Austin, of Hatton-garden, Middlesex, Civil Engineer, for "*Improvements in the construction of water closets.*"—Granted July 20, 1843; enrolled January 20, 1844.

The first part of these improvements relates to the machinery or apparatus for the discharge or supply of water; and, secondly, to the method of working and actuating the machinery; and, lastly, to a mode of forcing water into water closets, when there is little or no fall provided for the supply. The seat of this improved water closet is made to work on pivots, or centres, at the sides, so as to move up and down by the weight of a person using the water closet. Fig. 1 shows a sectional elevation of a water closet, constructed according to the first and second part of these improvements; *a* the supply pipe, leading from the supply cistern, *b* a water box, *c* the discharge pipe, which is made flat at the lower end, and so as to fit round the pan, *d* an air pipe, fixed upon the water box, *e* the seat, which moves upon centres or pivots fixed at the sides, *f* a valve, actuated by the lever *g*, and connecting rod *h*, one end of which is attached to the end of the lever *g*, and the other, or lower end, to the back part of the seat. When the water closet is not in use, the connecting rod, lever, and valve are in the position shown in the diagram, that is to say, the valve *f* in such case fits against the end of the supply

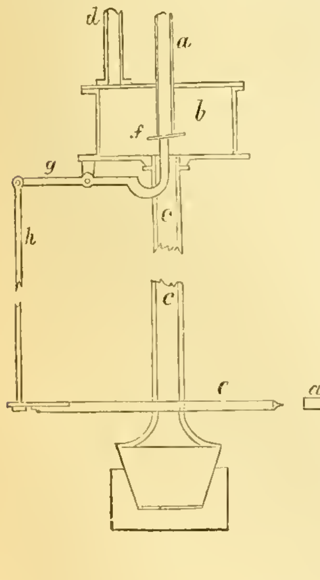


Fig. 1.

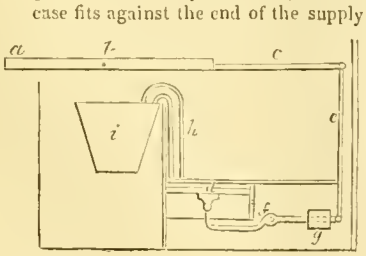

Fig. 2.

pipe *a*, (which may be about one inch in diameter); but when the closet is in use, the weight of the person on the seat causes the same, by means of the connecting rod, to raise one end of the lever *g*, and lower the opposite end, so as to bring the valve *f* upon the end of the pipe *c*; in this position the water will begin to flow from the supply cistern into the box *b*, but on the weight being removed from the seat, the valve, by means of the weight of the connecting rod, will ascend to the position shown, and the water contained in the box will rush down the pipe *c*, and into the pan or vessel. Fig. 2 shows the arrangement of parts for causing a force of water sufficient for the purpose, when there is little or no fall, provided *a* is the seat moving upon centres *b*, to the back part of the seat is attached an arm *c*, which actuates the piston *d*, by means of the connecting rod *e*, and lever *f*. When the seat is depressed, the piston *d* will be partially withdrawn from the box or cylinder. Just above the piston, when in this position, there are two or more small holes through the sides of the box or cylinder, through which the cylinder is filled with water. On the weight being removed from the seat, the piston will begin to ascend in the box by means of a counterbalance weight *g*, and the water contained in the box will be forced through the pipe *h*, and into the pan *i*, with sufficient impetus to remove any deposit; by this arrangement a force of water sufficient for the purpose is said to be obtained, when its level is below that of the pan.

A NEW MASTIC OR CEMENT.

Charles Bertram, Newcastle-upon-Tyne, for "*An improved mastic or cement which may also be employed as an artificial stone, and for coating stone and other substances.*"—Granted July 20, 1843; enrolled January 20, 1844.

This improved mastic or cement is made as follows:—About 70 parts of turf or peat, as it comes from the field, is subjected to pressure or heat, in order to free it from the greater portion of water which it contains, after which the turf is mixed with about 30 parts of pitch or tar from the gas-works (preferring the latter); this compound, after being allowed to rest for some hours, is put in a vessel and kept at a boiling heat for three hours; the product, after being well incorporated, is a mastic or cement, called by the inventor "*Sercollane*," and is of a very tenacious and adhesive quality. When this mastic or cement is to be employed for coating ships, the inventor employs to each 100 parts of peat or turf, two parts of yellow soap, and 10 parts of oxide of iron, or other like poisonous matter, the object of which is to prevent barnacles, sea-weed, and other matter, adhering to the sides and bottom of the vessel. When this cement is to be used as an artificial stone, the inventor mixes about 35 parts of peat or turf, and 35 parts of mud taken from the bottom of rivers, ponds, canals, or marshes, intermixed with dry sand or fine gravel; this mixture is treated in the same way precisely as above described, and then moulded into blocks or slabs, of the form required for paving or flagging. The above composition is the same in every respect as that for which a patent was obtained by Mr. William Mylam in June last, the inventor, therefore, only claims the application of the aforesaid cement to the purposes above described.

ROLLING IRON INTO SHEETS.

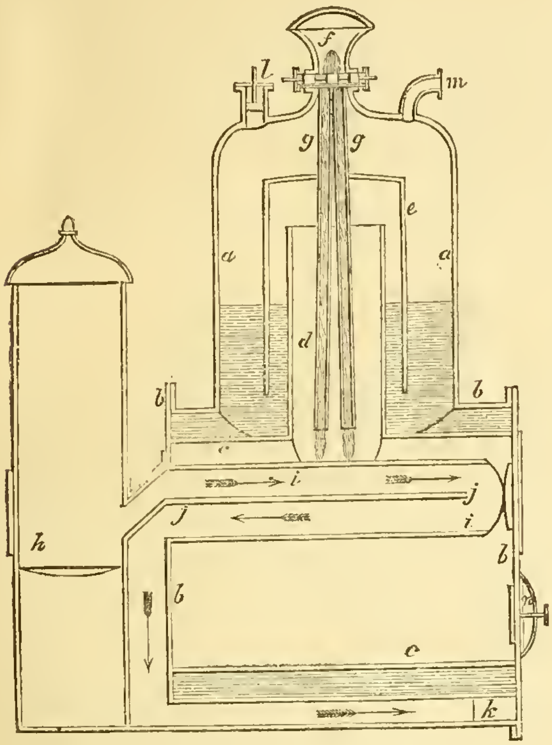
William Daniell, of Abercarn, near Newport, Monmouthshire, Tin-plate Manufacturer, for "*Improvements in rolling iron into plates or sheets.*"—Granted July 22, 1843; enrolled January 22, 1844.

The object of these improvements is to avoid the repeated processes hitherto necessary, in the manufacture of thin plates or sheets of iron, of piling and reheating, whereby a saving of fuel and iron is effected, and the repeated processes of piling, heating, hammering, and rolling is avoided. The process is as follows:—A ball of iron is taken from a puddling furnace or refinery, and submitted to the process of hammering, after which it is to be rolled into a bloom of about 6in. wide, and 5in. deep; this bloom is then cut by a saw, or other instrument, into lengths of from 4 to 6in.; after which the pieces are to be immediately rolled between rollers, taking care that the grain of such pieces is in a vertical direction, by which means the upper and under sides of the bars produced will be the clean cut surfaces; these pieces, if care be taken, can be rolled, without reheating, into bars of about 5in. wide, and 2in. thick. The process so far is stated to have been the subject of a patent granted to Mr. Daniell in April. 1822; but, instead of proceeding as therein described, the patentee commences at once to roll the pieces in a transverse or opposite direction, so that the bars, in place of being piled and hammered, are finished into thin plates or sheets, by rolling the pieces in the reverse direction to that in which the bars were rolled. The bars are then cut into lengths, according to the size of the plates to be made; these pieces are then heated in a suitable furnace, and rolled in grooved rollers, the grooves of which are the same length as the pieces of iron to be rolled, the rolling being effected at right angles to the previous rolling; the rolling is thus continued until the piece is about a quarter of an inch thick, after which it is to be rolled in plain rollers until such piece is reduced to one-eighth of an inch in thickness; in this state the piece of iron is technically called a "moulding," and is to be completed in a tin-plate mill. The patentee claims the mode of rolling iron into thin plates for the manufacture of tinned sheets, &c., by causing pieces of iron to be rolled out into sheets or plates, by rolling them at right angles to the direction to which they have been produced, when such pieces have been obtained by rolling cut iron with the grain in a vertical direction, the upper and under surfaces being the cut surfaces.

GAS POWER.

James Neville, of Walworth, Surrey, Civil Engineer, for "*Improvements in obtaining power by means of gases applicable to working machines.*"—Granted July 13, 1843; enrolled January 13, 1844.

For this purpose the patentee employs the rough nitrates of potass or soda, combined with charcoal, or bituminous coal, or other combustible matter, which will have the effect of decomposing the said nitrates. The coal or charcoal and nitrates are mixed together in such proportions as to completely effect the decomposition of the nitric acid of the said nitrates, and the compound or separate gases, and heat produced therefrom, are made available for producing motive power.



The annexed engraving is a sectional elevation of the apparatus employed for collecting and applying the gases to the purpose of generating steam, and is as follows:—*a a* and *b b* are two cylindrical vessels affixed at right angles to each other, as shown; *c c* is another cylindrical vessel, placed within the latter, or vessel *b b*, on the top of which is placed a pipe or tube *d*; *e* is a vessel suspended within the vessel *a* in an inverted position, with its lower end dipping into the water contained in the vessels *a* and *b*, which vessels form or constitute a boiler; *f* is a hopper, to which are attached two pipes *g*, *g*, which pass through the end of the vessel *c*, as shown; *h* is a furnace, and *i* a retort, divided by a plate or partition *j*. The action of this apparatus is as follows: the hopper *f* being filled with the above mixture or compound, a fire is lighted within the furnace *h*, the heat of which passes in the direction shown by the arrows, and escapes through an opening at *k*. When the retort *i* has become sufficiently heated, the compound or mixture contained in the hopper is allowed to fall down the pipes *g g* upon the heated retort, whereby the particles of the mixture become ignited, and the gases and caloric obtained therefrom pass up the tube *d*, and between the annular space formed by the vessel *e* and tube *d*, so that the gases and vapours are made to pass through water, in their passage to the boiler, and communicate their high temperature thereto, which will have the effect of producing a considerable quantity of steam, which, combined with the gases, may be applied for producing mechanical power; *l* is stated to be a contrivance for regulating the pressure in the boiler, and is the eduction pipe for the steam and other vapours. The patentee states that the residue of the nitrates employed may be removed through an opening formed at *n*; *videlicet*, the sub-nitrates of potass or soda will nearly repay the original cost of the raw material. The claim is for the application and use of gases and caloric obtained from the decomposition of the said nitrates, whether combined or not with aqueous vapour, as a means of producing mechanical power.

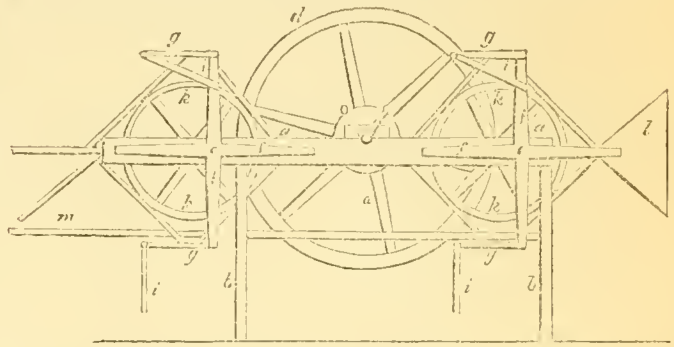
PRIMING OF BOILERS.

David Napier, of York Road, Lambeth, Surrey, Engineer, for "*Improvements applicable to boilers, or apparatus for generating steam.*"—Granted July 25, 1843; enrolled January 25, 1844.

These improvements in boilers or apparatus for generating steam are intended to prevent what is technically called priming or flushing, or, in other words, the water from passing off in conjunction with the steam, and is effected in the following simple manner. The surface of the water in the boiler is covered with one or more tiers of hollow metallic balls or other buoyant substance, or the same may be effected by substances that are not buoyant; such as perforated plates, supported in the boiler by any mechanical means, or wood may be advantageously employed; but the patentee prefers hollow metal balls of about 2 inches diameter; a tier of these balls being placed upon the surface of the water form a number of interstices, which will be greatly reduced by placing another layer or tier upon the first, and the same will prevent the water, when in a state of ebullition, from rising up and passing off in conjunction with the steam. The claim is for the method above described of preventing the priming and flushing, of whatsoever form or material the substances employed, and whether buoyant or supported by mechanical means.

AERIAL LOCOMOTION.

William Crofton Moat, of Upper Berkeley Street, Marylebone, Middlesex, Surgeon, for "*A method of obtaining aerial locomotion.*"—Granted July 26, 1843; enrolled January 26, 1844.



This machine or apparatus, intended for the purpose of aerial locomotion, consists of a rectangular or oblong frame of wood, or other material, supported, when on the ground, by four legs; to the upper part of the frame there is a transverse shaft with two double cranks, this shaft gives motion, by means of two other shafts, to 16 propelling flappers, which latter give motion to the machine. The following description and accompanying engraving, which is a longitudinal elevation, will serve to show the principle of the invention.—*a a* is the rectangular frame of wood, supported on legs *b b*; *c* is a transverse shaft, supported by centres, passing through the frame sides this shaft has two double cranks, one of which is shown in dotted lines; upon this shaft, and about the middle of the framing, there is keyed, or otherwise firmly fixed, a large wood wheel *d*, this wheel imparts motion by means of a rope or gut passing round its periphery, to two shafts, which are also supported by the framing at *e e*, upon the end of each of these shafts there is a frame consisting of two pieces of wood *f f*, at right angles to each other, in the form of a cross, to each of the ends of these cross pieces there is attached a wood frame *g*, and to each of these frames is attached, by means of a hinge joint, a propelling flapper *i*, consisting of a rectangular frame of wood, covered with parchment or other material; *k*, *k*, are wheels and square wood frames placed eccentrically with shafts that carry the crosses, the position of these eccentric wheels can be altered by means of ropes and tackle, but for what purpose is not clearly shown in the specification; *l* is the rudder, which is actuated by two ropes passing along the frame sides to opposite ends of the machine, and *m* a platform, which may be extended to any desired length, and is intended for the person to stand upon, whose office it should be to guide or govern the machine. On motion being given to the large wheel, which is effected by four men standing upon the platform *n*, a rotary motion is imparted to the cross pieces, which carry the frames and propelling flappers, which cause the latter to strike successively upon the air in a direction the opposite to that of the line of gravity; these combined effects, it is presumed by the inventor, will cause the machine to ascend and be propelled through the air. The claim is for the general arrangement and combination of parts, and the application of the same to obtain aerial locomotion.

GOVERNMENT CONTRACT FOR STEAMERS.

We have much pleasure in being able to give a copy of the specification issued by the Lords Commissioners of the Admiralty, on the 20th of January last, to the principal engineers, who are invited to contract for steam engines for two of Her Majesty's steam vessels of the first class and four of the second class. The tenders are to be delivered on the 5th March next. It will be perceived that the engineers are not limited to power, the object of Government being to obtain as great a power as possible within the limit assigned for the engine room, and within the limited weight.

Specification of certain particulars to be strictly observed in the construction of four pairs of marine steam engines, referred to in the Admiralty letter of the 20th of January, 1844.

For vessels of the Second Class.

The tenders are to be made (in triplicate) on the accompanying printed forms, every particular in which is to be strictly and carefully filled up; and all drawings, models, and boxes containing them, are to be distinctly marked with the names of the parties transmitting them. The whole weight of each pair of engines, including the boilers (with the water in them), the coal boxes, paddle wheels, spare gear, the floor plates, ladders, guard rails, and *all other articles*, to be supplied under the contract, is not to exceed 300 tons.

N.B. If this condition is not strictly complied with, the contractor is to forfeit £1000., or their Lordships are to be at liberty to reject the engines, the manufacturers paying £1000. for the disappointment.

The coal boxes (in the space of the engine room) are not to contain less than 350 tons, computed at 48 cubic feet to the ton, and more if possible. Sufficient details of the coal boxes are to be shown in the drawing, to enable a calculation of their contents to be made. In this computation, the space below the deck to the depth of 6 in. is to be excluded, to allow for the space occupied by the beams, and for the difficulty of completely filling the boxes with coals.

The consumption of coal per horse power, and the number of days' coals which the boxes will contain, are to be accurately stated in the tender. To avoid the possibility of mistake in the dimensions given in the drawings furnished to the respective parties, it is to be understood that

	feet.	inches.
The length of engine room in the clear is ..	50	0
Breadth of ditto	33	0
Depth of ditto	21	0
Centre of shaft above water line	8	9

The horizontal situation of ditto as per drawing, or as near as can be.

Those tenders, however, which place engines of sufficient power in a space less than 50 ft., and give the largest stowage of coals, will be preferred.

The holding down bolts are to be secured by nuts let into the lower sleepers, so as not to require the bolts to pass through the vessel's bottom, and the bolts are to have at the lower end of their points wrought iron washers about 8 in. square and 1 in. thick placed between the nuts and the wood. Should this mode of security be inapplicable to the particular kind of engine proposed, the engineer is fully to describe any other secure mode which he may think the most advisable to adopt.

The pistons are to be fitted with metallic packing. The blow off pipes are to be $3\frac{1}{2}$ in. in diameter, and not less than $\frac{1}{4}$ in. in thickness.

Discharge or escape valves are to be fitted at the top and bottom of each cylinder, for allowing the escape of water therefrom; the valves to have suitable metallic cases, to prevent danger of persons being scalded by escape of boiling water, reverse valves are to be fitted to the boilers, and stop valves at the ship's side to the waste water pipes.

Each cylinder is likewise to be fitted with a separate movement and valve, for the purpose of using the steam expansively in various degrees, as may from time to time be found eligible. The air pumps are to be lined with gun metal of $\frac{1}{2}$ in. in thickness when finished. The air pump buckets are to be of gun metal, with packing rings. The air pump rods are to be of gun metal or Muntz metal, or of wrought iron cased with gun metal.

The threads of all screwed bolts, nuts and pins used in engines and boilers, and in every other part of the work furnished by the contractor are to agree with the threads used in the steam department at Woolwich.

A small engine is to be fitted capable of working one of the pumps for feeding the boilers, in every case when the boilers are tubular. Pipes to be fitted for supplying, in the event of a leak in the vessel, the requisite quantity of water from the bilge to the condensers.

The hand pump to be made capable of being worked by the engine also, and to be arranged to pump into the boilers on deck or overboard, and to draw water from the boilers, from the bilge, or from the sea. The feed apparatus to be complete, independently of any feed from a cistern above the deck, should such be fitted.

The steam pipes and all other pipes to be of copper, and their respective thicknesses and diameters to be specified in the tender. A separate damper to be fitted to every boiler. Brine pumps, or some other equally efficient apparatus, with refrigerator, to be fitted to the boilers, and blow-off pipes so arranged, that any boiler may be blown off separately.

A small flat iron vessel to be fixed in one of the paddle boxes, with two pipes, one communicating with the stoke hole, and the other with the boiler, for obtaining a small supply of distilled water from the boiler.

Air tubes to be fixed in the coal boxes, for ascertaining their temperature. Particulars will be furnished to the contractors on application to the Captain Superintendant at Woolwich.

The Boilers are to be of the tubular construction, and the tender is to specify the cost with iron tubes, and with brass tubes respectively; and it is desirable that the upper part should not be a greater distance above the water line than circumstances render necessary. They are to be constructed in three or more separate parts, each of which may be used independently of the others. Sufficient details of the boilers are to be shown, to enable a calculation to be made of the area of fire grate and of the fire and flue surface.

A space of 13 in. wide is to be left clear between the boilers and the coal boxes in every part.

The paddle wheels are to be of the common construction, and to be fitted with suitable breaks.

The tenders are to specify the highest power of engines which may be compatible with the foregoing specification. The calculation is to be made, allowing the effective pressure on each square inch of the piston to be 7 lb., and the speed of the piston—

For 4 0 ft.	stroke not to exceed	196	feet per minute.
,, 4 6 ,,	,,	204	,,
,, 5 0 ,,	,,	210	,,
,, 5 6 ,,	,,	216	,,
,, 6 0 ,,	,,	222	,,
,, 6 6 ,,	,,	226	,,
,, 7 0 ,,	,,	231	,,
,, 7 6 ,,	,,	236	,,
,, 8 0 ,,	,,	240	,,

If any other than beam engines are proposed they must be described very minutely, with proper drawings or models.

All the necessary ladders for the engine room, together with fenders, guard rails, and floor plates, are to be included in the tender, and likewise the expense of trying and fitting the spare gear. It is to be understood that the practice of fixing new engines on board Her Majesty's vessels at Woolwich Dockyard is to be entirely discontinued. The ports to which their Lordships will for the convenience of manufacturers allow vessels to be taken, are those of London, Liverpool, Greenock, Glasgow and Dundee, provided the places at which the vessels are to be in those ports shall be named in the tender, and approved of by their Lordships.

In the case of vessels receiving their engines on board in the port of London, they will in the first instance be brought to Woolwich; and no subsequent charge will be allowed for transporting the vessel to the place where they are to be fixed on board; for coals in trying the engines until they are complete; for boats, anchors, men, lighters, pilotage, canal or dock dues, shipwright's work, or for any other expence whatever occasioned by the engines not being fixed on board at Woolwich. The "watching" of vessels is to be performed in future by officers and men in Her Majesty's service; but no shipwrights will be provided by Government.

In all cases of vessels receiving their engines on board at any other port than that of London, a deduction of 2 per cent. will be made from the price of the engines named in the tender, as a compensation for the expense, wear and tear, and risk thereby incurred.

The expense of clothing (in the following manner) the cylinders, steam pipes, and boilers, is also to be included in the tender.

The cylinders are to be covered with hair felt to the thickness of two inches, the felt is to be covered with thoroughly dried wood, well fitted, and bound together by iron or brass hoops.

The steam pipes are to be clothed with felt, which is to be moulded with spun yarn, and then to be covered with canvass, the whole to be of such thickness as to be even with the flanches.

After it has been ascertained by trial that every part of the boilers is perfectly tight, two good coats of red lead paint are to be put on them, and felt applied to the tops, sides, and ends, to the thickness of two inches, while the paint is moist.

For the more convenient application of the felt, it is to be previously stitched to canvass for the purpose of holding it together. The canvass is then to be well painted and carefully covered with thoroughly dried one inch deal boards, having rabetted or grooved and tongued joints, and bound up to the boilers with suitable iron stays.

The coating of felt and boards on the top of the boilers or steam chest is to be kept at least 18 in. from the funnel, and the circular space between the coating and the funnel is to be covered with a 3 in. course of bricks set in cement, and surrounded and held together by an iron hoop.

The boards and bricks on the upper parts of the boilers are to be covered with sheet lead, 4 lb. to the square foot, so as to prevent any leaks from the deck reaching the felt.

The specification for two pairs of engines for first class vessels, is exactly similar to the foregoing for the second class excepting the following—

	feet.	inches.
The engine room is to be in length ..	54	0
Breadth	34	4
Depth	23	0
Centre of shaft above water line ..	8	6

Coals to be stowed in the boxes, 400 tons (or more if possible.)

Weight of machinery, &c., complete as specification, 350 tons.

The blow-off pipes are to be four inches diameter and a quarter of an inch thick in metal.

GRAVESEND TERRACE PIER.

Considerable progress has now been made with the above work, for the carrying out of which an Act of Parliament was obtained during the session of 1842, the Royal Assent being given on the 18th June of that year; plans of the work were immediately afterwards prepared, in accordance with designs previously submitted to the Admiralty and to the Thames Navigation Committee, while the proposed undertaking was before Parliament, and which had been approved by those bodies. A contract was entered into on the 15th November following between the Commissioners, appointed by the Act for carrying it into execution, and Messrs. Fox, Henderson, & Co., of the London Works, Birmingham, for the execution of the whole of the works connected with the pier, and which were eventually commenced early in April last, from the designs and under the superintendence of Mr. John Balding Redman.

The site of the pier is, perhaps, as fine as that of any similar work in the kingdom, being immediately in front of the Terrace Gardens' embankment, the road of approach to the pier crossing those picturesque gardens, and rapidly descending from the end of Harmer Street, which, together with the terrace at right angles to it, are at an elevation of 30 feet above the level of high water of spring tides; to meet this, and to give ample room for the navigation of small craft along the shore of the river, in accordance with the wishes of the Thames Navigation Committee, the platform of the pier will be 12 ft. above the level of a high spring tide, and 32 ft. above the level of low water of similar tides, and will be nearly even with the crown of the arch which carries the road over the gardens, and the circular road of approach to the pier entrance, to be obtained by the embankment now in course of formation, will be level throughout, and of the same altitude as the platform of the pier: the precipitous descent from the archway to the present wooden pier, now so inconvenient, will thus be obviated, and the rapid descent of carriages from the town will be checked before arriving at the pier.

The entrance to the pier is flanked on either side, east and west, by two stone offices, of a substantial character, formed of Kentish wrag ashlar, with Derbyshire stone plinths, quoins, cornices, and dressings to windows and doors, the walls of which are now completed; the one will be surmounted by a clock turret, and the other by a belfry; the pier will project northwards 240 ft. beyond these offices, or 200 ft. into the river beyond the embankment, the walk along which will be continued uninterrupted underneath the pier, between the main abutment and the first tier of columns; immediately north of the offices there will be distinct approaches on each side to the vans and coaches, accommodation for which will be provided on the raised terrace formed by the retaining walls on each side of the abutment, and commodious flights of granite steps will be laid down on each side, from the platform of the pier to the terrace promenade, and to the gardens, parallel with the appruaches to the carriages.

The pier will be supported on 22 cast iron Doric columns; one-third of the number are fixed, and the whole of them cast; they are considered to be the largest and heaviest columns ever formed of cast iron; they are 28 ft. in length, and weigh from 9 to 10 tons each; their bases are, when fixed, level with low water of spring tides, and their capitals 8 ft. above the level of high water of the same tides. This will be the waterway throughout under the pier, as the girders supporting the platform and superstructure are horizontal. The width of the platform will be 30 ft., and there are three columns in the width of the pier, at each point of support. The first span or opening under the pier is of 22 ft. over the terrace promenade, and from thence two spans of 50 ft., and one of 51 ft. to the pier head, which is formed by a return at right angles to the main portion, 90 ft. long by 30 ft. wide, termed a T head from its resemblance to that letter, and formed by 13 columns, viz., seven at the junction and three at each extremity.

The approach from the river will be by a double staircase, formed of cast iron bearers, supported between the outer columns, carrying transverse oak steps, and spacious landings at various levels, to suit any state of tide: a transverse flight will lead from the upper landing to the summit of the pier.

The platform will be formed of fir planking on joists laid transversely upon the cast iron girders, the external ones of which will support a cast iron Doric entablature, enclosing the platform and forming the parapets; the entablature will be surmounted by coupled pilasters, filled in with a panelling of corrugated iron, supporting a light wrought or corrugated iron roof, which will cover the whole surface of the pier, and an ornamental cast iron cornice of the same level and meeting that of the offices, will run round the eaves of the roof and form a gutter, the pilasters forming rain water pipes to lead off the water: the pier may eventually be enclosed at will, on either side, by shutters to slide behind the panels, formed by the pilasters; from the platform to the ridge of the roof the height will be 16 ft.

The junction of the roofs at the T head will be surmounted by a lantern tower, from which will be exhibited a powerful and distinctive light for the benefit of shipping, to be erected subject to the approval and under the direction of the elder brethren of the Trinity House; this light will be at an elevation of 60 ft. above low water of spring tides, and 40 ft. above high water, and will be exhibited from a plate glass lantern, surmounted by a copper dome and vane, and supported upon an octagonal iron tower.

The whole area of the pier is at present enclosed by timber piles, braced together, forming a defence to the works and supporting horizontal longitudinal bearers, upon which rails are laid, which are traversed by a huge travelling machine *framed of timber on four railway wheels*, and supporting at top a powerful crab, which traverses upon rails laid upon the traveller at right angles to those below: the span of the traveller is 40 ft., and the machinery is at an elevation of 60 ft. above low water mark.

The foundations of the pier are now nearly finished up to the T head; and the abutment, wing walls, and offices nearly completed, one third of the main columns fixed, and some of the girders laid in their places. All the heavy castings are completed, and it is anticipated that the pier will be available to the public early in the ensuing summer.

The advantages gained by the construction here adopted, are an uninterrupted and free waterway at high water, very little impediment to the tidal currents, an easy approach from the shore, and an efficient protection to those frequenting the pier as a landing place or promenade from wind and weather.

The wooden pier now used will be removed upon the completion of the new pier.

METROPOLITAN IMPROVEMENTS.

A letter, headed as above, and of very unusual length, especially on such a subject lately appeared in the *Morning Chronicle*, which we should have noticed ere now had it not escaped our attention at the time. Be the writer, who affixes only his initials, E. P., professional or non-professional, there is a good deal of judicious remark in what he says, among other things, in regard to the consideration which ought to be bestowed beforehand on the style of architecture to be adopted for the new streets, now in the course of being formed from Leicester Square to Bloomsbury. If anything more than the dull regularity of uniform rows of plain-fronted houses is to be aimed at, it is highly desirable that the opportunity thus afforded should be made the most of, and turned to far better account than has been done in preceding "improvements" of the kind, whether at the west-end of the town or the east. With the writer of the letter in the *Chronicle*, we deprecate "a second edition of Regent Street," and its meretricious, tawdry compilation of downright architectural frippery; but of Moorgate Street we do not entertain quite so high an opinion as he seems to do. While it is a degree or two better than Regent Street, and free from most of the gross solecisms displayed there, it partakes of the defects of the same system of misplaced and overacted architectural pomposity. In as far as a mere order of columns or pilasters can bestow it, it possesses an air of magnificence, which though it may strike for a moment, too plainly betrays itself to be only in the "High life below stairs" taste. The shops on the ground-floor inevitably throw a degree of ridicule on the mock dignity of the upper part of the fronts: the effect thus produced is somewhat ludicrous—akin to that which must have attended Sarah Siddons' occasional starts in the tragic vein—as when she would ask a servant for beer at dinner time, in blank verse uttered in the tones of Lady Macbeth.

Besides the evident misapplication of a columnar style for such purposes, we generally find it, when so made use of, to have been adopted not so much from any particular affection for or relish of it, as from indolence, or else the inability to produce any sort of character or variety by any other means. Pomposity and mock dignity of a different kind are occasioned by these "joint-stock" façades being carried on to the extent they generally are;—whereby, instead of being increased, the sort of grandeur which is aimed at is lost. Were not more houses grouped together into one composition than would give nine, eleven, or thirteen windows in breadth, such fronts would carry with them a far stronger appearance of belonging to distinct houses on a large scale; and as such they would at the same time appear more lofty also. This is tolerably evident from the group of clubhouses in Pall Mall, which are infinitely more impressive than a uniform range of building of "respectable" common-place design would have been, even had it been extended along the whole street. Whatever may be the reason for it, it almost invariably happens that in wholesale masses of houses packed together to form one continuous front, study of design and effect is in inverse ratio to the ambitious pretension of the ensemble: hence not only poverty, but even paltriness, and sometimes vulgarity of expression. Such is the case with nearly every one of the "Terraces," "Places," "Squares"—or whatever other may be the polite designation bestowed upon them—which have sprung up of late years along the western outskirts of the metropolis. Considered as architecture, they are for the most part, sad rubbishly stuff, bedizened out with coarse finery, so essentially vulgar in taste, that the extreme of plainness is preferable to it, since at all events it does not court notice. It must be acknowledged that we have in many instances fallen into a sort of "swell mob" style of architecture in some of our "public improvements."

To return to the writer in the *Chronicle;* we are not a little puzzled by what he says on the subject of the British Museum. "Time and criticism would be wasted on it. The question is not an open one. The architect, by the style in which he has already finished two sides of the quadrangle, has already determined, within an ornament, more or less, the character of the front of the building. To him, without any meddling interference, should be left the completion of his design."

This is surely strange sort of argument: in the first place, *now* is the very "time" for "criticism" to interfere—to step in ere it be altogether too late, and demand that what remains to be done to the buildings should be made, as even now might be, to redeem its thorough unsatisfactoriness as far as it is advanced, It is *because* the quadrangle shows us pretty plainly what will be the quality of the external façade, that we protest against the original design being so carried into execution.

It is nonsense to say that the question is not an open one, when the matter itself is a public one, and it may be presumed, of some importance, unless the importance of our advancing in art, has been prodigiously exaggerated. In one sense, it certainly is not an "open question," because, instead of being made such, and public opinion being sounded by those who possess any authority or influence in the business, there is evidently an effort, although a silent one, to *gag* all questioning—a determination to weary out remonstrance, by turning a deaf ear to it, and to smother both inquiry and observation. But this must not be—dogged and unflinching sulkiness on one side must be met by unrelenting perseverance on the other. To suffer the matter to drop because all that has hitherto been said has produced very little if any apparent effect, would be very ill-advised, since it is the sudden silence which has succeeded to the loud and even stormy outcry raised at first in some quarters, which has thrown a damp upon the matter, as if it were found to be utterly hopeless and irremediable.

If nothing else, the ominous symptoms now manifesting themselves in Great Russell Street, would, we should have thought, elicited fresh remark. There is, indeed, one reason for their not having done so, though not of a kind very flattering either to the architect or the edifice; for many seem to have no suspicion that the row of "houses" a little to the west of the present buildings of the Museum, is intended to be connected with the "grand façade," as a wing to it. It was but the other day, that we ourselves were asked if a new street were going to be opened there—a very natural mistake, for that range of building certainly does look like a row of mere "street houses." Therefore, as soon as it comes to be seen what they are intended for, perhaps even those who have hitherto been silent may begin to express some disappointment and dissatisfaction, more especially as they have not been prepared for anything of the kind, by any of the so-called views professing to exhibit to us the new front of the Museum, but suppressing those very conspicuous appendages to it.

In the mean while, even those who would persuade us that Sir Robert Smirke ought to be left to go on entirely in his own way, do not expect more from him than a structure of "a pure, austere, cold, classical character, worthy of its object, though perhaps not a work which will inspire many persons with warm admiration and pleasure." That it will be cold and austere enough, we may rest assured; but that it will be "pure" and "classical," we very much doubt—or rather are not quite so fortunate as to have any doubts, for if we had, we might then have hopes also. If chilling bareness be purity—if the introduction of alien and disturbing features, and the rejection of classical treatment and classical embellishment, be classicality, why then we shall have both that and purity:—not otherwise. Still, "let no one" says the *Chronicle's* correspondent, "let no one hint at the substitution of any other architect. A total failure would bring disgrace on us for the rash and uncourteous interference. Against such an imprudent transfer, Buckingham House taken from Mr. Nash and committed to Mr. Blore, exhibits some things which should act as a warning. Mr. Hardwick might bestow on the Museum some splendid and ornamental conceptions, which might resemble the noble palace he has erected for the Goldsmiths' Company; and Mr. Barry might enrich the building with a façade in the style of his admirable clubhouses. Some persons would be found, I do not in the least doubt, who would suggest an Elizabethan front; and again Mr. Barry might be led in a retrograde path, and to please an inferior taste of a majority in parliament, or a majority of commissioners, he would be induced to suppress the beautiful forms of Greek or Italian architecture, and only reproduce Hatfield or a Town Hall of the Netherlands."

The precedent here produced for superseding the architect originally employed, by calling in another, says more for that course being now adopted, than all the rest does against it. Without stopping to inquire how far Mr. Blore altered for the better or for the worse, what had been done by Nash, we are hardly warranted in inferring, from want of better success in that particular instance, that a similar result must necessarily attend every other case of the kind. Besides, Buckingham Palace is still essentially what Nash made it, for his successor did not erect a *new façade*, and even the alterations were but inconsiderable. As to what is said of Mr. Barry, and the probability that he would adopt, or that any one else would think of recommending, the *domestic* palazzo Italian, or Elizabethan, is quite preposterous. In regard to the style or mode there could be but one opinion: Greek or Greco-Roman and columnar it would be as matter of course; and although he has not much practised it, we have very satisfactory evidence of what Barry is capable of achieving in that style, in the Royal Institution of Manchester—one of his earliest productions; and again in the masterly design exhibited some years ago for the Town Hall of Birmingham. After all, too, Mr. Barry is almost out of the question, he being engaged on another national structure upon a far more magnificent scale than the Museum. It were, besides, idle to mention any individual beforehand: full time enough will it be to look about for a successor to Sir Robert when he shall have been advised to feel the indispensable necessity of retiring from his very arduous and long protracted exertions in the service of—the public. His attachment to the public service is undoubtedly very great—far more so than his deference to public opinion, and his readiness to comply with what has been demanded of him by the public. Even his would-be apologist in the *Chronicle*, lectures him rather sharply for not complying with the call for the exhibition of the model for the façade of the Museum. "It is uncourteous, it is unwise, and it is unjust to withhold from the public the design which is determined upon." Yes; and it is not over wise or gracious either upon the part of those who have the power of enforcing compliance, not to do so.

To Sir Robert Smirke himself it may, probably, be matter of utter indifference should the building afterwards cause universal dissatisfaction, and heap disgrace upon its author. But it is not or ought not to be matter of indifference to us, the public, whether the Museum reflect credit or disgrace upon our national taste in architecture. Personal interest and party favour may, indeed, ward off censure from the architect in some quarters, and sycophancy may *award to* him its applause, but honest criticism and sound opinion will ultimately prevail, and then both that and all his other works will be estimated very differently from what they have been during the tide of a forced popularity. "Sir Robert Smirke," observes an intelligent contemporary, "has sailed with a fair wind and few impediments down the stream, and if he has not reached a peaceful haven, he has at least been embayed in a fertile and fragrant nook. Whether he has started fairly, and sailed in his own boat, we will not at present inquire; but if he values a repose which in his old age we would not disturb—if he wishes to be spared from the bitter criticisms which his works are calculated to call forth—whether regard be had to his *expensive constructions. and lifeless, frigid designs*, or to his *jobs, failures, and laborious puerilities*—we should desire him no longer to dare the public censure."

OBSERVATIONS ON ARCHITECTS AND ARCHITECTURE.

By Henry Fulton, M.D.

No. 6.

The world, that is to say the architectural profession, is divided on the subject of competition designs; one moiety, and that not the least talented, stand aloof and leave the field to be occupied by the remainder; who, although they do not condescend to write in favour of competition, yet take every advantage of it in practice; and if competition goes on, this section will enjoy a monopoly.

Undoubtedly, if the practice of modern architecture had attained such a state of perfection as painting and sculpture have done under such master-minds as Buonorotti, Raphael, Da Vinci, Canova, &c., and that the public were as well qualified to judge of architecture as of the sister arts, the aristocracy of the profession would be quite right in standing on higher grounds, and treating the practice with contempt; nor do I imagine the public, if well informed, would require it; all that would be necessary for committees of selection to do, would be to fix on the style of the intended edifice, and then employ the architect within their reach, who was known to excel in that particular style.

But, alas, this is not the case, at least as far as the public are concerned; and as long as things so continue, and competitors are to be found to enter the lists, competition designs will be in request: and it is in vain that the anticompetitors, either by precept or example, endeavour to stem the current; better then to sail with it, than waste their strength in useless efforts to sail against it: better it would be to endeavour to turn it to their own advantage, and that of the art, by modifying, directing, and improving it, and not leave the harvest to be reaped and housed by others, less qualified, perhaps, than themselves for the undertaking.

I readily admit, that in very many instances competitions turn out badly; sometimes the architects do not know exactly what the advertising committees want, and it would be scarcely reasonable to expect that they should, as the committees seldom know it themselves. Not unfrequently the competition is all a farce got up to save appearances, the architect having been fixed on previously. I knew an instance of competition where the limit for the estimate was £20,000, and the prize was given for a design which the architect admitted would cost £80,000 (in fact he was not aware that there had been any limit.) It looked better on paper than any of the other plans, and the architect got 70*l.* prize, and what was better, he got £600 for altering it. On the parties being told that "the design never would have a firmer foundation than the paper on which it was drawn," their wrath was great, however, the event proved the correctness of the vaticination, for the design was thrown into the fire. Such adjudication as this brings its own punishment with it; for I believe it cost, together with a world of litigation, nearly £1,500 without any result.

Such misadventures, however, do not occur in every case, as I believe the nation generally is well satisfied with the result of the competition which placed the erection of the Houses of Parliament in the hands of Mr. Barry. As a contrast to this, Sir Robert Smirke (without competition) is to design the façade of the Museum. I much doubt if it will prove equally satisfactory. Where, as in the instance of the Museum, there is to be no competition, it appears to me that the architect, if not in honour, is at least in duty, bound to submit his design for the opinion of those who are, or even wish to be considered, judges of its merits: not indeed that I would have the architect, like the old man in the fable, make an ass of himself by endeavouring to please every body, but I would have him, as the old man ought to have done, listen to the objections, suggestions, and observations of others, and then use his own discretion as to whether he should lead, drive, carry, or be carried. It never can be injurious, either to the fame or interest of any well informed person, to hear and weigh the opinions of others, even although they may not be so wise as he is himself. So thought Edmund Burke, no mean authority in matters of taste; speaking generally, he says, "I have known, and according to my measure, have co-operated with great men; and I have never yet seen any plan which has not been mended by the observations of those who were much inferior in understanding to the persons who took the lead in the business."

It may be asked if architects in refusing to enter the lists as competitors, under existing circumstances do not begin at the wrong end. They ought to improve the public in taste before it can be supposed competent to appreciate individual merit; they ought also to be able to point out to the public such and such works on which to rest their claims for confidence. The establishment of an annual exhibition of designs and models, as pointed out in a former paper, No. V., would afford to every architect an opportunity of making himself known to the public.

Certainly the proposals for competition designs are very frequently absurd enough, and tend to place the profession on a very low scale indeed; for instance a joint stock company in connexion with the Dublin and Drogheda Railway have just advertised for plans for buildings, to cost £15,000, and the successful competitor, who shall furnish the most approved "plans, specifications and estimates," shall receive the munificent sum of ten guineas! There is on the advertising committee the name of one gentleman who could not have been aware of this insulting offer to the architectural profession. Architects competing *in any case* should not furnish or be required to furnish any working plan, specification, or detailed estimate: these with the supervision of the works ought to be subsequently paid for at a fair rate. This would simplify the thing and frustrate the mean intentions of advertising committees: indeed, as to the estimates, under the present system, they are generally most absurd, and quite on a level with the *designs*, though seldom in accordance with the interests and wishes of those committees, who speculate on having the plans carried into effect by a builder, without any farther aid from an architect.

II. It is almost as rare to find a failure in Gothic as it is success in the Greek style; which does away in a great measure with the necessity for competiton where the former style is the one selected. Would it be easy to find an architect who could design one part of a Gothic edifice equally respectable as the portico of the new Exchange, committing so great an error in any other part, as has been committed in polytrigliphing the interior, and exhibiting a base prostitution of a beautiful ornament. The reason of this success is, that fortunately we have no Palladian Gothic unless it be the exterior of the Duomo at Milan, and some reminiscences of Sir C. Wren and Jones at Westminster and Winchester.

It is true we often find in the same edifice a mixture of the details which more properly belong to different eras of the style. The style however, admits of great latitude in this respect; but it ought not to be carried too far, as for instance, the alternation of pointed and circular headed windows; or even their introduction in the same composition, which would be just as bad taste as the mixture of Ionic and Corinthian columns in a Greek composition; it would seem to be taking a leaf out of the Palladian "analysis of beauty," where it is considered a great perfection to exhibit an alternation of segmental and pyramidal headed window pediments.

III. One cause of the ignorance of the public on architectural subjects, is the criticisms of the miscellaneous press—almost every edifice spoken of in the newspapers is praised: those who know anything of the way in which newspapers in general are conducted, will be at no loss to account for this, as I believe those reports are for the most part written by the parties most interested; the editors in general being as ignorant of architecture as their readers; and it would be hard for the blind to lead the blind with safety and security. It is most essential, therefore, for the public not to be led away by representations of that description. Every person with any pretensions to good taste and correct judgment join in the condemnation of the National Gallery, both as regards fitness and beauty; and yet was it not praised beyond measure by the newspapers of the day? Oh! how it grieves me to think of the National Gallery of Berlin, in comparison with our own. When it shall be found, as I am confident it soon will be, that another and more suitable edifice is requisite, the palace at Kensington ought to be appropriated for that purpose. It would be sufficiently out of the smoke of London, and yet at a convenient distance for visitors. But I find myself digressing too much from the subject commenced with.

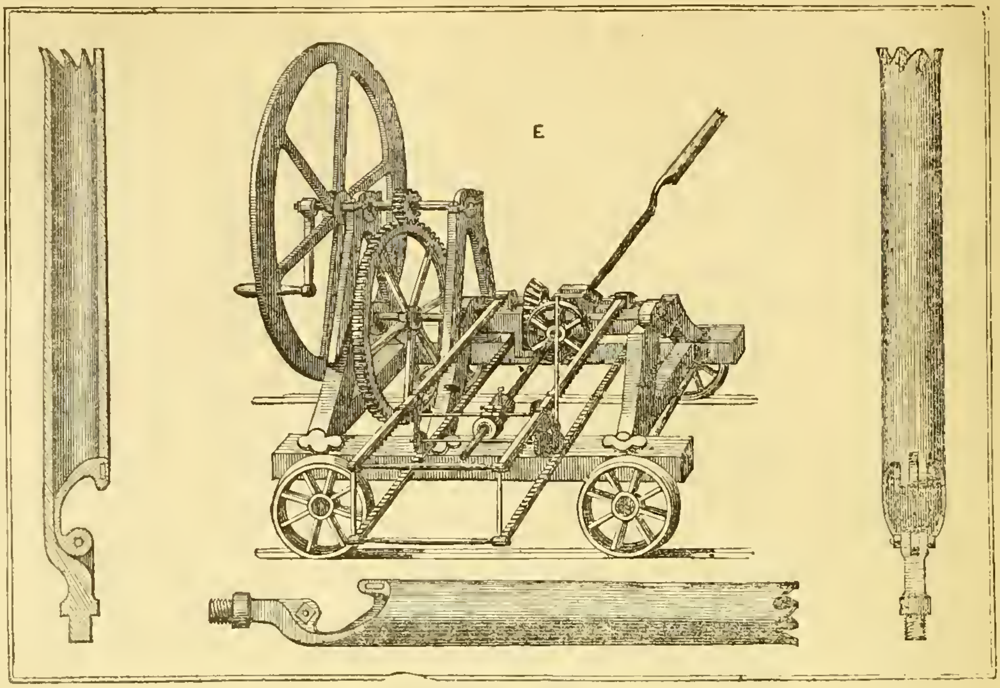
IV. At page 26 of this Volume C. D. of Milford, objects to the notice with which the Conciliation Hall, Dublin, is introduced to the readers of this Journal, as he considers the edifice below criticism. Is C. D. one of that school who object to "vilanous saltpetre" being dug from the harmless bowels of the earth? Does he not know that the end of a journal is in holding up the mirror to art, to shew deformity its own image, as well as beauty her own feature? In dissecting (which C. D. is pleased to remind me of,) pathology must be attended to as well as physiology, the diseased as well as the healthy functions. C. D. may be right as to there being no committee of selection in the case of the Conciliation Hall. The observations on that subject were intended to be general.

The Admiralty have purchased the working model of the Trafalgar Square Nelson with which to adorn their offices, which stand sadly in need of it.

WATSON'S PATENT IMPROVEMENTS IN DRAINING.

In our last Number, in describing the Patent Drain Pipe, we alluded to the Boring Machine, which is the most important part of the Patent, as it enables the drain pipes to be inserted with facility, which, without it, would be a very troublesome affair.

The Patent Boring Machine, shown in the annexed engraving, fig. 1, is worked by two men turning the handle which gives the rotary motion; the advancing motion is given by another man, who leans on a lever, which is represented in a perpendicular position; this when pressed downwards propels a pinion wheel, which advancing up the rack, impels a collar, and, by means of a thumb-screw, clips the boring rod passing through it. Double racks are used for the sake of obtaining a steady motion.



Fig, 1.—Patent Boring Machine and Augurs.

The action of the auger may be very advantageously used for brick work; it cuts out a complete cylinder of brick, and thus brings out a solid core. No other tool has been found to produce such a result. Augers and drills of every shape had been tried by the patentee before he hit upon this.

Fig. 2 is a front elevation and section of the retaining wall in the cutting of the London and Birmingham Railway between Euston Square and Camden Town; at the back of the wall is that difficult soil, the London clay, which has given so much trouble in consequence of being occasionally saturated with water; the clay has now yielded to the influence of the ventilation, by the introduction of the drain pipes, inserted at the back of the wall, as shown in engraving; they are inserted to the distance of 16ft. from the face of the brickwork. When the pipes were introduced, it was found that there were very few springs in it, but a considerable accumulation of rain water, and which now runs freely out after a heavy shower of rain from every pipe.

In a clay soil like the above, the borings must be made much closer than in a gravelly soil, or even a sandy one. An inspection of brickwork that has been thus placed for a few years, shows clearly that neither bricks nor mortar will endure long under such circumstances; and also it is proved that ventilation will harden softened bricks, though it cannot of course restore the washed out mortar.

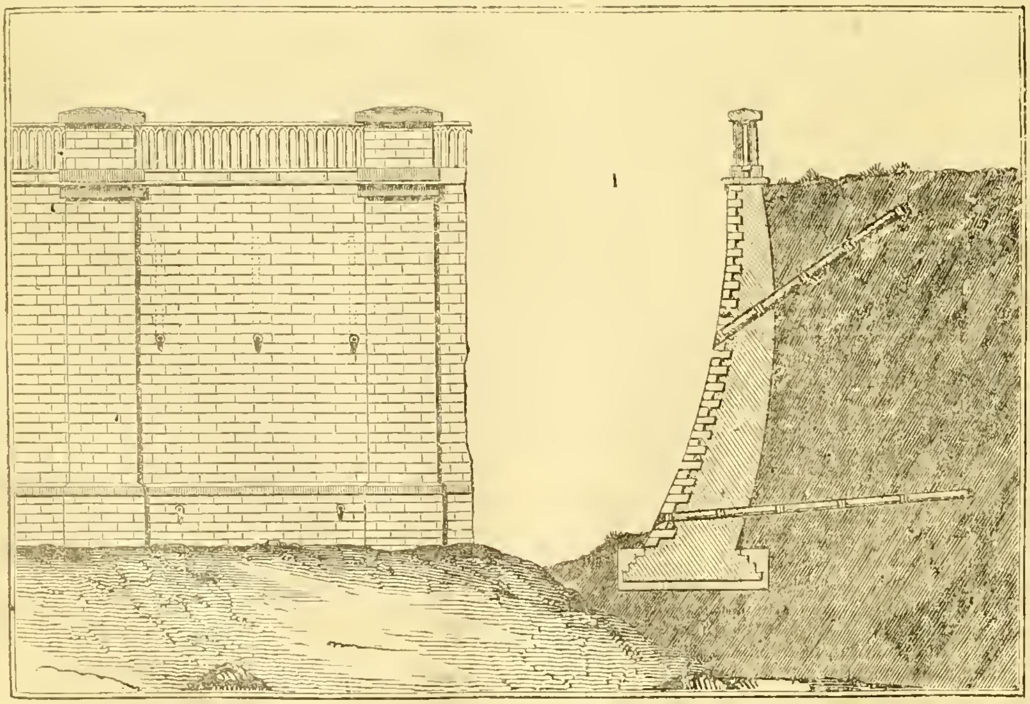


Fig. 2.—Front Elevation and Section of the Retaining Wall, London and Birmingham Railway.

WROUGHT IRON BEACON.

Description of a Wrought Iron Beacon erected at the harbour of Black Rock, in Long Island Sound, in the summer of 1843. By W. H. Swift, Capt. Corps Topl. Engs. (From the *American Journal of the Franklin Institute.*)

In March, 1843, an appropriation of 10,000 dollars having been made by Congress, for rebuilding the Black Rock Beacon, the Secretary of the Treasury applied to the Secretary of War to allow this beacon to be constructed under the direction of the Chief Topographical Engineer, and by the orders of Colonel J. J. Abert, the work was entrusted to the superintendence of Captain W. H. Swift.

The beacon stands 1½ mile south of the entrance to the harbour, and is exposed to all winds from E.N.E.; around by the south to W.S.W.; from the east it is open entirely to the rake of the sea for a distance of sixty miles.

When the first beacon was built in 1829, a large quantity of pebble stone was carried in vessels to the proposed site, and there thrown into the water around a single rock called the "Old Huncher," and upon which there had been an iron spindle in former years; this rock was conical in shape, about 4 ft. in diameter at top, and bare at very low water. Upon this loose stone, thus deposited, the superstructure was reared, and when the beacon was overthrown, the materials of which it was composed, were, of course, added to the rubble stone bed, and they, in turn, became the foundation for the beacon of 1835.

In the examination which I made of the site in June, preparatory to making the final plan for the iron work, I ascertained that the stone below low water, had, apparently, remained unmoved for a long time, and I subsequently found, by inquiring of Captain Wilson, the contractor, who had repaired the beacon in 1836, and who had maintained it in repair for five years, that such was the fact; while, as he stated, and it was evidently true, the stones between low and high water were thrown about by the force of the sea in every gale. This was fully exemplified too by the appearance which the injured part of the old beacon presented; the base, or that part below low water, was entirely undisturbed, the breach being between high and low water marks; all the stones below low water remaining, as stated by Capt. Wilson, as they were when the beacon was repaired in 1835.

There being no stone of sufficient size at the old beacon into which the iron shafts of the new structure could be secured, I found it necessary to procure elsewhere such as were suitable for the purpose, and to transport them to the site, and imbed them below the line of low water, in order that the sea might not disturb them after they should be laid.

Stone Foundation.—The beacon, according to the general plan which I had made, and submitted to Col. Abert on the 30th of April last, was to be elevated 36 ft., and for this height I decided to give the iron shafts a spread, or base, of 16 ft., with an inclination towards the centre of about 1 to 6. In order that there should be sufficient strength in the stone to resist any tendency there might be to fracture at the holes which were to receive the feet of the shafts, I adopted the dimension of 20 ft. as a suitable diameter for the stone bed designed for the shafts to be secured to; this dimension gave a distance of about 2½ ft. from the centre of the shaft holes to the edge of the stone at top, while at the bottom of the stone, where the strain is less, it would be 2 ft. The bed then is composed of 6 pieces of hammered granite, 2½ ft. thick; the middle stone is round, and is 8 ft. in diameter, the five outer stones are 6 ft. wide by about 12 ft. in length, each stone weighing nearly 12 tons; the stones are cramped and doweled together with 1½ in. round copper,[1] two at each joint, the cramps 2 ft. long, and the dowels 10 and 12 in. long.

The excavation which was made in what may be called the artificial island (for at low water an extent of 105 ft. from east to west, and 88 ft. from north to south is exposed,) for the reception of the stone bed is a few feet N.W. from the old beacon; it was 26 ft. in diameter, and 3 ft. below *ordinary* low water. When the excavation was completed, a layer of concrete composed of 5 parts of hydraulic lime, to 8 parts of sand, was spread over the bottom of the pit by means of a trough of wood for the foundation stone to rest upon. After the stones were laid, which was effected by means of a heavy pair of shears, and a "Lewis," the unoccupied space in the pit around the outside of the stone bed, was filled with concrete and rubble stone, flush with the top of the foundation stone. As it was only at, or near low water, that this part of the work could be carried on, that is to say ordinarily, about three hours per day in good weather, considerable time was necessarily consumed in getting in the foundation; from the day the shears were erected, to the day the stone work was completed, was just five weeks.

Iron Work.—The figure of the beacon is that of a truncated pyramid: it is formed of six wrought iron shafts, five of them 36 ft. 7 in. in length, standing in the periphery of a circle of 16 ft. diameter, and one 36 ft. long at the centre, the outer shafts incline towards the middle in such proportion, as to fall at the top within the circumference of a circle of 3 ft. diameter; each of these shafts is composed of two pieces of equal length, the diameter at the foot of the lower piece is 5¼ in., and at the top 4 in.; the diameter of the upper piece is 4 in. at the foot, and 3 in. at the top, they are united by a cast iron socket of 3 ft. in length, 2½ in. thick at the joint of the shafts, which is at the middle of the socket, 2 in. thick at the top and bottom, and 1 in. thick elsewhere; the top of the lower shaft is made concave, and the bottom of the upper shaft convex, fitting one into the other. At the distance of one foot from the joint of the shafts, a steel key, 2 in. deep by ¾ of an inch wide, passes through the socket and each shaft to secure them together; the sockets inside, and 18 in. of the ends of the shafts are turned and accurately fitted to each other. At a distance of 2½ ft. from the foot of the lower shafts, are four shoulders one foot long, and projecting, at the lower extremity, one inch from the shaft to form points of support for the same at the surface of the foundation stone. Above and below the joints of the shafts, and at distances of 9 ft. and 18 ft. respectively above the top of the stone, are two sets of braces extending from the middle shaft to each outer shaft, and from one outer shaft to another, making ten in each set; the braces are of wrought iron 2½ in. square, the extremities are secured by 1¼ in. screw bolts to cast iron collars, these collars are strengthened by two wrought iron bands, and are firmly attached to the shafts by steel keys; the space between the collar and shaft, and between the keys is filled with zinc; the braces are secured to the collars in such a manner that they serve for ties in case of any unforseen strain acting from the *interior* of the beacon, such as might possibly be occasioned by ice, or any other floating body.

The tops of the shafts are provided with shoulders to support a cast iron cap, composed of five arms, each 3 ft. in length, and 4 in. in width, strengthened by a rib, or flanch, of 3½ in. in depth; the shafts pass through this cap 18 in. from the centre of it, and are there keyed in place; a wrought iron band 3 in. wide, and ½ in. thick, is shrunk upon the extremity of these arms to add to its strength; from the ends of the arms of the cap, 3 ft. from the centre, braces of 2 in. round iron descend 4½ ft. to the main shafts, and are there secured by screw bolts passing through their extremities, and through the shafts also. At this junction of the braces with the shafts, a wrought iron band, similar to that which encircles the cast iron cap, is fitted and bolted at a distance of 4½ ft.; again below this second band is a third band similar to the two others, and similarly secured by screw bolts through the shafts; finally, there are 10 panels or gratings, 4½ ft. long, corresponding in shape and dimension with the wrought iron bands between the shafts, and the wrought iron bands; these gratings are made of boiler iron $\frac{3}{16}$ths of an inch thick, with eight horizontal and three vertical slats, or bars, 3 in. wide, riveted together; the horizontal slats are 3 in. apart, but at the distance of 500 yards, the top of the beacon presents the appearance of an opaque body 9½ ft. long by 6 ft. wide at the top and bottom, and 4½ ft. wide midway of the same.

The feet of the iron shafts penetrate the stone foundation 2½ ft., and are secured in their places by heavy iron wedges fitted to the unoccupied spaces between the sides of the holes in the stone and the shafts; the holes being inclined, and the braces between the shafts being immoveable. It is evident that the feet cannot be withdrawn from their places without rupture. Now, the braces are of 2½ in. square iron, and the thickness of the stone outside of the hole is 2½ ft. and this would seem to present sufficient strength to resist a shock from any ordinary cause.

In addition to the concrete around the outside of the stone, and the cramps and dowels to secure the same together, there are five iron ties of 1½ in. diameter, extending from a collar of two inch wrought iron, which surrounds the middle shaft, to each of the outer shafts to which they are firmly and securely attached by means of heavy iron stirrups; the ends of the ties are furnished with screws and nuts, and by this means can be kept in a constant state of tension. This arrangement was resorted to as an additional means of preventing any tendency there might be in the outer foundation stones to separate themselves from the middle stone.

The beacon, as finished, stands 34 ft. above low water, and 3 ft. higher than the old beacon; the cage, or grating, is painted black, and the shafts vermilion red.

The iron work was executed in Boston by Messrs. Cyrus Alger & Co., under the immediate superintendence of Mr. Lester; the entire weight is upwards of 19,000 lb. The foundation was prepared, and

[1] York stone or slate dowels and cramps are now generally adopted in England; they are far better and cheaper.—Ed. C. E. & A. Journal.

the beacon erected in place by Mr. Benjamin Pomeroy, of Stonington, Connecticut, under a contract made with him for that purpose. The entire cost of the iron work and foundation was about 4,600 dollars, and the time consumed in the construction was three months.

I had it in contemplation at one time to coat the iron work with zinc, by means of electro-galvanism, but I found that too much time would be required for preparing the necessary tanks and apparatus. I venture to hope, however, that another occasion may present itself, and that in the more important structure of the "screw pile light," which I trust I shall one day see executed upon our own shores, that the galvanizing process may be successfully applied.

In conclusion, I beg to call attention to one or two of the more important advantages which this application of one of the principles of Mitchell's Screw-pile, (see *Civil Engineer & Architect's Journal*, p. 182, vol. 3, 1840,) to the construction of light houses and beacons, presents.

In a very exposed situation, a light, or a beacon, if built of masonry, can only stand when the best description of work is introduced; this, of course, involves great expense, and much time. The mode of construction for such situations must, in principle, be similar to that adopted for the Eddystone and Bell Rock lights, and this, as all know who understand the subject, would, in the case of our own coast, present *an insuperable objection*: for example, the Bell Rock Light, on the coast of Scotland, cost £360,000, and four years were required to build it, this too in a situation where the rock upon which it is placed is bare at low water. The Eddystone was neither so costly, nor did it require so much time to complete it, still the amount would, with us, justly be considered out of the question for a single light.[2] There are many places upon our coast at which the screw pile light could be erected at a very moderate cost, far less, indeed, than that of a light ship; notwithstanding this, there are at this time several floating lights in Pamlico Sound, on the coast of North Carolina. The Middle Ground, in Long Island Sound, upon which there are only 3 feet at low water, and at which a light boat is now maintained, is, of all others, the most suitable point to make the first experiment upon with this description of light.

In reference to the *durability of wrought iron* exposed to the action of sea water, I have not a great deal of information to impart, still I have some which bears upon this question. Upon many of the reefs in Long Island Sound, and more particularly in Fisher's Island Sound, it has been the practice for many years to erect wrought iron spindles of about 4 in. diameter, and from 15 to 25 ft. in height; such spindles last from 15 to 20 years, unless carried away by ice. The contractor who placed several of these spindles, informed me that one upon a reef in Fisher's Island Sound had been up 20 years without being renewed; the wasting takes place principally between high and low water, and in this particular case, the size of the spindle is reduced from 4 to 2 inches in diameter. If, however, the zincing process, or if a precipitate of copper be resorted to, there is every reason for believing that the iron thus protected would last twice, or three times, 20 years. In short, economy in cost and in time, and the application of the principle of the screw pile in situations where masonry could not be resorted to without inordinate expense, would seem to be advantages in themselves sufficient to justify extensive experiments in a branch of the public service of such importance as that of our light-house system.

2 The Car Rock Beacon, on the coast of Scotland, cost £5,000; six years were required for the construction; it was intended to build it entirely of stone, but when half finished the upper part was constructed of cast iron. The cast iron beacon on York Ledge Maine, is an exact copy of the Car Rock Beacon: it cost £2,000.

PATENT SCREW-PILE BATTERY AND LIGHT-HOUSE.

Mr. Mitchell, the Patentee of the Screw-pile, previously described in our *Journal*, proposes to adapt them for the purposes of forming foundations for the erecting of batteries in the open sea, in such situations as the Goodwin Sands, and other sub-marine sand-banks.

The principle of such foundations has already been well tested both on the east and west coast of England—off the shores of which have been erected, screw-pile light-houses, that have now withstood the storms of several winters, without exhibiting the slightest symptom of insecurity or decay. The stability of such structures depends on two causes:—First, the firm hold which the broad screw takes of the ground, by being forced far beneath its surface. And, secondly, the solid part of the building being placed above the reach of the highest sea—no broad surface is opposed to the free passage of the waves—consequently, the structure is not affected by them.

The first foundation of this description was fixed in the Maplin Sands, by Mr. Mitchell in 1838, by order of the Trinity House, at the recommendation of their engineer, Mr. James Walker, for the Maplin Light-house; and, though it stands upon a bank of loose sand, many miles from the nearest coast, and exposed to the swell from the German Ocean, yet it is as stable and likely to endure, as if based upon a rock. But the first light-house of this description was erected by Mr. Mitchell in 1839, at the entrance of the sea reach, leading to the town of Fleetwood-on-Wyre; both these light-houses have been previously noticed in the 3rd & 5th volumes of the *Journal*. The stability of both these light-houses shows with what perfect security many descriptions of work may be placed on sub-marine sand-banks, by means of screw-piles; especially as Mr. Mitchell proposed for batteries, in consequence of some observations which fell incidentally from the Duke of Wellington, when giving evidence before the Shipwreck Committee of the House of Commons.

His Grace, while speaking on the subject of harbours of refuge, took occasion to observe, that the extensive application of steam, to maritime purposes, would effect an important change in naval warfare. That persons on the French coast, the sun being at their back, could see more distinctly what was passing in the channel, than could persons on the English side; which, by enabling steam cruisers to seize upon our merchant ships, at the most defenceless points, would, in times of war, seriously affect the trade of London itself; and, on this subject, his Grace concluded by alluding to the possibility of constructing places of defence on the Goodwin Sands, and other banks upon this coast, for the protection of our trade. For the necessity of such works, we have thus the highest military authority. For the purpose of a battery, Mr. Mitchell proposes to render his screw-piles available in the following manner, for a battery of 28 guns:—It is proposed to support it on forty-one malleable iron piles, placed in five parallel rows, the three interior ranges consisting of nine, and the two exterior, of seven piles each,—on the top of these piles an oblong platform is constructed, upon which the battery is formed, with a barrack and a light-house in the centre.

Among the many advantages to be derived from such places of defence, it may be mentioned the perfect practicability of placing them on sub-marine banks, adjacent to wide harbours, roadsteads, or estuaries of rivers, such as the Thames, where, from the absence of high and commanding positions, or even dry ground in their neighbourhood, ships of war constitute the only means of defending our trade, in time of war; the difficulty of which will now be much increased, in consequence of the introduction of steam in the navy. As compared with ships, the risk to such batteries, from hostile attacks, appears trifling; the narrow surface and rounded form of the piles, and each part of the frame-work, rendering it nearly ball proof; for, unless struck in the direct line of the centre, shot would glance off from their curved surface; and, even bar or chain shot could have no effect on the main supports of the building, owing to their great strength and weight.

OBITUARY OF MEMBERS OF THE INSTITUTITION OF CIVIL ENGINEERS.[1]

Professor Wallace.

William Wallace, LL.D., Hon. M. Inst. C. E., late Professor of Mathematics in the University of Edinburgh, was born at Dysart, in the county of Fife, in 1768. From birth, fortune, or education, he derived no advantages whatever, and the eminent station he eventually occupied as a mathematician, was achieved solely by his own industry and love of scientific knowledge, aided by natural talents of a high order. He was appointed, at the age of twenty-six, assistant teacher of mathematics in the academy of Perth. In 1803 he obtained a professorship in the Royal Military College at Great Marlow (afterwards removed to Sandhurst); and in 1819, upon the death of Mr. Playfair, and the removal of Mr. Leslie to the chair of Natural Philosophy, he was elected professor of mathematics in the University of Edinburgh. His pursuits and studies were chiefly connected with abstract mathematics, but some of the subjects to which he directed his attention may be here noticed, as having more immediate reference to the objects of this Institution.

The Eidograph, an instrument for making reduced copies of drawings, which he invented about the year 1821, and exhibited at a meeting of the Institution in 1839, is considered superior in many respects to the Pentogragh. It possesses greater smoothness and flexibility of motion, and while the copies may be reduced or enlarged in any proportion, their similarity to the original is preserved with geometrical precision. By a particular modification, the instrument is made not only to reduce, but to reverse the copies, whereby it is rendered peculiarly applicable to the purposes of the engraver.

Among the papers which he contributed to the "Transactions of the Royal Society of Edinburgh," there is one on the subject of curves of equilibration, which is interesting to us on account of its connexion with the theory of suspension bridges. From the development of a certain functional equation, he deduces series for computing the co-ordinates of the catenary, and gives tables of the corresponding values of the co-ordinates so computed; thus furnishing engineers with a ready means of constructing arches having the forms of equilibrated curves.

Professor Wallace obtained a high reputation, as a mathematician, at an early age, and during his whole life he laboured assiduously to extend and facilitate the study of his favourite science. Besides his contributions to the

1 From the Annual Report of the Institute.

memoirs of scientific societies (chiefly the Royal Society of Edinburgh), he was the author of nearly the whole of the articles on pure mathematics in the fourth and subsequent editions of the "Encyclopædia Britannica," and likewise of the greater part of those in Brewster's "Edinburgh Encyclopædia." His health having given way so far as to render him unable to discharge his duties in the University, he resigned his chair in 1838. During the remainder of his life, although an invalid, his scientific ardour suffered no abatement, for while confined to his chamber, he composed the memoir on equilibrated curves, as well as a work intituled "Geometrical Theorems and Analytical Formulæ," which was published in 1839. His disposition was amiable and benevolent; he was beloved by his friends, and respected by his fellow-citizens; and he died, universally regretted, at Edinburgh, on the 28th of April, 1843, in his seventy-fifth year.

Mr. Buddle.

Mr. John Buddle, M. Inst. C. E., was born at Kyo, near Lanchester, in the county of Durham, in 1773, and resided there nearly twenty years, when he removed to Wallseod with his father, who had then attained considerable eminence as a colliery viewer. The elder Mr. Buddle was a man of considerable attainments in mathematics; he was a correspondent of Hutton, Emerson, and other eminent men, and contributed many papers to the scientific publications of that period. He was remarkable for the systematic manner in which he conducted his professional avocations; and to him we are indebted for the introduction of iron tubbing for sinking shafts, which, it is believed, was first used at the Wallsend colliery.

At an early age Mr. John Buddle evinced an attachment for active occupation, and an eager pursuit of experimental knowledge. These studies and pursuits were encouraged by his father, from whom he derived nearly the whole of his education, having only been at school during one year when very young. He became very early the assistant of his father as a colliery viewer; and on one occasion, when, as usual in cases of emergency, the viewers of different collieries were called together, to consult on the means of stopping an extensive fire of gas in the Washington pits, he suggested the trial of a jet of water moved rapidly, alternately, across the flame, in the same manner as in his boyish experiments he had cut off the flame of gas with a knife: the plan was adopted, and being carried into effect by himself, was perfectly successful. After the death of the elder Mr. Buddle, his son succeeded him in the management of the Wallsend colliery, and there, in 1810, he introduced those extensive improvements in ventilation which have been so much imitated.[2] He was engaged as the viewer and consulting engineer of a number of the principal collieries in the North of England. His experience in all the details of the coal trade led to his being frequently examined as a witness in Parliamentary Committees; and he was also employed as consulting engineer on railways and general engineering questions. In 1838 he was appointed one of the Dean Forest Mining Commissioners, and his tact and experience materially aided in the successful completion of their labours. As he advanced in life he became the proprietor of coal mines, as well as of landed, shipping, and other property, which, under prudent management, produced a considerable income; indeed, when it is remembered that he was a bachelor, and that his habits were very simple, it is surprising that he did not accumulate greater wealth. He was very liberal, and his charities were extensive. He took great interest in the local scientific societies, and, even amidst his numerous engagements, found time to communicate to them some valuable papers. To all who have visited the coal-mines of the North of England, or have taken any interest in the history of coal-mining, the name of Mr. John Buddle is familiar. He was active, steady, and unremitting in the discharge of duties which were attended at all times with much personal fatigue, and frequently with imminent danger. He was extremely exact in his extensive correspondence, and kept a diary, which may probably furnish materials for a detailed and useful memoir. In private life he was distinguished by many excellent qualities and social virtues. Among other accomplishments he was a superior musician; and his retentive memory, and happy mode of explaining and illustrating his subject, rendered him as agreeable a companion as he was a valuable friend. His habits were extremely simple, but his house for nearly half a century was the resort of most of the scientific strangers who visited the North of England, and his hospitality was unbounded. Whether viewed in his professional or private character, he has left solid claims to admiration and esteem, and his death may justly be regarded as a public loss. He died on the 10th of October, 1843, at the age of seventy years, and was interred in the ground which he had given for a cemetery, and where a church had been erected, on his estate at Benwell, near Newcastle.

Mr. Penn.

Mr. John Penn, M. Inst. C. E., was born near Taunton, in Somersetshire, in the year 1770, and was apprenticed to a millwright at Bridgewater, whence he travelled to Bristol, and worked there as an operative; he soon became the foreman of an important work, when only twenty-two years of age, and was celebrated for his theoretical and practical knowledge of the forms of the teeth of wheels, which branch of construction was, at that period, only imperfectly understood by mechanics. He removed to London about the year 1793, and after working at and being a foreman in several works, he commenced business on his own account in 1801. His attention was at first chiefly directed to the construction of flour-mills, in which he made many improvements, particularly in the substitution of metal, for wood framing. In consequence of the injudicious proceedings of the Millwright's Union, he was induced to oppose a determined resistance to their demands, and by the introduction of self-acting tools, and the instructions given by him to another class of workmen, the millwrights lost many of the privileges they had previously enjoyed. The tread-mills for prisons[3] were first constructed at Mr. Penn's works, and latterly he (in conjunction with his son) manufactured many marine engines, particularly those with oscillating cylinders.[4] Mr. Penn was well versed in general science; he was an amateur astronomer, and possessed some valuable instruments; much of his leisure time was devoted to horticultural pursuits, which led to several improvements in the methods of heating conservatories and forcing houses. He died suddenly on the 6th June, 1843, in the 73rd year of his age, having enjoyed for many years the confidence and esteem of a large circle of friends.

Mr. Aher.

Mr. David Aher, M. Inst. C. E., was born in the year 1780; he attained very early a proficiency in physical science, and at fifteen years of age commenced his studies as a civil engineer. In 1803, he surveyed and superintended several of the works of the Grand Canal Company (Ireland), and subsequently directed the collieries in the County Kilkenny and Queen's County, an occupation for which he was well suited, from his knowledge of geology, a science at that time but little cultivated in Ireland. By his judicious direction of borings and other trials, discoveries were made which have proved very valuable to the neighbouring coal proprietors. His inventions and improvements in mining and boring machinery (which have been generally adopted), are remarkable for the mechanical ingenuity displayed in them, for the simplicity of their construction, and for their practical utility. In the years 1810, 1811, and 1812, he was engaged in making experiments and reports for the Commissioners appointed by Government, to inquire into the nature and extent of the "Bogs in Ireland, and their capability of being made available for cultivation, or other purposes." While engaged in the direction of the collieries, he laid out nearly all the new lines of road which have been made through the County Kilkenny and neighbourhood, and also the Great Leinster and Munster Railway, from Dublin to Cork, by Kilkenny, Clonmel, Cahir, &c. In 1840 he met with some disappointments and losses, which weighed heavily on his mind, and were the principal cause of the illness which terminated his life. He died in the 62nd year of his age, respected for his high professional attainments and strict integrity of character, and regretted by all who knew him.

Mr. Ranson.

Mr. Robert Gill Ranson, Assoc. Inst. C. E., was a manufacturer of paper at Ipswich in 1810 he introduced an improved mode of sizing and drying machine-made paper, substituting for the ordinary tedious process of tub-sizing (in which it was requisite that the paper should be previously cut into sheets), a method by which he was enabled to size and dry writing or drawing papers, in the lengths made by Fourdrinier's machine: by this process, the time occupied in the manufacture was reduced, and the uncertainty of the effect of the weather in drying was avoided. In consequence of a long illness, preceding his decease, this invention was not extensively carried out, but it appears now probable that it will be generally adopted. Mr. Ranson only became an Associate of the Institution in 1842, but he demonstrated the interest he felt in its welfare, by exhibiting at the President's conversazione a sheet of drawing paper 400 feet in length, which had been completed by his process from the state of rags, in the short space of 48 hours. He was highly respected by his friends, and his decease, at the age of 51 years, was much regretted.

---

2 The Museum of Economic Geology, Craig's Court, contains a model which exemplifies this system of ventilation.

3 Designed by Mr. William Cubitt, V.P. in 1818.

4 First patented by Mr. Aaron Manby, in 1816.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

Feb. 6.—The President in the Chair.

The first paper read was by Mr. S. B. Moody; it described "*a water wheel,*" constructed by Mr. W. Fairbairn, from the designs of Mr. B. Albano, and erected at the Flax Mills in Lombardy. The chief peculiarities of this wheel consisted in the introduction of the tension principle for the arms and the ventilation principle for the buckets. The use of wrought iron bars as arms and braces on the tension principle, diminished the weight, as fewer centres and arms were required, and consequently a lighter shaft could also be employed; repairs were less frequent, and also were not so expensive as with cast iron arms. In the old form of the buckets, the air entering with the water prevented them from filling, but, by the introduction of an inner sheathing, forming a space between it and the sole plate, the air was permitted to pass off freely, and the buckets, being thus ventilated, were enabled to be more completely filled, and the effective power of the wheel was increased. Mr. Albano explained its construction, and stated its speed was about 6 ft. per second; and that the useful effect obtained was equal to $\frac{6}{10}$ths. of the power expended, which was higher than many of the best wheels had attained; he then described a very ingenious adaptation of the balance weight governor for the penstock, for regulating the flow of the water to the wheel.

A description of *a Water-meter*, by Mr. P. Carmichael was then read. The mode of operation of this meter, which was attached to the feed pumps of three steam boilers supplying an 80 horse engine, was thus described: as the water proceeds through the discharge valve, the float sinks until it comes in contact with a detent or catch attached to a rod, which is suspended from a lever, this moves round a spanner and pendulum, until it passes the centre of gravity, when the pendulum falls and strikes a spanner, which shuts the discharge valve and opens the inlet valve from the reservoir to the closed box which supplies the boiler; a dial, the hand of which was acted upon by the spanner, indicated the number of times of the emptying of the reservoir, and it was stated that the action of the reservoir was very correct.

Dr. Roth's *Automaton* calculator was exhibited, and its action explained by Mr. Wertheimber. He gave a short review of the various attempts at constructing calculating machines, noticing the Roman Abacus, the calculating boxes of the Chinese and Russians; the several classes of instruments invented by Napier in 1617, by Perrault and others in 1720, and subsequently; the slide rule invented by Michael Scheffelt of Ulm, in 1699; the more important machines attempted by Pascal in 1640, by Moreland in 1673, by Gersten and by Leibnitz, which were submitted to the Royal Society of London, and the Académie des Sciences in Paris: he then mentioned the machine of Mr. Babbage, upon which upwards of £20,000 had been expended before the project was abandoned, and the finished part, which formed tables of progression up to five figures, was consigned to the museum of King's College, London. Dr. Roth's machine appeared very simple, and its results, which were severally tested, were very accurate; it performed all the operations of arithmetic from simple addition, subtraction, multiplication, and division of numbers, or of pounds, shillings, and pence to vulgar and decimal fractions, involution and evolution, and arithmetical and geometrical progression: it appeared particularly adapted for checking long calculations of quantities, for contractors, for the merchant's counting house, or for government offices. The same principle had been adopted as counters for rotary or reciprocating machines, and they appeared from the compactness of their form and their regularity of action to be well adapted for the purpose.

ACADEMY OF SCIENCES, PARIS.

Jan. 2.—The first business of the evening was the election of officers. M. Charles Dupin was elected President, and M. Elie de Beaumont, Vice-President.

M. Hombron, surgeon to the last expedition of M. Dumont-d'Urville, read a paper "*On the Topography of the Austral Frozen Region.*"

M. Morren communicated the results of some experiments on the variations in the composition of air dissolved in sea-water at different hours of the day and in different seasons of the year.

The next paper read was a communication from M. Collegno, "*On the Character of the Italian Alps.*"

Jan. 8.—A paper, by M. Francois, was read, "*On Lights for Lighthouses.*" That gentleman has succeeded in manufacturing lenses of much greater power than any before known; so powerful is their illuminating property, that from an experiment made at the Observatory at Paris, it was proved that a revolving lamp of four wicks gave a light equal to 140 Carcel lamps, while the oil used was only 700 grammes ($1\frac{1}{2}$ lb.)—a single Carcel lamp consuming 42 grammes. M. Arago observed, in respect to this invention, that an order had been received for their application in England.

Jan. 15.—M. Arago made a further communication respecting the comet discovered by M. Faye, from which it appears that it is a periodical, having a revolution of six years and 200 days.

Papers were read from M. Milne Edwards relative to the organization of various non-vertebrated animals of the coasts of the Channel; by M. Bonjean, on the effects of the ergot in rye; and by M. Robinet, on the formation of silk by the silk-worm.

Jan. 22.—On this day were announced the rewards awarded by the committee of the Academy as follows—to MM. Stromeyer and Dieffenbach, for having conceived and performed the operation of strabism upon dead bodies, and for having been first to practise it with success on the living subject, 6000fr.; to MM. Bourgeray and Jacob, for their work on anatomy, 5000fr.; to Dr. Thibert, for his specimens of artificial anatomy, 4000fr.; to Dr. Longet, for his work on anatomy, 3000fr.; and to Dr. Valleix, for his treatise on neuralgia, 2000fr.—M. Frémy read a paper on metallic acids.

M. Biot presented to the Academy his articles in the *Journal des Savans* "*On the History of Observative Astronomy relative to the Theory of the Moon.*" He observes, that the Arab treatise of Abul Wefa, said to contain the discovery of the variation, has not the slightest reference to it, and that the supposed passage is nearly a literal translation from Ptolemy, relative to the second element of the crection.

M. De Gasparin read a paper "*On the Flooding of the Rhone,*" which he considered not as attributable to clearing the wood from the mountains and the elevation of the bed of the river, which he recognised as secondary causes, but to a meteorological phenomenon, arising from the deposition of rain by the south and south-east winds. This evil, he avers, is irremediable, but he recommends all engineering measures of defence to be adopted.

M. Chevandier read a paper "*On the Cultivation of Forest Timber.*"

Jan. 29.—M. Chaussenot's Safety Valves were again brought before the Academy, being now adopted in several places.

M. Morin made some observations on steam engines, from experiments made with Watt's steam pressure indicator. He considered from the examination of the curves made by the indicator—1st. That notwithstanding the various modes of communicating motion to the distributive valves, the pressure which takes place in the cylinder during the admission of the steam, is sensibly constant, and that to obtain this constant pressure from the beginning of the piston stroke, it is sufficient to give a little advance to the admission of the steam. 2nd. That in well-proportioned engines, in which the orifices, tubes, &c. have a sectional area of about $\frac{1}{25}$th of the piston in low-pressure engines, and $\frac{1}{18}$th to $\frac{1}{20}$th or less in high-pressure engines worked expansively, the pressure in the cylinder differs a little from that in the boiler. 3rd. That it is essential by regulation of the slide valves, to give a certain advance to the emission of the steam, in order to diminish the resisting pressure from the beginning of the stroke.

A paper was read by M. Eugène Chevandier, on the elements of the composition of the various woods grown in France, and the annual average produce of hectare ($2\frac{1}{2}$ English acres) of forest land.

M. Raulin, vice-secretary of the Geological Society of France, read a paper on the opinion of M. Marcel de Serres, that native mercury is not to be found in more recent strata than the red granite, and that there does not exist in the Aveyron any native mercury analogous to that of Idria.

A communication was read from M. Duchartre, on an *exhausted volcano* near Beziers, on the *Rocque-Haute*. He states that the crater is perfectly distinct, and can only account for its not having been mentioned in any of the recent works of geology by supposing that the wood with which the plateau of *Rocque-Haute* is crowned has caused it to escape notice.

A communication was read from M. Micallet, a physician of Malta, on the surprising effects of the sesquiodine of mercury in ulcerations of the cornea, particularly with scrofulous patients.

A communication was read from M. d'Hombres Firmas, on the electrometer of M. Majocci, of Milan. The writer states, that with this instrument the nature of every kind of electrical current may be fully ascertained.

NOTES OF THE WEEK.

It will be seen that it is in contemplation to hold a meeting at the Horticultural Society's Room in Regent Street, on Saturday, 17th inst., to adopt some measures for rewarding the public services of the late Mr. Loudon, and for securing the unincumbered possession of his works to his family. Upon his services to architecture by the foundation and conduct of the Architectural Magazine, during a number of years, it is unnecessary for us to enlarge, nor upon his valuable contributions to architectural literature by the publications of the Encyclopædia of Architecture, Repton's Landscape Gardening, Suburban Gardener, and his numerous works relative to architecture and landscape gardening. For careful observation. conscientious and laborious compilation, and minute completeness, no works have exceeded those to which we have just referred, and we beg to urge most strongly such of our readers as have not the whole of his works, to take the present opportunity of purchasing such as they may require, as indispensable to the formation of a truly useful professional library, while they will at the same time have the pleasure of knowing that they have paid a tribute due to a zealous and badly remunerated labourer for the public weal, and contributed to the comfort and welfare of a lady, scarce less deserving on her own account than as Mr. Loudon's representative.

The imposing façade of the Palais Saint Pierre, on the Place des Terreaux, at Lyons, is about to receive additions in the shape of a pavilion at each wing, similar to those in the centre. Each pavilion will be united to that of the centre by the erection of four colossal statues on the capitals of the pilasters which adorn the façade. This work is at the expence of a private person, a citizen of Lyons, and will prove a munificent public gift. A statue of the Virgin, by M. Auguste Préault, is about to be placed in the Ursuline Convent at Nogent sur Seine.—The French have sent 200 convicts to Stora to construct a wharf and road, and to restore the ancient Roman aqueducts.—The hotel Lambert, in the Isle of St. Louis, at Paris, a monument in the Louis Quatorze style, has been restored at the expence of the Princess Czartoriska. The ceilings are by Lebrun and Lesueur.

The parish church of Klosternburg at Vienna, and several houses have been destroyed by lightning.

The painter Margenstern, son of the perspective painter of that name, died at Frankfort on the 21st ult., aged 66.—The Goethe monument, at Frankfort, by Schwanthaler, is to be erected on the place of the theatre. This sculptor has also completed a colossal statue in brass, of the Margrave Frederick of Bayreuth, who founded Erlangen University.

Barberi, the mosaicist at Rome, has executed for Viscount Middleton, a restoration of the celebrated Pompeian mosaic, supposed to be a battle of Alexander and Darius.

The king of Prussia has restored the castle of Stolzenfels, on the Rhine.

St. Paul's church, at Auckland, in New Zealand, is completed, and a small church is to be erected at Windsor.

The lightning conductors for the Royal Exchange have been arranged under the direction of Mr. C. Walker, the able secrerary of the London Electrical Society, and author of the continuation of Dr. Lardner's work on electricity.

The Exposition of Arts and Manufactures at Berlin, was opened on the 24th ult. It belongs to the Trade Union, a society established four and twenty years, reckoning 972 subscribers, and now largely endowed.

The Cologne and Bonn railway is completed. This opens the communication with Antwerp and Ostend.

The General Steam Navigation Company have offered to establish a daily communication between Brighton and Dieppe, if the authorities of Dieppe will go to a little expence in dredging the channel.

The works in Trafalgar Square are, with the exception of the Nelson monument, fast coming to a completion. The stone is all down, the concrete is commenced as well as the bitumen of the Bastenne Company, and when the weather will admit the completion of the concreting, the bitumen paving, which is to cover the whole area around the fountains, will be finished. This will be the largest space so covered in this country, and will form a new feature in our public, as well as private walks. It appears by the works proceeding during the late frost, that there is no fear of any injurious effect from this description of material being laid in winter as well as summer. We hope to be able very shortly to give a plan of the square, describing the terrace and fountains, and also showing how the different stones, bitumen and cement have been used.

The South Eastern Railway was opened on Tuesday throughout to Dover.

AGRICULTURAL CHEMISTRY.

A Course of ten Lectures by Professor Braude, F.R.S., *at the Royal Institution, delivered January 27th. (Specially reported for this Journal.)*

Lecture I.

The Professor commenced by observing that he entered upon this course of lectures with great diffidence and anxiety, and at the same time with a great deal of pleasure—he was aware that the subject of Agricultural Chemistry is one that is attracting a great share of attention, and that it is in the hands of eminent chemists and skilful practical agriculturists; he was also aware that a great deal has been held out as to what chemistry may do, and can do, and will do in this very important subject; upon this subject he would endeavour to bring before his hearers, in plain and intelligent language, the main subject which the agricultural chemist ought to attend to—in fact, the practical agriculturist; because he did not hesitate to say that every farmer—every practical agriculturist, ought to be acquainted with at least the principles of agricultural chemistry.

He entered upon the subject with pleasure, because he was appointed by Sir Humphrey Davy. many years ago, to deliver a course of lectures to the then existing board of agriculture, at the time that he retired from the office of Professor of Agricultural Chemistry to that body. He had still the notes and memoranda which Sir Humphrey gave him upon that occasion, and he looked back to them with much pleasure as containing the germs of almost everything that has been done in agricultural chemistry since that period. The business of the practical farmer is in fact very simple. It is, to raise from a given extent of land the largest quantity of the most valuable produce, and to do that in the most economical way, both as regards time and money, and further in such a manner as permanently to impoverish the soil as little as possible. It is his business to show what aids are derivable from chemistry in reference to the accomplishment of this highly important object. The subject of agricultural chemistry, if we consider it as bearing upon the improvement of land, in its practical, rather than its theoretical, bearing—has now of course become a matter of the greatest importance. Our population increases rapidly upon our territory, and unless means be found to increase the produce of the land, emigration or other difficulties must occur to a great extent; and he thought it was perfectly obvious that a great deal of cultivated land in this country may be brought into a higher state of cultivation, and that a great deal of uncultivated land may be brought into a state of practical cultivation. There is something very extraordinary—though being every day before our eyes, we do not regard it as such, in the growth of a seed.—If we take for instance a seed of turnip, or rape, or wheat, we find that in the course of a certain time, and under particular circumstances, it produces a plant or a tree. Nothing, for example, can be more remarkable than that in the course of a few weeks, a small seed becomes a perfect plant; nothing can be more astonishing, if we look at it in all its details, than that a small acorn in a few years grows into the stately and majestic oak. The question we have to examine into is, "How is all this to be effected?" and to this end it is obvious that we should consider the changes in the seed itself, which is a matter of great importance. We find when the seed is placed in a congenial soil, that it soon expands, and then the germ begins to grow, it puts forth a rootlet, and after a time it makes its way downwards, and the stem makes its way upwards. During these changes there are very curious chemical alterations going on in the constitution of the seed itself, to which he will hereafter call your attention. Here we find that as soon as the young plant has taken such nourishment as it could get from the seed, it becomes dependent upon the soil which contains the root, and upon the atmosphere to which the branches are exposed. From the soil there is a considerable quantity of matter taken, and the leaves also imbibe a considerable quantity from the air. These agents therefore we have to create.

1st. As to the soil—we have to consider it as the mechanical support of the plant, and in this respect the texture of the soil is a matter of importance. Then we find that it derives nourishment from the soil in three ways:—1st. we have to examine the *inorganic* constituents which the soil gives to the plant—and if we take the stem, or the leaves, or any other portion of a plant, it will be found that it contains a quantity of saline, or earthy, or other particles which we call inorganic matter, which it cannot take from the air, and which therefore it must take from the soil. 2nd. There is also a quantity of *organic matter* taken up from the soil—and 3rd. It will be found to be undergoing changes through the influence of the air affecting both itself and the atmosphere.

These are some of the principles to which the learned Professor observed that he should have to revert in reference to the soil.—Next, in reference to the state of the air. Having determined what are the elements of the plant, and which it cannot get from the soil, we must search the air, and having ascertained its constituents, ascertain how far they contribute to the growth of the plant. It is extraordinary, but nevertheless true with regard to plants, that the nourishment they derive from the soil is very insignificant compared with what it obtains from the air. Take an oak for instance, in the course of a certain number of years it will contain perhaps several tons of wood. Now it is quite clear that the oak must have derived this either from the soil or the atmosphere. Has it impoverished the soil?—taken anything from it?—Certainly not; on the contrary, we find that the soil so far from having imparted organic substances, has in fact gained them, and there is an increase of the organic matter in the soil, arising from the shedding of the leaves, or the accidental fall of a branch, &c.—It is obvious then that this great acquisition of matter must have come from the atmosphere.—The atmosphere is a continual source of food to the plant; and as the plant cannot go about like an animal to search for its food, the atmosphere is continually wafting about the plant, and no sooner is the nourishment abstracted from one portion of atmosphere, than a fresh portion brings fresh nourishment which the plant greedily devours,

Without the soil it is true the plant could not get those inorganic constituents to which he has referred. If, for instance, we find in a plant lime, a phosphoric acid, it is clear they must come from the soil; but the carbon, hydrogen, and oxygen come from the atmosphere—not entirely, but principally—and in such quantities as not only enable the tree to grow, but, as he said before, by the shedding of the leaves, &c. to enrich the soil: and we do find actually that by the growth of trees the soil is considerably enriched, as far as organic matter is involved.

Having then examined how far the soil and the air are concerned in these matters, we are next to look at what will be brought before you as the ultimate and proximate elements of a vegetable. By ultimate elements, we mean those actual elementary substances which cannot be decomposed: by proximate elements, their secondary arrangements and results—sugar, starch, gum, &c., and the approximate elements of a vegetable.

Then there is another subject I must bring before you, viz., "What are the functions of the different class of plants?" And lastly, how far mechanical and chemical expedients may be resorted to, to render barren soils fertile, and fertile soils continuously so. We shall find that the roots and the leaves of plants affect peculiar functions—that the roots take up certain matters from the soil, and that the leaves and all the green parts of the plant are energetically employed in taking up an immense quantity of nourishment from the atmosphere, We are all aware of the beautiful provision by which the vegetable is made to take up, as it were, the refuse of animals. We may say that we are deteriorating the air as far as we ourselves are concerned, but we are impuring it for the growth of plants. We are like organs engaged in infusing into the air what is proper for plants, which they take up, thereby again rendering the atmosphere fit for our use.

Under the head of the mechanical and chemical expedients to be resorted to for rendering barren soils fertile, and fertile soils continuously, so we shall of course come to a number of facts connected with the influence of manures and the different operations of tillage. Looking at soils, in the first place they must of course originate in the action of the air, water, heat and light, or of those agents commonly designated under the term of "the weather" upon the earth; and as the different rocks or strata which form the crust of the earth, are some exposed in one place and some in another, giving thereby a different constitution to the soil, we see the important bearing of geological science upon agriculture.

Originally the surface of the earth consisted entirely of hard rocks, which by the influence of moisture and other agents, have gradually become disintegrated and fitted for the growth of plants. It is obvious. therefore, that the nature of the soil must greatly depend upon the character of the rock upon which the soil rests—though not always so. in consequence of the soil from one rock being sometimes carried to a rock of a different description. In examining a geological map we find immense tracts of chalk, red sandstone, limestone, clay, coal, and so on. all of which give rise to different soils; and it is important to consider this branch of the subject, for it explains to us how one system of amelioration which answers in one place, does not succeed in another.

The different strata give rise to what are usually called the different rocks, the term "rock" being usually applied in agriculture to the base on which the sub-soil immediately lies. The sub-soil is the matter supposed to be derived directly from the disintegration of the rock itself: then upon the top of the sub-soil comes the superficial soil, which in its mineral contents will agree with the rock and the subsoil, but which is nevertheless greatly different, in consequence of the animal matter which falls upon it, and the long exposure to the air, moisture, heat and light.

"I propose," says Mr. Brande, "1st. to lay before you a short account of the inorganic constituents of the soil, and endeavour to show how the preponderance of one or other of these constituents gives a different character to the soil—in other words, what is meant by a sandy soil, a clayey soil, a marly soil, a chalky soil, &c. And in reference to these matters, I shall endeavour to limit myself to such an account as presses immediately upon agriculture."

There are four substances usually called earthy bodies which are met with more or less in all fertile soils, and it is highly essential that an agriculturist should be acquainted with their particular characters and peculiarities. They are silica, or siliceous earth; alumina, or aluminous earth; lime, or calcareous earth; and magnesia; all of which are resolved by the chemist in their purest state to the form of a white powder. Chemically speaking, these substances are all metallic oxydes, and not as was formerly supposed, simple bodies. With regard to silica, that very important and abundant ingredient in almost every soil, it has this curious constitution, that it is composed of equal weights of a metallic body and oxygen.

He would have his hearers particularly to bear in mind the following proportions of the four earthy bodies which he had just referred to—all of them consisting of a metal and oxygen, viz.:—

8 parts of oxygen combine with 8 parts of the metal silicium, to form 16 parts of oxyde of silicium, or silica.

8 parts of oxygen combine with 9 of the metal aluminum, to form 17 parts of oxyde of aluminum, or alumina.

8 parts of oxygen combine with 20 of the metal calcium, to form 28 parts of lime.

And 8 parts of oxygen combine with 12 of the metal magnesium, to form 20 parts of magnesia.

The Professor then observed that he would pass through as quickly as he could an outline of the properties of these bodies. To commence with silica Silica exists in nature in a great variety of forms, absolutely, or very nearly pure. We find it in rock crystal quite pure, very nearly so in flint, which contains in addition some slight colouring matter, which we do not perfectly understand, and perhaps about 1 per cent. of foreign matter. If you heat flint, or rock crystal to a red heat, and then plunge it in water, it immediately becomes opaque, and can then be readily rubbed down to a fine powder. Another very abundant source of silica is to be found in the white pebbles which are so often met with in the beds of streams. And we also find a considerable quantity of silica in the form of sand, of which we cannot take a better specimen than the white sand from the western extremity of the Isle of Wight, or from Lynn, in Norfolk. It is a curious fact with regard to sand, if we examine it microscopically, we find it to consist partly of minute crystals, and partly of small rounded particles, so that a part may be regarded as the crystals of flints, and part as small pebbles. It would appear that crystallized sand arises from decomposed granite—granite consisting of three substances, quartz which is afterwards sand, felspar, and mica.

The extraordinary property which strikes us as being very important with regard to silica, is its utter insolubility in water and almost everything else. You may keep even the finest sand you can obtain in water for any length of time, and yet not the smallest portion will be dissolved. Silica, however, does find its way into plants, and into some in considerable quantities—in common straw, for instance, corn, and any grass, we find a great quantity of this insoluble substance; and it becomes a curious question to ascertain how silica is rendered soluble and finds its way into plants. Silica is indeed of the utmost importance to the texture of plants—if we take a stalk of wheat we shall find that it is silica which gives it firmness, enables it to bear the ear in due season, and imparts to it all those properties which belong to the more perfect and better kinds of straw. But though silica is insoluble in water, it is readily soluble in potass, soda, lime, and other alkalis. In some strata we observe silica presented to the roots of plants in a soluble form; but if we dissolve silica in an alkali, and then throw it down again, we find that in some cases it may be thrown down perfectly insoluble and sometimes quite soluble. Sometimes it is taken up in a soluble form and sometimes retained in an insoluble form. No doubt the silica in this wisp of straw *has been* soluble, *now* it is perfectly insoluble in water. Glass is a compound of silica and soda, yet glass is insoluble in water, for we know that it is employed as a vessel for holding water. This arises from the mechanical texture of the glass; for if we rub glass to a fine powder, we find that it does become soluble in water. This application of silica to the soil becomes a very important question; because there is no doubt that certain crops fail, not for the want of silica, because there shall be plenty, but for the want of it in a soluble state. Now some agriculturists actually mix pounded glass, or another substance, which I will show you presently, with their manure, and employ it with great success. If, instead of common glass, they take another compound of silica, viz., glass with more soda, they have a substance which readily dissolves in water. The Lecturer here exhibited a solution—called by the ancients "liquor of flints," and then proceeded to observe, "I can at pleasure separate the silica from it in a particularly soluble, or in a particularly insoluble state." He then proceeded with the following experiment. In a glass containing the "liquor of flints" he added a large quantity of water: and in another glass he had some of the liquor in a more concentrated state. To each of these solutions, he added a little of almost any acid; in the strong solution silica was thrown down in the form of a jelly, and by adding more water he showed that it would not re-dissolve the silica. In the weaker solution no such result was obtained, although he added as much acid as to the other, yet it remained perfectly clear. "In the first state," said Mr. Brande, "I need hardly tell you silica would be perfectly inert in the growth of plants—in the other state it would be readily taken up. We find also, though common glass in its usual state does not appear to be acted upon by the air and water, that it does yield, when acted upon by those agents for a long time. Pieces of glass are often met with in a field of all kinds of colours, and so soft, that they will give way to the nail.

There is another curious agent, which has the power of acting upon silica, and of carrying it at once away, and when he comes to analyze soils, he must show this substance—it is fluoric acid. Now it would appear that we have to consider silica first as a mere mechanical ingredient of the soil—that is, giving to the soil a certain looseness of texture possessed by all sandy soils: and then, also, with reference to the component parts of the crops growing upon the soil.

Another substance to which he adverted, is the argillaceous earth or alumina. It is an ingredient in all fertile soils, and from it they derive some very important properties. In the first place, all clays contain alumina: and he need not advert to the importance of clay in soils, and to the functions which alumina performs in them. It is a very hydrometic substance, that is, it has a great attraction for water, which it absorbs and retains in great quantities. It is the only substance which gives plasticity when mixed with other bodies; and whenever we have a plastic substance, then we have alumina.

Alumina is a most useful ingredient in the soil, provided that it does not exist in excessive quantities; if there be too much of it, it forms that stiff, clayey, unmanageable soil, of which there is so much in England. I must take you to it in its pure state, and we get it out of alum. If we dissolve a quantity of alum in water and add an alkali, we shall throw down alumina in a pure state, or very nearly so.

If we only take 10 or 12 per cent. of alumina, and mix it with silica, we shall find that it will give to it the plastic nature of clay. Indeed, a very small portion of alumina gives plasticity and adhesiveness and other important properties, especially as relates to moisture, in any soil. Like silica, it also forms a component part of the growing crop. Some vegetables cannot grow without alumina; none, perhaps, can grow well without it in the soil: some few actually require it as food. There are certain vines which cannot be cultivated without alumina; in those vines we find alumina composing a certain part of the plant—nay, we find it even in the grape—and even in the wine. The Rhenish wines contain a considerable quantity of alumina; and it is a curious fact, that a quantity of wine was actually stopped at the Custom House some time ago, which it was thought had been adulterated with alum, when, in fact, it contained no more alumina than it had taken up from the soil. Alumina at once differs from silica, in that it is equally soluble in acid and alkali. Another character of alumina is, that it combines with sulphuric acid and potass, and crystallizes very readily; but we have to deal with alumina only in reference to the soil and its agricultural purposes.

AGRICULTURAL CHEMISTRY.

By Professor Brande, F.R.S., &c.

Lecture II.—February 3, 1844.

(Specially reported for this Journal.)

The next most important constituent of the soil is lime. Now lime is found in nature in various states of combinatinn, but principally either as carbonate, phosphate, or sulphate. As carbonate it exists in most fertile soils. It is added, also, largely to fields as a fertilizing agent. But for this purpose it is not used in combination, but in a free state, as caustic or quick lime, in which condition it is obtained by exposing limestone rocks, which are carbonate of lime, to a strong heat in properly constructed kilns; this drives off its carbonic acid, and reduces it to the state of pure lime. If chalk, for instance, is heated, water first escapes, then carbonic acid, and the heat should be continued till it ceases to lose weight. As the limestones are not all pure, but are mixed with other ingredients, so the resulting lime is of different qualities, and receives various names, such as hydraulic lime, fat lime, and meagre lime, each being adapted for some particular object, some being used largely in mortars and cements. In lime-burning there are several circumstances that must be attended to, or success will not be obtained; one is, that the proper degree of heat be maintained, another, that a good current of air be kept up. It has been found, by the experiments of Sir James Hall and others, that when carbonates of lime are heated to the most intense heat in closed vessels, only a part of the carbonic acid escapes; indeed, they have shown, that if heated under pressure, none of the gas escapes from it, but that it is converted into a semi-crystalline mass resembling marble; in fact, it is supposed that in this manner marble has been formed in nature, by the intense heat of streams of volcanic lava acting on the chalk whilst imbedded beneath other strata, the pressure not allowing the gas to escape, and during its slow cooling assuming a crystalline arrangement. Hence we see the importance of constructing the kiln so as to allow a good current of air to carry off the carbonic acid as fast as liberated; which is also assisted by the steam produced from the moisture in the chalk. Now the change of quality produced by this burning, was by the old chemists, and is even by many of the unscientific agriculturists of the present day, attributed to something that it abstracts from the fire, and hence, say they, its caustic quality. But Dr. Black showed, long ago, that such was not the case. He found that when 50 lb. of pure chalk were converted into lime, it only weighed 28 lb., hence 22 lb. had passed off as an invisible gas, which by further experiments was proved to be carbonic acid, and the remaining 28 lb. of lime has been shown by Sir H. Davy, to consist of 20 lb. of a metal which he named calcium, together with 8 lb. of oxygen gas, forming oxide of calcium, or lime. Hence the composition of pure carbonate of lime may be represented thus:—

$$50 \text{ carbonate of lime}\begin{cases}\text{carbonic acid}\begin{cases}\text{carbon} \ldots & 6\\ 2\ \text{oxygen} & 16\end{cases}\\ \text{lime} \ \ldots \ \ldots \begin{cases}\text{calcium} \ . & 20\\ \text{oxygen} \ldots & 8\end{cases}\end{cases}$$

$$\overline{\quad 50 \quad}$$

When lime is exposed to the air it crumbles down into a fine powder, and if then examined it will be found to have combined with water from the air and become what is termed slaked. The same effect may be produced by pouring water on to lime. By taking a portion of fresh lime and pouring water on it, it will be observed to swell considerably, and to become very hot, sufficiently so even to char wood and to fire gunpowder, at the same time falling into a dry powder, which weighs much more than it did originally, every 28 lb. of lime having combined with 9 lb. of water, forming 37 lb. of hydrate of lime or slaked lime. If left longer exposed, it is found then to combine with the carbonic acid always present in the air, parting again with the water, and returning to the state from which it set out, of carbonate of lime.

There are other methods of getting the carbonic acid from a carbonate than by heat. If to 1,000 grains of chalk, an acid be added which has a stronger attraction for the lime, the carbonic acid will be set free, and may be collected as gas in a glass vessel inverted over water. This is the ordinary method of obtaining carbonic acid for experiment. But the lime in this case is not obtained pure, as it combines with the acid employed. Then if an equal weight of chalk be heated so as to drive off, in that manner, all its carbonic acid, and then placed in the glass vessel full of gas, it will be found that after a time the water will rise in the glass, showing that the lime is absorbing the gas, and again becoming carbonate.

Lime is soluble in water, and although it requires 800 times its weight of water to dissolve it, the solution will exhibit most of the properties of lime. It strongly reddens turmeric test paper, showing that it is alkaline: it absorbs carbonic acid from the air, the surface becoming covered with a crust of chalk: added in excess to rain or river water, it produces a cloudiness, proving that they contain carbonic acid; but if the water containing the carbonic acid is in excess, the carbonate first formed is redissolved, on account of the formation of the very soluble bi-carbonate of lime. To this latter property is owing a beautiful appearance frequently met with in limestone districts; the rain, falling on the surface, becomes impregnated with carbonic acid from the soil, and then filtering through some crevice in the limestone, renders some of it soluble; it then, perhaps, finds an outlet at the roof of a cavern, and here, being exposed to the air, parts with the extra quantity of carbonic acid, depositing the insoluble carbonate of lime, which first encrusts the roof, then by constant dripping, forms a series of beautiful crystalline icicles termed stactalites, the remainder falling on the floor, forms large stony masses termed stalagmites.

The consideration of these properties of quick lime will explain its utility when added to the soil. Its first action when strewn on the field, is to absorb moisture, to swell considerably, thereby loosening the texture of the soil—then, when acted on by rain, to form a solution which is destructive to animal life, killing all grubs and worms—when brought in contact with organic matter, to decompose it, which may be illustrated by mixing sawdust, lime and water into a paste, when it becomes dark brown, evolving carbonic acid—to decompose salts of alumina and iron which might be pernicious to the young plant—and, ultimately, by uniting with carbonic acid, to diffuse carbonate of lime through the soil in a finer state of division than it can be obtained in by other processes. One of the uses of lime which has till lately been overlooked, because taking place more slowly, is the property it has of disintegrating several kinds of rock, such as felspar, clay slate, and mica slate, setting free their alkali, which is highly necessary for vegetation. This accounts for the power attributed to lime, by many agriculturists, of awakening the dormant energies of some soils, bringing them, in the course of four or five years, into excellent condition.

The tests for lime are few and simple. In limestones, the application of an acid causes effervescence, as it generally exists in the state of carbonate. In river water, such, for instance, as the Thames, it exists as carbonate, and on boiling, is deposited, as is evident by the fur which accumulates in kettles. In spring water, so that it is not too near the chalk, in our blue clay, for instance, it is found as sulphate. Oxalate of ammonia is a very delicate test for the presence of lime in solution, causing turbidness even when a very minute portion is present. Ammonia causes no precipitate in solutions of lime, and is therefore useful, in analysing soils, in order to remove first those substances which *are* precipitated by it, and then the addition of carbonate of ammonia will throw down the lime.

A fourth ingredient of the soil is magnesia, which though not in so great quantity as the former, is still important This is found as carbonate in some limestones, which are then termed dolomites, or magnesian limestones. They are very excellent for building purposes, being very strong and durable, and were highly recommended by the Commission appointed to select stones for the Houses of Parliament. A curious point in their history relates to their use as manure, in Yorkshire, where they abound. It was found that when burnt for lime, they killed the young plant. Now this is owing to the fact that the carbonate of magnesia, when burnt, is reduced to the caustic state, or pure magnesia, similar to the lime; also, where strewn on the soil, it absorbs carbonic acid, but so much more slowly than the lime, that when the young plant shoots up, it still retains its causticity, and destroys it. This difficulty is, by careful management, got over, and it is now much used. Magnesia is found as pure carbonate in some parts of Asia and America. It is also a constituent of the serpentine rocks of Cornwall, and forms a large part of steatite, augite, hornblende, and meerschaum. Many of these are characterised by a peculiar greasy feel, hence steatite is well known by the name of soap stone. It is also abundant in sea water; when the salt has been crystallized from it, it imparts a very bitter taste to the residue, which, on that account, is termed bittern. From this it is separated in large quantities and used in medicine as Epsom salts, or sulphate of magnesia. Pure magnesia is almost tasteless, but possesses a slight reddening power on test paper; it is therefore an alkaline earth From solutions of magnesian salts, carbonate of potash throws down the insoluble carbonate of magnesia, which bears the same relation to pure magnesia that chalk does to lime. Carbonate of ammonia does not produce any precipitate, which may therefore be used to separate lime from magnesia; but if to the mixture phosphoric acid be added, a precipitate is slowly deposited, which is therefore a very characteristic test for magnesia.

To these four earths, which are all metallic oxides, may be added, as a common ingredient of the soil, oxide of iron. There are two oxides of iron, the red, which is insoluble and consequently harmless, and the black, which is very noxious. Both of these frequently impart colour to soils. The one is commonly known as rust of iron, the other, as slag. Dissolved in acids, and lime or ammonia added, the respective oxides are precipitated combined with water, as hydrates. But the lower or black oxide has always a strong tendency to pass into the higher state of oxidation, even by exposure to air. This may often be seen in ferruginous springs, which at their source are quite clear, but as they flow along, the protoxide of iron is converted into the peroxide, and is deposited on the banks as an insoluble red powder. The best tests whereby to recognise iron are striking and delicate. One of the best is a solution of any astringent matter, green tea for instance, but a solution of galls is best, which changes it to a dark purple, forming, indeed, ink. It is on this account that spring water, which frequently contains iron, spoils tea. Prussiate of potash, also, may be used, which gives a dark blue, which is Prussian blue.

These are the principal constituents of the soil. But there are other substances also present, which, though only in minute quantity, and once overlooked as unimportant, are now considered to be of vital consequence to plants, and which will be considered in the next lecture.

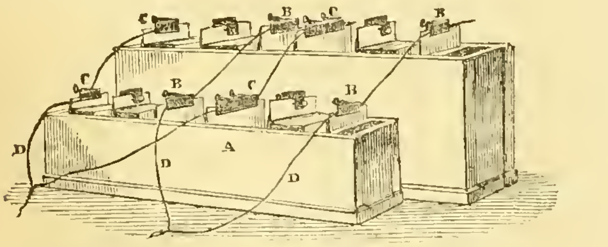
ELECTRO-METALLURGY.

The importance of the recent discoveries in electro-magnetism, have in no instance been more completely shown, than in their applications to metallic productions. The application of electro-magnetic power for plating, emanates from Mr. Spencer, of Liverpool, who was so shamefully used by the British Association. The Messrs. Elkington had, however, long before taken out patents for plating, although on other grounds. They subsequently made experiments with regard to the use of electro-magnetism in gilding and silvering, and the result has been several valuable processes of manufacture. From a very interesting little work, published by Messrs. Elkington, we extract the following descriptions:—

Galvanic Battery.—In speaking of the discovery of this Art, we have been led to describe what a Galvanic Battery is. Many different arrangements of battery have been suggested, all more or less valuable, according to the particular object for which the arrangement is required, but we do not think it important to notice them.

In Electro-Metallurgy there are two distinct states (if such an expression may be allowed) of galvanism or electricity, viz., electricity in its condition of *quantity*, and *intensity*, and as it will be necessary to quote these terms, we shall endeavour to explain them.

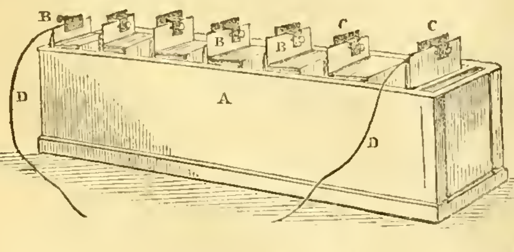
The *quantity* of electricity generated in a battery, is in proportion to the surface of zinc exposed to the exciting fluid, whether such consist of one or more pairs of plates; but if more than one pair be used, then the zinc of the first pair must be connected with the zinc of the second pair, and the copper with the copper; and thus the quantity may be increased as the numbers of pairs are augmented.



A, Battery Trough. B, Zinc Plates. C, Copper Plates. D, Connecting Wires.

Intensity is necessary when, from the nature of the solutions, or from any other cause, there is a resistance to be overcome; the electricity requiring *intensity* or power to force its way through, but the amount of metal deposited, depends wholly upon the *quantity* of the battery, and not upon the *intensity*.

Intensity is produced by arranging two or more pairs of plates, by connecting the zinc of the one pair with the *copper* of the next pair, and so on to any number of pairs—any number thus connected, forming a battery equal in *quantity* to one pair of plates only.



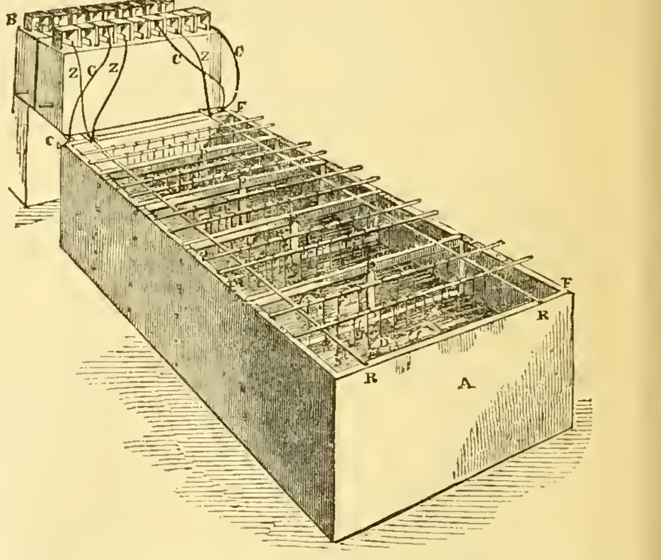
A, Battery Trough. B, Copper Plates. C, Zinc Plates. D, Connecting Wires,

With this knowledge a battery of several pairs of plates may be arranged so as to produce both the *quantity* and *intensity* required.

Metallic Salts.—All ordinary metals have the power of combining with other substances, forming compounds, capable of being dissolved, and held in solution by acids and certain alkalies; thus, for example:—When pure silver is put into pure nitric acid and heated, the metal is rapidly dissolved, forming the nitrate of the oxide of silver, or, as commonly designated, the nitrate of silver, and this may be held in solution in water. In forming a metallic salt for the purpose of electro-deposition, one general rule holds good in all cases, and may be considered a law (and if this law is attended to, no difficulty whatever *can* exist in electro-depositing); and this is, that the metal dissolved in acid or other solvent must have a *greater* affinity for such solvent, than the metallic article to be coated with the metal thus held in solution—for this simple reason, that if the article to be coated has a *greater* affinity for the solvent than the metal held in solution, a chemical substitution (preceding the galvanic action) takes place; the acid in preference combining with the metal, for which it has the greatest affinity, forming an oxide upon its surface, which oxide intervenes between the article and the metal deposited upon it. Such failures therefore as have taken place in electro-depositing have not been the result of any defect in the principle, but from want of knowledge in the operator, and principally from ignorance of the law just stated. For this reason the nitrate of silver cannot be used; the nitric acid having a stronger affinity for most *other* metals than for silver; another and better solvent therefore must be obtained, and this will be spoken of under the metal, silver.

Operation.—In proceeding to plate metals, it is necessary that the battery should be so arranged, that the *quantity* of electricity generated, should correspond with the surface of the articles to be coated, and the *intensity* should bear reference to the state of the solutions; that is, that the *quantity* should be sufficient to give the required coating of metal in a given time, and the *intensity* such as to drive the electricity through the solution to the articles. It is also essential that the plates of metal forming the positive pole in the solution, should be of corresponding surface to the articles to be coated, and face them on both sides.

Having procured the metallic salt best adapted for the purpose, the same is placed in an appropriate vessel, the articles to be coated are then suspended in the solution from wires attached to metallic rods, which cross the vessel at intervals, and which are connected with the zinc or negative terminal of the galvanic battery by means of long rods, placed longitudinally upon the vessel; plates of the same metal as that held in the solution are then placed therein upon either side of the articles; and connected with the positive or copper terminal of the same battery, by means of a slip of copper, fixed upon the edge of the vessel.



A, Vat or vessel containing the solution. B, Battery with Zinc pole Z, connected with rods RR; and Copper pole C, connected with the metallic sheets PP, in the solution; by means of the Copper slip F; DD, are articles suspended in the solution by wires from the rods RR; S, the solution.

The particular arrangement of battery shown in the above sketch we find the most useful in practice. The coppers being continued above the zincs instead of below, prevents their being affected by the mercury, which amalgamates the zinc. The plates also resting upon a shelf a few inches above the bottom of the trough, are always in contact with the least saturated portion of the exciting fluid, the sulphate of zinc formed, being specifically heavier, falls to the bottom.

So soon as the articles, which are connected with the negative pole of the battery, and the metallic sheets with the positive, are both immersed in the solution, the galvanic circuit is completed. The metal held in solution and the solvent combined originally from being in different electrical states, the metal being positive, and the solvent negative. When the galvanic circuit is completed, the solution becomes a part of that circuit: the electricity then passing through the solution decomposes it, the positive element—the metal going to the negative pole, which is the article ; and the negative element—the solvent—passing to the positive pole, which is the plate of metal suspended in the solution, with which it combines. So that for every atom of metal attracted to the negative pole, a corresponding atom is dissolved from the positive, and the solution is maintained in the same state.

In proceeding to plate an article by the electro-process, great care should be taken that it is free from all grease and oxide ; for this purpose the first operation is to boil it in a solution of caustic alkali, by which any grease is saponified; it is then scoured with sand and water, after which it is dipped into dilute acid, which removes any oxide that may be on the surface; after rincing in water, it may be placed in the solution. It is sometimes well, before placing the article in the solution, to dip it into a dilute solution of the nitrate or cyanide of mercury, and this may be found necessary when the metal to be operated upon has an affinity for the solvent of the solution used.

It is generally believed that metals deposited by electricity are necessarily *soft*, because pure, but this is not a consequent: from experiments we have frequently made, it appears that the hardness of the deposited metal varies with the intensity of the battery; a battery of three or four pairs intensity producing silver sufficiently hard to scratch ordinary sheet silver, whilst sheet silver will not scratch it. When the intensity of twelve or fourteen pairs of plates is used, the hardness is so great that burnishing with a steel tool fails in producing a polish upon it.

Metals deposited.—The following metals have been deposited by Messrs Elkington by the electro-process—gold, platinum, silver, copper, zinc, antimony, arsenic, bismuth, nickel, cobalt, palladium, titanium, cadmium, lead, and tin ; those which are principally adapted to manufacturing purposes are gold, silver, copper, and zinc : and upon these we shall make a few remarks, pointing out the peculiar adaptation of the electro-process to their use.

Gold.—Cyanide of potassium is the salt we prefer for dissolving this metal for electro-depositing, it is obtained by fusing eight parts of dry ferro-cyanide of potassium with three parts of carbonate of potash. The gilding solution may be prepared by placing sheets of gold in a solution of pure cyanide of potassium, and attaching to the negative pole of a galvanic battery a small plate of gold, and to the positive a much larger plate ; when but a small quantity of solution is required, this method answers very well, and makes a pure solution ; but when a large quantity is wanted, time will be saved by dissolving gold in nitro-muriatic acid, and precipitating it by magnesia, the oxide thus obtained being again dissolved in cyanide of potassium and water. This solution should be used at a temperature of 130 deg., the arrangement of the battery and articles being the same as already described.

Silver.—The salt of silver, best suited for electro-depositing, is also the cyanide.

Silver being allowed to remain in a solution of cyanide of potassium, is dissolved, or take the nitrate of silver, to which add a solution of cyanide of potassium, the silver combines with the cyanogen, and precipitates as a white powder ; the liquid is then decanted, and the precipitate well washed with pure water ; to this more cyanide of potassium is added, which dissolves the precipitate, forming the double salt of cyanide of potassium and silver ; this constitutes the plating solution.

The same general arrangement is to be observed for plating with silver as already described, the *quantity* of battery power, being in proportion to the surface of the articles to be plated, and the *intensity* agreeing with the density of the solution. In a few seconds after the articles are placed in the solution and connected with the battery, they are covered with silver, and are allowed to remain therein until the necessary coating is obtained, and this is effected in from four to six hours. In order to ascertain correctly that the required quantity of silver has been received, every article is weighed previously to being placed in the solution, and again after the process is completed, and the weight entered in a book against each. After the plating is finished, the articles are taken to a lathe, and brushed with brass brushes, when they are ready for burnishing. this process consists in rubbing the surface with great force, with a highly polished steel or blood-stone tool, until it is as bright as a mirror. This is a severe test for any plated article, by whatever process made, and if a most perfect cohesion did not exist, it would at once be detected in the burnishing.

Copper.—It was, as we have already noticed, the deposition of this metal from its sulphate, which suggested to Spencer, in England, and to Jacobi, in Russia, the application of the electric current to the multiplication of works of art.

For all purposes of solid deposit, for electrotyping, &c., the solution of the sulphate is found to answer best, and is the cheapest ; the method of operating with it is now generally well understood. A considerable improvement, however, may be made in this solution, (when used for the purpose of covering metals) by the addition of caustic potash or soda, which should be added by small quantities until the precipitate formed by it, is no longer re-dissolved by the solution. The ordinary sulphate of copper contains one atom of acid for one of copper, so that, in decomposing by the electric current one atom of this salt, we have *one* atom of copper only deposited ; but by the addition of caustic alkali, a part of the acid is taken up by the alkali, leaving *two* or *three* atoms of copper combined with the remaining acid, forming a different salt of copper. This we find superior to the ordinary sulphate, and in practice effects a saving of battery power, besides the deposit being obtained in a shorter time.

The arrangement of battery best adapted for solid deposits of copper is the single cell. A plate of amalgamated zinc is put into a vessel of unglazed earthenware, or any other porous substance, containing dilute acid, and placed in the copper solution, the articles to be coppered are attached to the zinc plate. In this arrangement crystals of sulphate of copper should be suspended in the solution, to compensate for the metal deposited : but when the neutralized solution above described is employed, it is necessary now and then to add caustic alkali to maintain the proper qualities of this salt.

But the simplest of all single cell arrangements, and which we find the best in practice, is to wrap the amalgamated zinc in a double sheet of ordinary brown paper, tied round with string, the joints being cemented with glue; care should be taken in this, as well as in every other single cell arrangement, that the surface of zinc be equal to the surface of the article or articles to be coated ; the better plan being to suspend before each article a corresponding surface of zinc.

From the qualities and cheapness of copper and its salts, it is generally used for all purposes of electrotyping and solid deposition ; and it may also be used as a coating for the protection of iron from rust, besides rendering it highly ornamental.

The alkaline salt of copper best suited to the coating of iron, is the double salt of cyanide of potassium and copper ; it is thus prepared :—Take pure dry crystals of sulphate of copper, dissolve them in water and precipitate with the ferro-cyanide of potassium, wash the precipitate and dissolve it in cyanide of potassium and water. After the iron has been properly cleaned, which is effected by allowing it to remain for a short period in dilute sulphuric acid heated, it is placed in the cyanide solution, heated to about 120 deg., and connected with the battery ; in from two to five minutes it will be found completely coated ; the iron should then be scoured with sand, and placed in the sulphate solution ; if any portion should have been imperfectly coated in the alkaline solution, it will immediately turn black in this, in which case it should be cleaned and returned to the alkaline solution for one or two minutes.

By this process every article of iron work, either cast or wrought, may be firmly coated with copper, and afterwards bronzed, the articles retaining all the strength of the iron, with the beauty and indestructible qualities of the copper ; and with the aid of our patents for the production of works of art before described, copies of the beautiful marbles and bronzes of the antique may be successfully produced.

Zinc.—All metals, in ordinary circumstances, possess a certain definite galvanic character, and when any two are together exposed to an exciting fluid, there is immediately generated a galvanic action ; the electro-positive metal is gradually destroyed, whilst the negative is protected by the action which destroys the positive. Thus zinc and copper placed in connexion, in an exciting fluid, form a galvanic battery ; the positive metal, zinc, being destroyed, and the negative, copper, protected. The effect of this action may be noticed upon iron railings which have been connected with the stone work of buildings by lead, a metal *negative* to iron ; after long exposure they will be found much more wasted upon the parts touching, or adjacent to the lead, than in any other ; this arises wholly from the galvanic action induced by the two metals in contact, and at the expense of the more positive. Zinc is galvanically *positive* to all ordinary metals, and, from this property, protects them when in contact with them ; whilst the zinc wastes away, but very slowly ; because " When exposed to air or placed in water, its surface becomes covered with a grey film of suboxide, which does not increase ; and this film is better calculated to resist the mechanical and chemical effects of other bodies than the metal itself." Thus, while zinc has the property of protecting other metals by its electro-positive state towards them, its own decay is prevented by its oxide, which exists only as a thin film, is insoluble in water, and is not easily removed. These properties of zinc have long been known ; but have not until now been practically taken advantage of for two reasons :—1st. The impossibility of procuring *pure* zinc, except at a cost so great as to prevent its use. And, 2ndly. The impossibility of applying pure zinc in a melted state to iron. Impure zinc is of *little* or no value as a protection to other metals, because the impurities it contains being all electro-negative to it, are by their galvanic action operating to its destruction ; and there is no method of procuring the metal pure, but by distillation or deposition. But supposing pure zinc to be obtained, the difficulty is still to be overcome, of applying it, except by deposition.

The best and cheapest solution of zinc is the sulphate, which may be safely used to coat articles of iron, the zinc having the greatest affinity for the solvent of the solution. One pound of dry crystallized sulphate of zinc, to one gallon of water, forms a very good solution; very little intensity of battery is necessary, indeed, if the *quantity* be well balanced with the surface of the articles in the solution, and the electricity has not too far to travel, *no* intensity is required. The electro process therefore offers a cheap and effectual mode of protecting iron from oxidation, by coating it with pure zinc.

Metallic Cloth is another adaptation of this art, for which article we have recently obtained patents, and which is valuable from its properties of resisting the effects of the atmosphere, as well as being water and fire proof, besides being so light that a surface of nine square feet may be made to weigh only 18 ounces. The mode of manufacturing is as follows:—On a surface of copper, attach very evenly stout linen, cotton, or woollen cloth, and connect it with the negative pole of a galvanic battery, immerse it in a solution of copper or other metal, connecting a piece of the same metal as that in solution, with the positive pole: decomposition takes place, and endeavouring to reach the copper plate, the metal insinuates itself into all the pores of the cloth, forming a perfect metallic sheet.

IMPROVEMENTS IN THE MANUFACTURE OF IRON.

Patented by Thomas W. Booker, Esq., of Melin Griffith, near Cardiff. (From the *Transactions of the Society of Arts.*)

The method usually, now and heretofore, adopted in the manufacture of bar iron (where the dangerous, and, as the author thinks, reprehensible practice of puddling the crude or raw pig iron, without the intervention of the refining process, is not adopted), is as follows:—The pig iron is thrown up on what is called the milling finery, or run into the finery in a fluid state, from the smelting or blast furnace, and after undergoing the process of refining, it is run out into cakes or moulds, and suffered to get cold; it is then broken up into lumps of a convenient size, and thrown into the puddling reverberatory furnace, which is usually constructed with one door, and at which only one man can work at a time. The author's improved method is detailed in his specification, plan, and model, and its effect is this—a saving of full 50 per cent. in fuel, and nearly 50 per cent. in metal, an immense saving of labour, and a greatly increased product of work in the puddling furnace—the usual product of a puddling furnace being from fourteen to eighteen tons in a week, while the author's will as easily produce from forty to fifty tons in a week. The author thus combines the processes of refining with puddling, and to show the importance of preserving, and the hazard of dispensing with the refining process, he subjoins the results of analysis by M. Berthier of three samples of cinder or scoria, in one of which the remarkable fact of the presence of phosphoric acid shows how important this operation is to the purification of the iron:—

	Silica.	Protoxide of Iron.	Alumina.	Phosphoric Acid.
A Staffordshire sample..	0·276	0·612	0·040	0·072
A South Wales sample..	0·368	06·10	0·015	none
Ditto do.	0·424	0·520	0·033	none

The object of Mr. Booker's invention is to simplify and accelerate the conversion of cast iron from its crude state into malleable or wrought iron, for which purpose the refinery or furnace is adapted to the various qualities or descriptions of cast or pig iron which it may be necessary to use, by surrounding or enclosing the hearth with blocks of cast iron, into and through which water is allowed to flow or not as may be expedient, and as is well understood in making refinery furnaces, the blast of air being introduced through one, two, or more apertures or tuyres, as usual.

The refinery is connected with the reverberatory or puddling furnace, which is constructed of the requisite form and dimensions. The bottom of the body of the furnace, and the grate bars, and binding plates and bars, are formed of iron; the other parts of the furnace are constructed with firebricks, sandstone, or fire clay, as is well understood. In the neck, or near the flue of the reverberatory furnace is an aperture through which the iron, when it has become decarburetted or refined in the refinery, is introduced or run in a fluid state direct from the refining hearth into the puddling or reverberatory furnace. On each side of which reverberatory furnace a door is constructed; the door in the one side being immediately opposite to the door in the other, through which two doors the workmen perform the process of puddling in the ordinary way in which puddling is done, when working only with one door, which is the general practice.

As respects the Refining.—Having thrown up the fuel, and having, by the application of fire and blast, produced the necessary heat, a charge of nine cwt. or thereabouts of pig or cast iron, of the description generally used for forge purposes, is thrown on and melted down and decarburetted or refined in the ordinary way; and when the refining process is completed, the whole charge of metal is run off in a fluid state direct into the reverberatory or puddling furnace previously prepared to receive it, by having been already heated to a proper degree of temperature, and by the bottom, sides, bridge, and opening to the flue being protected in the ordinary way, by the workmen having previously thrown in a sufficient quantity of limestone and iron cinder. The metal having been introduced into the reverberatory or puddling furnace in a fluid state, the workmen raise, apply, and regulate, and vary the heat in the ordinary way, by feeding and moving the fire in the grate, and raising or lowering the damper on the top of the stack or flue, as circumstances require, and as is well understood; they at the same time stir and agitate the iron with bars and puddles, while the escape of the oxide of carbon in a gaseous shape takes place, and until the whole mass of iron agglutinates. The workmen then divide it into lumps or balls of a convenient size, and draw the charge from the furnace, passing the lumps to the squeezer, hammer, or rolling cylinders, or such other contrivance or machinery as is used for forging or compressing the iron.

During the process of refining the iron, by the application of heat and blast, in the open refining hearth, a considerable quantity of scoria or cinder is produced, which is tapped and run off as heretofore, as circumstances require; but it is to be observed, that during the process which the iron undergoes in the reverberatory or puddling furnace, the author does not find that any cinder need be generated or produced, and cinders and limestones are thrown in, as already described, for the protection of the various parts of the furnace exposed to the action or agitation of the fluid metal, but no cinder need be tapped or drawn off.

Mr. Aikin's opinion.—The principal novelty in Mr. Booker's invention consists in placing the refining and the puddling furnace so near each other that the refined iron may be run in a liquid state into the puddling furnace, instead of allowing it (as is usual) to cool and become solid when let out of the refinery, previous to its being transferred to the puddling furnace. The heat lost by the iron is thus saved, as well as the time required to bring the solid refined iron to a state of fusion. Both the refining and puddling are to be performed, according to Mr. Booker, in the usual way; it was therefore incumbent on him to show how it happens that while the common process of puddling produces slag, his does not.

Mr. Booker's statement that by his process a saving of full 50 per cent. in fuel, and nearly 50 per cent. in metal, is effected, appears to be an enormous exaggeration; the saving in the former being only (as far as appears) the fuel required to melt the refined iron. In making iron of the best quality, 31·74 cwt. of pig iron give 26·45 refined, which is reduced to 23 in the puddling process. 8·74, therefore, is the loss which 31·74 pig suffers in becoming puddled iron. Half this loss, namely, 4·37, will represent 50 per cent. of saving, and this, added to 23, makes 27·37, which is 0·92 more than the entire quantity of refined iron.

Berthier's analysis of two samples of scoriæ from South Wales, and one from Staffordshire, showing the presence of phosphoric acid in the former and none in the latter, has no bearing on Mr. Booker's statement, that in the process of refining, the phosphoric acid is separated from the iron.

If the quality of the iron produced by Mr. Booker's process is not worse than that of iron refined and puddled in the usual method, Mr. B.'s process deserves the approbation of the Society. But I would recommend that Sir J. Guest, or some other practical iron master, should be consulted.

In answer to a communication from the Secretary, Mr. Booker writes:—

"I account for 'the production of slag in the common puddling furnace, and its non-production in mine, as follows:—The common puddling furnace is so constructed that the iron operated upon in it is exposed to a very rapid draught or current of air, which rushes in at the grate at the back of the furnace, and passes off through the body and into the flue and stack at the head thereof. This draught is so great as to oxidize the iron, and transform a great portion of it into slag or scoria during the process of puddling, which process, moreover, is effected so slowly, that the charge of iron, consisting of from 3½ cwt. to 4½ cwt. is exposed to the heat and draughts in the puddling furnace during the space of full an hour and a half.

"My puddling furnace is so constructed, that the draught or current of air admitted at the grate is broken, and its oxidizing effects upon the surface of the iron while fluid, and upon the fibrous particles as they cohere, after the oxide of carbon has been expelled, are entirely neutralised. That portion, therefore, of the charge which in the common puddling furnace is converted into slag or cinder, in mine is not wasted or oxidised, but remains, and is converted into pure malleable iron.

"'The saving of fuel' is accounted for thus:—In the common puddling furnace not more than 4½ cwt. of metal is admitted at one time, and this in a solid cold state. In mine, double the quantity is admitted, and that in a melted and fluid state. It is obvious that the time, fuel, and labour necessary for melting the iron are saved, and that double the quantity of iron is converted from a cast into a malleable state within half the same space of time.'

THE PHILOSOPHY OF DESERT FORMATIONS.

(Continued from page 42.)

In vain, in this grand and universal wreck of by-gone existences, will the geologist look for the mixed material composing many of the older soils of Europe: the fossils of the one and of the other speak alike of a common origin, of causes similating to causes, effects to effects; but the mineral kingdom is still in its infancy, is still but partially developed: it has naphtha, bitumen, mineral pitch, and bituminous rocks, but no coal: it has the metalloyds in their uncombined, and even in their combined state; but it has neither iron, copper, silver, tin, or other mines of metallic substance; and, where the metals are developed, as M. Guielin truly observes, they are but superficially disposed upon or near the surface of the earth: it has no lacustrine or terrestrial deposits, no aluminous clays, no formations analogous to the lias, no fossils which tell of its previous occupation by terrestrial forms of life; the beds of its lowest valleys and plains, as its most elevated tracks, denote the one common origin, and exhibit properties and fossil bodies common to both. Wherever the fresh waters descend from above, or percolate through the porous strata, there fertility appears; the soils of the desert, like the island in the midst of the ocean, when favourably disposed, teeming with vegetation, and demonstrating by its abundance and the sterility around it that nature operates by general laws. Every locality has its local phenomena, and from no one portion can we take a sample as illustrative of the one great whole: the groups and families of mollusca, the chains of reefs, and the beds of marl filled with reliquæ, are all peculiar to their respective regions, and confined to that geographical area within which alone they can exist. To whatever depth these soils have been explored the same phenomena is presented to observation, and in no one instance throughout these extensive tracks, on digging for water, have vegetable earths or other products generated by their presence been discovered; tbey are alike deficient of the gems and metals common to older soils, or lands more favourably situate for their development and increase. In these localities disposed within rainy regions, or watered by rivers, the mineral kingdom is largely developed, and many of the metals towards the eastern and southern regions of Africa are found in abundance; but the only metal generally disseminated over the virgin earth is iron in its oxidated state united with calx, or developed in saline beds in the form of iron glance; in this latter state it abounds in Mount Ormus in the Persian Gulf, which elevation is almost wholly composed of muriate of soda: beyond the state of sulphate, phosphate or carbonate, iron ore is rarely or never seen, and only where water is present. Again, in these soils, the stones continue for indefinite periods of time in the petrified state, similating in their general composition and character; and such is the case with desert sands, the one and the other becoming translucent and crystalline, as they are exposed to the conjoint action of heat and water: thus in the river Nile, many of the sands are exceedingly beautiful, and other of the stones are converted into varieties of quartz and mineral gems.

All the plains and elevations of the deserts are more or less impregnated with salt, and the greater part of the springs are so saline as to render the water wholly unfit for man or animal to drink. By the sea of Abyssinia, the salt exists in dry solid masses: the summit of the mountains which border the desert to the west of Grand Cairo present an immense plain, covered with a mass of salt extending over a surface of 30 or 40 square miles. In the Mesopotamian deserts there is an abundance of rock salt, much of it in very large transparent crystals. In the kingdom of Tunis, mount Had Delfu is entirely composed of rock salt, and in fact there are few parts of the desert where it is not to be found. The earths of soda and magnesia are also exceedingly abundant, entering into the composition of rocks, and decomposed masses of calcareous matter, and giving character to the marls.

The hills which form the boundaries of Upper Egypt are all of fossil composition, some of them have passed by gradual transition into compact limestone, and when within the reach of the waters have assumed a quartzose structure: others are in the state of soft carbonate of lime, indurating as they become exposed to the hot dry air, and the fossil shell fish contained therein are discovered in their various stages of conversion into chalk, from which state, on exposure to the atmosphere, they silicify, and eventually become Egyptian jasper. Many extensive formations are wholly composed of Cirrhipedes, pipe corals, ostræ, &c.; the upper plains exhibit a great variety of species in their fossilized state, particularly echini, ostræ, radiati, and other fish of a calcareous nature; in some places the limpets and rock oysters are seen fossilizing as the rocks indurate; in fact their changes and re-combinations are, generally speaking, indefinite. Many of the hill ranges in the very heart of the Nubian and Suez deserts have a striking similarity in character and composition, to the very recent formations bordering the Red Sea, being of a calcareous nature, and containing vast quantities of the same species of marine exuviæ: the perpendicular fronts of both mark the action of the waters as they have slowly decreased, and their upper surface terminating in considerable plains covered with salt and fossil bodies; and where the dry hot sands have covered in the fossils for a series of ages, they have been preserved from change, so that when taken therefrom, pearl oysters have exhibited all their native freshness, as though recently abstracted from the waters: they also contain aggregates of an indeterminate character between granite and sandstone, or limestone and sandstone, in which are numerous crystalline secretions of sulphate of iron: some of the beds gradually assuming a lamellated appearance, the fossils and chalk being in alternate layers, as is often exhibited by the chalk formations of this country. In some of the extensive valleys the whole of the fossil bodies spread over the surface are covered with a delicate bloom of sulphate of magnesia; in other places the eye is dazzled by the lustre reflected from crystalline salt or selinite.

Green marble (serpentine) is very prevalent in the Nubian and Egyptian deserts, rose jasper in its various stages of formation, from the slightly adhesive mass of silicifying pebbles and calcareous matter, until the whole of the aggregates become united by the silicious waters, jasper is exceedingly abundant, and Mr. Bruce mentions small pieces having green, white, and red spots, called in Italy Diaspo Sanguineo: the granites and porphyries sometimes form entire hills, and with marbles and limestone entire mountains; and the mountains bordering the sea, or those which receive the rains, have a reddish or brownish hue, the calcareous matter spreading over their surface having passed into various stages of change. Both Buchardt and Bruce speak of enormous masses of red granite, hornblende and rose quartz as being exceedingly abundant, particularly near the borders of the Nile, and in the rainy regions. It was from the heart of the desert, between Cosseir and the river Nile that the ancients quarried their fine granites, marbles, and porphyries.

Of the phenomena of the desert, the moving pillars of sand are not the least remarkable. Bruce says, "we were at once surprised and terrified by a sight, one of the most magnificent in the world. In that vast expanse of desert (Waadi el Habsud), from W. to N.W. of us, we saw a number of prodigious pillars of sand at different distances, at times moving with great celerity, at others stalking on with a majestic slowness; at intervals we thought they were coming in a very few minutes to overwhelm us, and small quantities of sand did actually more than once reach us; again they would retreat so as to be almost out of sight, their tops reaching to the very clouds. There the tops often separated from the bodies; and these once disjoined, and dispersed in the air, did not again appear. Sometimes they were broken near the middle, as if struck by a large cannon shot. About noon they began to advance with considerable swiftness upon us, the wind being very strong at north. Eleven of them ranged along side of us about the distance of three miles. The greatest diameter of the largest appeared to me at that distance as if it would measure 10 feet. They retired from us with a wind at S.E., leaving an impression upon the mind to which I can give no name, though surely one ingredient in it was fear." This phenomenon is common to the deserts of Nubia and Arabia, and generally occurs in plains surrounded by high mountains: it is produced in like manner as waterspouts, by contending currents in the atmosphere, the upper and prevailing current being opposed by the other, changes its force of direction towards the earth, descending in a spiral form, and rebounding from the earth passes upwards within the vortex it creates, until it reaches the prevailing current, when it is immediately broken to pieces; the sands are preserved in their pillar like form by the encircling current. I have often encountered them in the Arabian deserts, with a sensation of pleasure rather than fear, for it does not appear that any danger exists either of being carried up by the whirlwind, or being choked by the falling sands.

The Samiel (signifying angel of death), sometimes termed the Simoon, is in reality dangerous and deserving its name, and instances of entire caravans having been overwhelmed are related by many historians. While in the midst of an extensive plain where all retreat is cut off, it is seen advancing in a dull yellowish fog, extending from the surface of the earth to an inconsiderable height; its outer edge has the copper colour hue of clouds preceding a hurricane in the West Indies; its searching influence is felt long before it reaches you, and even the camel, shows symptoms of alarm, uttering loud cries; and every traveller falls prostrate with his face towards the earth to prevent suffocation. In one of the Waadis of Nubia I encountered this venomous blast, and as it passed over my prostrate form, every part of my body tingled as though innumerable sparks of fire had come in contact with the flesh. When blown over, which was in about ten minutes, I found my water skins dried up, and the sands on the wind-ward side reaching to the saddle-bow of my camel. This terrific blast consists of sulphuretted hydrogen and carburetted hydrogen, and other noxious exhalations of the earth, uniting within their volumes an enormous quantity of burning sands, so exceedingly minute, as to be invisible to the eye: it is said, and I believe truly, that no human being can fully inhale this vapour without having the lungs irreparably injured, and instant death is very often the consequence.

In some parts of the desert, towards the land of Abyssinia, about Narea and Caffa, there are immense marshes where the waters annually accumulate, until in the overflow they empty themselves into the beds of the rivers,—this gives a new character to the oceanic fossil soil, the grey marls are converted into a red bole, the sands in many places consolidate as sandstone, and much terrestrial matter or vegetable earth is blended with the various substances primarily composing these plains. Again a portion of these waters passes off by filtration into valleys disposed at a great distance from them, carrying with them the causes of effects manifest in the changes of fossil matters into minerals. The entire Delta of the Nile is spread over a marine formation, being generally of a calcareous nature, or consisting of sands silicified, marine exuviæ, and marls converted into clay in consequence of uniting with the overlying matters.

The deserts, in whatever parts of the globe they are disposed, even exhibit phenomena peculiar to themselves, and as such at variance with the geological notions of the day; in our researches, no remains of lacustrine fresh water or land species have hitherto been found beneath this marine strata, the organic character disappears the lower we descend, but, the lower beds, to the greatest extent known, consist of sands and ocean marls. We cannot therefore conclude that in the changes of this planetary body, the waters have experienced no diminution, but that the great preponderance of oceanic matter, composing in entirely ancient soils, as well as in recent formations, the phenomena of the deserts, and of newly formed islands and continents, all demonstrate priority of existence to the soils formed by the operations of nature on dry land, and it is palpably manifest to all men that the ocean earths form the basis of land vegetation, and of all things produced thereon by the influence of the atmosphere.

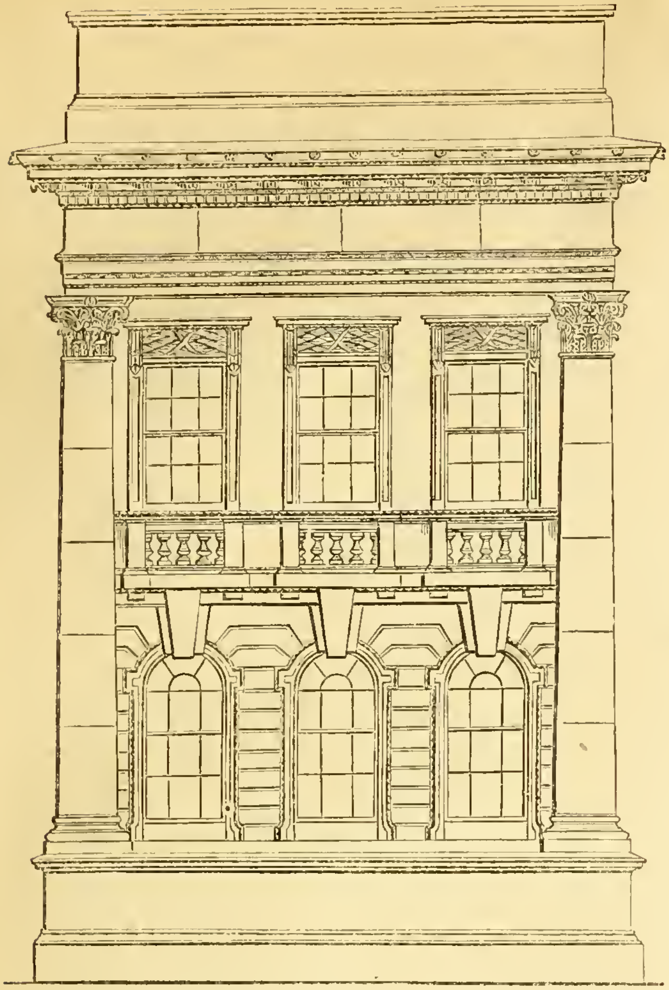
In one of the preceding articles, has already been explained the reason why the term "terrestrial" is used to designate the earth or dry land, in contradistinction to the term "oceanic." It is palpably manifest to men of even common sense, that there are organic species peculiar to the waters, and organic species peculiar to dry land: also that there are earths peculiar to the one, and to the other, as for instance *vegetable earth* and *ocean marl:* in reality the one and the other are the products of animal and vegetable organic bodies—ocean marl implies or embraces varieties, but vegetable earths do not, although much animal matter is blended therewith, they are in fact the earths of earths, species of dry land proceeding from oceanic earth; the term "terrestrial" in contradistinction to "oceanic," implies no contradiction. It has also been observed that gelatinous matter, whether generated by animal or vegetable species favours the conglomeration of silica, and there are few analytical chemists of the present day who will be found to dispute this acknowledged and palpable truth. I go a step beyond this and prove that gelatine favours the generation of silica. A correspondent holds it to be absurd to suppose that the comminuted particles of shell fish can be converted into sands. "The earthy matter in shells," being, as the correspondent says, "wholly *lime*;" truly this is some new discovery, the elementary constituents of living creatures of the deep are various, the most simple organization being purely gelatinous, others combine in their elements albumen and gelatine, with phosphorus; others with these, marine acid, the earths of sodium, &c.,—the abundance of these elementary compounds is manifest in the ocean slime, the phosphorescent light, and saline quality of the waters; the slime is the natural cement of the shells of mollusca, as it is the natural and sole constituent of many species, the elements of the gelatine generated by living organic action, and forming other combinations, become converted into albumen, and then again gelatine and albumen on the death of the animal, form other combinations, entering the mineral kingdom with *silica*, &c. Otherwise, whence comes the silica which constitutes full two-thirds of the entire bulk of the earth? it is not found in the waters oosing from the ocean beds, for the generation and increase of species, is invariably followed by the continuous increase of fossil beds. Mr. Lyell would supply calcium from internal reservoirs. Whence will he derive his supply of silica and other earths? It is said that silica is composed of definite elements, so is the living organic body; in death this mathematical union is sometimes wholly dissolved, and other mathematical and mechanical combinations take place, the results being definite; undecompounded bodies, defying the art of the chemist to separate the elements of their composition but being of necessity compound bodies, and therefore susceptible under some, though to us unknown circumstances, to change.

To the highly intellectual body to whom I address myself, no subject can be more interesting than "The Architecture of this Earth;" from the elementary works alluded to by *a Correspondent*, they derive ideas of the general building, but from me they learn the nature and composition of the material, and the circumstances under which it was and is produced: geologists see the building through geological spectacles clouded by crude i leas and contradictory opinions, and are told to rest satisfied with this general view, and not to look for foundations to the building or primary causes of its being, as that is not their province: I simply hold up the mirror of nature and permit men to judge for themselves. Twenty years travel and observation is worth at least double the quantity of closet philosophy. Geologists teach that crystalline rocks are produced from a previous heated liquid state. I maintain that aggregate masses are combined together by certain common bases or cements, and under the influence of long continuous atmospheric heat or chemical action. Geologists maintain that the material of crystalline rocks has been upraised from the interior of the earth; I am prepared to prove that the most elevated crystalline bodies are produced by atmospheric influences, and that they do not exist at any considerable depth within the earth; geologists term these rocks primary, and say that the causes of effects thus manifest have universally ceased: I prove that many of them are recent, and that the causes of their formation are even now more active than ever they were. It was only a short time since that much learned eloquence was put forth by geologists to prove that from the geological character of the soil no coal could possibly be found in the Falkland Islands, but the existence of coal in those islands was well known to individuals at that time, and it has since been proved that there is abundance of coal, and that the great beds pass by gradual transition into this mineralized form, specimens of which are now to be seen in the "Museum of Economic Geology." Again, bodies every year are added to the number of known undecompounded bodies. Who then shall presume that natural philosophy is now perfect? Geology at present is a very uncertain and fluctuating science.

The effects of heat and cold, water and atmospheric air, gases and vapours, upon bodies exposed to them, or chemically combining with each other, are palpably manifest to all men, however limited their sphere of action may be; the flowers of the garden, the grasses of the field, the creature which exists by the one or the other, all exist by sufferance of temperature and association. On the island wholly composed of marine exuviæ and sands, vegetable species, peculiar to that island, make their appearance, and as they generate and die off, or periodically shed their fruits, flowers, and leaves, so the formated soil becomes covered with a coating of mould gradually increasing in thickness; the plants yield potash; whence is the potash derived? It cannot be from the oceanic soil, because in this soil potash has no place; and, again, its quantities multiply as vegetable matter increases; if derived from the soil, and eventually returned to the soil, there would be no perceptible increase. It is not a constituent of ocean waters. If, then, it be an inorganic substance, whence can it be derived? Certainly not from the atmosphere. It cannot, therefore, be primary, not being antecedent but contemporaneous with, as necessarily appertaining to, the vegetable body: under other aspects the same plant yields soda and not potash. It is found as a constituent of many mineral bodies, and its presence truly denotes the presence of vegetable matter, lost in combinations with other compounds: affording demonstrable evidence that the rock, of which it forms a constituent part, assumed its consolidated form after this earthy matter was deposited, consequently that the rock is a secondary product.

On the Advantages of employing Large Specula and Elevated Situations for Astronomical Observations, by C. P. Smyth, Esq., in a paper lately read at the Astronomical Society, the author adverts to methods proposed by Mr. H. F. Talbot for the multiplication of copies of specula by means of the electrotype, and for observing astronomical objects with a telescope absolutely fixed, by means of a revolving plane mirror, which methods he considers might, if carried out, produce great improvements in astronomy. Amongst the advantages of the latter method he enumerates the following, arising chiefly from the unlimited focal length which it would be possible to give to the mirror: First, The obviation of the necessity of an accurate parabolic shape for the reflector; Secondly, The magnifying of the image without distortion or colour; Thirdly, The small effect which inaccuracies of the screw of the micrometer would produce, eye-pieces of low power being employed; Fourthly, The elimination of errors dependent on the contraction or expansion of the tubes of telescopes; and lastly, The advantage of having the eye in a fixed position. The author then enlarges on the advantages which would attend the use of such a fixed telescope if placed on the slope of a high mountain, with the object-mirror and the eye-piece fixed on piers, and separated by a considerable interval, the mirror being beneath.

GRESHAM COLLEGE.



Scale 12 feet to 1 inch.

In our last volume, p. 276, we gave a plate showing the Basinghall Street front of Gresham College, at which time we made some observations on the merits and demerits of the building. We now exhibit the minor front in Cateaton Street, which has less pretensions to display.

ON THE PYRAMIDS OF EGYPT.

By J. J. Scoles, Esq., Fellow.

(Read at the Royal Institute of British Architects.)

About three years since the two first parts of the magnificent work of Colonel Vyse on the Pyramids of Egypt, were presented to the Institute, and Mr. Scoles then read a paper on the subject of the discoveries made by Colonel Vyse, and described the pyramids at Ghizeh. On the presentation of the concluding number of the work, he took the opportunity, on the last meeting of the Institute, to resume the subject and to describe the further discoveries which have been made in the pyramids situated at Sakkarah, Dashhour, and other places in the "Faioum;" and which are delineated in the third number from drawings by Mr. Perring, the civil engineer, under whose direction the various excavations were made at the expense of the gallant Colonel.

There appear to be thirty-nine pyramids in Middle and Lower Egypt, all of which have been explored by Mr. Perring. They are situate on the western side of the Nile, chiefly on the desert hills, occupying a space measuring from north to south of fifty-three English miles.

The first pyramid described by Col. Vyse is known by the name of *Abou Roash*; the base is 320 ft. square. The bulk of it is built of the mountain rock, (a sort of hard chalk,) which has been reduced to a level around it, and the defective places have been made good with masonry. No part of the external casing is to be found; indeed the edifice was not probably ever completed or raised to a considerable height. A passage about 160 ft. long, commencing on the north and descending at an angle of 22° 35′ leads to an apartment about 40 ft. by 15 ft.; above it smaller chambers appear tho have been constructed similar to those in the king's chamber in the great pyramid of Ghizeh, called "Chambers of Construction," because they relieve the lower part from the superincumbent weight. Near to the pyramid are heaps of broken granite, which may be the chips of the blocks for the extreme casing; the blocks themselves probably have been re-used in modern times, as the pyramids have been a sort of quarry for ages past. The fragments, though granite, crumble to pieces upon being handled, and are much decomposed, either from great antiquity or from an exposure not merely to the corroding air of the desert, but also to the moist winds of the Delta. The common saying that it never rains in Egypt, only applies to the upper country. In the Delta, extending from the sea to the district of the pyramids, rain is frequent and copious, and it was noticed that persons have arrived at Alexandria and remained there some time, subject to continual rain, and have left with the impression that it always rained in Egypt, although their idea before visiting the country was, that there it never rained.

The next pyramid is situate at *Rhegah*. Mr. Scoles here remarked that the names given to the pyramids and by which they are known, are derived from the villages nearest these monuments, and have no reference to their ancient names, though frequently the site of an ancient city is to be traced in the modern name of the villages in the vicinity. This pyramid of Rhegah is curious, on account of being carried up in two inclines, like a pyramid at Dashhour. Mr. Perring did not succeed in discovering any entrance to it; but in the course of his excavation he discovered fragments of stone sculptured and coloured, and some marked with golden stars upon a dark blue ground, as if belonging to the ceiling of an apartment.

At *Abouseer* are five pyramids, some tolerably perfect; Mr. Perring experienced great difficulty in exploring the interiors, as large masses of rubble masonry constantly fell in and seriously injured some of the explorers. The interior of three of these pyramids are similar in their arrangement. The entrance passages leading from the centre of the northern fronts are at first inclined and afterwards horizontal. The apartments in the centre, range from east to west, and are covered by inclined roofs, formed of several courses of stones. The bulk of the northern building has been in the first instance carried up in degrees or steps, and afterwards completed in the pyramidal form. The masonry in general is very rude, consisting of rough blocks of various sizes put together like rubble work with *Nile earth* instead of mortar. The passages are lined with granite and were closed by portcullis of granite; this material was apparently introduced to give strength to the masonry where its solidity was weakened by passages, &c., and as an additional security there had been three tiers of roof blocks over the chamber, and the base of the upper tier had been carried beyond those of the lower, in order to distribute the pressure over as great a base as possible. These blocks were of immense size, some 45 ft. long, 9 ft. wide, and 12 ft. thick, and yet so completely had they been destroyed by the indefatigable exertions of the people who broke into these pyramids, that only two perfect blocks and fragments of two others remain. The marks of wedges were every way visible, but Mr. Perring observes, it is difficult to imagine any power but that of gunpowder could have effected so much destruction. A recess in the casing above the entrance appears to have been intended to receive an inscription like that, as we are informed by Diodorus, was placed over the entrance of the third pyramid of Ghizeh; and this circumstance may account for the inscription said by Herodotus and by other authors to have been seen upon the great pyramids. In one of the Abouseer pyramids blocks of granite filled up the entrance passage and remained in their original positions, clearly proving that the interior of the pyramids was not intended for any astronomical purposes. The pyramids of Ghizeh had the passages similarly filled up, and the violators of these monuments of the dead had in the first instances forced a way down to the chambers through the solid masonry.

The larger of these Abouseer pyramids was built in steps or degrees covered over with flat stones, and the space between these and the pyramidal casing was perhaps filled up with a rubble work of smaller stones. The mortar used in this pyramid was composed of Nile earth mixed with a small quantity of lime or pounded limestone. In this pyramid we have a specimen of the durability of wood, for a long piece of this material had been worked into the masonry, which though rather shaky, was completely sound, and must have been built in the masonry at the time of the original creation of the building, a considerable portion of the same still remaining inclosed among the stones that have not been disturbed, and the mortar adhering to its surface, which could only have taken place when it was first laid on. A portion of this very piece of wood is in the British Museum. In the smaller pyramid the apartment was 12 ft. 2 in. long, and 10 ft. 6 in. wide; the roof was covered with blocks laid horizontally, and which had given way.

At Sakkarah are eleven pyramids and a large building called the Throne of Pharaoh. They are built of stone, and are much decayed, except the large one, which is built in degrees, and this and another towards the north-east are the only two at present open. Mr. Perring has given a sketch of these pyramids, and that gentleman remarks that Bruce probably alluded to this view, when he observed that "the traveller is lost in the immense expanse of desert, which he sees full of pyramids before him—is struck with terror at the unusual scene of vastness, and shrinks from attempting any discovery among the moving sands of Sakkarah." In the second pyramid the regular inclined passage in the centre of the northern front remains closed up with masonry. The two apartments have pointed roofs, the blocks which form the sides are not laid in horizontal beds, but are laid on an inclined plane like the beds of the queen's chamber in the great pyramid of Ghizeh.

The great pyramid of Sakkarah is called by the Arabs, Haram el Modarrggeh, "The Pyramid of Degrees." It is evident that the exterior of the edifice originally consisted of six degrees or stories, varying in height and gradually diminishing in height towards the top, each of which had the shape of a truncated pyramid, and was successively smaller than that below it; but by the effect of time and violence, the whole of the eastern and nearly the whole of the northern and of the southern sides of the lowest tier have been removed. Two attempts have also been made to force an entrance on the southern side, and the French are said to have employed artillery for the purpose. The bulk of the masonry consists of loose rubble work, and is inclosed by walls about 9 ft. in thickness, and are composed of rudely squared stones set to the angle of the face; and the breadth of the building from north to south has apparently been increased by an additional wall on each of these sides. The walls of the lowest tier are 10 ft. thick. The mortar is of various kinds, but it is principally composed of the gravel of the desert and of lime, or of Nile earth, and of small pieces of calcareous stone. The face of each story has an angle of 73° 30′ with the horizon. The entrance is in a pit which opens into a passage partly horizontal and partly inclined, leading to the lower part of the large apartment. Near the entrance of the passage is a hole for the pivot of a door. Another passage from the northern front leads to the same apartment at 7 ft. 6 in. above the floor. A third entrance from the same front communicates with a recess in the upper part of the apartment. A fourth entrance proceeding from a pit on the southern side, communicates by a horizontal gallery with another recess 70 ft. above the floor of the apartment. The gallery is an excavation, but as the rock above it was not of sufficient thickness to sustain the weight of the superincumbent masonry, the ceiling is supported by a row of 22 short columns formed with blocks of compact limestone. The columns have been brought to their bearings by wedges of wood. The southern end of this gallery did not seem to have been previously visited, as nearly 30 mummies were found in it apparently undisturbed. They had neither coffins or sarcophagi, but three or four had painted decorations; they were enclosed in wrappers with pitch and bitumen: but as Mr. Perring did not meet with any of the objects usually deposited with mummies, excepting some of the common stone idols on the body of a female, he therefore concluded they were the bodies of persons employed on the building.

The large apartment (measuring 24 ft. by 23 ft., and 77 ft. high) is an excavation. The original ceiling was examined by the help of torches made of greased rags, and ascertained to have been formed with planks, supported by a platform of timber, consisting of cross bearers of oak, larch and cedar, and of two principal beams of oak about 18 by 12, and strutted from each side by angle pieces. The larch was in the soundest state. Beneath the floor of this large apartment, which consists of blocks of granite 3 ft. 6 in. to 4 ft. 6 in. thickness, a remarkable chamber 10 ft. long, 5 ft. 4 in. wide, and 5 ft. 4 in. high had been formed; the entrance to it had been closed by a conical block of granite shaped like the stopper of a bottle, above four tons weight.

The Baron von Minutoli supposes this chamber to have been the place of an oracle; but Mr. Perring is of opinion the place was intended for a treasury, because there did not appear any secret entrance by which a man could easily have got into it, and because the ponderous block by which it was closed did not seem fitted for mysterious purposes, as a number of men and machinery also would be required to raise it; because likewise no acoustic effect was perceived which would peculiarly qualify the place for an oracle.

The floor of the large apartment was supported by pillars of loose masonry wedged up with wood to an uniform height; broken pieces of wood, crooked branches, &c. have been inserted between the pillars to tie them together. The extensive employment of wood is peculiar to this pyramid. There are other smaller apartments in this pyramid. The doorway in one of them is bordered with hieroglyphics in relief, and small stars in relief are sculptured on the headings of this and another doorway.

The sides of some of the apartments are ornamented with rows of convex pieces of bluish-green porcelain about 6 in. by 4½ in., inscribed on the back with a hieroglyphic, the impression of which remained on the cement. The porcelain had been removed. At the back of each piece of porcelain was a projection pierced through with a hole, into which the moist stucco upon the wall entered (the stucco was composed principally of plaster of Paris); in some instances to increase the adhesion the wall was also perforated in the same manner. This pyramid differs from the rest in many respects. It is the only one in Egypt the sides of which do not exactly face the cardinal points, the northern front being 4° 35′ east of the true north. It differs in the form and mode of building, in the number and complexity of the passages and apartments, having four entrances, one being on the southern side; by the hieroglyphics and peculiar ornaments on the walls of the chambers, and also in containing a large apartment covered with timber. The remaining pyramids at Sakkarah are very much ruined, and have not any peculiar arrangements or construction to require particular notice. The throne of Pharaoh, so called, from an Arabian tradition that an ancient king of Egypt erected it for his seat, is a pyramidal building, composed of very large stones and constructed in two degrees or stories. The materials consist of coarse calcareous stones, in which are semi-petrified oyster shells. The building has no doubt been a tomb, but no entrance has been discovered.

At Dashhour are three pyramids of stone and two of crude brick. The north stone pyramid is the most perfect of any in this district. The stones are laid in horizontal courses, and the masonry is good; the angle at the apex is nearly a right angle, and the building has on that account a handsome and solid appearance. The usual inclined passage leads to the chambers about 12 ft. wide, which are covered over by the courses of the walls over sailing about 6 in. on each side, leaving the ceiling 1 ft. 2 in. in width.

The southern stone pyramid is built in two inclinations, so that the lower part has the form of a truncated and the upper that of a perfect pyramid, which mode of construction, according to Sir Gardner Wilkinson, was probably occasioned by a desire to complete the building more quickly than it was at first intended: this conjecture was in some degree confirmed by Mr. Perring's researches, by which it appeared that the upper part had been carried up with less care than the lower, and was also composed of smaller stones; but whatever may have been the cause, all architects must agree with Mr. Perring that the effect is unpleasant, and very inferior to that of the other regular formed pyramids. The beds of the casing stones are not horizontal; but incline downwards towards the interior of the edifice, in order probably to obtain greater solidity, as likewise to save the materials, as less of the external faces of the stones thus laid would require to be worked away to complete the exterior of the building. This inclination, however, is not uniform, nor at right angles to the exterior, but it seems to be regulated by the shape of the blocks. The usual inclined passage leads to several chambers, which are covered by the side courses approaching each other.

The northern brick pyramid is composed of crude bricks 16 in. long, 8 in. wide, and from 4½ in. to 5½ in. thick, some composed of alluvial soil, some of sandy loam mixed up with Nile earth and a little straw. All the bricks are remarkably solid, laid principally in courses from north to south, occasionally intersected by courses from east to west. The bricks were bedded in, and the interstices between them were filled in with fine dry sand. The bricks were marked on the upper surface, by means of the fingers, with different signs, apparently according to their quality and also according to their position. The most usual mark had been made by two fingers about 1 in. apart, having been drawn down the middle. This building was cased with stone, and it was supposed that stone might have been also employed in their interior for the construction of the apartments, or that the interior might afford additional proof of the antiquity of the arch, because ceilings to any extent could not have been formed with bricks in any other manner; but with all Mr. Perring's excavations and researches, he could not discover any entrance or apartments within, but he discovered a very curious and interesting mode of forming a foundation. It seems that the stony surface of the desert had been made level by a layer of fine sand, and confined on all sides by a stone platform 14 ft. 6 in. wide and 2 ft. 9 in. thick, which supported the external casing, and the pyramid was built upon the sand, which is firm and solid. Mr. Perring has met with many other instances in Egypt where sand had been thus used, and provided it be retained in its place it apparently may be depended upon. The blocks composing the platform were laid upon four courses of bricks. Several of the blocks of the casing were held together by stone cramps of the double wedge form.

According to Herodotus, Asychis, the successor of Myserinus, added lofty propylæa to the eastern front of the temple of Vulcan, and from a desire to surpass his predecessors, constructed a pyramid with bricks, upon which was this inscription—"Do not degrade me by comparing me with the pyramids built with stone, which I excel as much as Jupiter excels the other gods, for those who built me thrust poles into the lakes, and collecting together the mud which adhered to them, they made bricks, and thus they constructed me." The pyramid in question has been supposed by Mr. Hamilton and by other good authorities, to have been built by Asychis: and in support of that opinion it may be observed that it is the most considerable pyramid built with bricks, and that it is near the other pyramids built with stone, with which it might have been compared, and also that it is within a short distance of the Temple of Vulcan, which Asychis had so considerably embellished: the solidity of its construction is likewise remarkable, not a single brick appears to have settled from its place; and although the boasting terms of the inscription has excited much surprise, it is difficult to imagine a mass more solid and also more durable, as long as it was protected by an external casing of stone from the effects of the atmosphere. It is certainly, therefore, as superior to those built with common stone rubble, as Jupiter may have been supposed to the other gods. As the whole of the bricks are not composed of alluvial soil, the latter part of the inscription can only refer to those formed of the mud or clay drawn out of one of the sacred lakes. If it be urged that this pyramid could not have been built by Asychis, because from having been cased it must have had the appearance of stone, it may be remarked, that all the brick pyramids in Egypt (which are four) appear to have been covered with stone; and likewise that the above-mentioned inscription would have been unnecessary had the material of which the pyramid was formed been apparent.

The southern brick pyramid is much destroyed, and Mr. Perring did not discover any traces of the chamber, the roof of which is stated by Dr. Richardson and others, to have fallen in, nor did he perceive any considerable settlement. It is built in the same manner, but not so carefully, as the other brick pyramids. The bricks contain a greater quantity of straw, and vary from $15\frac{3}{4}$ in. to $13\frac{1}{2}$ in. long, and $7\frac{1}{2}$ in. to $6\frac{1}{2}$ in. wide, and $5\frac{1}{2}$ in. to $4\frac{1}{2}$ in. thick. The upper surfaces have been marked with the fingers.

The pyramid of Meydoom is called the false pyramid, because the base is supposed to have been formed out of a knoll of rock, and it certainly has that appearance. The base is about 530 ft. square, and 124 ft. 6 in. high. It is formed in three degrees, each having the form of a truncated pyramid, at an angle of 74° 10′. The blocks are of compact limestone 2 ft. thick; they are laid at right angles to the external face, and have been worked and put together with great skill. The entrance was not discovered. Mr. Perring thinks the whole has probably been covered with large unsquared blocks, so as to complete the shape of a regular pyramid. The appearance is very striking from the river, and particularly commanded the attention of Mr. Scoles and his fellow-travellers in passing up the Nile.

The Illahoon pyramid is built round the knoll of a rock, which is nearly 40 ft. higher than the base; the rock has been faced with crude bricks, and a superstructure has been erected over it, composed of the same material, and supported by walls of stone which proceed from the centre of the edifice. The bricks are laid in a mortar formed of Nile earth, as high as the walls extend, and above them in gravel. They measure $16\frac{3}{4}$ in. by $8\frac{3}{4}$ in., and about $5\frac{1}{2}$ in. in thickness, are well worked, and are formed of Nile earth, mixed up with various proportions of chopped straw, and are marked with the fingers as at Dashhour.

Another ruined brick pyramid exists at Howarah: the bricks laid in fine gravel. No entrance to it has been discovered. There are three other pyramids, two at Biahhmo and one at El Koofa, both built of stone, but of small dimensions.

Most of the pyramids have been connected with the plain by inclined causeways formed of large blocks of stone, some with a parapet wall on each side. These inclined roads were no doubt originally constructed for the conveyance of the stone, and of the other materials used in the erection of the pyramids, but they seem afterwards to have constituted the regular approaches. Herodotus mentions that they were adorned with the figures of animals, which were probably either sculptured hieroglyphics, or an avenue of sphinxes; and at Abouseer fragments of black basalt, at nearly equal distances, were found on the causeway. Pavements about two feet in thickness extended around the buildings, and where the rock was low the pavement was placed upon a layer of sand.

The pyramids correspond in their general arrangement; with one exception their sides are placed exact to the cardinal points; and in the excepted one the difference is only 4° 35′; the entrances are on the north side (the pyramid at Sakkarah being the only one having, in addition, an entrance on the south side), and in having the inclined passages leading to various apartments, which passages, to a considerable way down, have been filled up with solid blocks of stone or granite of the exact size of the apertures.

The discovery of sarcophagi, mummies, and other memorials of the dead, show that the pyramids were used for tombs, and the filling in of the passages with solid blocks proves that the interior could not have been used for astronomical purposes, and the question of those passages having been constructed for the purpose of seeing the Polar Star is set at rest by that circumstance; and Colonel Vyse, in his desire to further elucidate the question of the astronomical theory, communicated with Dr. Herschell, and has appended that distinguished astronomer's reply, which is to the following effect, viz.:—"That 4,000 years ago the present Polar Star, or Ursa Minoris, could by no possibility have been seen at any time in the twenty-four hours through the gallery in the great pyramid; but that the star α Draconis was at that time the Polar Star, and as it is comparatively insignificant, and only of the third magnitude, if so much, it can scarcely be supposed that it could have been seen in the day time, even in the climate of Ghizeh, or even in such a recess as the inclined entrance of the Great Pyramid, though it would have been directly in view of an observer stationed in the descending passage. No other astronomical relation can be drawn from the table containing the angles and dimensions of the passages, for although they all point within five degrees of the pole of the heavens, they differ too much and too irregularly to admit of any conclusions. The exterior angles of the buildings are remarkably uniform, but the angle of 52° is not connected with any astronomical fact, and was probably adopted for architectural reasons."

Col. Vyse's work also contains some valuable information in the form of notes by Mr. Birch, of the British Museum, upon the hieroglyphics discovered in the pyramids, with reference to the dates, pre-nomens, and royal standards of the monarchs by whom the pyramids were erected; but many of these hieroglyphics are quarry marks, some in red ochre, but instead of having been inscribed, like those on the pyramids at Ghizeh, upon stone brought from the Mokattam quarries, they were found also upon blocks quarried on the spot, and Mr. Birch observes—"This is remarkable; in the former instance they may have been intended to distinguish the materials which had been prepared for a royal edifice, but in the present case their use is not obvious, and they can only have served to denote the founder of each particular pyramid." But Mr. Harris, an English merchant, who has been resident in Egypt above twenty years, in a letter to Mr. Perring gives a more matter of fact meaning, by supposing that these incriptions were directions to guide those who embarked the stones at the quarries, who conveyed it to its destination, and who built it when there, and that some of the characters indicate the building for which the stones were destined, and others the position in which they were to be placed, and that these directions could not be necessary to all the stones of a building, but would be requisite for all or most of those composing the linings of the chambers, passages, and other particular positions.

The desecration of these magnificent mausoleæ by the intombment of subjects, as the inscriptions relate to the interments of a royal scribe and a military chief, is a surprising fact, which cannot now be satisfactorily accounted for; although history informs us that the memory of the monarchs who erected some of the pyramids was not held in much veneration.

As regards the period in which the pyramids were erected Mr. Scoles could not offer any satisfactory opinion; by some authors they are placed more than 2,000 B.C., or about 4,000 years since; by others 1,200 years later, or only 2,300 since. This latter opinion is supported by Mr. Wathen, an architect, who, in his work on the arts, antiquities, and chronicles of ancient Egypt, from observations made in 1839, has very fully entered into this subject, and supposes the spoils, the gold and silver, taken from the Temple of Solomon, by the king Shishak of Scripture, 970 B.C., were applied to build these pyramids, and the author has given some curious dissertations on the chronology and dynasties of ancient Egypt. Many circumstances show that those at Ghizeh were the first erected, and that the pyramids of Dashhour were constructed in imitation of the stone ones, and to have been formed of bricks on account of the comparative cheapness.

The circumstance of many of these pyramids being carried up in degrees or steps, agrees with a passage in Herodotus relative to the mode of building the large pyramid, which he describes as follows:—"This pyramid (the large one)," he says, "was constructed in the manner of steps, by some called parapets, by others little altars; such being its original construction, they raised the remaining stones with machines made of short pieces of wood, from the ground to the first layer of steps, and when the stone was let down on this, it rested on a second machine standing on the first layer, from this it was drawn to a second layer, where another machine lay to receive it, for there were just as many machines as layers of stones, or perhaps, continues Herodotus, they transferred the same single portable machines to each layer on removing the stone, and thus the upper part of the pyramid was first finished off, then the next part, and last of all the lower ground part. Now these parapets as they are termed correspond with the side degrees or platforms, as we would call them, seen in these pyramids, and on which the machines were placed; for the small steps formed by the sets-off of each course, as were seen in the large pyramid, previous to the insertion of the casing stones, would not have been wide enough for the machines to rest on."

The word parapet, as used in the translation, does not mean a protecting wall to a platform, as we in general understand it, but evidently the platform, and in the North of England it is so applied at the present time, and the foot pavement is called the parapet.

As connected with the pyramids, Colonel Vyse has given an account of Captain Caviglia's excavations in 1818 in front of the sphinx; when he discovered the steps, and a small temple in front of this gigantic figure, which is cut out of the solid rock. The paws stretch out 50 ft. in advance, and are built of masonry. That the monument is imposing in its aspect, cannot be doubted; but in its defaced state, it is difficult to perceive (to quote the words of the explorer) "the contemplative turn of the eye, the mild expression of the mouth, and the beautiful disposition of the drapery at the angle of the forehead," which rivetted so much the attention of Captain Caviglia.

Mr. Perring has annexed some remarks on the measure by which the pyramids were built, with reference to the cubit. The length of the ordinary cubit, as the name implies, was the distance from the elbow to the middle finger, containing six hands breadth, each of which was divided into four finger breadths. Mr. Perring says the dimensions of the pyramid agreed with a cubit as described in Ezekiel chap. xl. v. 5, "In the man's hand a measuring reed, of six cubits long by the cubit and a hands breadth," and therefore contained seven hands breadth, equal in English feet to 1·707 ft., and that by this measure a general agreement is obvious in the dimensions of the building.

The stone arched tomb near the great pyramid, named after Colonel Campbell, the Consul in Egypt, was next referred to; by some called the Nile girt tomb, being placed in a pit 30 ft. 6 in. by 26 ft. 3 in. wide, and 53 ft. deep, surrounded by a trench or narrow canal 5 ft. 4 in. wide and 73 ft. deep. The bottom course of slabs 5 ft. in length was bedded on a layer of sand 2 ft. 6 in. thick, (another instance of this mode of forming an artificial foundation), and the side walls were formed with small stones. The ceiling of the chamber is formed of slanting stones, with a horizontal one or stretcher between, making the middle part of the ceiling flat and the sides inclined. Immediately above this ceiling an arch commenced, which covered in the upper chamber; the intrados of this arch formed the segment of a circle which had a radius of 6 ft. 2 in., and a span of 11 ft., was 3 ft. 10 in. thick, composed of four separate courses, each well breaking joint. It had not been built upon a centering observes Mr. P. (but how he ascertained this does not appear.) The stones were 4 ft. long and 15 in. broad. Those of the first course had been cut to fit the joints, which radiated from the centre; with this course great care had been taken, but in the other rings the stones were rectangular and packed up at the back with chips. Each course was separately grouted with fluid mortar. The masonry was beautifully worked, and the joints were scarcely perceptible in the interior. The undersoil of the stones of the inner course of the arch have had the arrisses taken off, and were tooled round so as to resemble rusticated work.

There were indications that the central excavation and the trench also was covered by an arch, and the whole was probably covered by a pyramid. From an inscription on this monument, the tomb was made for a scribe named Ohaikop, either during the reign of Psammetichus II., anterior to 604 B.C., or of Apries, posterior to 570 B.C. This tomb contained three sarcophagi: one of the granite and a fragment of the basalt one is now in the British Museum.

This arch being in the present day one of ordinary construction would not have required so full a description, if it were not about the oldest stone one we are acquainted with; it shows that the principle of the arch was well understood at the time, and that many arches had been previously formed. The brick arches in the tombs at Thebes are of much older date, according to Sir Gardner Wilkinson.

It was worthy of notice that the arch of Campbell's tomb has no abutments and stood by itself, and its resemblance to the form of the sewers in the City of Westminster, must be apparent to every one conversant in that mode of building.

It was singular the Greeks, with these examples before them, did not construct arches (the curved form for ceilings being much used), and that the introduction of the arch was not, with these exceptions, more general, at least, in Egypt; and Mr. Scoles expressed himself on this account sceptical on the subject of the antiquity of these arches. He was of opinion that the arrangements and dates of the dynasties by Egyptian antiquaries, was not so satisfactorily based as to make it clear to his mind that the periods in which the kings lived, in whose reign these arches are said to be built, was free from the suspicion of error, and he concluded his paper by remarking, that the descriptions he had given of the pyramids, and other buildings, was entirely taken from Colonel Vyse's work, and that in general he had used the very words of the text.

REVIEWS.

Architecture of the Reign of George III. and the Regency. Pictorial History of England.

Historia quoquo modo delectat, says the great Roman orator; but he would probably have greatly altered his opinion, had he lived to read history as it is sometimes written now-a-days. Most assuredly we have not received so much *delectation* or disappointment from the concluding—and what we hoped to find the most interesting chapter of all on the history of English architecture and art in the "Pictorial England," the ground to be passed over being quite fresh, and consequently affording scope for original remark, and something more stirring than the mere echoes of long established opinions. We should have thought that any writer qualified for the task at all, would eagerly have availed himself of the opportunity so offered, to enter tolerably into critical remark upon the several architects and their works, of the period under review. Possibly we may wrong the writer himself, for the work being by various hands and literary assistants, subject to the control of the editor in chief, it is not at all unlikely that his manuscript may have undergone a good deal of pruning and curtailment; and should such be the case, we really compassionate him, it being one of the hardest miseries of authorship, except to a mere hack, who cares for nothing beyond his pay for the job.

However, we have only to take what we find, just as it is; and must therefore report of it as being an exceedingly rapid and condensed sketch, in which several names are merely *catalogued*, without comment of any kind—so that they stand like shadowy ghosts, of whom we are left to guess whether they are destined for Elysium or Hades.

Sir John Soane, indeed, may be said to be here put into the former place, and he is spoken of at much greater length than any one else. He is, besides, the only architect complimented with his portrait; but his spirit, we suspect, would not be a little perturbed, could it behold it, since this must be some degrees more offensive than the unlucky one painted by Maclise, which caused at the time such ire and so much *rumpus*.

But before we proceed to the estimate of Soane's professional character, we will quote an excellent remark from the opening paragraph of the architectural portion of the chapter.

"The exquisite refinement of Greek art, as it had been revealed by the great work of Athenian Stuart, and the other researches and publications to which it had given rise, had suddenly affected the public mind in a manner which left little room for the exercise of the judgment, and Greek art was unfortunately adopted, not as a *principle*, but as a *fashion*. The reproduction of its forms was demanded without reference to the propriety of their application, or to the relations which essentially constitute the beauty of architecture. A system which reduced the art and science of architecture to the appropriation of ready-made temples, and dispensed with so much of the burden of study and thought—a faith, in art, whose yoke was so easy—could scarcely fail to attract disciples; and Greek architecture (so called) came into existence in England in the most *abortive shape in which the narrowest spirit of imitation could produce it.*"

This is excellent; and the concluding words, which we have marked by italics, point out, in the clearest manner, one most mischievous radical error in the system of our Anglo or pseudo-Greek style, which, owing to opposite elements being merely brought into contact, instead of being, as far as possible, reconciled together and harmonized, is for the most part a patched and piebald one, and generally bald enough in all other respects. Let us hope, then, that this soul-less, mechanical, Brummagem Greek has had its day with us; for though a great deal of it will hardly outlive the century, there are, unhappily, some "*monumens*" in it which will record the classical dullness of the period when they were erected.

In the same degree as we cordially assent to the opinion above quoted, do we differ from that expressed by the writer in what he says in regard to Soane. Great praise is undoubtedly due to Sir John: he pursued his art, *con amore*, at all events—which is more than can be said of every one who writes himself architect;—he ventured to think for himself, and to break through the trammels of mere rules, and he certainly was fertile in ingenious ideas, expedients, and contrivances; this we readily admit, but never can we subscribe to the opinion, that the "great merit of his peculiar style is to be found in consistency of detail;" or that his compositions "derive, from a detail based on the purest examples of antiquity, and *always harmonious*, a character more essentially Greek than can ever be attained by the most literal transcript of Greek art, misunderstood and misapplied."

Of course what is misunderstood and misapplied is bad, and so far much of Soane's detail may be greatly preferable, but it does not therefore follow that it is entitled to be described as a Grecian character. The truth is that although, after he first began to do so, he was always aiming at a style of his own, he never wrought out for himself, even the consistent elements of one: he just got up to a certain point, and there stuck fast, unable either to advance, or to turn back again. Never was any artist more unequal,—not only in different, but in the very same productions. Even the Bank itself—his great and most studied work, exhibits almost the very opposite extremes of taste, on its exterior, for instance, in that charming little poetical bit of design at the north-west angle; and in the centre of the south front, which is little better than a mean and unmeaning jumble. The same in regard to the interior: there are many admirable ideas and delightful bits; but of the former, not one is fully wrought out; and the others are exhibited only in patches, or so as to appear such. "Considered as his architectural scrap book," observes a writer in the 'London Interiors,' —"the interior of the Bank is highly interesting, it is a collection of architectural episodes, but no regular architectural epic." Soane seems to have been always studying—and in that he was to be commended; but he was also, unfortunately too much addicted to the practice of mere experimentalizing, and of applying desultory and unfinished "studies" to what were intended to be finished works, utterly disregarding a very salutary precept inculcated in one of his own publications, advising that a design should be laid aside for awhile, and then be rigorously scrutinized and scanned with a fresh eye,—revised and corrected in every part. If he himself, therefore, followed this judicious piece of advice of his own, he was unable to detect in his own designs, those strange inequalities and incoherencies, and that want of keeping in them, which are so disagreeably striking to almost every one else. Even his contrivance was sometimes terribly at fault, as in the Treasury Buildings at Whitehall, where he has put a row of entresol windows immediately behind the hollow entablature of the order!—as he has also done in the centre of the south front of the Bank—a terrible failure, by the by, in every respect, for before he came to that part of the structure, he seems to have exhausted his ideas, and to be fairly at his wits' ends.

Specimens of Decorations in the Italian Style. By J. W. and W. A. Papworth. London: Ackerman, 1844.

We suppose that the connexion of the elder Mr. Papworth with the Royal School of Design showed the necessity and utility of this work, which consists of selections from the splendid Roman publications on the decoration of the Vatican, after the designs of Raffaello, and sometimes called the Raffaellesque style. The popularization of these beautiful designs is a worthy work; and we had great pleasure some time ago in publishing in the *Journal* (vol. vi. p. 1) some able observations of Mr. Poynter relating to the Loggie, which he had read before the Royal Institute of British Architects. There is in the Loggie to be found abundant examples of original conception, pure taste, and luxuriant imagination, than which no better studies can be presented to the artist in arabesque. The subjects, however, are so extensive, and the work in which they are recorded so elaborate, as to be entirely beyond the means of the bulk of the public, no plan could therefore be better than to present a selection of them at a moderate price. The Messrs. Papworth's work fulfils these conditions, and we most earnest recommends its use. At the same time we think it due to the importance of the subject, and to the standing of Messrs. Papworth in the world of art, to make some observations as to the mode in which the design has been carried out. It is a decided improvement on the ordinary works of the class, with Louis Quatorze and Louis Quinze ornaments, and decorations by Watteau, Lancret, &c. It affords copious materials for borders, corners, centres, bands panels, frames, wreaths, brackets, finials, scrollwork, pateræ, bosses,, foliage, &c. Thus the artist and artizan will have abundant choice of subjects, not merely for pictorial representations on flat surfaces, but also for works in metal.

On the due application of such examples in study, we should have liked to have seen some observations, for which we know the competency of the Messrs. Papworth, for this volume will necessarily be sought after, and in many instances, instead of becoming a stimulus to ingenuity, will only be used as a refuge for dullness. We are not in favour of cram works, to which a stolid individual resorts, picks out two or three bits and joins them together, we cannot say combines or unites them. This is a grand evil and requires redress: we do not want Raffaello mutilated; we do not want art dislocated, and nature bepatched; but we want compositions which shall breathe the spirit of Raffaello, and follow out the course which he himself has shown. We do not expect that every one should be possessed of genius or originality, but the key note being given we may obtain a well modulated exercise, or the works of Raffaello may teach a still better lesson, "Go and study in the school that he did—in the world." We should have liked to have seen some observations on this subject from the pen of the Messrs. Papworth, or if not, they might have availed themselves of that able and interesting criticism of Mr. Poynter, to which we have already referred. With this they must be well acquainted; but we do not observe that they have profitted by it, or shown that refined discrimination, which we have a right to expect from them. The Chimæras with breeches on (Part 1st, Plate 2nd,) might well have been excluded, and indeed the fabulous animals so frequently introduced might without any great prejudice have been totally omitted. To the trophies, small vases, and St. Peter's keys, (Part 2nd, Plate 4th,) we must also object. These are trifling points; but a work by the Messrs. Papworth should show care in trifles, for it is perhaps destined to teach the elements of taste to many a poor mechanic. We also consider the drawing in many places, particularly of the human figures, very careless. It is very true the authors say, "To bring them within the means of every designer, no needless delicacy of the graver has been expended upon these—the amusements of our leisure hours." Delicacy and carelessness are, however, two very different things.

The selection is of a very fragmental character; that may in some idea attach to the nature of the work, but we should like to have a better selection and a better collation. There are many specimens in an impure Roman style, such as Adams has shown in the pilasters of the Adelphi, while we should more willingly have seen such graceful, broad, and beautiful studies, as the acanthus, in plate 6, of the second part. We think, too, specimens allied in style might have been brought together. As to style, however, our ideas are rather at variance with those of the Messrs. Papworth, who hold forth the application of some of these ornaments to the Elizabethian style. This sounds to us something like barbarism; but at the best it is a clap-trap to catch the plasterers and compo-builders. Why did not the authors introduce more of Raffaelle's admirable adaptations of fruits, flowers, birds, and animals in composition? These form an admirable basis for study.

The observations we have made we should esteem hypercritical if applied to individuals of less popular standing than the Messrs. Papworth, but they do at all detract from our recommendation of the work as one of great value, and we are indeed so highly satisfied with it, that we recommend to the consideration of these gentlemen the propriety of also publishing some of these ornaments on an enlarged scale, say folio, for the use of students in schools of design. The Messrs. Papworth have rendered great service by this publication, and we hope they will persevere in this course of instruction.

The Year Book of Facts in Science and Art. By the Editor of the *Arcana of Science.* London: Bogue, 1844.

This is the volume for last year of this popular annual register of the sciences, containing a number of facts collated from various works published during the year. We are sorry not to see so many references to standard authorities as in previous years.

The Art of Land Surveying for the use of Schools. By John Quested. London: Relfe and Fletcher, 1843.

This little manual is for the use of schools, to which purpose it seems well adapted; we must, however, regret that so many books are accumulated on this subject with so few new results.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

Feb. 13.—George Rennie, Esq. in the Chair.

A paper by Mr. J. Grantham described a series of experiments on an iron vessel called the *Liverpool Screw*. This boat was 60 ft. long, 12 ft. 6 in. beam, and had 3 ft. 9 in. draught of water; she was propelled by two high-pressure oscillating engines with cylinders 13 in. diameter, and 18 in. stroke; the pressure of the steam in the boiler varied from 50 lb. to 60 lb. per square inch, and it was cut off at one-fourth of the length of stroke, working the remainder by expansion; the nominal power was 20 horses, but it did not really exceed $18\frac{1}{2}$ horses. The cylinders were placed diagonally, with both the piston rods working on the same crank, the driving shaft being beneath the cylinders, and running direct to the propeller without the intervention of either gearing or bands. The screw propeller was enlarged three times, and at last was left at 5 ft. 4 in. diameter by 20 in. in length; it was set out with a pitch expanding from 10 to 11 ft. on Woodcroft's plan; it was made of wrought iron, with four short arms with broad shovel ends, whose united area was 16 square feet, 13 ft. only of it being immersed, as some portion of the arms was constantly above the water; the angle of the centre of the float was 45°; the speed of the propeller was generally 95 revolutions per minute. With these dimensions the speed attained was described as $10\frac{1}{2}$ statute miles per hour. The amount of "slip" of the screw in the water, as ascertained by Massey's log, was stated not to exceed 5 per cent. Several experiments were detailed, which showed that there was not more tendency to "list" or to turn round by the action of the screw, than with paddle-wheels, and the vessel was said to have excelled all the other steamers of the port of Liverpool in towing out vessels in a rough sea.

Designs were submitted on this principle for a steam frigate and for large steamers working with oscillating cylinders direct upon the main shaft.

In the discussion which ensued, the various forms and modifications of screw propellers, and their relative merits were very ably treated by a number of speakers.

Mr. Rennie gave a sketch of the introduction of a kind of screw used by Mr. S. Brown with his gas engine, which was tried on the Thames; the more successful attempt of Mr. Smith, and the building of the *Archimedes* and other vessels; he mentioned also the claims of Mr. Sauvage, of Boulogne, to the invention, and his being recently rewarded by the King of the French. Mr. Rennie entered largely into the theory of the forms of the propellers, and in this he was followed by Mr. Farey, Mr. Galloway, Mr. Samuda, and others, and Monsieur Normand, of Havre, who is celebrated for giving such superior forms to the vessels built by him: he gave a slight sketch of the *Napoleon* French frigate, in which he eulogized the engines constructed by Mr. Barnes and the general result obtained with the vessel, but it appeared that the speed was not superior to what had been obtained with paddle wheels.

Pump Valves.—A model was exhibited by permission of Sir H. T. De la Bèche, from the Museum of Economic Geology, showing all the kinds of valves used in the pumps for draining the Cornish mines, and the merits and defects of the various kinds were very ably explained and commented upon by Mr. Jordan, under whose directions the model was constructed. Mr. John Taylor gave an historical sketch of the introduction of the various improvements, the causes which led to them, and the effects they had produced; the length of the discussion on the screw propeller left so little time for the subject of the valves that it was announced to be renewed at the next meeting, on Tuesday, February 20th.

THE ROYAL SCOTTISH SOCIETY OF ARTS.

January 22.—Professor Traill, M.D., F.R.S.E., President in the chair.

The following communications were made:—

1. Sir George S. Mackenzie, Bart., exhibited three elegant specimens of Mr. Cheverton's work in ivory, in a different style from that formerly shown, and communicated part of a letter from him. The subjects were the Mercury and Pandora of Flaxman, and Morning and Night by Thorwaldsen. These specimens were much admired. They can be executed at twenty guineas, inclusive of the frame. Their effect, when viewed as semi-transparencies, is also very fine.

2. *A Ball and Socket Levelling Instrument*, constructed by Mr. Adie, for Thomas Stevenson, Esq., C.E., and also an improved Portable Levelling Instrument and Rod, were exhibited. Communicated by David Stevenson, Esq., F.R.S.S.A., civil engineer. In this ball and socket spirit-level, designed by Mr. Thomas Stevenson, civil engineer, the first peculiarity is the substitution of a small circular level fixed upon the upper side of the tube for facilitating the setting of the instrument, instead of the delicate cross level at present in use. But the principal advantage of Mr. T. Stevenson's improvement consists in the combination of the ball and socket motion for the first setting, previous to the application of the parallel plate screws for the final adjustment. The ball and socket was long in use, but for about half a century it has been almost entirely discarded, and the parallel plate-screws substituted. In the level exhibited to the Society, the ball and socket has been restored, and the parallel plate screws retained, so that by this union the advantages peculiar to both systems have been attained. The person using this instrument is in consequence rendered quite independent of the rugged nature of the ground on which it is set, or the inclination of the telescope to the horizon, as by looking first at the small circular level, he can in an instant bring it nearly right by means of the ball and socket, after which, a slight touch of the parallel plate screws perfects the adjustment. In this way the observer can set his instrument with exactly the same rapidity and ease on a steep slope as on level ground, and is enabled to proceed with equal facility at such rugged stations as would in the instrument now in common use altogether exceed the range of the parallel plate screws. The practical surveyor will see the great saving of time and trouble resulting from the use of Mr. Stevenson's instrument.

Mr. David Stevenson also showed a *portable level and rod*, constructed to his directions, by Mr. Adie. With nearly the same accuracy as the large levels, this instrument possesses the advantage of much greater portability. It combines a telescope 10 inches long, a compass, and a level, and is packed in a flat leathern case measuring about 6 in. by $2\frac{3}{4}$ in., rendering it very convenient for perambulatory surveying, for which it was made. It rests on a tripod, which is also very portable. The levelling rod accompanying this instrument, when closed, forms a round staff 3 ft. 6 in. long, which is cut longitudinally through the centre. The two parts are hinged at one extremity, and when the rod is to be used they are opened and fixed by a spring. The scale is marked on the flat side, and when the staff is closed the figures are protected from injury.

3. (Part 1.) *Observations on, and Improvements proposed in the Ventilating and Warming of Factories;* with Remarks upon the essential importance of pure air for the preservation of the health of those engaged in employments carried on in a confined atmosphere, whatever be its temperature. By Robert Ritchie, Esq., Civil Engineer, Edinburgh. The first part of the paper gave a short account of the different methods which had been employed in heating factories by steam pipes, as now nearly universally adopted, describing the manner in which these were generally arranged; and concluded with a short description of improved ventilating arrangements which had been adopted in some extensive factories.

SECOND GENERAL MEETING OF THE ARCHITECTS AND ENGINEERS OF GERMANY.

Held at Bamberg on the 8th, 9th, & 10th of September, 1843.

We find in the *Allgemeine Bauzeitung* an account of the second meeting of the architects and engineers of Germany, which was last year held at Bamberg in Bavaria, on the 8th, 9th, and 10th of September. The first meeting was held at Leipsic. The meeting at Bamberg was held in the public assembly room, called the Concordia. Around the hall were exhibited the architectural drawings sent to the meeting.

Sep. 8th.—A public breakfast was held early in the morning. The rest of the morning was employed in the examination of the cathedral and other curiosities of the city. At 11 the meeting commenced, when Herr Barlet welcomed the members to Bamberg in the name of the citizens. To this speech Dr. Puttrich replied in the name of the members.

Dr. Puttrich then took the chair.

Professor Stier read a paper containing some remarks on the present state of architecture and its early condition.

Professor Wiessenfeld, of Prague, then communicated a plan for a third bridge at Prague, of wood, and of large span, to cross the river Moldau. The design was by a carpenter of Prague, for a colossal structure of wood and other materials, partly on the suspension principle, the span of which is proposed to be of 600 feet. A long discussion ensued on this, but without any determinate conclusion being come to as to its practicability.

Sep. 9.—Professor Stier opened the meeting with a paper on architecture, on rectilinear and arched or curved architecture, and their prospects in the present day.

Herr C. W. Hoffmann, architect, of Berlin, made a communication on the discovery by Ehrenberg of infusorial earth.

Herr Krafft, C.E., of Stettin, read a paper on béton or concrete foundations, as applied by Herr Neuhaus, C.E., on the Stettin Railway along the Oder, where it had been necessary to build a coffer-dam 30 ft. to 35 ft. deep, the depth of water being upwards of 20 ft. Herr Krafft strongly recommended the use of concrete for such purposes. In the present instance a strong sheathing of planks covers the water side and the inside, within which the concrete is rammed in to about a foot below the lowest water line and the rest of the wall of the embankment is then carried up with masonry. In the second design the masonry is also supported by piles under the concrete.

Herr Kollman, architect, of Augsburg, made some observations on the various legal rights existing with regard to water power, and the want of defined principles of legislation affecting it.

Herr Winkelmann, architect, of Berlin, gave an account of an improvement in Cupel furnaces introduced into the royal foundry at Berlin, and also into Borsig's foundry, consisting of a new arrangement of the blast-holes. The furnace is surrounded with a hollow cast iron girdle, having eight blast holes communicating with the furnace. The blast is said to be so much increased as to melt with 20 lb of coal 2½ cwt. of iron, whereas before it melted only 1½ cwt. Another advantage of this plan is, that by means of a pane of thick plate glass, set on the outside, the progress of the melting can be watched.

Herr Winkelmann also exhibited a model of the trussing for a bridge on a new construction.

Herr Hermes, architect, of Schwerin, gave a description, with drawings, of an improvement on the Turbine, introduced by Herr C. L. Nagel, of Hamburgh.

After dinner, at twelve or one o'clock, the Association took a trip by water to examine the Ludwig canal.

Sept. 10.—The Association met at breakfast at seven o'clock in the morning, and afterwards examined the City picture gallery. The business proceedings began at ten o'clock. The time for the meeting this year was left to the committee, and it was suggested that four days' meetings should be held instead of three. The place of meeting fixed upon is Prague.

This routine business being over, the company went to examine the collection of paintings belonging to the Cathedral Chapter. At two o'clock the grand celebration dinner was held, when a hundred sat down. Thus concluded the proceedings.

The number of members who attended was 90, and the number of drawings exhibited was 129, very few of them, however were original, principally studies and representations of churches. They filled four rooms.

NOTES OF THE WEEK.

A most important discovery connected with Egyptian antiquities has been made, fully confirming the anticipations of the great Dr. Young, that copies would be found of the decree inscribed on the Rosetta stone. Dr. Lepsius, in charge of the Royal Prussian Expedition, has discovered in Nubia a perfect copy of the decree, including the demotic inscription. This was announced last week in the *Literary Gazette*, and very great results are anticipated.

By the return of the Commissioners of Woods and Forests we find they have very laudably appropriated £580. to the purchase of old tenements, obscuring Holyrood House, and £711. for a similar purchase as connected with Arbroath Abbey. We wish this department were charged with the maintenance and restoration of our ancient monuments. In Scotland alone many fine ecclesiastical edifices might be preserved, which are now going to ruin.

A statue of General Bertrand is proposed to be erected by public subscription at Chateauroux, his birth-place.

A mining engineer is employed by the French government expressly to look after the mineral springs in France.

An exhibition of paintings will be held at Ghent next July, which will, it is said, be well worthy of the contributions of foreign artists, and of their examination.

A bronze statue by M. Moldknecht, life size, is to be erected at Condé sur Noireun to Captain Dûmont D'Urville, the navigator.

Mr. Cavé has lately completed a pair of 150 horse oscillating engines, or the two equal to 300 h.p., for an iron steam vessel, which he has likewise built for the French Government in Senegal; it is to be propelled by a screw made entirely of wrought iron, galvanized and coated with a peculiar varnish to prevent its corrosion by salt water. By a very simple contrivance, for which Mr. Cavé has taken out a patent in France, the screw can at all times be disengaged from the gearing and brought upon deck, so that the speed of the vessel may not be impeded by it when there is a sufficiency of wind to use sails without steam. Before Mr. Cavé decided on adopting any peculiar sort of screw, he caused an iron steam boat, with a steam engine of the power of 20 horses, to be tried up the river Seine, to be propelled by at least 20 different shaped screws, till at last he found one more effective than the other, which he adopted for the vessel.

We perceive by the daily papers that the launch of the *Janus* steam-frigate took place on Tuesday, the 6th instant, at Chatham Dock-yard, being a vessel of peculiar construction, designed by Vice-Admiral the Earl of Dundonald, better known as Lord Cochrane. After the launch she was taken charge of by the master-attendant, and was warped alongside the sheer hulk to have her machinery fitted. The form of the body of the vessel nearly resembles that of a wedge towards the extremities, is precisely similar at both ends, and is, consequently, capable of moving in either direction with equal facility; her capabilities of advancing and retreating in narrow channels, for the purpose of offensive warfare, are thereby made perfect. The following are her particular dimensions:—

	Feet.	Inches.
Length between the perpendiculars	180	0
Length of keel for tonnage	159	1
Breadth, extreme	30	0
Breadth, moulded	29	4
Depth in hold	19	1
Tonnage, old measurement .. 761 53-94		
Intended load draught of water, with 260 tons of coals	11	2
When launched her draught of water (with 40 tons of ballast on board), was—Forward ..	7	5
Abaft ..	7	2

The *Janus* is fitted with a rudder at each extremity, but on ordinary occasions one only will remain in place. The tillers work on deck. She has two capstans, and is provided with a pair of hawser-holes abaft as well as forward, but only one pair of riding bitts and one pair of catheads. Her armament will consist of a 10-inch gun at each extremity, throwing hollow shot of 86 lb. weight, and she will also be capable of mounting two 42-pounder guns. The engine by which this vessel is to be propelled is an invention of the gallant earl who designed her. It is to be a rotatory engine, which, it is said, will not occupy more than one-sixth of the space required for the common reciprocating engine. It may be placed so low as to be out of reach of gun-shot; it will have no beams, cranks, side rods, parallel motions, levers, &c.; and it may be fixed in less than a quarter of the time now required for fixing marine engines. While its first cost is considerably cheaper, it may be more easily kept in repair, (?) in the opinion of the projector, than the steam machinery now in use on board vessels of war.

A Government trial of the *Screw Propeller* took place on the 3rd instant with her Majesty's steamer *Rattler*, at the measured distance in Long Reach, in order to determine, as correctly as possible, her rate of going, as compared with that of her sister ship, *Prometheus*, which had been ascertained by the Government authorities the day before, by a similar trial. The *Rattler* having been built for the purpose of testing the merits of the screw propeller with those of the paddle wheels, is constructed as nearly as possible upon the lines and models as the *Prometheus*; they have both the same amount of engine power—viz., 200 horses; both vessels were laden to the same draught of water—viz., 11 ft. 3 in.; the steam pressure in both cases was regulated alike—in fact, every thing that could be conveniently done to render the trial a fair one was duly attended to. Under these circumstances more than ordinary interest was excited amongst the naval and engineering officers connected with the Woolwich Dockyard establishment, by whom the results of the various trials of both vessels were most minutely noted, and in the end summed up, contrary to the general expectation, in favour of the *Rattler*, to the extent of nearly half a knot per hour, their relative speed being as follows:—*Prometheus*, 8·757 knots; *Rattler*, 9·240 knots, or within a fraction of 10¾ statute miles per hour. The *Prometheus* is one of the third-class war steamers recently introduced into her Majesty's navy by the present surveyor, Sir William Symonds, and is, we are informed, under orders to sail almost immediately for the Mediterranean.

SEVERN IMPROVEMENT.

The Lincoln Lock and Weir being the first of the series connected with this important work, have been brought into full operation. The lock is 100 ft. long by 20 ft. wide, with a lift of 7 ft. at low water. The walls and invert are faced with blue Staffordshire bricks of excellent quality, and are built upon a foundation of red sandstone rock. The water is let in and discharged through a culvert 7 ft. high by 4 ft. 6 in. wide, built in one of the walls, and running parallel with the lock chamber, with which it communicates by seven arched openings, by this arrangement the lock is filled with such rapidity that vessels have been passed through it in 2½ minutes.

The weir which is 300 ft. in length, is constructed of two rows of sheet piling, the waling of which form the upper and lower sills, the intermediate space being filled with blocks of red sandstone; a large quantity of this material is also placed below the lower sill to protect the piles from the action of the water. Both the lock and the weir are placed in artificial cuttings, which arrangement required the waters of the Severn to be diverted from their original course. From a variety of causes this was a work of no small labour and difficulty, but it was successfully performed, and the water was turned into its new channel over the weir on the 30th of December last.

Four other locks, one being 150 ft. long by 30 ft. wide, together with their accompanying weirs, which range from 300 to 400 ft. in length, are in course of construction between Stourport and Deglis, near Worcester. The works below Worcester consist of a series of embankments, and the deepening of the navigable channel by dredging.

The whole of these works is being executed under the direction of Wm. Cubitt, Esq., as engineer in chief; Mr. E. Leader Williams, being the resident engineer, and Messrs. Grissell and Peto, the contractors.

CANNABIC COMPOSITION ORNAMENTS.

At the last meeting of the Royal Institute of British Architects and the Institution of Civil Engineers, several ornaments of this new material for decoration were exhibited. Any new material that may facilitate the introduction of ornaments into our dwellings cannot be otherwise than acceptable, for fortunately a great demand exists in the present day for decorations.

The Cannabic composition is an Italian invention, which, although it has been some years in existence, has only lately been brought to such a degree of advancement, as to justify its introduction into this country. The material which is used in this composition is the common hemp, which possessing great tenacity and equal pliability at the same time that it is procured in abundance and at a moderate price, affords every facility for carrying out the invention. It admits of application to any internal architectural ornament, as ceilings, bosses, truss moulding, brackets, panels, capitals, pilasters, and mouldings of every kind and in every style, as well as for external purposes. It has an exceedingly good surface, admitting of any kind of varnish, paint, or finish. For gilding it is most admirably adapted, likewise for painting, varnishing, burnishing, and bronzing, as may be seen, by specimens at Mr. Ponsonby's, the gilder and decorator in Piccadilly. It takes a beautiful bronze colour, and by gilding acquires quite a metallic surface and high burnish. The advantage of these properties in decoration will be well appreciated by the architect, as giving new resources for carrying out his ideas. Neither are the consistency and durability of the material less observable, being at the same time hard and elastic. From these properties it is not liable to crack when put up in a room. It possesses a great degree of sharpness and boldness, which it is the intention of the patentees to increase by using a greater degree of mechanical power. It is such a light material that it admits of being put up in large masses on ceilings and in other situations in relief. With regard to external properties, it is not at all effected by wet nor by the vicissitudes of the atmosphere, being waterproof. In centre pieces for ceilings, door-panels, and other compositions, as it admits of being executed in larger pieces, it is much less troublesome than the ordinary materials. The number of patterns for selection in the cannabic material at the present moment amounts to about four hundred, many of them quite new; but this number will speedily be increased, while the patentee will be most happy to afford every facility to architects who may wish to have patterns executed from their own designs.

The price, it is stated, ranges from about 10 to 20 per cent. below the prices of articles in common use, and it is on this ground that the patentees expect its extensive application. For decoration in the colonies and the East and West Indies, great difficulties at present exist, as most materials suffer rapid deterioration from the climate. The supply of a durable and cheap material will therefore be the means of extending ornamental decoration in our extensive possessions: it is likewise well adapted for the decoration of steam vessels.

ON SUPPLY OF WATER AT FIRES.

A great many proposals having lately been urged upon Government with the view of establishing in London, and all the large towns throughout the provinces, a system for the more speedy extinction of fires, viz., by attaching hose or leathern pipes, with branches, to the plugs and mains laid down in the streets, so that the water might be thrown to a sufficient altitude by its own pressure, without the aid of fire-engines, an experiment a few days since was made by Mr. Quick, the engineer of the Southwark Water Company, in order to ascertain how far it could be made applicable. The company not having the necessary apparatus to make the trial, the assistance of the Fire Brigade was granted to carry out the experiment, Mr. Braidwood, the superintendent of the force, being present on the occasion, the particulars of which will be found to be highly important. The report, which is extremely voluminous, states that it took place on the morning of Thursday, 8th instant, between the hours of 4 and 9 o'clock, Mr. Quick selecting Old Gravel-lane, Union-street, and Tooley-street, as the most favourable spots to carry on the operations. During the whole period the pressure of water at the company's works at Battersea was kept at 130 ft., and every service pipe or outlet was kept shut, so that the trial should be fairly made. The first experiment took place in Union-street, by having lengths of rivetted leathern hose ($2\frac{1}{2}$ in. in diameter and 40 ft. long) attached to 6 standcocks, placed into plugs, all situate within the space of about 700 yards. The water was conveyed from the head at Battersea, through 5,300 yards of iron piping, consisting of 4,250 yards of 20-in. main, 550 yards of 15-in. main, and 500 yards of 9-in. main. On one standcock being opened, the jet of water thrown from the copper branch (with $\frac{7}{8}$-in. hose pipe on) reached an elevation of 50 ft., and the delivery was at the rate of 100 gallons per minute. The next object sought was to ascertain the quantity of water that could be obtained from the plug. The branch-pipe for this purpose was taken off, but the length of hose remained on. The delivery was then found to be 260 gallons per minute, showing that nearly two-thirds of the water was lost by confining it to a small jet. Had the standcock and hose been taken away, there would have been quite sufficient water to supply three fire-engines, each delivery being equal to the discharge from the first standcock. Another was then opened, and the jet from the former was reduced to 45 ft. elevation. Other two were added, and the jet of the first was then 40 ft.; and on three being opened, the jet from the first rose to 35 ft. The fourth was opened, and the jet of the first decreased to 30 ft. The fifth was then brought into play (viz. six in all), and the jet from the first only measured 27 ft., fully showing that there was a regular gradation in the height of the jets, according to the number opened. The next trial was made in Tooley-street, the standcocks being used as in the former case. Some slight difference was observed in the elevation to which the jets were thrown, the first gaining 60 ft.; and when the whole were opened the height was reduced to 40 ft., the delivery of water being at the rate of 70 gallons per minute. Another trial was then made in a street leading into Tooley-street, where there was only a service-pipe laid down, called a 5-in. main. The first standcock threw a jet of 40 ft., and on the others being opened, the one furthermost from the first started only emitted a jet of 24 ft., and a delivery of 58 gallons.

FAILURE OF A QUAY WALL.

A good many years since a breast wall or quay was built at Ardentallan, in Argyleshire, for shipping stones from a quarry at which much work has been done. When Mr. David Smith, builder, at Oban, was erecting the beacon of Skervuil in Jura Sound, for the Northern Lights' Board, he fitted the courses of blocks for that work to their places on the quay, and has occasionally had upwards of 260 tons of stones upon it at a time, without accident. The quarry has lately been worked for the repairs of the Caledonian Canal, and on the 23d ult. there were between 170 and 180 tons of dressed stones lying upon the quay ready for shipment, when, to the astonishment of the quarriers, the crane upon the quay was observed to move and shake without any visible cause, and some openings appeared at the surface of the quay, which were rapidly widening; the men on the instant cried out for the foreman, who rushed to the spot, and saw the quay, with its crane and the cairn of blocks upon it, moving outwards from the shore, and sinking in the deep water; and in less than two hours the whole had proceeded seaward about 50 yards, and settled with a depth of 11 ft. water over them. This quay was 48 yards in length, and had a large space behind for arranging materials for shipment. The face wall was founded one foot under the lowest tide mark, upon a bed of strong blue clay, covered with a thin stratum of gravel; and at 100 yards from the site of the quay the water deepens to 4 fathoms. It is remarkable, that with much heavier loads this breast work should have stood so long without any apparent failure, and after the foundation was so much consolidated, that it should have completely left its site and settled in deep water. The whole mass is now so completely absorbed in mud and clay, that although the height of the quarry and materials could not be less than 20 ft., it has not lessened the depth of water at the entrance of the place.—*Scotsman.*

MEETINGS OF SOCIETIES FOR THE ENSUING WEEK.

Monday.—Royal Institute of British Architects at 8.—Some original Drawings, by Frederick Catherwood, Esq., Architect, Honorary and Corresponding Member, of Architectural Antiquities recently discovered in some ruined Cities in central America, will be exhibited and described.
—Chemical Society, at 8.

Tuesday.—The Institution of Civil Engineers at 8.—"Description of a bridge across the river Shannon at Portumna," by T. Rhodes, M. Inst. C.E.—"Description of a bridge over the river Whitadder at Allanton," by J. T. Syme.—"Description of a cast and wrought iron trussed girder for bridges, with a series of experiments on their strength," by F. Nash.

Wednesday.—Society of Arts, at 8.
—Geological Society, $8\frac{1}{2}$.
—London Institution, Finsbury Circus, at 7.

Thursday.—Royal Society, at $8\frac{1}{2}$.—Society of Antiquaries, at 8.

Friday.—Royal Institution, at $8\frac{1}{2}$.

Saturday.—Royal Institution, at 3.—Professor Brande, "On the Chemistry of Agriculture." Lecture IV.

AGRICULTURAL CHEMISTRY.

By Professor Brande, F.R.S., &c.

Lecture III.—*Delivered at the Royal Institution, Feb. 10, 1844.*

(Specially reported for this Journal.)

If the agricultural chemist had been asked, a few years ago, what were the essential ingredients of the soil, he would most assuredly have said that the earths and the organic matter present were all that were important; but that the principal part of the nourishment was due to the organic matter, and that the saline ingredients were of very little use. Now, however, he would have quite a different story to tell, and it is principally to Liebig that we are indebted for a more correct view of the subject; for it is now proved beyond doubt, that although the salts present in the soil may form a small per centage of the whole, yet they must not be considered as accidental, but as being perfectly indispensable to the plant, which, according to its nature, takes up one or other into its circulation, and without which it could not exist. By the salts must be understood all the substances consisting of a base united to an acid. The principal bases are potash, soda, lime, and magnesia; these are always present in fertile soils. The acids with which they are generally in combination are the carbonic, sulphuric, and phosphoric acids, and frequently silica, so that when the chemist talks of flint, he sometimes speaks of it as an acid, which it really is; for although not sour to the taste, being insoluble, it combines with bases, forming neutral and frequently soluble salts, which is a better proof of being an acid than the action on the tongue. When plants are burnt so as to destroy their organic part, their saline constituents alone are left, forming the ashes of plants, and the quantity of ash varies greatly with different plants and with different parts of the same plant, as will be evident by inspecting the following table:—

Quantity of Ash in 1000 parts of

Hay	90	Potatoe . . .	40	Birch	3
Red Clover . .	77	Turnips . . .	70	Oak	2
Wheat	12	,, leaves .	130	Elm leaves . .	120
,, straw . .	60	Elm	20	Willow leaves .	82
Oats	40	Willow . . .	5	Beech leaves .	42
,, straw . .	50	Beech . . .	4	Birch leaves .	50

An investigation of the properties of the principal salts in the soil and their components will make this part of our subject more intelligible. And first of their bases. These are metallic oxides, the metals of which were first obtained in a separate state by Sir H. Davy. They are named, respectively, of potash, potassium, of soda, sodium, of lime, calcium, of magnesia, magnesium, of baryta, barium, &c. But potassium, which, is, perhaps, the most easily obtained, may be taken as the type of the class. It is a white metal, like silver, lighter than water, which is also the case with sodium. When thrown into water it runs over the surface, decomposing it with great rapidity, liberating its hydrogen, which ignites from the heat evolved, and combining with the oxygen, forms potash, which is instantly dissolved. The alkaline property of the solution, may be rendered evident by its action on vegetable colours, turning yellow to brown, and frequently red to blue. If acids be added they will combine with it, forming neutral salts, which may be obtained by evaporation. The other alkaline metals go through the same process, although none so energetically as potassium; though sodium approaches very nearly to it in this respect. The proportions in which they combine are,

40 parts potassium to 8 oxygen, producing 48 potash,
or 24 ,, sodium to 8 ,, 32 soda.

From these figures it will be evident that wherever soda can be used as a substitute for potash, 32 lb. would do the work of 48 lb. of potash.

As it is very important to the agriculturist to ascertain whether a soil contains salts of potash or of soda, the distinguishing tests must be borne in mind. In order to get them in a proper state for testing, boiling water is poured on to a portion of the soil, and then the whole poured on to a filter; the water running through carries away all the soluble portions. If this be then evaporated, the resulting salt will frequently indicate, by its shape, solubility, and behaviour in air, which base it contains. They are generally in combination with sulphuric acid, and if it be the sulphate of potash present, it will be found to be very slightly soluble, and remaining unchanged by exposure; whereas if it be the sulphate of soda, it will be very soluble, and by exposure to air, become covered with a white powder, or efflorescence, as it is termed. This arises from its giving up to the air some of the water which it had combined with when crystallizing, and so falling into a white powder. The tests most commonly used in the laboratory, are tartaric acid and chloride of platinum. When the former is added to a solution containing soda, no precipitate is produced; but if to one containing potash, a very copious crystalline precipitate is produced of bi-tartrate of potash, or as it is commonly called, cream of tartar. When there is very little potash present, t forms very slowly, but it may be hastened by rubbing the sides of the vessel with a glass rod, when the crystals are deposited on the parts where the rod has rubbed, as though a little tickling coaxed the solution to deposit its crystals m re rapidly. With the chloride of platinum, soda gives no precipitate, but potash yields abundantly a yellowish brown deposit, consisting of the double chloride of platinum and potassium.

Some plants absorb but little alkali from the soil, whilst others take an immense quantity. Amongst the latter is the common wormwood, which impoverishes a soil of its alkali in a very short time. Indeed, so well known is that, that it has, for years past, been collected and burnt, and its ash, known as salts of wormwood, applied to many purposes on account of the quantity of alkali it contains. Similar to this is the grape, which appropriates to itself abundance of potash, which it deposits from its juice in fermenting, as salt of tartar. The alkalis are seldom found combined with carbonic acid, for although they are so in the ashes of plants, it arises from the decomposition by heat of other organic acids, they being converted into carbonic acid. In the wood sorrel, for instance, the juice is intensely sour, owing to the presence of binoxalate of potash; but after being burned, the oxalic acid is all decomposed into carbonic acid, the whole of the salt having become carbonate of potash.

But it will be interesting here to notice the bases of the inorganic acids. Silicic acid or silica has already been touched upon. Sulphur, the base of sulphuric acid, familiar to every one as brimstone, is found in nature both free and in combination; free, in abundance in Sicily, and in combination, plentiful in our own islands. With iron it is exceedingly common as iron pyrites or sulphuret of iron; recognized in coal by its bright yellow colour, and washed out of our chalk cliffs in rounded masses of almost every size, which are commonly looked upon as thunderbolts. When sulphur combines with oxygen, it forms sulphuric acid, which takes place spontaneously when iron pyrites is exposed to air and moisture. This acid may be formed artificially on a small scale by immersing a lighted mixture of sulphur and saltpetre (nitrate of potash) into a jar of oxygen gas standing over water; the sulphur then burns with a beautiful blue flame, combines with the oxygen, and forms sulphuric acid, which is dissolved by the water, forming a weak solution of oil of vitriol. Now this is remarkable for its fixity, so that it may be placed in a proper vessel over the fire, and the water boiled away, leaving the sulphuric acid. This is the method commonly employed in the manufactories for strengthening it. The acid consists of 16 parts of sulphur, 24 of oxygen and 9 of water, forming 49 parts of the strongest oil of vitriol. This acid is very rarely found free in the soil, as its noxious properties would make it the most sterile of land. But as will be shown hereafter, some plants possess the property not only of separating the acid from its alkili, but even of separating from it the sulphur, which it employs to form new combinations, as for instance, the essential oil of the mustard, and the radish, in which there is a considerable quantity of sulphur. But decaying vegetables will do the same, the sulphur in this case combining with the hydrogen which is being given off, and forming the offensive gas, sulphuretted hydrogen, familiar to all who have smelt a foul gun barrel, or a rotten egg. It is to this decompostion is due the nauseous smell of water in which vegetables have been boiled, and is continually taking place at the mouths of rivers, which empty into the sea vast quantities of rotting vegetable matter, which there meets with the sulphates in the sea water, and the decomposition takes place. Ships anchored in such situations have their copper corroded off in one-half the usual time, and to the same cause is also attributed the unhealthiness of certain African rivers. But although sulphuretted hydrogen is known to be very destructive of life when present in considerable quantity, it is doubtful whether it is so injurious to man when in the minute quantity which it must be in the open air, even in the worst situations; the daily experience of the chemist would seem to confirm this, for, from its being so much used as a test, he is continually breathing an atmosphere sensibly impregnated with it, and yet with impunity, as it has never been known to produce any effects analogous to the eastern fevers. To other causes, then, must be attributed the contagious influences present in the air of these shores, and nothing seems more probable than that it is due to certain decomposing organic particles, acting on the blood in the manner of a ferment. The best test for its presence, either in solution, or in the air, is a solution of sugar of lead, which it blackens even if present in a very minute quantity, producing sulphuret of lead. Though sulphuretted hydrogen is undoubtedly very pernicious to animal life, it is not so to plants, and its solution in water has been used with advantage even in horticulture, by Sir E. Solly. Indeed it is essential that many plants should be supplied with sulphur in some shape or other, as they require it to assist in forming some of their constituent parts. The gluten of wheat, for instance, could not be formed without it, and it is essential to the mustard, cabbage, turnip, water cress, and indeed to the whole of the large class of cruciferous plants. From this it is seen that the alkaline sulphates are frequently doubly useful in the soil, as being the source of alkali and also of sulphur. Their presence in solution is readily ascertained by baryta dissolved in nitric or muriatic acids, which forms the very insoluble white sulphate of baryta, not redissolved by nitric acid. By this means it is proved that whereas in wood ash the alkali is present as carbonate, in coal ash it is as sulphate, which is therefore a good top dressing for many crops.

When combined with lime, sulphuric acid forms sulphate of lime or gypsum. It is found in great abundance in many parts, in the neighbourhood of Paris as plaster-stone, where it is rendered anhydrous by burning, converting it into plaster of Paris, as it is termed. It crystallizes beautifully as selenite, found in clay districts. Satin spar is also a very beautiful variety of this substance. It is found anhydrous also, but not frequently. It exists in considerable quantity in the rock salt of Cheshire. In some countries it is found to form so large a portion of the rock salt, even of some kinds which are eaten at table, that if the table salt be dissolved from it, it still retains its form, as a spongy mass. In this way whole mountains are said to be disintegrated. This will also serve to explain an expression of scripture, which is otherwise obscure to us who use salt in a state of purity, respecting salt losing its savour; if a mass of rock salt containing much sulphate of lime, be exposed to heavy showers, the table salt is dissolved out, the original shape still being retained; and thus salt may be said to lose its savour. Of the virtues of gypsum as a manure, the agriculturist has lately heard a great deal, but there is no doubt that its virtues have been highly exaggerated. There is very little proof of its being useful to any plants which do not include sulphate of lime in their composition; but as lucerne, saintfoin, clover, and turnips contain a portion, there is no doubt it is of use to them, when applied as a top dressing. There are cases in which red clover may spring up, promising luxuriantly, but ultimately die away—the soil is tired of clover, as the farmer says; in this case sulphate of lime is frequently of great service, though it is by no means the only substance clover requires. We have Johnstone's evidence that clover and vetches are both improved by its use. Indeed the ashes of many plants show that they require it, as their sulphates frequently amount to as much as 10 per cent. of the ash. A wagon load of gypsum is said to be sufficient for 30 or 40 acres. The water falling on the surface slightly dissolves it, one part requiring 500 or 600 of water for solution. It may be owing to its sparing solubility in water, that we have so many contradictory statements of its efficacy, as the farmer who uses it on very dry land, or during a very dry season, would perhaps derive but little benefit from it.

The consideration of the phosphates, of bone manure, with the relation of the inorganic to the organic constituents of plants, will form the subject of the next lecture.

REGISTER OF PATENTS.

MACHINERY FOR CUTTING STONE.

Charlton James Wollaston, of Welling, Kent. Gentleman, for "*Improvements in machinery for cutting marble and stone.*"—Granted August 1. 1843; sealed February 1, 1844.

The first part of these improvements consists in a machine or apparatus for cutting blocks of marble or stone; the machine consists of a rectangular or oblong table of iron or other suitable material, supported upon the framing of the machine in a horizontal position upon two V slides, and is capable of being moved thereon in a direction of its length. On each side of the machine, and about the middle thereof, there is a vertical frame, and to this frame are attached the cutters, which are set at some distance apart, and stand off from the edge of the frame at different distances, so that each cutter, beginning from the lower one, will make its cut further and further into the block of marble or stone (which block is placed and secured by set screws upon the table of the machine), so that the cuts in the side of the stone will form a succession of steps, which peculiar arrangement of the cutters forms the principal feature in this part of the invention. The frames and cutters are moved up and down in a vertical direction by means of two connecting rods, each of which are attached by one end to the cutter frame, and at the other or lower end to a stud fixed into the face of the wheel, keyed on the end of a horizontal shaft, running under the table of the machine, the rotary motion of which gives the necessary motion to the cutter frame; the extent or range of the cutter frame can be regulated by putting the pin into certain holes drilled in the face of the wheel, at different distances from the centre thereof. There are also certain arrangements for moving the table upon which the block is fixed, so that the stone on the return stroke of the cutter frame moves back for giving clearance to the cutters, but when the same are about to cut into the sides of the block of stone, the table is moved forwards equal to the distance given for the clearance, and the depth intended for the next cut, all of which movements are self-acting or governed by the mechanical arrangements of the machine.—The second improvement consists in a mode of making stone pipes. The block of stone intended to be bored out is placed with its end upon a table; below the table, and in a vertical position, there is a metal tube, on the upper end of which is fixed several cutters; the table upon which the block of stone is fixed can be lowered by means of a screw, upon the end of the tubular cutter, which cutter, having a rotary motion given to it, bores a hole into the end of the stone equal in diameter to the cutter, the portion of stone cut out passes through the tubular cutter.

BLACK DYEING.

Frederick Steiner, of Hyndburn Cottage, near Accrington, Lancashire, Turkey Red Dyer, for "*A new manufacture of a certain colouring matter, commonly called garancine.*"—Granted August 8, 1843; enrolled February 7, 1844.

This invention relates to a mode of obtaining a colouring matter commonly called garancine, from spent madder, or madder after it has been used for dyeing, and is performed as follows:—The inventor constructs a large filter of brickwork, but without mortar, outside the dye-house, that is to say, a hole is to be dug in the ground, and lined with bricks, and upon the bricks is placed a quantity of stones or gravel, and a piece of fabric, such as common wrappering, and below the filter there is a drain to take off the water which passes through. A quantity of diluted sulphuric acid, of the specific gravity of 105°, water being 100°, is kept in a vessel near the filter; the spent madder which has been used for dyeing is allowed to pass, by means of a channel, from the dye pan to the filter, and when running in a portion of the dilute sulphuric acid, is allowed to run in with it, which changes the colour of the madder to an orange tint; after the water is drained off, the residue is put into bags, and the same put into an hydraulic press, and afterwards passed through a sieve, the madder is then put into a wooden or leaden vessel, and to every 5 cwt. of madder 1 cwt. of sulphuric acid of commerce is added by sprinkling, and the whole thoroughly mixed together. The madder in this stage is placed on a perforated lead plate, fixed about six inches from the bottom of a vessel, and between the bottom of the said vessel and the perforated plate, a quantity of steam is introduced, which passes through the said perforated plate and mixture contained in the vessel; a substance will now be obtained of a dark brown colour, approaching to a black, this substance is garancine and insoluble carbonized matter. The substance after being thrown out to cool, is washed with a quantity of clear cold water until all the acid is destroyed; it is then submitted to pressure, and after being dried in a stove is ground between a pair of ordinary madder stones, after which from 4 lb. to 5 lb. of carbonate of soda to every 100 cwt. of the mixture may be added to neutralize any acid which may remain. The patentee claims the manufacture of garancine from spent madder, or madder after it has been used for dyeing.

A NEW SUBSTANCE FOR PAPER.

Richard Archibald Brooman, of 166, Fleet Street, London, Gentleman, for the "*Manufacture of paper, cordage, matting, and other textile fabrics, as also for the application of the said materials to the stuffing of cushions and mattresses.*" Granted August 10, 1843; enrolled February 10, 1844.—Communicated.

This invention consists in a mode of manufacturing paper from the convolvuli of the cissus genus of plants, which are found in Guiana, coast of Africa West India islands, and other parts. The mode of converting this vegetable into paper is as follows:—The bark or rind is in the first place stripped off the stems, and the fibres separated by being bruised, after which the fibres are to be dried in a stove, or by other suitable means, to free them from the sap; they are then boiled for some hours with a quantity of American potass, and afterwards washed, and then bleached by the application of chlorine or other suitable matter; the next process, after the fibres have been properly bleached, is to card them with a metal comb, after which they are reduced by suitable machinery into a pulp, and may then be manufactured by the ordinary process into paper. The inventor states that the above may be combined with rag pulp, or other suitable material. There are also other herbs, known in the West Indian islands by the name of herbs conpunts, and also the bark of the West Indian pear tree, from which a good paper may be manufactured. That part of the specification, which relates to the manufacture of cordage, matting, and other textile fabrics, consists merely in the application of the herbs before referred to, which are rendered into filaments and then manufactured in the same manner as flax or hempen ropes. And lastly, this invention relates to the application of the aforesaid material, when reduced into fibres, to stuffing chair cushions, mattresses, &c. The patentee claims the application of the aforesaid material to the manufacture of paper, cordage, matting, &c., as above described.

PRESERVING OF PROVISIONS.

James Cooper, of St. John's Street, Clerkenwell, Middlesex, Provision Merchant, for "*Vessels of peculiar construction, and an apparatus for the purpose of preserving various articles of provisions for the use of families.*"—Granted December 5, 1843; enrolled February 5, 1843.

This invention, in the first place, relates simply to the arrangement and application of certain vessels for preserving fruit and other articles of provision; and, secondly, to a mode of stopping the vessels containing the fruit, &c., with corks or bungs. In carrying out the first part of these supposed improvements, the patentee, for the purpose of affording greater facility to private families in preserving meats, constructs a vessel of two or more parts made to fit one another, so that the vessel can be enlarged or diminished according to the size of a jar, containing the fruits or other matters to be preserved to be placed within it. This vessel is made at the lower end to fit an aperture, formed in the boiler of an ordinary kitchen range, so that the steam generated in such boiler can be turned to some useful account; this vessel is provided with a perforated bottom in order to allow the steam from the boiler to pass into the same; the jars containing the fruit or other article of food intended to be partially cooked, are successively placed within the aforesaid vessel, and subjected to the steaming process, when they have remained a sufficient length of time, the jars or vessels containing the fruit, which are made with a conical neck or opening, are to be tightly corked with as much expedition as possible, for this purpose the inventor forces the corks or bungs into the necks of the jars by means of a screw, which constitutes the second part of the invention; and consists in the application of a screw to the cork or bung, similar to that used in an ordinary screw press, this screw is to be kept constantly applied to the stoppers of the vessels until the contents are nearly cool. The patentee claims the mode of constructing a vessel or vessels in such manner that they may be applied to the boiler of an ordinary kitchen range, in order to preserve provisions in jars by the application of steam; and, secondly, to a mode of constructing apparatus for stopping jars and securing such stoppers till the contents of the vessels are cooled.

MUNTZ'S METAL SHEATHING PATENT.

In the Court of Common Pleas, Feb. 8 to 13. (Sittings at Nisi Prius, at Westminster, before Lord Chief Justice Tindal and a Special Jury.)

MUNTZ *v.* FOSTER AND OTHERS.

The trial of this cause, which lasted five days, commenced on Thursday, the 8th inst., and concluded on Tuesday evening, the 13th inst. about seven o'clock.

The Attorney-General, the Solicitor-General, Sir T. Wilde, Mr. Serjeant Bompas, Mr. M. D. Hill, and Mr. Cowling were counsel for the plaintiff; and Mr. Kelly, Mr. Jervis, Mr. Serjeant Channell, and Mr. Webster appeared for the defendants.

This action was brought for an alleged infringement of a patent granted on the 22d of October, 1832, to Mr. G. F. Muntz, M.P. for Birmingham, for "an improved manufacture of metal plates for sheathing the bottoms of ships and other such vessels." Copper sheathing for ships was lately in such general use, that it may not be recollected by the major part of the public that it was only about 50 or 60 years ago that the practice of sheathing the bottoms of vessels with metal was introduced, in order to protect the bottom from the barnacles and seaweed which adhered to a rough surface, and impeded the sailing of the vessel. Expensive as the process of coppering the bottom was, on account of the prime cost of the metal, the expense of rolling it into sheets, and the corrosion to which the metal was subjected by the action of sea water, the use of copper was found to be attended with this further inconvenience, viz., that being fastened to the bottom of the ship with iron nails, the iron very quickly rusted, the fastenings ceased to hold the metal, and the copper came off. Great as these drawbacks against the use of copper for this purpose were, the coppering of the bottoms of ships yielded advantages which more than counterbalanced the inconveniences by which the process was attended, and in order to make the invention still more useful Sir Humphry Davy turned his attention to the subject, and endeavoured to devise some method for counteracting the rapid oxydation which took place; as formerly the copper bottom of a ship rarely lasted longer than five or six years. It struck Sir H. Davy that if a portion of zinc were applied to the copper it would counteract the process of oxydation, and a vessel sheathed with copper and zinc plates, in accordance with his theory, was sent a voyage to a distant part of the world, from which it returned perfectly uninjured, so far as the bottom was concerned, by the salt water, but at the same time it was as foul as if there had been no metal at all upon the bottom. The experiment had succeeded too well; it had prevented any oxydation from taking place. The problem, therefore, still remained to be solved, whether any metallic composition could be found for the sheathing of ships, by the use of which the bottom could be kept clean, and at the same time too great a degree of oxydation might be prevented. To the solution of this problem Mr. Muntz, who is a metal roller at Birmingham, directed his mind, and commenced a series of practical experiments, for the results of which he took out a patent in 1832. The invention slowly but steadily attracted the notice of the shipping interest of the country; and it appeared that in 1834, in the port of London, 20 ships were sheathed with metal under Muntz's patent, the number gradually increasing, till, in the year 1843, there were in the same port 257 vessels sheathed with the new composition, of which 17,947 cwt. were sold in the last-mentioned year. The composition was a mixture of copper and zinc, which was cheaper than copper, was more easily worked, and lasted longer, being also sufficiently hard to allow of its being fastened to the sides of the ship with nails of the same composition.

The specification of the plaintiff's patent thus described the nature of his invention:—"I take that quality of copper known to the trade by the appellation of 'best selected copper,' and that quality of zinc known in England as 'foreign zinc,' and melt them together in the usual manner, in any proportions between 50 per cent. of copper to 50 per cent. of zinc, and 63 per cent. of copper to 37 per cent. of zinc, both of which extremes, and all intermediate proportions, will roll at a red heat; but, as too large a proportion of copper increases the difficulty of working the metal, and too large a proportion of zinc renders the metal too hard when cold, and not sufficiently liable to oxydation, I prefer the alloy to consist of about 60 per cent. of copper to 40 per cent. of zinc." It was proved by the testimony of several witnesses who were examined on the part of the plaintiff, and who were not contradicted, that any person acquainted with the trade of a metal roller could manufacture this composition from the description of the invention contained in the specification; and it appeared that between February and April, 1843, the defendants had made a quantity of sheathing, amounting in value to about 700*l.* or 800*l.*, some of which was sold by them in Liverpool, and which was declared, upon subjecting it to a minute analysis, to be as nearly as possible composed of the same proportions of copper and zinc as those pointed out in the plaintiff's specification as the best alloy for the purpose, namely, 60 per cent. of copper and 40 per cent. of zinc.

The defence set up was, that there had been no infringement of the patent; that the invention was not new, and that Mr. Muntz was not the first and true inventor; and, also, that the specification was bad for uncertainty, &c. Upon the first point, the infringement, the evidence seemed very clear; but the main ground of defence was, that in the year 1800 a Mr. Collins took out a patent for a composition for sheathing ships, which it was argued was substantially the same invention as that which the plaintiff claimed as his own. The specification of Collins's patent said, "The yellow sheathing (the sheathing in question) consists chiefly of zinc and copper. The compound must be heated, and in that state rolled. 100 parts of copper and 80 of zinc afford a good composition; but the proportions may be varied, or other metallic substances added, provided the property of bearing the mechanical process, when added, is not destroyed." Evidence was given on the part of the defendants to show that some of the metal sheathing made by them after April, 1843, was made from the specification in Collins's patent alone, and several witnesses were also called to prove, on their behalf, that a composition of copper and zinc, in the proportion of 60 per cent. of the former to 40 per cent. of the latter, had been made in the years 1828 and 1829, but it did not appear that any plates of this composition had ever been applied to the sheathing of ships. The defendants also raised various objections to the specification of the plaintiff's patent.

Lord Chief Justice Tindal, before he proceeded to charge the jury, told them that if they were desirous of hearing the whole of the evidence read over which had been given during the five days through which the trial had lasted, he should wish to take another day for the purpose of reading it through, in order that he might save their time; but if, having heard the evidence, to which they had paid great attention, and having taken copious notes, they did not require that assistance he would at once proceed to call their attention to the points on which they would have to give verdict.

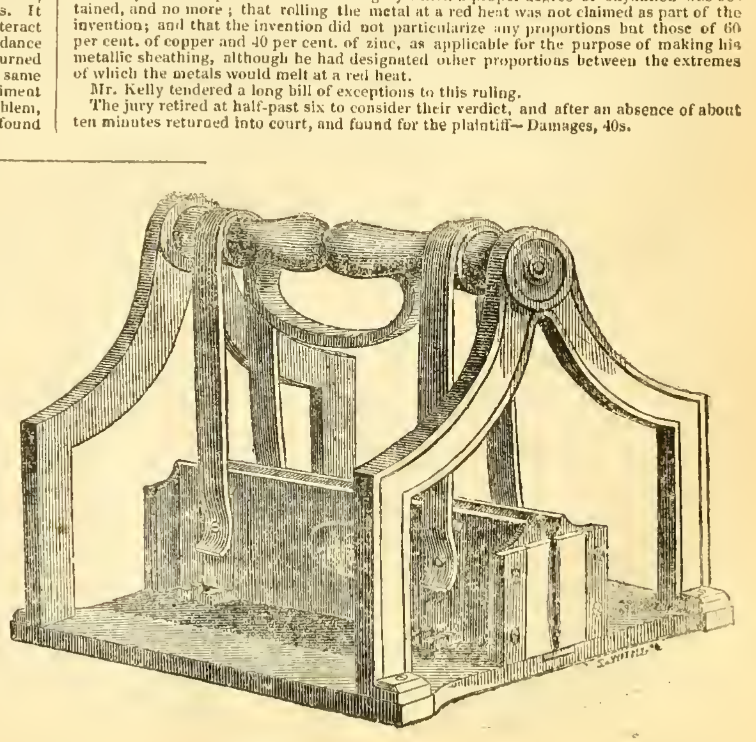
The jury immediately said, that it would not be at all necessary for his Lordship to read over the evidence to them.

The Lord Chief Justice then left it to them to say, In the first place, whether there had been any infringement of the patent granted to the plaintiff, assuming the patent to be good; secondly, if so, whether the manufacture was a new invention, or whether it had been already made public by Collins's patent; and, thirdly, whether the specification of the plaintiff's patent was sufficiently plain and intelligible to enable other persons to make the composition for which the patent had been granted. His Lordship also gave it as his opinion, upon the matters of law arising in the case, that the nature of the plaintiff's invention was well described by the title of the patent—"An improved manufacture of metal plates for sheathing the bottoms of ships or other such vessels;" that neither "best selected copper" nor "foreign zinc" formed part of the invention, which consisted in the discovery of a composition for sheathing by which a proper degree of oxydation was obtained, and no more; that rolling the metal at a red heat was not claimed as part of the invention; and that the invention did not particularize any proportions but those of 60 per cent. of copper and 40 per cent. of zinc, as applicable for the purpose of making his metallic sheathing, although he had designated other proportions between the extremes of which the metals would melt at a red heat.

Mr. Kelly tendered a long bill of exceptions to this ruling.

The jury retired at half-past six to consider their verdict, and after an absence of about ten minutes returned into court, and found for the plaintiff—Damages, 40s.

MADDEN'S IMPROVED KNIFE CLEANER.



THE accompanying engraving is a representation of a new Knife Cleaner, Polisher, and Sharpener, the invention of Mr. Madden, of George Street, Adelphi. It performs what it professes to do in a very effectual manner, with one half the labour and time by the old method, making no dust or noise. The great merit of the invention is its compactness and portability.

The machine is fixed upon a stand 12 in. long by 8 in.; it consists of two parallel cheeks of iron, the interior faces of which are slightly bevilled, and lined with buff leather; these cheeks are pressed together by two springs by which they are suspended: on the top of the cheeks is a groove to receive the brick-dust. When a knife is to be cleaned, it is placed between the cheeks at one end, and drawn backwards and forwards, which causes a small portion of the brick-dust to drop down, and by which means the knife is thoroughly cleaned.

The price of the machine is 15*s*.

CARRINGTON BRIDGE, NOTTINGHAM.

(With Engravings, Plate 2.)

This bridge was erected from the designs of H. M. Wood, Esq., Architect to the Corporation of Nottingham, and subject to the approval of Thomas Woodhouse, Esq., C. E. to the Midland Counties Railway. It was built at the joint expense of the Corporation of Nottingham and the Midland Counties Railway Company, at a cost of £5,945*l.*, and makes a new and beautiful approach to the Railway Station. The novelty of this bridge consists in the flatness of the arch (the span being 70 feet and the versed sine only 5, which is less than any iron bridge I am aware of,) it is also remarkable for having ornamental scrolls for spandrils. The width of the roadway is 50 feet. The masonry and approaches were executed by Mr. Henry Sharp, and the ironwork by Messrs. Cort and Co., ironfounders, &c., of Nottingham, and Leicester, and the work was completed in the most substantial and durable manner. The quantity of cast iron used in the course of erection amounted to 146 tons, and the wrought iron, including bolt and tension rods, about 1,568lb.

This bridge now forms a very pleasing object, and is one of the principal ornaments to the interesting town of Nottingham, and does equal credit to the public spirit of the inhabitants, the talent of the architect and the skill and enterprise of the contractors.

The bridge was commenced in the early part of 1842, and completed the same year, and much to the credit of those that were employed, not the slightest accident occurred during the progress of the works, not even so much as fracturing a stone or breaking a rope. After proper scaffolding had been thrown across the canal from abutment to abutment (under which the boats containing the ribs were brought), with necessary hoisting tackle, and a crab on each abutment, the whole of the ribs were hoisted into their places in 15 days. An attempt was made to test the ribs in the foundry yard, but in consequence of the difficulty in procuring suitable abutting places to carry the heavy weights intended to be applied, and the probability that they would not be fairly proved, it was abandoned, and they were afterwards tested in their places at the bridge in pairs, the weight consisting of pig lead, equally distributed over the whole length of the ribs, and the following is the result:—

		Weight applied.		Deflexion.
1st pair	..	50 tons	..	$\frac{3}{8}$
2d "	..	80 "	..	$\frac{3}{4}$
3d "	..	80 "	..	$\frac{3}{4}$
4th "	..	80 "	..	1
5th "	..	80 "	.	$1\frac{1}{8}$

No permanent set of any consequence was perceptible after the weight was withdrawn. Before the experiment, the ribs were securely wedged in their places, as shown in the drawings, and no evil effect appears to have arisen since the completion of the bridge from the expansion and contraction of the metal, as assumed by some engineers, and for which they make allowance in their works.

To form the roadway, Memel planks 4 in. thick were bolted to the ribs, this is, in my opinion, the only defect in the design of the bridge, as in works of this nature imperishable materials only should be used, covering plates of cast iron should have been substituted, which, although more expensive in the first instance, would have been the cheapest in the end, as timber in such a situation cannot be calculated to endure more than 20 years. The joints of the planks having been properly caulked, a layer of tar and pitch of equal parts mixed with sand, in proportion of half a peck of sand to nine gallons of tar and pitch, was applied in a hot and fluid state three quarters of an inch thick, which made a covering impervious to moisture. The roadway was formed of Mount Sorrel granite, with which was mixed a small portion of tar and pitch, and from the adhesive nature of the resinous matter, with the assistance of a roller, it readily consolidated and formed a compact mass. Roads or streets composed of this material make a very smooth and pleasant surface to travel over; it forms a very hard road, is perfectly clean in the winter, as the subsoil cannot work through it, and is free from dust in summer, an advantage of which no other road material, that I am aware of, can boast.

Iron as a material for bridges is growing more extensively into use, and its superiority over other materials, as to durability, facility of construction, and its capability of being moulded to any pattern, so as to form highly ornamental structures, becomes daily more evident; and its more general introduction in public buildings, manufactories, &c., would be of great utility.

The details of construction will be sufficiently understood by a reference to the engravings.

TUBULAR BOILERS.

(With Engravings, Fig. 1 to 4, Plate 3.)

It is our intention occasionally to give drawings founded upon the most approved mode of construction, of marine engines and boilers; we now commence with a tubular boiler for 60 H.P., and shall hereafter give designs for one of 150 H.P., and afterwards of 300 H.P., up to 500 H.P.

The drawings represent a tubular boiler, of the most improved construction, as used on board our fast river steamers, and now introduced into the vessels of Her Majesty's navy. The power is of 60 horses, say two marine engines of 30 H.P., or 3 ft. stroke, and $31\frac{1}{2}$ in. cylinders, making 30 strokes per minute. It may be manufactured in one piece, and with its apparatus *complete*, would weigh not more than 10 tons, a manifest improvement on the old system of *flue boilers*, which, for the same power, could not be made of less weight than 16 to 17 tons, and occupying, superficially, a space of 14 ft. square. The weight on the safety valve may be 10 lb. per square inch. The steam expanding in the cylinder at one-third of the stroke. It would easily perform this duty, with a moderate consumption of fuel.

The surface, and detail of construction, are as follows:—There are six rows of tubes of 19 each, or 114 in all: they are $2\frac{3}{4}$ in. diam. inside and about 3 in. outside. The superficial area will be $2\frac{3}{4}$ diam. = 5·94 area × 114 tubes = 677 square inches total sectional area of tubes.

The surface of tubes

$$2\tfrac{3}{4}\text{ diam.} = 8{\cdot}64\text{ cir.} \times 66\text{ in. long} \times 114\text{ tubes} = \frac{65007}{144} = 451{\cdot}4\text{ sq. ft.}$$

Plate surface. Fires (above grate) and uptakes .. 148·8

Total absorbent surface of boiler .. .. 600·0

Grate bar surface 7·0 × 2·1 × 3 fires = 43·9 square feet.
Area of grate uptake = 12 in. by 75 in. = 900 square inches.
Area of tubes (as above) .. = 677 ditto.
Area of chimney uptake 14 in. × 48 in. = 672 ditto.
Area of chimney = 24 in. diam. .. = 452 ditto.

To be evaporated per hour = $74\frac{1}{2}$ cubic feet of water, under a pressure of 16 lb. per square inch.

Results of surface, per nominal horse.

Grate bar surface $= \frac{43{\cdot}9}{60} =$ 07·25 square feet per horse.

Tube surface $= \frac{451{\cdot}}{60} =$ 7·5 ditto ditto

Plate surface $= \frac{148{\cdot}8}{60} =$ 2·5 ditto ditto

Total 10 square feet 10·0

Area of tubes $\frac{677}{60} =$ 11·25 square inches per horse.

Ditto of grate uptake $\frac{900}{60} =$ 15·00 ditto ditto

Ditto of chimney ditto $\frac{672}{60} =$ 11·20 ditto ditto

Ditto of chimney $\frac{452}{60} =$ 7·50 ditto ditto

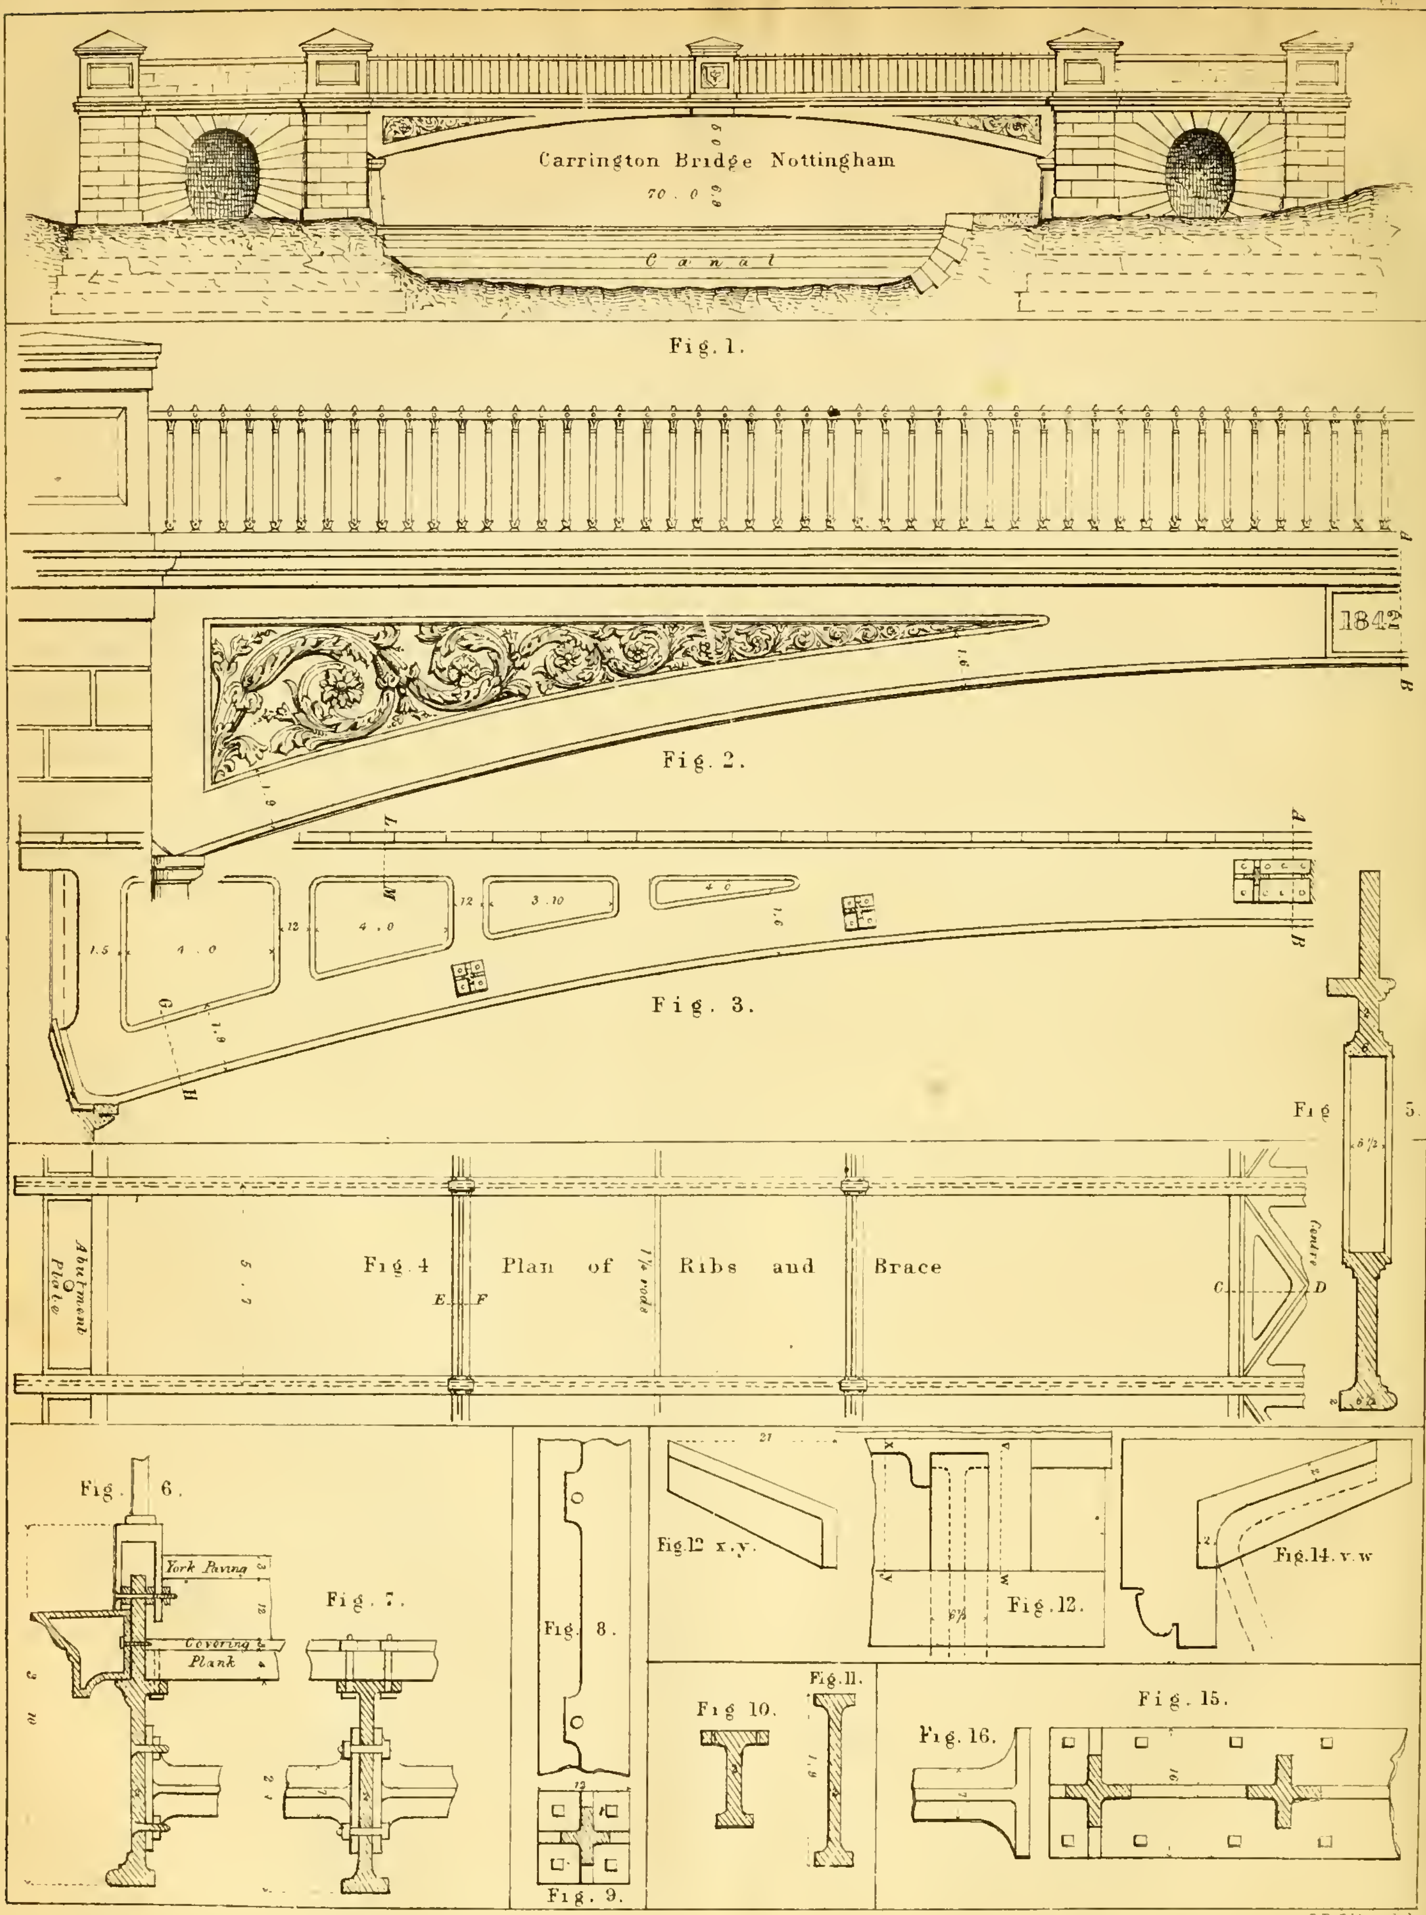
Parkyn's Direct Action Engine.
Air Pump



J. R. Jobbins lith

The materials of which such boilers should be constructed, are as follows—

Furnaces, of best Low Moor iron ⅜ in. thick; the grate and uptake should be of the same kind and substance. The tube plates are sometimes made of mixed metal; but we prefer Low Moor iron of ⅝ inch gauge. The tubes (if of brass) should they be those made by Alston, which are bare ⅛ in. thick, or 12 wire gauge. If made of iron, they should be those of Russell & Co.

A difference of opinion exists as to the advantages arising from the use of brass or iron tubes, although practice has hitherto been almost confined to the former; but it appears likely that a great change will shortly take place in this particular, arising from the injurious effects produced by galvanic action on the iron shell of the boiler, which in many boilers has occurred to an alarming extent. Of course this would be actively obviated by the use of iron tubes, and the advantage of the one over the other, is solely a commercial question, determinable by practice only. We think the *iron* tubes will be found the best in all respects, especially if means are taken (and they are simple) to prevent the accumulation of salt and calcareous deposits.

The shell and chimney uptake may be of best Staffordshire iron, ⅜ in. thick, and ½ in. below, say for 2 ft. up from the bottom, where the decay is generally very rapid. Care should be taken in properly staying every part.

PARKYN'S DIRECT ACTION ENGINE.

(With an Engraving, Plate 3.)

Sir—I herewith send you a drawing of a Double Cylinder Engine, which I patented in England last year. I have erected an engine, similar to that shown on board, the Iron Boat, Prince Albert, built for the Montreal and Laprairie Ferry.

The engraving is a longitudinal section through the engine, showing the method of connecting the cylinders with the air-pump, and transmitting the power to the main shaft. The novelty of the plan is the way in which the air-pump is worked, securing greater economy of space and fewer moving parts, and consequently less friction—these being the primary objects to be attained by all plans of direct acting engines. The cylinders are 42 inches in diameter, and 5 feet stroke. The air-pump is 28 inches, and the same stroke. The plunger of the air-pump is worked down to within 3 in. of the flooring of the vessel, thus securing the longest possible stroke for a given height, with an adequate length of connecting rod, which in the engine shown is ten feet. F, F, are the two foot valves—the discharge is at the side. The two valves G, G, in the air-pump plunger are to allow for the exit of any air that may collect in the pump.

The valves of the engine are four in number, two for the steam on the left, and two for the exhaust on the right they are of the kind generally denominated the Equilibrium Valve, and worked by two eccentrics, one for each pair; this is adopted to secure the means of cutting off the steam valve at any part of the stroke. The engine can be started, stopped and handled by a force not exceeding 40 lb. applied to a lever 3 feet long. The condenser is immediately below the nozzles, thus securing instant condensation.

The engine at ordinary working makes 21 revolutions with a pressure of steam of 18 lb. per square inch in the boiler, and cutting off at half stroke, driving a wheel 26 ft. 6 in. diameter, 7 feet wide with 20 inches of dip. The vacuum in condenser averages 28½ inches as indicated by the barometer.

The boat is 178 feet long between the perpendiculars, 175 feet on keel, 25 feet beam, depth of hold 8 feet, and 2 ft. 9 in. draught of water when light. The boilers are upon the tubular principle, and constructed to burn wood fuel. The boat before the navigation closed was 23 days upon her station, and seemed to answer all the purposes for which she was built.

I thus submit to the criticism of English engineers the first Double Cylinder Engine that has been manufactured in Canada, and erected on board the first iron boat built in the colony.

I am, Sir, your obedient servant,

William Parkyn.

St. Mary's Foundry,
Montreal, Dec. 12, 1843.

P.S. In such class of vessel as the Helen Macgregor, described in the *Journal* for November, an engine on the plan here submitted could be got in the same space, having a 6 feet stroke and 12 feet connecting rod.

[It is very evident that Mr. Parkyn's engine is a copy of the double cylinder engines of Messrs. Maudslay & Co.; this engine being in every respect, but one, exactly similar to that patented by Joseph Maudslay and Joshua Field on the 7th of May, 1839, and described in the *Journal*, p. 73, Vol. III, 1840. The only novelty, is in placing the air-pump between the cylinders, and making it the guide for the bottom end of the connecting rod; the air-pump is therefore necessarily open topped, and working under the pressure of the atmosphere. This arrangement most undoubtedly reduces this kind of engine to a minimum of space per horse power, and admits of a longer connecting rod than Messrs. Maudslay and Field's engine, for the reasons given by Mr. Parkyn—his working the air-pump piston to within an inch or two of the vessel's bottom. There is considerable ingenuity in the scheme, although, if our memory serves us rightly, we have seen it before printed and described in some work, but which we cannot refer to just now. It possesses all the faults of Maudslay's engines, and which we think have been urged against them with much reason—namely, greatly unbalanced weight, and consequent irregularity of motion, and perhaps of more consequence still—the surety of a difference in the friction of the two pistons, throwing a heavy strain, and wear and tear on the piston rods and working parts connected therewith.

Mr. Parkyn's engine possesses all these disadvantages, to which must be added his open topped air-pump, which adds to, instead of reducing the unbalanced weight—for he has to bring up the bucket or plunger against the atmosphere, which in a pump of 28 in. diameter, is equal to four tons or close upon half the power of one cylinder (vacuum pressure.)

As the condensation water is, under ordinary working, about equal to one fourth of the air-pump's content per stroke, it follows that the power requisite for its expulsion into the hot well is exerted only during the last quarter of its descent, and until it reaches that point it is totally inefficient as a balance to the working parts, and then it has become useless from their accelerated motion. Messrs. Maudslay avoid this, although they increase their weight and space, by placing the air-pump as shown in the drawing before referred to (Vol. III., 1840.)

There is still another objection to Mr. Parkyn's plan. The velocity of the air-pump plunger is *double* that generally given, it is necessarily the same as the piston, instead of a moiety, and this would be a serious objection in the minds of many English engineers. In the case of a *bucket with valves*, we should agree as to its impracticability, but we do not think the objection applies with so much force when a solid plunger is used, (as by Mr. Parkyn,) and the delivery valves are made of sufficient capacity. We know of several good engines, that have the strokes of their cylinders and air-pumps equal, the *Prince Albert*, of London, for instance, just occurs to us. The friction is, of course, greater, in the ratio of 2 to 3, and probably the wear of the air-pump would be considerable, from the oblique action of the connecting rod: but these are matters for practice to determine, and we shall be glad to hear again from Mr. Parkyn, after his engines have been at work for some time, and perhaps he can then favour us with some indicator diagrams taken from the cylinder and from the *under side* of the air-pump plunger—these would assist our judgment materially, and be very interesting.

The steam and eduction valves, used by Mr. Parkyn, are those of the Cornish engines—generally known by the name of double beat valves; two sets of eccentrics are applied, and the expansion of the steam is effected by a slot in the eccentric notch, which can be altered at pleasure, and is both novel, simple and effective: but it is not applicable to slide valves.

On the whole it is a creditable production, although, as we have said before, it is a decided infringement of Maudslay's patent, in so far as the employment of two cylinders, piston-rods, T piece, &c., is concerned. However, we cannot help again expressing our pleasure at these liberal exchanges of practical knowledge, between the new and old world, and feel gratified at our *Journal* being the means of communicating them to the public.]—Editor C. E. & A. Journal.

Railways.—First Report from the Select Committee.—The Select Committee appointed to consider whether any what new provisions ought to be introduced into such railway bills as may come before this House during the present or future sessions, for the advantage of the public and the improvement of the railway system, and likewise to consider whether any and what changes ought to be made in the standing orders relating to railways, and who were empowered to report their opinion thereupon from time to time to the House, have considered the matter referred to them, and have agreed to the following clause be inserted in all the railway bills now coming before or passing through Parliament, viz., "And be it further enacted, that nothing herein contained shall be deemed or construed to exempt the railway by this or the said recited acts authorized to be made from the provisions of any general act relating to such bills which may pass during the present session of Parliament, or of any general act relating to railways which may pass during the present or any future session of Parliament."

VALVES AND ECCENTRICS FOR WORKING STEAM EXPANSIVELY.

(With Engravings, Figs. 1 to 7 Plate 3.)

Sir—Enclosed I send you a description and sketches of an elegant apparatus for cutting off the steam at any required part of the stroke; which (judging from the clumsy manner in which that object is often done) I believe to be not generally known.

The accompanying sketches (Plate 3, Figs. 1 to 7,) are taken from the engine used for mechanically ventilating the Reform Club House, in Pall Mall, made by Messrs. Easton and Amos, Engineers, Southwark, and is, I believe, their invention, and has been found to answer the purpose well. It is a curious fact that the same valves have been patented twice *since* they were introduced at the Reform Club House in 1840. In the Mechanic's Magazine, July 15, 1843, there are abstracts of the patents referred to,—1st. Robert Wilson, engineer, of Manchester, specification enrolled June 22, 1843.—2nd. James Morris, merchant, of Cateaton-street, London, specification enrolled June 22, 1843; so that these patents were both sealed and enrolled on the same day for the identical invention, and that invention having been in public use at least two years previous. I hope this will show you the value, if well executed, of your new plan of giving abstracts of all patents connected with the professions of the engineer and architect.

I remain, Sir, your obedient servant,

George Spencer.

Engineer's Draughtsman.

5, Hungerford Street, Strand.

Description of the Valves and Eccentrics.

Fig. 1, is a Section through the Passages, Cylinder, Valves, and Valve Box.—Fig. 2, Front Elevation of Cylinder Face.—Fig. 3, Plan of Valve.—Fig. 4, Valve Cover.—Fig. 6, Plan of Non-Shifting Eccentric.—Fig. 7, The Shifting Eccentric.—Fig. 12, Section showing both Eccentrics together.

The valve A is similar in construction to the ordinary slide valves, except that there are two steam ways passing *through* the valve; this valve is made to slide on the cylinder face by means of the non-shifting eccentric C, and never varies in the distance it travels. The valve cover B is made to cover the two steam ways exactly, and slides on the top of the valve A, and is worked by the shifting eccentric D. The eccentrics C and D are bolted together by a bolt passing through one of the square holes E in C, figs. 5, 6, and 7, and through the circular slot *g g*, in D; bands T pass round both eccentrics, to which the rods acting on the weigh-shaft levers are attached. The object gained by this arrangement is to give a uniform sliding motion to the valve A, while the slide cover B, and its eccentric D, are so contrived that its travelling distance may be varied as required. This adjustment is managed in the following manner:—on the non-shifting eccentric C, a boss *g* is cast, on which the shifting eccentric D fits, and may be moved round and bolted in any required position as before mentioned; now if the point x of D be brought to the point x of C, the eccentric will not cause any motion to the valve cover B, but if the point x of D be brought to the point x 1 of C, then the valve cover B will have a rectilinear motion equal to the diameter of the circle of which the distance from x to x 1 is the radius, or any intermediate length of motion may be given to the valve cover by altering the position of the shifting eccentric—and thus the steam may be cut off easily at any required part of the stroke.

NOTES OF THE WEEK.

The Director of the Silesian Railway has invented the following means to enable passengers, in case of distress, to communicate with the engine driver. A circular hole, closed by a flap, is made in the top of each carriage roof, and which can be opened by means of a string, so that the passengers can pass through the hole a signal of distress, which the engine driver can see, and instantly stop the train. An instance of the utility of this arrangement recently occurred on the line, a noise like the bubbling of boiling water being heard behind one of the carriages; after waiting for some time, a civil engineer in the carriage passed through the roof the distress flag, and the train being stopped, it was found that one of the axles had got red hot, no doubt for want of grease. Of course the danger was immediately checked. We do not, however, place too great a value on the contrivance, as it would be a great source of annoyance in the hands of silly old women.

A description of the interesting, but little known, objects of antiquity in the Sagre Grotte Vaticane, or Hypogeum of St. Peter's, has at last been published by direction of the Papal Government, from the pens of Sarti and Setclini, illustrated with 42 copper-plates.

An elegant building has been erected at the Hermitage, on Mount Vesuvius, called the Vesuvian Meteorological Observatory.

A plan for the improvement and restoration of the Campagna Vicana, has been well received by the King of Naples.

A new grotto has been discovered at Monte di Cuma, near Naples, by the seaside. It is esteemed by some to be the true Sybil's grotto.

The first artesian well has been begun at Naples in the garden of the Royal Palace.

Great exertions are being made for the maintenance of the Flemish language and literature in Belgium.

The Government of Hamburgh have signed a contract with an Anglo-Hamburgher company for lighting the city with gas.

Nine statues, representing the nine Muses, have recently been brought to the Hotel de Ville, at Paris. They are for the decoration of the grand festival gallery. More than 200 sculptural artizans are employed in finishing that magnificent gallery.

The town of Breteuil is about to erect, in gratitude to M. Laffitte, a fountain, surmounted by his bust. The amount voted is £80. In 1829, M. Laffitte gave to the town a hall and market-house, which cost £1,600.

The ruins of a Gallo-Roman town, of great extent, have been found in a large forest near St. Saulge, in the Nivernais. It possessed a temple, forum, many streets, and every day vases, pottery, and objects of sculpture, are discovered.

The Minister of the Interior, in France, has given orders for the opening of a part of the Museum of the Hôtel de Cluny on the 15th inst.

The bronze statue of Admiral Duquesne has been placed on a provisional pedestal, alongside of the statues of the other marine commanders in the midst of the Court of the Louvre. It is only placed there for public exhibition, being destined for Dieppe. This is a very good way of exhibiting public statues, and should be imitated here.

The Minister of the Interior, in France, has presented to the town of L'Orient a picture representing a naval exploit of Captain Dusaulçhoy.

Father Ungaretti, employed on the catalogue of Egyptian antiquities at Rome, has been struck with a paralytic stroke.

A panorama is being exhibited in Germany of Hamburgh before and after the fire.

The City Picture Gallery, at Mentz has finally been located in the saloon of the Palace.

News has been received of Mr. Fellowes' operations in Lycia. The expedition is in excellent health, and a great many good things have been obtained. Among them is a monument representing a mythological being driving a car, in which is a triple-headed monster, being a lion at one end, with a goat rising from its back, and a scorpion or serpent at the other end. Mr. Fellowes has named it the Chimæra tomb, and to prepare it for shipment he has caused it to be sawed in two. The Medea is to begin embarking the objects of art by the end of the month.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

February 19.—T. L. Donaldson, Esq., V.P., in the chair.

A paper was read by Frederick Catherwood, Esq., Architect, Hon. and Corresponding Member, on the "*Antiquities of Central America.*"

The Mexican Indians, besides a perfect knowledge of stone cutting, and laying, were well acquainted with various kinds of mortar, stuccoes, and cements, and large masses of excellent concrete are found in many of their buildings. They were, in fact, so far as the mechanical part went, accomplished masons. In another department of art which requires more knowledge and science than the building of pyramids and temples, they were in no wise inferior to the Egyptians—to the preparation, mixing, and use of pigments. Their painting is indeed superior both to their architecture and sculpture, and they went even beyond the Egyptians in the blending of colours; approaching more nearly to the paintings found at Pompeii and Herculaneum.

In one of the rooms of a large building at Chichen Itza are paintings covering the entire walls from the floor to the ceiling. (For a plan of Chichen Itza see *Civil Engineer and Architect's Journal*, Vol. VI. p. 133.) The apartment may be 30ft. long, 12ft. wide, and 15ft. high. The figures are not more than 6in. to 8in. in height, but most interesting subjects are represented, abounding with life, animation, and nature. In one place are seen warriors preparing for battle, in another the fight is at its height, castles are attacked, defended, and taken, and various military executions follow. This forms one section of the wall. In another are seen labours of husbandry, planting, sowing, and reaping, and the cultivation of fruit and flowers. Then follow domestic scenes, and others apparently of a mythological nature; indeed, almost everything requisite to give us an intimate acquaintance with Indian life is depicted. The subjects are too numerous to mention, and such was the multitude of figures and objects, that a month would not have sufficed for delineating them. Unfortunately these beautiful paintings are fast hastening to decay, and every day adds to their approaching obliteration, from the visits of Indians.

The pervading type of the architecture in the central parts of America and Yucatan, consists in first constructing immense pyramidal mounds, or terraces, of greater or less height, and on these placing their sacred edifices and palaces. Whether these mounds, or, as some call them, pyramids, (and by the Indians they are called teocalli,) are in general solid, or contain in all cases passages and apartments, remains yet to be ascertained. In the few that have been opened, by accident or design, small arched rooms have been found. The buildings are generally long, low, arched, and of a single story, a plan frequently adopted by the Spaniards on account of the shocks of earthquake to which many parts of the country are exposed. In a few instances buildings of two and three stories were met with. The teocalli before-mentioned are found in great numbers throughout the country. They are frequently of large dimensions, of a pyramidal form, but do not terminate in a point like the Egyptian structures. They have on their summits platforms of sufficient extent for their temples, which contained statues of their deities, and in front was seen conspicuous the sacrificial stone or altar, convex on its upper surface so as to raise the chest of the human victim.

Mr. Catherwood thought there could be but one opinion as to the altars, idols, and sacrificial stones at Quirigua and Copan, having been constructed and used for these dismal rites. Indeed the channels cut on the upper surfaces of these sacrificial stones left no doubt on his mind as to the uses to which they were applied.

Another, and not less distinguishing, feature than their mounds and pyramids are the arched rooms found in all their buildings; he called it an arch, because it has all the appearance of one, and answers most of its purposes, and the inventors were on the very threshold of discovering the true principles of the arch. It invariably consists of stones overlaying each other from opposite walls, until the last meet over the centre of the room, or what is still more commonly the case, when the last stones approach within about 12 inches of each other, a flat stone is laid on the top, covered either with solid masonry or concrete. The joints of the stones are all horizontal. The roofs have a slight inclination to throw off the rain, and are cemented. This form of arch appears at first sight original, and is so in as much as regards the Indians, but the same principle was used in the earliest times by the Egyptians, the Greeks, and the Etrurians, and would, in all probability, suggest itself to any people who had to construct a stone roof over a space too wide for them to cover with flat stones. He had been indebted to Mr. Ainsley a short time ago for a sight of his beautiful drawings of Etrurian remains, and among them is shown an arch, which, if he had met with it in Central America or Yucatan, he should have undoubtedly taken for one of the usual arches of the country. It is at a place called Cervetri, and forms a part of the Galassi tomb. The finding similar arches in Etruria and Yucatan, and not very dissimilar pyramids in the latter country and Egypt, was no proof to his mind that a communication must have anciently existed between the respective countries. Similar necessities may well have produced similar results.

As regards analogies in architectural ornaments in the new and old world, the same argument applies. The one most frequently met with, and perfectly alike in Greece and Yucatan (which he would call the twisted rope or cable), is an ornament likely to be found wherever rope making was understood.

Copan may be called the City of Idols, as it abounds with monolithic statues of Indian deities. The city stood on the bank of a river, and was surrounded by walls; that on the river side is still from 60 to 90 feet in height in some places. The remains of a vast temple or collection of temples lie scattered about, with innumerable fragments of mutilated ornaments and statues. The statues are generally about 12 feet in height and four feet square, the front and back having representations of human figures, habited in a most singular manner, with towering head-dresses of feathers and skins of animals, the necks adorned with necklaces, the ears with ear-rings, and the feet with sandals, like those of the ancient Romans. The sides are carved with hieroglyphics, which no one has yet been able to decipher. They were all painted. There are no remains of arched buildings here, though no doubt such formerly existed, but immense pyramidal mounds and terraced walls are met with to a great distance in the surrounding forests.

Quirigua is the next place of interest in this part of the country. It is in many respects similar to Copan, but probably more ancient. It consists of ruined mounds and terraces, with many colossal statues, deeply buried in the entanglement of a tropical forest. Some of the statues are 26 feet in height of a single stone, the sculpture is in low relief, and as usual there are numerous hieroglyphics.

At Ocosingo the arch was met with, before alluded to, with the usual accompaniments of mounds and terraces, and an ornament over one of the doorways not unlike the winged globe of Egypt.

Palenque, in Chiapas, the most southern province of Mexico, is better known than any other of the ruined American cities. It was probably abandoned and in ruins when Cortes passed near it in his celebrated march from Mexico to Honduras, as no mention is made of it in his despatches. The principal building is called the palace. It stands on an artificial mound, whose base is 313 × 260ft. and 40ft. high, with staircases on the four sides. The building itself measures 228 × 180ft., 25ft. high, and of one story. The front and rear have each 14 doorways, and eleven on each end. The piers dividing the doorways still present traces of admirable stuccoes, which were painted. The interior is divided into three court-yards, with a tower in one of them. Every part appears to have been elaborately decorated with sculpture in stone, stuccoes, and paintings. In several of the apartments Mr. Catherwood noticed that the walls had been painted several times, as traces of earlier subjects were discernible where the outer coat of paint had been destroyed. The paintings were of the same nature as the frescoes of Italy, water colours applied to cement. The other buildings are inferior in size to the palace, but all on high mounds, richly decorated with numerous stone tablets of hieroglyphics, and sculpture of figures, well executed, which have awakened a lively interest in the antiquarian world. The whole is shrouded in the depths of a tropical forest, which has to be cleared away at every fresh visit of the traveller.

Next came the ruins of Uxmal, which for their vast extent, their variety, and being for the most part in good preservation, may claim precedence of any other remains of antiquity in Yucatan. (Of these a plan and view will be found in Vol. VI. of the *Journal*, p. 135.)

The Casa de las Monjas, or House of the Nuns, is a building forming four sides of a square, and enclosing a court-yard about 300ft. each way. Each of the four buildings presents a different design, so also do the rear fronts and the ends, presenting no less than sixteen different façades.

The Grand Teocallis, called by the Indians the House of the Diviner, stood to the eastward of the last-mentioned building, and within a hundred yards of it. The pyramidal part rose to the height of 100ft. above the plain, with two noble flights of stairs leading to the platform on the top.

The Casa del Gobernador, or House of the Governor, is next in importance. This immense building is constructed entirely of hewn stone, and measures 320ft. in front, by 40ft. in depth. The height is about 26ft. It has 11 doorways in front and two at the ends. The apartments are narrow, seldom exceeding 12ft., just large enough to swing a hammock, which was, and still is, the substitute for beds throughout the country. Some of the rooms are long, measuring 60ft. and 23ft. high. There does not appear to have been any internal decorations, nor are there any windows. The lower part of the edifice is of plain wrought stone, but the upper part is singularly rich in ornament. Taking the front, the ends, and the rear of the building, we have a length of 712ft. of elaborate carving, on which traces of painting are still visible. The peculiar arch of the country has been employed in every room. The lintels of the doorways were of wood, a more costly but less durable material than stone, and from its hardness more difficult to be worked. Unfortunately they have all decayed, and the masonry they supported has fallen down, and much of the beauty of the building is thus destroyed. The Casa del Gobernador stands on three terraces, the lowest is 3ft. high, 15ft. wide, and 575 long; the second is 20ft. high, 250ft. wide, and 545ft. long; and the third is 19ft. high, 30ft. broad, and 360ft. long. They are all of stone, and in a tolerable state of preservation. These are the principal buildings at Uxmal, and the others are much inferior in size and preservation.

At Kabah, in addition to richly decorated façades, some very curious internal decorations were found. At Zayi an immense edifice of three stories in height. (Of Zayi a description and engraving will be found in Vol. VI., p. 135.) At Labnah a handsome gateway. At Bolonchen a natural curiosity in a deep subterranean well, the descent to which is by long ranges of ladders of dangerous construction. At Tuloom a walled city. At Izamal some large mounds, and a colossal head. And, finally, at Aké a collection of large stones on a high mound, not unlike a Druidical monument.

With regard to the age of these monuments, Mr. Catherwood differed from Del Rio, Du Paix, Lord Kingsborough, and Waldeck. The growth of tropical trees has not been sufficiently studied to make them a safe criterion to judge of the age of such monuments. The accumulation of vegetable mould to the depth of 9ft. is another proof that has been adduced in favour of their high antiquity, and doubtless in a northern climate would indicate a remote age, but not so in the tropics; vegetation there is so rank and rapid, that within less than twelve months from the first visit to Uxmal, Mr. Catherwood found the whole place so overgrown with shrubs and small trees, that nothing but the high Tescalli were visible, and the outline of the other monuments, and a thick deposit of vegetable mould covered the places they had so short a time before cleared away. Mr. Catherwood met with no physical marks surely indicating a high antiquity; on the contrary, the whole course of his observations led him to form an opposite opinion. It is also proved by undoubted testimony that many of the buildings, now in ruins, were in use by the Indians at the time of the Spanish invasion. He did not think he should be safe in ascribing to any of the monuments (which still retain their form) a greater age than from 800 to 1,000 years, and those which are perfect enough to be delineated he thought it likely were not more than from 400 to 600 years. The roots of trees, and the tropical rains, are the chief elements of destruction, and daily and hourly is the work going on. Another century will hardly have elapsed before the whole of these interesting monuments will have become undistinguishable heaps of ruins.

If it be so difficult to determine the age of the monuments, it can scarcely be less so to ascertain who were their architects. At all events it is probable that the Tolteques and their descendants erected the buildings we have been considering this evening. The Mexicans, or Aztecs, adopted the arts and civilization of their predecessors, and used the same method of astronomical calculation.

Mr. Tite observed that the greatest resemblances to the American styles he had observed, were in the buildings of Ceylon and Java, described in the works of Sir Stamford Raffles. There seemed to him something like an analogy in the buildings.—Mr. Catherwood said he had not noticed it.—Mr. Tite asked whether he had examined the masonry with regard to the way in which it is formed, and whether it is so executed as to induce the belief that the Toltecs were a cultivated people. He also inquired whether they were acquainted with the working of metal, as for instance, had any idols of bronze been found, as in Egypt and elsewhere.—Mr. Catherwood said decidedly that the masonry was regular and well executed. All that is known with regard to their power of working metal, was the testimony to it adduced by the historians of the early conquests of Cortes and others. There had also been found many beautiful objects, some of gold, some of silver, but mostly of copper. Their proficiency in the arts was also illustrated by the delicate paintings on their MSS., some of which he had intended to have brought with him, but being on a kind of bark, they were so fragile as to be liable to injury.—Mr. Tite said he had some wood engravings of them in the well-known work *Purchas's Pilgrim.*—Mr. Poynter, in reference to the analogies discoverable in the ornaments, cited a case of the peculiar Greek scroll, which is an emblem of water, being formed on a Peruvian vase, where it evidently had the same meaning, the fish being represented underneath it, as it is sometimes found in the Greek.—Mr. Donaldson inquired if any windows were found in the Toltecan buildings.—Mr. Catherwood said none, only doors. The doors in some of the large buildings were very ornamental. That at Chichen Itza was highly decorated.—Mr. Donaldson asked if there were any bed-mouldings to their cornices.—Mr. Catherwood said none. In answer to another inquiry, he said the material of the buildings he had seen was limestone, there had been none of sandstone or granite seen by him, and he was disinclined to believe there were any. It was said that the great sacrificial stone in the city of Mexico was of granite, but he had not examined it. It is very generally supposed that the Egyptian buildings are of granite, but he had been much surprised after two years residence in the country, to find that with the exception of one or two small buildings, they were all of grey sandstone. He said that no cramps had been found among the masonry, and that the material of the beams of the doors was sapote wood, on which the carving is very sharp and beautiful. Mr. Stephens had got two beams away, but they were afterwards destroyed by fire. Mr. Donaldson asked whether the wood was used as an object of rarity, or because they had not stones long enough to cover the entrances.—Mr. Catherwood said the wood was used purely as an object of luxury, as it admitted of richer carving.—Mr. Poynter asked if any quarries had been found.—Mr. Catherwood replied none, nor tombs. This was a matter of deep regret, for such a discovery would have been highly interesting. They heard of many campos santos, but in only one instance did they find a burial ground, when they obtained a skull, which had been examined by Dr. Morton of Philadelphia, who had pronounced it exceedingly curious.—Thanks were then voted by acclamation to Mr. Catherwood. We should observe that around the room were arranged a number of drawings by Mr. Catherwood, which excited much attention, from their remarkable union of architectural precision with pictorial effect.

INSTITUTION OF CIVIL ENGINEERS.

Feb. 20.—The President in the Chair.

The discussion on the *screw propeller*, which was carried to so great a length at the last meeting, was resumed. Mr. Grantham explained the construction of the propeller used on board the *Liverpool Screw.* It was formed of four arms.

Mr. Grantham being present, stated that he had come prepared to answer a question which had been put at the last meeting respecting the angle at which the blades were set. The mean angle of the blade, taken in the line of the radius, was 45°, and this had given a most admirable result. The particular object of his paper had been to prove, by the data obtained in the experiments on the *Liverpool Screw*, that it was both practicable and desirable to construct the wheel of such a large diameter and long pitch, that its motion would be comparatively slow, so much so, as to admit of its being driven direct from the engines similar to the ordinary paddle wheels, and to use the condensing engine. He stated that he most approved of the form of screw adopted by Mr. Ericsson with the expanding pitch. He objected to the form exhibited in some of the models laid on the table; propellers thus constructed could not conveniently be made to present a large surface to the water, without which a considerable slip would take place and a consequent loss of effect. It also formed an additional obstacle to direct action. Mr. E. Galloway contended that the amount of slip was greater than was imagined owing to the following current at the stern. He also argued that there was no advantage to be gained by the expanding pitch. Mr. Cowper related some experiments made on a small toy, (with blades in the form of a screw propeller,) which is projected into the air, by having a rapid rotary motion communicated to it—form these he was to give a decided preference to the expanding pitch. Mr. Braithwaite confirmed Mr. Grantham's statement regarding Ecrisson's propeller, and promised at a future meeting to give the results obtained on board the *Princeton* steamer, U. S. America.

The discussion upon the *valves of pumps* was also resumed. The resemblance between the disc valve of Palmer and Perkins, and that invented by Belidor was examined, and the general opinion appeared to be that Messrs. Palmer and Perkins' valve would be found very useful in large pumps for mines, through which much sand or chips passed. The general question of valves with large openings with their influence on the working of the deep mines of Cornwall and other places was noticed.

The discussion occupied so much time that no papers could be read; those, therefore, which had been appointed for the 20th, were announced for reading on the 27th instant.

ELECTRO-MAGNETIC MOTIVE POWER.

At the Royal Institution, on February 9th, W. R. Grove, Esq., gave a lecture "*On the Progress made in the Application of Electricity as a Motive Power.*"

The subjects of Mr. Grove's communication were, 1, a brief summary of the laws of the electro-magnetic force; 2, a description of the chief modifications of the engines to which that force has hitherto been applied; 3, the commercial statistics of its application; 4, the purposes for which this power is available. In dealing with the first of these subjects, Mr. Grove exhibited, by many illustrative and successful experiments, the well-known re-actions of iron and other metals on each other, when exposed to the influence of an electric current. The actual application of these familiar phenomena was then shown in the working models of several machines, which were set in action by the nitric acid (or Grove's) battery, invented by Mr. Grove, and described by him four years ago at the Royal Institution. These machines may be divided into three classes; first, those acting by the immediate deflecting force, as shown in the galvanometre, Barlow's wheel, &c.; secondly, those on what is called the suspension principle. In these, two powerful electro-magnets are fixed contiguous to the periphery of a wheel, and in the line of its diameter, plates of soft iron being fastened on this periphery at short and equal intervals. The electro-magnets are so arranged as to lose their attractive power as soon as they have drawn through a given space each plate of iron, necessarily presented to them by the revolution of the wheel, but are immediatly re-invested with this power, in order to operate on the next plate. By these means the wheel is kept in constant rotation on its axis. The remaining class of electrically-driven machines are applications of the principle of Ritchie's revolving magnet. In these, an electro-magnet, balanced on a pivot, so as to rotate in a horizontal plane, is arranged between the poles of a permanent magnet. Hence, the alternate attractions of the opposite magnetic poles, combined with its own momentum, cause the electro-magnet to continue rapidly revolving. Having noticed machines, on these various principles, by H. Fox Talbot, Esq., Mr. Hill, of Swansea, and Professor Wheatstone, Mr. Grove proceeded to his third subject, the commercial statistics of electro-magnetic power. It appears by the experiments of Dr. Botto, that the consumption of 45 lb. of zinc will produce an effect equivalent to a single-horse power for 24 hours. The cost of the zinc metal, at 3*d.* the pound, would amount to 11*s.* 3*d.* About 50¼ lb. of the nitric acid of commerce would be required to dissolve the metal in the most economical and effective manner. The charge of this, at 6*d.* the pound, would be 1*l.* 5*s.* 3*d.* The whole expense, therefore, of obtaining the effect of a one-horse power by an electro-motive apparatus, would be 1*l.* 16*s.* 6*d.* In this calculation the cost of the requisite sulphuric acid is assumed to be fully covered by the value of the salts of zinc produced in the operation. The same amount of power produced by a steam engine would not cost more than a few shillings. Mr. Grove explained that this comparitive costliness of the electro-magnetic machines resulted from the sources of their force, zinc and acid being manufactured, and consequently costly articles; whereas, coal and water, the elements of the steam engine's force, were raw materials, supplied at once from the earth. Mr. Grove took this occasion to observe, that the experiments of Botto, just alluded to, were made with his (Grove's) battery; and that upon the cost of the constituents of this, the calculations were founded. At first sight, this battery would appear a dear form, from the expense of the nitric acid; but a little consideration proves the contrary of this. Compare it, for example, with a battery merely charged with dilute sulphuric acid (the cheapest possible electrolyte), to perform an equivalent of work, (as the decomposition of a given quantity of water,) a series of three cells of the ordinary battery is necessary; hence the consumption of three equivalents of zinc, and three of sulphuric acid. But the intensity of the Grove's battery is such, that the same resistance can be overcome by one cell, consuming only one equivalent of zinc, one of sulphuric acid, and one-third of nitric (there being in this acid three available equivalents of oxygen.) Independently of this smaller consumption, Grove's battery has the advantage of occupying only $\frac{1}{16}$th of the space of the other constructions. In concluding his communication, Mr. Grove mentioned the two well-known applications of electric power—the electric telegraph and the electric clock. To neither of these can steam, or, indeed, any known force, be so applicable as that which travels with a greater velocity than light itself.

STEAM NAVIGATION.

THE GOVERNMENT STEAM VESSEL CONTRACT.

Since the publication by us of the Specification and Conditions issued to engineers for constructing engines for four second class and two first class vessels, Government have extended the space allowed for the engine room 6 feet in length for both class vessels; this is still too little: if the beam engine is to be introduced, it ought to have been extended to at least 12 feet, otherwise engineers will not be able to carry out their own ideas as to the most effective mode of construction; they will be obliged to cramp their ideas to make the engine suitable to the Government dictates as to space. We believe the limitation originated in a great mistake, as it is supposed by many persons that the tubular boiler, which is now being very generally introduced, occupies less space; this is true as to bulk, but not superficially, for it is requisite to construct tubular boilers with as large a fire grate and back flue as for the flue boiler, for if a given quantity of steam is to be generated, the same quantity of fuel will be required for a tubular boiler as for a well constructed flue boiler. We consider that Government was most decidedly wrong in limiting the space at all; it ought to have been left entirely to the judgment of the engineer to make their own designs, and it would then have been the duty of the Government officers, to have compared each design, and decided upon that engine which appeared to them to be the most effective for *permanent* service, for a few feet in length in such large vessels, as from 180 to 220 feet in length, cannot be of such consequence as the effective working of the engine.

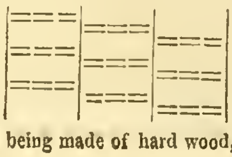
We have before alluded to the necessity of Government making a rigid enquiry as to the comparative duty, expense of working and repairs of each description of engines, whether beam or direct action of the several descriptions that have been introduced within the last 10 years; we trust this will be no longer delayed: and there is one other enquiry that ought also to be made, that is, as to the length of the Government steamers; in our opinion the second and first class vessels are too short, they would be better if built from 10 to 20 feet longer, which would give that space which is so essentially requisite to make a comfortable engine room, the most important part of a steamer.

THE SCREW AND PADDLE WHEEL TRIAL.

In page 85, of last week's *Journal*, we gave the particulars of the Government trial of the screw propeller and the paddle wheel, with her Majesty's steam ships the *Rattler* and *Prometheus*, the former vessel was fitted with the screw, and the latter the paddle wheel; as the experiment is one of importance, we have taken the trouble to obtain the proportions of the *Rattler*. We understand that as far as the build of the vessel, the proportions of the *Prometheus* are nearly the same.

Dimensions of H.M.S. Rattler.	Feet.	Inches.
Length, extreme	195	0
Ditto on decks	176	6
Ditto on keel for tonnage	157	$9\frac{1}{2}$
Breadth, extreme	32	$8\frac{1}{2}$
Ditto moulded	31	10
Depth of hold	18	$7\frac{1}{2}$
Burthen in tons $888\frac{34}{94}$		
Draught of water (mean)	11	3
Area of midship section at 11 ft. 3 in. ..	280	
Engines—Maudslay's 4 cylinders, aggregate power 200 horses:—		
Diameter of cylinders	0	40
Length of stroke	4	0
Diameter of screw	9	0
Pitch of ditto..	11	0
Length originally	5	6
Do. as reduced on the occasion of the trial	3	0
Number of threads two.		

The gearing at present consists of two motions, which gives a velocity of four to one of the engine. The first motion of two to one consists of a large spur wheel and pinion, the cogs of which are divided into three parts thus—



those of the larger wheel being made of hard wood, and the smaller one of iron; this sub-division of the wheels, prevents that very disagreeable rattling which is so much complained of.

The second motion consists of a large and small drum, with their surfaces divided into seven convex parts, thus—

upon which seven leather straps, of five inches in width, are kept tight by a suitable pulley or drum for that purpose. The drum and straps have merely been put in to try their efficiency, and to allow the multiple to be diminished or increased as circumstances may require. It is intended, when the experiments have been completed, to remove the drums and straps, which will be replaced by a single wheel and pinion of requisite proportions.

It is estimated that from 18 to 20 H.P. is absorbed in transmitting the power of the engine through the medium of straps at so great a velocity as is required to drive the screw.

Diameter of Gearing.	Feet.	Inches.
Diameter of spur wheel	11	2
Width	2	6
Pitch	0	5
Diameter of pinion	4	4
Ditto large drum	10	6
Ditto of small drum	6	9

The boilers are upon the ordinary flue principle.

The boilers of the *Prometheus* are upon the new tubular principle, the diameter of her two cylinders $52\frac{1}{2}$ in., length of stroke 4 ft. 6 in.

LAUNCH OF THE "QUEEN" NEW FERRY STEAMER.

On Saturday, 12th inst., a fine iron steam boat, the property of the Birkenhead Commissioners, and intended to ply between Woodside Ferry and George's pier, was launched from the yard of Mr. John Laird, the builder, North Birkenhead—amidst a large concourse of spectators, the occasion having excited considerable local interest, the vessel being of a new and peculiar construction, which it is fully expected will greatly expedite the trip across the Mersey, particularly from the Cheshire side. She is somewhat larger than the *Nun*, (the largest boat now on the station,) being 110 ft. long by 22 ft. beam; her plates and ribs are of extra strength; and she is put together with that fidelity, firmness, and improved fastenings, for which the constructor (who has had greater experience than any other iron ship-builder) has long been justly celebrated. Her deck is flush, and uninterrupted by unwieldly erections, from end to end, her paddle frame-work being carried along her whole length, dying into her extremities, and enclosed by continuous bulwarks, so that the full length and breadth, including the over-hangings, is rendered available for the accommodation of passengers. She is moreover finely moulded, and will doubtless prove herself very speedy. Her peculiarity consists in her being constructed that she may be propelled with either end foremost, so that the delay of backing out, and then running a-head from the shore, especially from the Woodside slip, and which occupies on an average from four to five minutes each trip, (or nearly half the time of crossing,) will be altogether avoided—itself a great desideratum not only as regards passengers, but expenditure of fuel. This is accomplished by a rudder at each end, so contrived that it may be fixed firmly amidships, forming a cutwater when that end (which was before the stern) is required to become the bow. So far the plan has before been in operation, though with but partial success, from the difficulty of securing the respective rudders to form a stem, and their liability, even on slight contact at their outer edge, to be carried away or deranged. Mr. Laird has, however, contrived a remedy for this liability to damage by an outward and standing guard of iron, forming a cutwater outside the rudder when that end is the bow, and within and just clear of which the rudder works, when it becomes the stern, in which case, from its comparative thinness, it offers little or no resistance to the speed of the vessel as a stopwater. This guard is secured, below, to the keel, and above to the stern. The rudders do not rise, as in ordinary vessels, to the top of the external part of the stern post, but occupy the space only between the line of the keel and the water or draught-mark of the vessel. When not in use it is not perceptible to the eye, forming, as it were, a secret door. It is secured, when forming part of the stern below, by dropping a strong bolt, which firmly attaches its outer edge to the guard, so that the whole becomes as one piece, forming a deep holding-on fore-foot. A steam frigate for the navy has recently been built, having two rudders, with the object here sought, on the suggestion of Lord Dundonald. How she will succeed we have not yet ascertained; but we doubt not but additional strength and safety would be secured by the adoption of Mr. Laird's "patent guard." Another steamer of precisely the same size and construction, and for the same proprietary, is in a forward state in Mr. Laird's yard. The *Queen* will be propelled by engines of 60 H.P., with oscillating cylinders, by Messrs. George Forrester & Co. (See *Journal* for last November, p. 367, and Plate XIII.) The engines and boilers will occupy a space of only 21 ft., leaving a large space forward and aft for cabin accommodation.

The Princeton.—The *Times* correspondent (A Genevese Traveller) writes—"A great object of interest to our citizens at this time is the United States war-steamer Princeton, just built under the superintendence of Capt. Stockton, which now lies in this harbour, and is daily visited by crowds of interested spectators. This steamer is constructed with Ericsson's propeller. Its steam machinery is placed entirely below the water line, out of the reach of shot. Its engine is extremely light and simple of construction, occupying only about one-eighth of the bulk required by the ordinary British marine-engine of the same power. It gives a direct motion to the axis of the propeller without the aid of cog-wheels or auxiliary gearing of any description. It is styled the semi-cylindrical steam engine, and is the invention of Captain Ericsson. For the vast power which it includes in so small a compass, and for the exquisite symmetry and proportion of all its working parts, this engine is the theme of general admiration. The armament of the Princeton includes two huge wrought iron guns (introduced by Capt. Stockton), placed one at each end of the ship, the largest weighing 10 tons, and with a bore of 12 inches, carrying a ball of 213lb. This gun is placed on a wrought iron carriage, also contrived by Captain Ericsson, and which, without the use of the ordinary breaching, checks the immense recoil, and the vessel suffers but a very slight shock from the discharge. By means of this carriage this huge gun is managed by half-a-dozen hands with perfect facility. The peculiarity of the steam machinery of the Princeton and its being placed out of the reach of shot are supposed to give her obvious advantages over all other steamers now afloat intended for naval warfare."

Clock-work.—The Paris papers speak of a psychological phenomenon, who is astonishing the people of that city, by a remarkable display of mechanical contrivance and mental resource. The objects of curiosity are a peasant of the Tarn, and his clock, (similar to the famous one of Strasburg, whose recent restoration by M. Schwilgue excited so much interest,) which this peasant, with no other aid than a strong will, a marvellous instinct' and an enthusiastic imagination—undertook to construct. For several years, he has been engaged on this work, and has succeeded, through difficulties which would seem quite insurmountable, and by mechanism whose simplicity is its greatest wonder, in combining the various and complicated movements—showing the hour of day at the principal points of the globe, the four Evangelists and twelve Apostles who strike the hours and quarters, the cock that crows at noon-day, &c.

A bust of Parian marble, in good preservation, and of excellent style, as it is said, has recently been dug up, at Cherchell, in Africa, supposed to be that of Ptolemy, son of the second Juba, and last King of Mauritania Tingitana, which is valuable as being unique. Cherchell is the ancient Cæsarea, the capital of that kingdom. The bust is the portrait of a man in the freshness of youth, with the royal fillet on his brow; and has a striking resemblance to the likeness on the coins of the Ptolemy in question. It is destined for the Royal Museum.

Another method of applying the waves of the sea has been recently contrived, which promises more practical results than the propelling scheme. The object is to make the breakers on a dangerous coast serve as their own warning signals to sailors. The inventor proposes to have hollow buoys moored near the dangerous coast or sand bank, to which buoys pipes somewhat like organ pipes are to be affixed. Metal tongues, on the principle of accordions, are to be fitted to the pipes, so that when the buoys are tossed up and down by the breakers the air may be forced through, and cause them to utter warning sounds, which would become louder and louder as the sea raged more fiercely and the danger increased.—Morning Post.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM JANUARY 27, TO FEBRUARY 24, 1844.

Six Months allowed for Enrolment, unless otherwise expressed.

Robert Johnstone, of Baker Street, Middlesex, gent., for "Improvements in the construction of lamps for the combustion of naphtha, turpentine, and other resinous oils." January 27.

Henry Vernon Physick, of Bath, civil engineer, for "Improvements applicable to machinery for driving piles." January 30.

William Edward Newton, of Chancery Lane, civil engineer, for "Improvements in the preparation of caoutchouc or India rubber, and in manufacturing various fabrics, of which caoutchouc forms a component part." (A communication.)—January 30.

Ezra Washington Burrows, of Swinton Street, St. Pancras, civil engineer, for "Improvements in the construction of engines for producing and communicating motive power by the elastic force of steam, or by manual or animal labour." January 30.

George Millar Clark, of Albany Street, Regent's Park, tallow chandler, for "Improvements in night lights, and in apparatus used therewith." January 30.

William Lucas Sargant, of Birmingham, for "Improvements in the manufacture of barrels for fire arms." (Partly a communication.)—January 30.

Baptiste Buret, of Leicester Square, merchant, and François Marius David, of the same place, manufacturer of gas apparatus, for "Improvements in the manufacture of gas." January 30.

William Fletcher, of Moreton House, Buckingham, clerk, for "Improvements in the construction of locks and latches applicable for doors and other purposes." January 30.

James Silcock, of Birmingham, engineer, for "Improvements in planes." January 31.

Robert Hodgson, of Princes Street, Clapham Road, Surrey, engineer, for "Improvements in propelling vessels, and in the machinery for working the same." February 2.

William Sangster, of Regent Street, Middlesex, umbrella and parasol manufacturer, for "Improvements in umbrellas and parasols." February 6.

Benjamin Aingworth, of Birmingham, gent., for "Improvements in manufacturing buttons for wearing apparel." February 6.

Thomas Southall, of Kidderminster, druggist, and Charles Crudgington, of the same place, banker, for "Improvements in the manufacture of iron and steel." February 8.

James Johnstone, of Willow Park, Greenock, Esq., for "Improvements in steam boilers." February 8.

Christopher Nickels, of the York Road, Lambeth, gent., for "Improvements in the manufacture of crape, or substitutes for crape." February 8.

Ezra Jenks Coates, of Bread Street, Cheapside, merchant, for "Improvements in apparatus for facilitating the reduction of fractures, dislocations of bones, and for maintaining their parts in their just positions. (A communication.)—February 8.

Charles Wheatstone, of Conduit Street, Hanover Square, gent., for "Improvements on the concertina and other musical instruments, in which the sounds are produced by the action of wind on vibratory springs." February 8.

John Cox, and George Cox, of Georgie Mills, near Edinburgh, manufacture of leather and gelatine, or "Improvements in the manufacture of leather and gelatine." Feb. 8.

George Straker, of Newcastle-upon-Tyne, shipowner, for "An improvement, or improvements in ships' windlasses." February 8.

Edwin Sheppard, of Manchester, foreman in the works of Messrs. G. C. Pauling & Co., contractors and builders, for "Improvements in machinery or apparatus for planing, sawing, and cutting wood, and other substances."—February 8.

William Edward Newton, of Chancery Lane, civil engineer, for "A new or improved system or apparatus for obtaining and applying motive power for propelling on railways or water, and for raising heavy bodies, applicable also to various other purposes where power is required." (A communication.)—February 8.

Joseph Gibson, jun., of Birmingham, japanner, for "Improvements in ornamenting glass."—February 10.

Henry Hawes Fox, of Northwoods, Gloucester, doctor of medicine, for "An improved mode of constructing fire-proof floors, ceilings and roofs."—Feb. 10.

William Geeves, of Little Portland Street, cork and cork gun wadding manufacturer, for "improvements in prepared wood for lighting or kindling fires."—February 12.

William Edward Newton, of Chancery Lane, civil engineer, for "An improvement or improvements in furnaces." (A communication.)—February 12.

Job Haines, of Tipton, Stafford, coal master, and Richard Haines, of the same place, coal master, for "An improved method or methods of making or manufacturing links for the construction of flat chains used for mining and other purposes."—February 13.

Bennet Woodcroft, of Manchester, consulting engineer, for "Improvements in propelling vessels."—February 13.

James Overend, of Liverpool, gentleman, for "Improvements in printing fabrics with metallic matters, and in finishing silks and other fabrics." (A communication.)—Feb. 13.

Andrew Kurtz, of Liverpool, manufacturing chemist, for "Improvements in apparatus to be employed for drying, evaporating, distilling, torrefying, and calcining."—Feb. 13.

Elijah Galloway, of Union Place, City Road, civil engineer, for "Certain combinations of materials to be used as a substitute for canvas, and other surfaces employed as grounds for painting, and some of which combinations are applicable to other purposes."—February 14.

Samuel Dobree, of Putney, Surrey, esquire, for "Improvements in the manufacture of fuel." (A communication.)—February 17.

John Lionel Hood, of Old Broad Street, gentleman, for "An improved composition, or mixture of metals, applicable to the manufacture of sheathing for ships and other vessels, bolts, nails, or other fastenings." (A communication.)—February 17.

John Kibble, of Glasgow, gentleman, for "Improvements in transmitting power in working machinery, where endless belts, chains, and straps are or may be used."—February 17.

William Losh, of Newcastle-upon-Tyne, esquire, for "Improvements in the manufacture of metal chains for mining and other purposes."—February 17.

Alexander Alliott, of Lenton, bleacher, for "Improvements in fulling, stretching, drying and dressing goods manufactured of wool, cotton, silk, and other fibrous materials."—February 19.

Caleb Bedells, of Leicester, manufacturer, for "Improvements in the manufacture of elastic fabrics."—Feb. 19.

Christopher Nickels and Benjamin Nickels, of York Road, Lambeth, manufacturers, for "Improvements in the manufacture of elastic fabrics, and in rendering elastic fabrics less elastic."—February 19.

Alfred Jeffery, of Bruton works, Limehouse, for "Improvements in treating wood, and certain other substances required to be exposed to water."—February 19.

Alexander Parkes, of Birmingham, artist, for "Improvements in the manufacture of certain alloys or combinations of metals, and in depositing certain metals."—February 21.

William Sheldon, of Birmingham, japan painter, for "Improvements in the manufacture of buttons and in japanner's ware, and articles in substitution of papier-maché."—February 21.

Ezra Jenks Coates, of Bread Street, Cheapside, merchant, for "Improvements in the forging of bolts, spikes, and nails."—February 21.

Henry Charles Howells, of Hay, gentleman, for "Improvements in the fastenings of parts of bedsteads and other frames." (A communication.)—February 21.

Thomas Liddell, of Newcastle, engineer, for "Improvements in apparatus for preventing explosion in steam boilers."—February 21.

Robert Rettie, of Gourock, Scotland, civil engineer, for "Improvements in gridirons, frying-pans, and other cooking utensils and heating apparatus."—February 24.

Francis Studley, of Shrewsbury, gentleman, for "An improved mill, or apparatus for grinding grain, with or without sifter or dresser, also for cobbling, bruising, crushing cutting, splitting, or dividing seed, pulse, berry, or other articles."—February 24.

Alexander Alliott, of Lenton, Nottingham, bleacher, for "Improvements in scouring, bleaching, and dyeing."—February 24.

Thomas Masterman, of the Dolphin Brewery, Broad Street, Ratcliffe, common brewer, for "A method of mechanism for the speedy cooling of liquids, being within certain degrees of temperature, and which method, or mechanism, he terms a "Refrigerator." February 24; two months.

William Rouse, of Great Barton, Bury Saint Edmund's, wheelwright, for "Improvements in carriages, and in parts of carriages applicable to certain purposes." Feb. 8.

Peter Rothwell Jackson, of Strawberry Hill, Manchester, engineer, for "Improvements in the construction and manufacture of wheels, cylinders, hoops, and rollers, and in the machinery or apparatus connected therewith, and also improvements in steam valves." February 24.

Henry Brown, of Selkirk, for "Improvements in carding silk, cotton, and other fibres." February 24.

Benjamin Bailey, of Leicester, framesmith, for "Improvements in machinery for manufacturing looped fabrics." February 24.

Caleb Bedells, of the borough of Leicester, manufacturer, for "improvements in the manufacture of bonnets, collars, capes, caps, shawls, coats, gaiters, scarfs, stockings, gloves, and mits." February 24.

Gaspare Conti, of James Street, Buckingham Gate, gent., for "Improvements in hydraulic machinery to be used as a motive power." February 24.

John Aitken, of Surrey Square, for "Improvements in atmospheric railways." Feb. 24.

Archibald Trail, of Great Russell Street, Bloomsbury, for "An improvement in th manufacture of sails, for ships and other vessels." February 24.

James Smith, of Queen Square, Westminster, Esq., for "Improvements in slubbing, spinning, twisting, and doubling cotton, and other fibrous substances." February 24.

OBSERVATIONS ON ARCHITECTS AND ARCHITECTURE.

By Henry Fulton, M.D.

No. 7.

Antrim House, Dublin.

Madame Catalani, according to report, had ceased to exist; this, however, has happily turned out to be erroneous. The Royal Institute of the Architects of Ireland, was also reported to have expired: this is also happily unfounded; for although lately showing but little sign of life, they have roused from a state of lethargy and have had a meeting. All we know of this meeting is, that "a very interesting paper was read from the respected Vice-President:"—how we wish we could get a peep at it. But although when the queen of song shall be removed from us, she will leave us no memorial of her skill, save the perishable recollection of her powers of melody; not so the Royal Institute of the Architects of Ireland, who have favoured us with the more lasting memorial of their skill and taste in compo, of which we endeavour to give an outline at the head of this article, and if the reader do not admire it as much as we think he should, let the fault rest with the sketch rather than the original.

To do the Institute justice, and if in political matters justice be not done to Ireland, there shall be no portion of it withheld on the present occasion: in justice then, we must say, that one of the best situations which the City of Dublin affords has been selected; an old friend was to have a new face. Antrim House is situated at the angle of the best and most fashionable if not the largest square in Dublin; a noble street opens on the other side of the square, forming a vista, at the end of which the edifice is situated, occupying the field of vision; it was an old fashioned brick building, without any pretension to architectural display, having seven windows on the first floor, and presenting a frontage of 72 feet.

On its coming into possession of the late noble President of the Institute shortly after his election, it was no doubt thought a good opportunity to show his taste, and that of the Institute, and to rescue the latter from the imputation that it had done little or nothing as a body to further the art. Some persons go so far as to say that the Institute had nothing to do with the *in-compo-rable* alterations, and that the design was given by a mere builder, but I think it must in all fairness be presumed that the council of the Institute were consulted. I do not assert positively that such was the case, but it is reasonable to suppose it, for the noble President was what Mr. Gwilt would call a "mere amateur," and how could he know anything about it, unless indeed his taste was "formed, guided and directed," by Mr. Gwilt's Encyclopædia. No, we must suppose that he left all to the Institute, except the payment of the bills. And on the occasion of his lordship being installed as President, the Institute called his attention to the discreditable fact of "grossly ignorant pretenders being confounded with the instructed professors of the art," and in reply his Lordship expressed "his desire to promote the interests and objects of the Institute, by affording them his countenance and support." The Institute also informed his Lordship, that "it would ill become a body whose profession has a peculiar connexion with the principles of good taste to address the language of adulation to a nobleman whom they deemed fitted, from his nice perception of those principles, to be their patron and their guide." And again, "your good taste and your information are too well known and too generally admitted to allow your judgment to be disregarded. Those who have hitherto looked with coldness on our professional claims, will not willingly bear the discredit of appearing indifferent to a society which your Lordship sanctions and adorns, by your connexion with it." By the way, that is laying the compo on his Lordship in good style; but, at all events, it proves my position, that it is impossible the design could be that of a mere builder or "grossly ignorant pretender." Some might think that his Lordship himself had designed the demi-façade, for such it is; but this cannot be, for I have understood that after it was finished he did not approve of it, and men seldom disapprove of their own works, or at least confess it if they do.

Having thus disposed of the preliminaries, we proceed to speak of the demi-façade itself, and although it is undoubtedly a pleasing task to speak of an edifice where everything is to be admired, still we feel overwhelmed with the responsibility and the fear that it may be beyond our ability to do justice to its merits.

The first thing we have to admire is the head of this front, in common parlance we shall call it a cornice, although not certain that it is exactly one. It is certainly not a *bold* cornice, no, that would have been unsuitable in Ireland, for there the word "bold" is synonymous with naughty, hence they say in that country "a bold boy," meaning a naughty one; this is not, therefore, a naughty cornice, and as it is a remarkable one, it must consequently have more than a negative quality, and be a remarkably good one; that it is so, may be proved, for it does not excite the least alarm in the mind of the most timid as to its stability, or the power of the walls to support it, and any old gentlewoman, either in pantaloons or petticoats, may pass under it without apprehension; besides, it has the advantage of casting no shadow, and surely it would have been bad taste to throw any part of the demi-façade into the shade: moreover, it would have been unfair to have taken an undue advantage of a good situation to have placed a bold cornice where *it* could only be seen to advantage: no, no, equal justice forbids us to think such an expedient would have been proper; let those who admire bold cornices reserve them for bad situations and not throw them away on good ones.

> "To throw perfume on the violet
> Is wasteful and ridiculous excess."

The Greeks to be sure sought to obtain broad shadows and the play of light and shade in their compositions; but they were quite wrong, for the more enlightened Chinese consider shade in a picture as a decided blemish, let us, therefore, hear no more senseless twaddle about *chiaro oscuro*, for the noble President of the Institute was at the same time President of the Board of Control, and in that capacity well acquainted with the state of taste in the East, and it may be taken for granted that the President's taste was more Chinese than the exploded "*gusto Greco*," so ably opposed by Sir William Chambers. Indeed, according to that highly esteemed architect, the Greeks knew little or nothing of the art, for we find him saying—"In the constructive part of architecture, the ancients do not seem to have been great proficients; I am inclined to believe that many of the deformities observable in the Grecian buildings must be ascribed to their deficiency in that particular." To be sure he never saw a Greek edifice; but what of that, for if they presented nothing worthy of observation, what would have been gained by seeing them? He had, however, a perfect conception of the deficiencies of the Parthenon, and was the first almost to suggest that it would have been improved by the suitable addition of a steeple!

We hear a great deal now-a-days of the advantage of obtaining a play of light and shade by means of detached columns and bold cornices; but I would ask what right have columns and cornices to play with light and shade, let them mind their own business, and be prevented from playing idle pranks like *bold* boys.

Observe, again, in this edifice, the happy expedient with regard to pediments: the Greeks and Romans placed them on the gable ends of their edifices; but if so placed in the present instance, they would have been hid by the adjoining houses, and we might as well have had none at all; but by placing them above the windows, we are left nothing to regret. Small minds, indeed, might object that they were necessarily diminutive in such situations, but magnitude is relative, and if any of the inhabitants of Lilliput will favour us with a visit they must deem these pediments to be as large as those forming the gable end of any temple in their own country. But although these pediments are necessarily small, yet they are worthy of being praised more highly than it is in our power to do, on account of having their cornices with an equal if not greater projection than the crowning cornice of the edifice itself; this latter is 72 feet long, and each of the pediments little more than half as many inches, which shows the talent and resources of the projectors in giving greater importance to the lesser parts.

The original idea of a pediment was that it should surmount a portico, now a portico is an opening, so is a door, so is a window, therefore why should not a window or a door have a pediment? These pediments are not all of the same form, but by a happy mixture of pyramidal and segmental, the spectator is presented with "a pleasing variety." We may be indebted for this to a difference of opinion existing in the council of the Institute as to the relative merits of the two figures, not that the reader is for one moment to suppose that it is intended to insinuate that the members of the Institute are not most harmonious on all matters of importance; but only that they were divided in the selection of two figures of equal merit. How happy should we be with either, and still more so with both.

Ignorant persons may be inclined to find fault with the slashing, gashing and frosting of the lower portion of the façade; but if they will only be at the trouble of examining the tatooed head of a New Zealand chief in the British Museum, they may see that the beauty and interest of it consist in those kind of gashes and slashes; and if such expedients add to the beauty of the human face, why may they not be suitable to the face or façade of the human dwelling? And in point of fact the frost-work, though rustic and vulgar in itself, yet in such master hands seems as if produced by the fair fingers of science to set off the edifice to advantage. Formerly the house had only one door, now it has two.

With a due regard to economy, as well as to afford a pleasing contrast, the compo is only carried up as far as the window stools of the first floor, thus forming a demi-façade, which viewed in connexion with the parallelopepids of the remainder and the window ornaments and cornice, obviate the effects of monotony, so frequently to be observed in other designs. Suetonious mentions in praise of Augustus, that he found the city of brick and left it of marble; may we not conclude in praise of the Institute, that it found Antrim house of brick and left the half of it compo.

II. *Gresham Club, London.*—In the West-end we have clubs, and why should we not have clubs in the East? The wise men are said to have come from the East, but certes the architects of that quarter do not display much wisdom in such erections as we are threatened with in the shape of the Gresham Club, as it appears in the published lithographic design. The outline of the edifice is well enough; that is, it is in keeping with the Farnese style, and although there is a kind of offset or bay at the end of the main building, yet as this is not carried up all the height, it has not the effect of breaking up the general outline, thus far all is well; but how shall we speak of the miserable details?

I have never yet spoken of such devices, as the centre window above the entrance presents to us, because I thought such windows had been scouted out of practice by every one having the least pretension to taste in architecture: in short, I considered that a reference to them, "even by a mere amateur," would almost have been tantamount to an insult to the profession; but here it is, an ugly arch with an ugly key stone springing from two Corinthian columns, and these latter flanked by two others connected by bits of cornice, and the interspaces fitted with transoms and muntons, forming what is called a French window. Bad indeed must be the taste of any one who conceives that any form of arch is improved by a projecting keystone, inasmuch as it destroys its completeness and simplicity of form, however, the keystone in the plan appears to break into the frieze which is placed above the arch; and above this frieze we have a cornice, on the centre of which rests a window supported in heraldic style by two curly-cues something like a lion and unicorn, giving the said last-mentioned window the effect of a broken pediment. Hercules with *his club* might have been substituted for the upper window, or like the Colossus of Rhodes he could stand with a foot on the apex of each curly-cue, and admit the window between his legs, to complete the picture. The principle of arches imposed on columns, as here exhibited, is the state of architecture in the transition or debased Diocletian style before it passes into the Gothic; it is the worthless grub before it expands into the beautiful butterfly.

The Rev. James Dallaway, in his "Discourses on Architecture," (a very interesting work,) has fallen into a mistake with regard to the date of the origin of arches on columns. At page 7, London, 1833, he says, "the Basilica of St. Paul's at Rome, by Constantine, has the earliest instance of arches constructed on columns instead of piers, which was universally the Roman method." Now if the reader will look at Adam's views of Diocletian's palace at Spaltro, he can see examples of it in almost every plate, and many of them flanked by rectangular compartments, as in the Gresham design, and in the east end of St. Martin's Church. Although the interval between the time of Diocletian and Constantine is so short as scarcely to require notice, yet the precise date, as well as the locality, is of great importance, as fixing the Pagan and not Christian origin of the practice.

Columns are quite unsuited for window ornaments, for their effect never can be good in any case or under any circumstances when the intercolumniations must be wider than the best examples of antiquity. Columns well proportioned and properly placed form the great and distinguishing beauty of the Greek style, and this never should be lost sight of even in its degenerate offspring, which climate, manners, uses, and convenience impose on our adoption. But although the Greek style does not furnish us with columns for any such illegitimate purpose as we see them here applied to, it gives us mouldings in abundance, which may with advantage be used instead of them.

A due proportion of ornament gives pleasure to the spectator, but the thing overdone turns the composition into ridicule, and, as in the Gresham Club, places it on a level with the tasty exhibition of the compo shops in the Paddington and Commercial Road, for besides the window with the arched head and rectangular wings, we have no less than twelve pedimented windows in front, destroying all repose and preventing the edifice from having the least claim to dignity, which it would otherwise have from its unbroken outline. And again, the cornices which support these pediments rest on pulvinated friezes or bustles; and if there be one form in ancient or modern architecture worse than another, the pulvinated frieze is the example; it too forcibly reminds one, of those of our fellow creatures, whose heads appear too heavy to be supported on the vertibral column, and hence their backs protrude, so these friezes protude, weighed down as it were by the *great* weight of the *little* gables, which they appear to have been unable to support.

> "Atlas groaned the world beneath—
> They groan beneath "—a pediment.

It has been urged, and with some reason, that the use of projecting quoins is necessary to define, I may say insulate, a composition, and that it gives it the appearance of stability; but if quoins are to be used with that intention, surely it is not absolutely necessary that they should be pared and frittered away to show open joints. I admit that I never saw or heard of projecting quoins (headers and stretchers as I believe they are called) with *close joints*; but would they not look better than open ones, and give all the desired effect with more simplicity and less effort and expense than the present mode.

It will be long ere "even the mere amateur" of Greek architecture shall be reconciled to the expedient of transplanting triglyphs to friezes which have no architraves and columns beneath them; the soil is not congenial, nor does their introduction in the Gresham Club House seem likely to prove an exception. To be sure we find these well placed in such situations in the Egyptian style, but there they have a different character; nor are the Egyptian the debased offspring, but rather the parent of the Greek triglyphs—as we may almost say—the cause and not the effect.

It is to be hoped that if *Clubs* shall continue to be trumps, those architects who hold the honours in their hands will in future play the game according to Hoyle, and not lead the knave to be taken by their competitors queen. With all its imperfections (and it has some to which many of the remarks in this paper are applicable) the Reform Club is still the king of trumps; but the best court card has yet to be played.

CANDIDUS'S NOTE-BOOK.

FASCICULUS LVI.

> "I must have liberty
> Withal, as large a charter as the winds,
> To blow on whom I please."

I. Some of our own public buildings are strange patchwork—merely masked just in front, though more than that side may be exposed to view. The National Gallery, for one, betrays more offensive meanness, as we are allowed to see that the back is a mere brick wall; a defect that might have been avoided by continuing the east end so as to form an architectural screen with a mere portal or opening through it for the public thoroughfare behind the building; which would also have given some importance—now very much wanted to that elevation. The exterior of the British Museum is the work of a mere builder, without the slightest pretension to architectural design or effect. What its façade will turn out we shall see in good time. The Post Office has nothing but its portico to recommend it as a work of architecture; all the rest is of very inferior character: and even were the façade many degrees better, the general effect in the view from the north west, would always be unsatisfactory, unless the north end of the building were altogether different from what it now is.

II. There is a point in Grecian architecture, as adopted by modern architects which does not seem to have been taken at all into consideration, particularly by American architects, who though they affect the Grecian temple form, in their principal structures, and lay so much stress upon classical columns, &c., of imposing dimensions, do not scruple to introduce windows without even attempting to keep up the style in those features, for more frequently than not, they are either mere apertures in the wall, or very tame and poor in design. This is one of the ill consequences of servilely copying features, wholly unfit for the intended purpose, without very great modifications—so great, in fact, as to convert them into something quite different from their original character. Where windows cannot be got rid of, at any rate columns may be dispensed with; and, as the former are, in such cases, absolutely necessary, so also should they be treated as *essential* features in the design, and be made to contribute to beauty instead of marring. In general, *astylar* composition is far better suited for modern purposes, than *columnar*. With reference to Gwilt's "Encyclopædia," we may here remark that nothing whatever is said on the subject of the architecture of the United States. Some little information relative to it may be picked up from Dunlap's work "On the arts of design, &c.," but it is so very meagre as to be more tantalizing than instructive.

III. It was rather a singular omission on the part of Mr. Gwilt, that when dealing out his blows against architectural amateurs, critics, and writers, he did not level a hit against lecturers upon architecture at literary institutions, and such places, for, they also contribute to increase the mischief, by giving persons a turn for amateurship, and directing their attention to the subject—at least, if they address their audiences to any purpose at all. If such teachers and leaders of the people are also professional men, instead of being an excuse, that can be only an aggravation of their offence—in the eyes at least of such very strict and orthodox persons as Mr. Gwilt—since they ought to know better than to divulge to the profane the profound *arcana* and mysteries of their art. Rather does it behove them to warn the "ignorant public" against prying into anything of the kind—very far above the reach of their faculties, and therefore to be submissively believed in, with becoming stupid wonderment, and with unquestioning confidence in the infallibility of those who are the lawful depositaries of all such mystic learning. It is odd, too, that Gwilt had not a fling at Loudon, if only because the latter, besides entertaining and advocating views directly opposite to his own, initiated architectural journalism, and, moreover, strenuously endeavoured to expel mere pedantry and mysticism from criticism, and establish principles of æsthetic rationalism in their place. In fact, hardly any two writers have laboured to promulgate more opposite views, and let them be ever so orthodox, Gwilt's are certainly by far the less liberal and less popular ones. That he goes against the stream is very evident, since so far from being attended with the desired effect, his attempt to throw ridicule and discredit upon, and so put a stop to non-professional—and as he deems it, unlicensed architectural writing and study, has only served to draw down upon himself a great deal of severe and not unmerited reproach. Instead of being at all intimidated by his growlings, the class of writers whom he would fain suppress altogether, seems to have gained fresh courage. Another reverend "literary idler" has just appeared in the field, in addition to those who had previously done so, since Mr. Gwilt first uttered his denunciation against the whole race. Exclusively of the opinions contained in it, his idea of an Encyclopædia is an unusual one, for persons naturally look, in a work of the kind, for the very latest and freshest information; whereas his stops short at the very point where abundance of new matter and fresh subjects presented themselves. Were we to judge from his work, we might fancy that the history of art in the present century, not only in this country, but all over Europe—in fact throughout the whole civilised world, was a mere blank. Yet, if excess of delicacy withheld him from venturing to comment on the works of contemporary architects at home—though it did not from falling foul upon contemporary writers—he might have ventured to express his opinions quite freely in regard to those of other countries. Besides, if he was fearful of giving umbrage by it, he might have dropped critical remark altogether, and confined himself to a mere historical report, and descriptions of buildings, as has been done in some other encyclopædias. He might too, without impropriety, have given a place in his "Catalogue" of books, to some of the best architectural treatises which have appeared in publications of the kind, for instance, those in Brewster's Encyclopædia, the Britannica, and the Metropolitana, by Telford, by Hosking, and by Narrien.

IV. Flattering as are just now the prospects of art in this country, as far as one great national work—the "Palace of Westminster," is concerned: it is matter of very doubtful question, if the influence so occasioned will be a permanent or an extensive one. There are two other influences equally powerful and active among us, which must more or less counteract, if they should not absolutely neutralize that of art; namely, party spirit on the one hand, and fashion on the other. Why the former, which is so entirely distinct from, should ever be allowed to interfere in matters of art, let others explain—if they can; yet so it is; highly favourable opportunities are frittered away, one after the other, by their being converted into little better than mere jobs bestowed by party favour—no matter on which side. It is no doubt very natural—perhaps amiable, in public men to endeavour to serve their friends, but it is frequently most fatal to the interests of art—a truth proved by many very striking and notorious instances. This is certainly not the way either to advance art or encourage talent among us—quite the contrary; therefore, if such unhappy and mischievous system cannot henceforth be set aside altogether, matters must continue to go on pretty much as they have done; for all the mere talking about art, will prove of no real service to it. In the ordinary affairs of life, common sense prevents people from postponing their own obvious interests to party considerations or political feeling. Provided he be a competent *artiste* in his profession, the most ultra conservative cares not though his *chef de cuisine* be an out and out radical; neither does his Grace of Canterbury relish his fare at all the worse because it may happen that his French cook is a Papist. And why should they? Is it not strange then that persons who would not risk the chance of an ill-dressed dinner, or, other domestic blunders, by employing incompetent servants, should thrust, as they not unfrequently do, very incompetent and ill-qualified ones upon the public.

V. As far as mere size goes, the Tract Society's new building in Paternoster Row, fully rivals the Reform Club House, and greatly surpasses any of the ornamental façades in Lothbury and Moorgate Street. There is plenty of it in regard to extent and height—more especially as the situation itself is exceedingly confined; nevertheless, it does not look by any means so large a mass as it might have been rendered in appearance, owing to its being not only so divided, but so varied in design, that it shows like five quite distinct and separate houses, viz., three of a single window (of three openings) in breadth on the upper floors, and two intermediate ones of three windows in breadth. In this case it is not the mere "*breaks*" in the elevation that are objectionable, on account of their cutting it up into too many petty divisions; that would have been a comparatively minor defect; but here the want of unity amounts to absolute contradiction and disruption of the whole, if intended to pass as a single piece of design, owing to the inserting, mixing up, and dovetailing together two quite different designs after cutting them into slices for the purpose, taking three of the one, and two of the other. Thus, three of the compartments on the ground or shop floor, have columns forming a small order raised on pedestals; while the intermediate ones have arches which rise higher than the capitals of those columns, whereby all continuity of line is completely broken, for it is not kept up in the degree it is done where the imposts of arches are on the same level with capitals of columns in other parts of a composition. As to the style, it must for the want of an other term, be accounted Italian; but it is certainly of a very lame and doggrel kind. If it seem harsh to say this, it is also not a little hard to be compelled to do so: here was at all events a very fair opportunity for producing a more than ordinarily good specimen of its peculiar kind; something exhibiting the same carefulness in design as is manifested in one or two façades lately erected in Lothbury and Moorgate Street. There is no economy in adopting a poor design, good taste costing no more than barbarous ugliness—if always so much.

Charcoal most effective in the Growth of Plants.—Mr. Barnes of Brecon, says, "Charcoal is the most astonishing article to make use of for all purposes of cultivation, and especially for plants under artificial treatment. I judge from many year's experience of its use. My pine soils consists of nothing but charcoal and loam, without a particle of manure of any sort. Every plant under my care has some charcoal used about it. I never saw the plant that did not delight in it, and to heaths it is most especially acceptable." Mr. Stewart, gardener at Stradsell Hall, has exhibited to the Horticultural Society some cucumbers grown in equal parts of loam and charcoal, without any manure. No stimulant could have given better fruit so far as health was concerned.

CATHEDRAL OF THRANDIA.

An extract from Torfæus relative to King Olave, and the Cathedral of Thrandia (Trondiem, or Dronthiem), in the kingdom of Norway; read at the Royal Institute of British Architects, as a supplementary paper to one read at a previous meeting, "*on the Architecture of Wisby, in the Island of Gothland,*" by John White, Esq., Architect. (See *Journal*, p. 144, Vol. IV., 1841.)

Four miles from Agdanesia towards the east, at the southern shore of the gulf of Thrandia, is situated the old and very famous city of Nidarosia, at this time generally called Thrandia, which that most powerful and pious king, Olave Fryggvinus, caused to be founded on the western bank of the mouth of the river Nid, where there was formerly the estate of Nidarnesia; and hence it obtained the name of Nidarosia, derived from the river Nid, which, in the genitive, makes *Nidar*, and the word *os* which means the mouth of a river.

Of the Cathedral of Thrandia.

This city of Nidarosia, not uncelebrated as being the residence of the archbishop, had many temples and monasteries, which, however, the cathedral church far eclipsed in magnificence, and the admirable elegance of its structure; which, in few words, we might clearly prove not to have any equal in artificial beauty, whilst it flourished entire, throughout the whole of Christendom. Now, however, the greater part of it, except only the sacred chapel or choir, lies prostrate and overthrown; and, when we confess candidly with much regret that we cannot give as a perfect description of it, as we ought, it may not be disagreeable to put forth to the public notice the few remarks, which are here subjoined.

Of the relics of St. Olave, and the building and magnificence of the Cathedral of Thrandia. History tells us that the body of Olave (who was called St. Olave), son of Harold, King of Norway killed by the hands of his subjects, was concealed and preserved, by removing it from place to place, by his friends, lest it should fall into the power of his enemies, and be ignominiously treated; until at length it was magnificently entombed in the temple of Nidarosia, (which was consecrated to St. Clement, by Bishop Grimkel and Einar Thambaskelfer) on the permission of King Sweyne, son of Canute, and his mother Alfiva, who at that time possessed the supreme authority, and that a short time afterwards it was exhumed (on account of some miracles by which it was declared to have been lifted up, after it was committed to the ground) and placed in the temple itself (where the place appeared fitter and more commodious), enclosed in a gilded tomb; this in the next following years they sometimes opened, and shaved the hair and beard, and pared the nails; and, impressed with a belief of its sanctity, the archbishop, with his bishops, abbots, priors, and monks, and the whole ecclesiastical synod, by spreading and propagating abroad these miracles, which were reported to take place at his corpse, occupied the minds of men, and, at stated periods of time, carried it about with great pomp and splendour, after the Papistical fashion: to which an immense multitude of persons, not only from Norway, but from Denmark also and Sweden (Suecia), and other distant parts flocked, offering large presents, whence were collected incredible sums of money; from which, among other things, a silver coffin was made, in which they placed the sacred (as they say) relics of the King; and this again was enclosed in two wooden shells, shining with gold, silver, and precious jewels. They built also a cathedral of a very ornamental structure (viz., the archbishop's of this place, supported by the assistance of the kings), of which even now a part appears entire; yet this admirable work was not finished in the reign of one king; in as much as Harold the Strong, King of Norway, and brother of St. Olave, first had its foundations laid on that sandy hill, where the body of his brother Olave had been buried first: and afterwards Olave, his son, surnamed the "Just," or "Peaceful," finished it, with the assistance of the Archbishop Eystein, and dedicated it to Christ, and placed upon its altar the coffin of St. Olave. (This is incorrect; for that Eystein, who built the cathedral, of which to this day some part remains, when that temple, which Harold erected, was destroyed, lived long after.) Under succeeding kings, however, in course of time, when immense weath was daily accumulating, as much by the presents of the natives as of foreigners, it was elegantly adorned in many ways; until at length one of the archbishops added a choir of a most beautiful and magnificent structure, and which, as we said above, is the only part that remains.

But as it never was our lot personally to examine with how much art this cathedral was reared, and of what dimensions it was, we can only subjoin here, in few words, what we have heard of it from the accounts of others. First, as regards its form; it is said chiefly to represent a cross, wholly composed of the natural (living) and cut rock; and the entire walls, inside as well as outside, every where sculptured with admirable skill, together with innumerable images, and figures executed with perfect workmanship; while, at the corner of the temple, where it verges towards the west, twelve stone statues of the apostles of colossal size are seen; these are all gilt over, and the corner of the temple is gilt also. It has, moreover, numerous rows of marble columns, within and without, made from different sorts and colours of marble, so exquisitely polished, that some think they were cast like metals. Of these you may see sixty, elegantly carved, at the southern gates of the temple; and as many think it would be an arduous and difficult task to determine the cost of rearing these gates, how much more difficult would it be, to ascertain the expense of rearing this whole temple, and to estimate it according to the magnificence of the whole work. It is said, too, that each sort of marble considered more excellent for this fabric, was conveyed hither from Ireland and Greenland: but that a softer, white, and variegated kind, was supplied in abundance from the district of Thrandia. And as this royal cathedral in elegance of structure and entire magnificence of execution shone pre-eminent, so also it surpassed in its other ornaments, for it had a most rich sacred repository, stored with books, cups, dishes, priestly garments, holy bags, with other things of the same kind, and vessels of the church. Thus the archbishop, with a pompous train, clothed with a mantle (superhumerale) of cloth of gold (attolicum), bore on his back an image of the Holy Trinity, made from pure gold, as they are commonly represented; and at the same time had carried about the coffin of St. Olave (which, as we said before, was placed in two wooden coffins enclosed in one another) by sixty men (no less were necessary); from the edges of the coffin, which was overlaid with gold and silver, innumerable purses were suspended to receive donations. Upon it stood the penitentiary priest, as he is called, offering the indulgences of the Pope of Rome, or remission of sins to those who gave money. This cathedral was also very rich, in proportion to the power of the kingdom, in vast revenues and large possesions; so that in the banquetting rooms of this place, jugs, cups, dishes, and plates of silver, and indeed every sort of silver implements, have been always used with the utmost prodigality, which in other places were preserved in the vestibule (exedra.)

But since this complete magnificence and glory of the world rested on an unstable and slippery foundation, quicker than one could have conceived, it all fell down with an awful destruction; the cathedral, indeed was thrice set on fire by lightning, and the fluid flying so as to be seen a long way across the Gulf of Thrandia, consumed the monastery called Holmklostur, and reduced it to ashes; which was a certain proof that this had not happened by chance but by the will of the Almighty, who would not permit their grave and dreadful errors and idolatry, by which they had seduced the wretched people, with their taking his holy name in vain, to go unpunished. And, in a similar way, the pomp and luxury of the ecclesiastics of this order, and the power and authority of worldly rule, all of which had depended upon the dominion of the Pontificate, fell altogether, upon the removal of their cause, when, by Divine grace, the light of the true Christian religion shone on these shores. Yet it is much rather to be lamented than recommended, that, at the beginning of the reformed religion, the reformers not content with taking away from the temples and monasteries whatever gold, silver, and other treasures once employed for the use of the Pontiffs, were found there (such as priest's garments and other utensils), but prompted by nothing else than an innate spirit of wantonness and malice, they threw down and destroyed those elegant structures; unnecessarily burning a great quantity of very useful works, and precious relics of antiquity, in a foul conflagration, stripping of every decoration entirely, the sacred temples, basely plundering them of all their ornaments, and perpetrating robbery detestable and totally unworthy of the name of Christianity.

In this way, too, Otto Stigius had burnt the very beautiful library of the Cathedral of Thrandia, with a number of useful books of great price, and monuments in the cemetery. By a similar conflagration, one Thordus, surnamed Kodde, maliciously destroyed all the books and ancient manuscripts of the repository of Stafangra (Stafan grenois exedra). In the same storm the silver coffin in which the body of St. Olave was buried, with the two wooden ones which were before spoken of, with all the gold and silver and precious jewels (of which one eclipsed the rest, and which the Archbishop Eric Valkendorp had bought for 240 tons of butter (Vigenti tonnarum, dodecadibus butiri) and had inserted amongst the rest on the edge of the coffin) stript off, was taken away, as was also the great silver cross, wont to be carried in state, by three men, before the tomb of St. Olave, the cups, dishes, holy bags (hierotheca), and the other treasures of the cathedral, gold and silver, chosen from the repository (exedra) and banquetting room. Besides the ornaments of the altar, jewels were also taken away, beautiful bells, and the like, laden with which a certain large ship, about to cross into Denmark, sunk before Agdanesia, and never afterwards appeared. And a little while before, a large portion of the same money, on its way into Denmark in a huge ship, was taken for booty by some Batavian pirates; this happened in the year 1541. Amongst the other ornamented works of this town, the royal throne in the precinct of the church, of which many steps were of rock sculptured and worked out with surprising art, most elegantly constructed, may be justly reckoned, on which formerly the kings when they were chosen, or when the people paid their homage, were wont to sit. And, indeed, whatever we have said of the elegant and magnificent structure of the Cathedral of Thrandia, is to be also understood of the work of the wall, and of the marble elaborately sculptured with the finest art. For it is sufficiently clear, that very many temples and edifices in the Christian world, have much eclipsed this one of Thrandia in the gold and silver, and more abundantly adorned with precious things; but that they are not to be compared to it in the artificial structure of its wall. Rutger, son of Hermann, in his description of Norway, has the following:—"There was once a most magnificent edifice, surpassing all the other temples in the whole of Europe, or indeed in the whole Christian world; and there are some who affirm that it had not a like or equal; for whether you regard the workmanship or extent, by its square blocks of stone, its splendid columns and perfect finish it moved every beholder with admiration." So spoke Rutger.

AGRICULTURAL IMPROVEMENT OF IRELAND.

Sir—I am encouraged by your article in the last number of the *Journal* on "Agriculture and Engineering," to send this paper, hoping from its appearance in a scientific journal, that the subject may obtain more attention than I suppose it would receive if inserted in a political one; and as the remarks made by you must naturally turn the attention of the profession to a subject peculiarly interesting to the inhabitants of this island, I propose giving some idea of the state of land, and of the subjects intimately connected with it, which a residence of a few years in this country has made me acquainted with, so that a correct opinion may be formed, in England, of the real wants of the *people*, and of the means of supplying them. As regards the profession, that it may be seen if proper steps be taken here, and *in England*, a vast field may be opened for the profitable display of those talents which the civil engineer's practice in the sister country has astonished the world with, and which (may I be forgiven for expressing the opinion) has, I believe, raised my native land to that proud position over the nations of Europe she now holds, "the pride and envy of them all."

The great want of the people is, *the means of subsistence*. This may be subdivided into want of labour, and want of the knowledge how to obtain the necessaries of life, which the holders of land in England usually have; that is, want of instruction in the business of farming, which they have not as yet, and which I fear from the present absence of example, and from the limited means of obtaining the necessary knowledge, they will be slow in acquiring. If remedies can be found for this state of things, my opinion is, the country will be prosperous and happy. The idea may be ridiculed, that the ills of Ireland are contained in these two deficiencies, yet to an unprejudiced mind, devoid of political animosities, or religious bigotry, acquainted with the situation and feelings of the peasantry, having but one object in view, the improvement of their temporal or social condition, and with a knowledge of what may be done by a change in the system of agriculture, I believe such a mind must acknowledge, that if *all* their necessities are not supplied by providing these deficiences, yet much will be done, and the remainder will follow. But it is a difficult thing to reason with men under daily privations, their whole prospect of spinning out the thread of life hanging upon holding the land they are in possession of, with nothing to fall back upon if they lose this, and with the knowledge, not anticipation, that their bodily strength will be useless in providing food—they cannot be employed, they are not wanted, there is nothing to be done. Is it not miserable to know that this is true, that in Ireland, a country more than any other requiring the employment of labour, where it can be obtained at the cheapest rate, and where the mass of the people are literally in want from the non-employment of them, that this should continue. It must not be so. You in England must remedy it, and when you have done so, the agitation which has so successfully ran over the country will be destroyed, and the people will not be led by the rhodomontade of designing men.

In considering the propositions I am about to make, it is necessary to bear in mind; 1st, That there is *no demand* for the labour of the people; and, 2d, That the small farmers who occupy from 10 to 20 acres of land are, from the want of instruction, unable to obtain one half of the profit that can be realized by a person understanding the business of agriculture. After describing the usual system of farming by such tenants, I think it will be unnecessary to enter into calculations to prove my second assertion; and as to the first, the fact is so well known, it will be supererogation to make a remark for substantiating it. The usual system practised, is to raise a crop of potatoes, after this wheat, then oats, 1, 2, and some times 3 or more successive crops, if the land is able to produce anything resembling one. The ground is covered with weeds, never fallowed, or fallow crops raised. Potatoes, from the mode of sowing, are useless for cleaning the ground. The land is then let out to *rest;* and it may be taken as the general system with occupiers of land in this class, that out of 10 acres, with land in grass to starve a cow upon, for it is not food for one, and with land at rest, one half of the farm never pays anything. The cause of resting land is the want of manure, and as the stock is roaming over the impoverished pasture for at least two-thirds of the year, the straw of the farm is only saturated with wet, and in place of being nutritious manure made under cattle, it is nothing but rotten straw, useless, as compared with what it might have been if the stock had been fed in stalls and the manure made by them. The reason they do this is, that no better mode is known to them; they have no examples, but bad ones, to copy; no one to instruct them, no place to obtain the necessary information.

To provide employment, I propose, 1st, the regulation, compressing, deepening, straightening, and widening of all the rivers that may be navigable or otherwise; all rivulets and streams, in every district, where they conduct the main supply of water from the valleys to a river or other large reservoir: and as this is the first step necessary for the improvement of property, it is the first thing that should be done. This will be more beneficial than railways at present; because railways congregate large numbers to one district, removing them from their homes, and are useful to the people only that reside near the line, or a few miles from it; the increased expense of living lessens very materially the advantages of labour to the man that is obliged to leave his family to obtain it, and besides the applicability of railways generally is a matter of some doubt; in a few cases they will pay a fair interest for the outlay, but if carried generally through Ireland they would not. The deficiency of manufacturing produce, the small number that travel by coaches, are fully explained in Mr. M'Neil's Report on the Dublin and Cashel line; the large districts which it is found necessary to include for the support of this undertaking, proves that this view of the case is something more than theoretic. Another reason why railways would not now be so useful as this plan is, that employment is required in every part of the country, which railways could not give, but the regulation of rivers and streams is required in all places, or nearly so. The interest on the outlay could be obtained everywhere, as the benefits from it would be immediate—results not so certain in railway speculation. The immense tracts of low land wastes might then be brought into profitable and permanent cultivation. An example will prove the correctness of my anticipations. A retired officer bought an estate in Tipperary: 200 acres of it was flooded by the Shannon for a great portion of the year; it was nearly valueless, it could not be drained, and was useless without it. The improvements at Killaloe lowered the waters of Lough Derg, they have not been since flooded, and his lands are improving rapidly. The Calla's are irrigated, and the appearance of the whole district in the short space of twelve months is quite altered. It is perfectly dry, crops are growing luxuriantly, where the Shannon rested for four months in the year; and I am sure the benefit to these 200 acres, by this alone, is not less than 80*l*. per annum.

Now, I know places on insignificant rivers where as much mischief is done to property as the mighty Shannon did on this; it is not in single places, but extends generally through Galway, Mayo, King's county, and Tipperary. In fact, I believe, and the opinion is founded on actual inspection, and considerable consideration, that one-twentieth of the lands of these counties is absolutely useless, and perfectly unprofitable, from this cause alone. A proprietor engaged me to inspect an estate which was much injured by a river, or rather rivulet, to report to him as to the means of remedying the injury, and to estimate the expense attending the execution of what I might propose to be done. I did so. About 150 acres of his land, 40 or 50 acres of his neighbour's, and 15 acres of a third party, were entirely unimprovable from an obstruction of the stream by a ledge of rocks; I proposed they should be blown out, and the level above reduced three feet; the estimate of the whole expense was less than 40*l*.; it was acknowledged that the 200 acres and upwards would be improved 10*s*. per acre per annum, without any further outlay, but if internal draining were carried out, the whole might be cultivated, and made equal to the higher land on the estate. Cattle can never be on it more than two months of the year, and then have nothing but coarse semi-aquatic grasses to feed on; these are produced on a fine alluvial soil, twelve inches deep, incumbent on lime stone gravel, but saturated with water. Still this has not been done. Why? Because only one of the proprietors agrees to assist in defraying the expenses of the work. In another case, an intelligent Scotch proprietor had 20 acres incapable of being drained, from the shallowness of the river, and consequently uncultivated; five acres are fit, to use his own terms, "as pasture for a flock of geese only," the cost of this work is £140; it is in progress of execution at his sole expense, and the increased value will be 8s. per acre by his estimate, by mine 12s.; however take his, and you will see the interest of 5 per cent. can be paid, even in the latter case. How much more in the former?

I think I have shown there is room for the profitable employment of the people, in the regulation of rivers, and that to a very considerable extent. But how is it to be done? Not by Government volunteering to assist proprietors for the purpose of *inducing* them to improve their estates; not by offering loans to the estates requiring them; nor by a drainage bill empowering two to force one, alone. If these steps are relied upon, they will be found miserably insufficient. Government if they wish to improve the condition of the landowners and peasantry, must act on Napoleon's plan. Give the proprietor a choice of borrowing from them the money required, and executing the work himself, under the direction of district engineers, appointed by a board of intelligent agricultural gentlemen, assisted by experienced civil engineers, sitting in Dublin; and then say if *you* do not do this *we* will, and will then apportion the share of expense according to the benefit derived, for which your estates must pay the interest. The law of the land recognises this principle. In 1732 the Barren Land Act was passed by the Irish Parliament, which empowered the Court of Chancery to enquire into the interests of persons claiming waste lands, *and to oblige them to contribute to the drainage thereof in proportion to such their interest.* Common sense points out, that where a dense and starving population require employment, and that means for providing them therewith can be usefully applied, not only for *their* benefit, but also for the benefit of the country at large, that where private objections, or narrow minded niggardliness, obstruct the good, that they should be disregarded; and even if it were allowed that the rights of property would be interfered with, still, is the public good to be sacrificed by the neglect and incompetence of landed proprietors? Should they not be compelled to see their own interests and benefit mankind? It is only such persons that could complain; the improving man of intelligence would rejoice; for the good he intended doing could no longer be nullified by the neglect of his neighbour.

Another means of giving employment and improving the condition of the people, is by the reclamation of waste lands; I do not mean the bogs: there is enough to do without them, and our successors in some centuries to come may find it to be then perhaps to their advantage to undertake this. The Waste Land Society, of which the Earl of Devon is chairman, have begun in the right way; but the limited means at their command, compared to the demand for their assistance, enable them to be a model only to Government. I attended the last annual inspection made by his Lordship on the lands of Ballinakill. Three years before that I visited it; then it was a wild, dreary, desolate mountain; now how does it look? Seventy or eighty families are living in comfort on it, the cottages are clean, neat and comfortable, the crops equalling, if not excelling, those grown in the demesne of the neighbouring Baronet; good roads have been formed, fences erected, draining executed, turnips and clovers feed their stock, and all appears improving and satisfactory. A neighbouring gentleman, Mr. Featherstone, has purchased a tract of the same mountain, his tenants surpassed, if possible, in improvement, the Society's. He has built a handsome residence for himself and family, young plantations have sprung up, and in as sheltered and comfortable a spot as the most fastidious could wish for, where a few years since a solitary bird could not be seen, so desolate appeared the place; there he told me all he did had paid him, he had *created* an estate, and that many of his tenants having reclaimed, with some little assistance from him, portions of land, had sold their interest in them to others for large sums, and taking a new spot, had begun again in the same mountain; and were in better circumstances than the lowland men holding the same sized farms. But how was this? The answer is worthy of particular attention. On the Society's and Mr. Featherstone's tracts the tenants were not allowed to waste their time in laborious unprofitableness; they were instructed what to do, in reclaiming, draining, and cropping, by experienced agriculturists, employed by the proprietors to do so; and in this only lies the secret. The educated man's duty was to think, advise, instruct: the labouring man's to act, and well has the system answered. There are a million and a half acres of such mountain wastes in Ireland, which if improved, would support 3000 families, or 180,000 persons. Without alluding to the advantage bringing this into cultivation would be to England, in the increased supply of provisions to your markets, without looking to the great national improvement this would be, but merely viewing it as a charitable act, how immeasurably does it surpass the poor relief acts, the emancipation and other political measures.

How can this be done? Easily. Large sums are annually voted to the Dublin Society, and expended in their botanic gardens, &c. Let Government grant £10,000. per annum to assist the Waste Land Society. Colonel Robinson knows well what to do with it; and if with so much money he should at all hesitate how to apply it, the Earl of Devon can assist him. Associated with them, let there be Captain Larcom, Captain Kennedy, or perhaps Mr. Stewart French, would be better, as he knows where, and how to begin; let him be the representative of Government; and I venture to say that with such men, with an efficient staff of practical men, and backed with the £10,000; more would be done for the improvement of this country, in an incredibly short space of time, than 100,000 soldiers could ever accomplish.

There are said to be 300,000 acres of land covered by the expansion of lakes and rivers, to which may be added 600,000 acres that are saturated with water, rendered unprofitable, but uncovered; £10,000,000 per annum of agricultural produce is said to be lost to the kingdom by unreclaimed land; and yet nearly three millions of the inhabitants are destitute from the want of employment. Now if such statements are true, and they have been reported by Government officers, if England pays for agricultural produce £10,000,000 per annum to foreign nations, which could be provided her by this country, and if in addition to this a dense and starving population are discontented, almost disaffected, and that this is occasioned by the want of employment, surely it is the interest of the British Government to try the experiment I most humbly have recommended, and the result, there can be no doubt, will fully equal that obtained by the Waste Land Society.

But these plans only relieve the persons without land; what is to be done for those occupying it? Before I state my opinion, allow me to put you right as to the landlords of Ireland. As a class, they are the most abused, but I am happy to say, it is by those who know least about them. Their worst fault is, I believe, that they do not see their own interests sufficiently, that they view their estates with local eyes, instead of doing so with eyes enlightened by a study of other countries, by viewing what has been done in other places through judicious improvements. It is really very difficult to convince many that their incomes can be at all increased by improvements; and when we see men who are presumed to be educated, still lingering in the old beaten track of dubiousness, unwilling to try for the improvement of their condition, because their fathers did not do, as we would, it is not a matter of surprise that those under them, the uneducated, should follow and persevere in the systems practised of old, which they have been taught almost to revere, certainly to follow, changes from which, their superiors have characterised as theoretic nonsense, wild speculations, mad schemes, &c. But to return to the calumnies heaped on landlords; many have ejected, in some cases I believe with unnecessary cruelty, *but it is not general;* I know many inheriting fine estates, and large debts, good men, incapable of assisting their tenants, and unable to allow time for payment of rent from the pressure of their creditors. These men, if they are not paid, are compelled to seek tenants capable of doing so. Then comes the difficulty of obtaining possession; the occupier knowing the impossibility of obtaining subsistence if he leaves, endeavours to retain possession in spite of law, and the landlord is compelled to obtain an *habere*—scenes of distress follow. But what is the cause of them? *Want of labour.* In fact, I believe if constant employment could be obtained, many of the small farmers would give up their holdings, and that farms might be consolidated, which, with improvement in the system of agriculture, would be a vast advantage to the country; but whilst the deficiency of employment continues, I consider it cannot be done without causing so much misery that no advantage to a few could justify. Had Irish landlords, English tenants, or tenants with the same capital, same education, and same intelligence, you would hear nothing of the disagreements of landlord and tenant. The Irish would not be a whit behind the English landlords, and Ireland would be prosperous; but to do this, *you* must raise the character of the Irish tenant, and this brings me to the subject of the improvement of the small Irish farmer. All you require to do, is to instruct him in the practice of agriculture. I look upon it to be as absurd to put a good piece of land into the hands of small farmers, uneducated, understanding nothing of the proper systems of farming, such as the Irish small farmer, and direct him to manage it, as it would be to give, one who never learned to write, a good pen, and order him to do so. They must be taught. Agriculture is a business, requiring an apprenticeship of practice and reading to be master of. But such perfect mastery is not required in the Irish farmer; let him be taught the primers of the business on the soil where he lives, by men fully competent to teach and direct him, let these agriculturists be men of intelligence, capable of understanding the composition and management of the various soils they will meet with; they must be fully conversant with green cropping. Rotation, house feeding, and soiling, the ingredients and application of manures, draining, sub-soiling, and irrigation; the management of dairies, and milch cows; and let them be located one in every parish where such services are required, paid out of the county cess by the grand juries, at or near the rate of £100 per annum, and be directly under the surveillance of a committee of gentlemen in each parish, and of the district inspectors appointed by the government board before referred to. The cost will be for the *whole country* about £250,000 per annum, to be continued for seven years; or in the whole £1,750,000, by which time there will be sufficient knowledge obtained by the people, for dispensing with their further services. To assist in meeting this sum, the police might be reduced in a few years, although at first it would be unwise to do so; but as the people increase in comfort, there will be less crime, and less need of such large forces to prevent it.

The advantage to the tenant would be, increased comfort, increased confidence with his landlord, and a prospect of continuous prosperity and eventual independence. To the landlord the advantage would be equally great, certainty of his income, peace and prosperity on his estate, in which he will be a sharer, from the tie that would then exist between the proprietor and occupier, and the increased value of his property, from the improved condition of the tenantry.

There is no interference with the rights of property in this; the benefits of proprietorship are increased. The necessity of supplying the information proposed, is shown by the adoption of the means, to an insignificant extent, certainly, by the agricultural societies. They have done much good, but not sufficient for the object in view, (viz.,) elevating generally the condition of occupiers of small farms; nor can it be done by such means, the instruction must be more general and more explicit, than the agriculturist has time and opportunity of giving.

Let me insist upon it, that all the tenants require is instruction, you may teach them reading, writing, arithmetic, and even the higher branches of education; but it is all useless as applied to the tenantry of this country, if they are not taught agriculture. It is this by which they are to subsist, by which landlords are to receive their incomes, by which Ireland is to prosper, and therefore this instruction should be provided by Government in the direct manner I have ventured to suggest. Increasing the franchise will not provide food; the equalization of churches will not grow potatoes; nor will the Repeal of the Union fatten cattle. But these effects are expected by a Repeal.

Reduction of rents are not *generally* necessary, nor would it be adequate to the wants of the people, and would be a decided injury to landlords. Instead of reductions of 10*s*. per acre, which in most cases would be 30 per cent., teach them to swell their 3*l*. produce into 5*l*., not by increase of prices, for that cannot be controlled, but by increased production. Remember, that potatoes and milk are their only fare, that with this they are contented, if they have sufficient; that their wants are few, and yet unsupplied; their privations many, and unrelieved; that a starving people may be made easily to rebel, perhaps be as easily subdued; that people in such circumstances deserve pity as much as punishment for many crimes; that immediate suffering, present distress, dread of the future, and remembrance of the past, have caused the rapid progress of the Repeal movement, and that you, Sir, with the English people, are alone able to relieve their distresses, to supply their wants, and this can be done by increasing the demand for labour, by supplying the practical information they require in the business of agriculture: then will plenty succeed poverty, happiness displace misery, and Ireland become a great and prosperous portion of the kingdom, a helpmate for England, and a blessing to our country in the over ruling hands of God.

Your very obedient servant,

J. B——N, C.E.

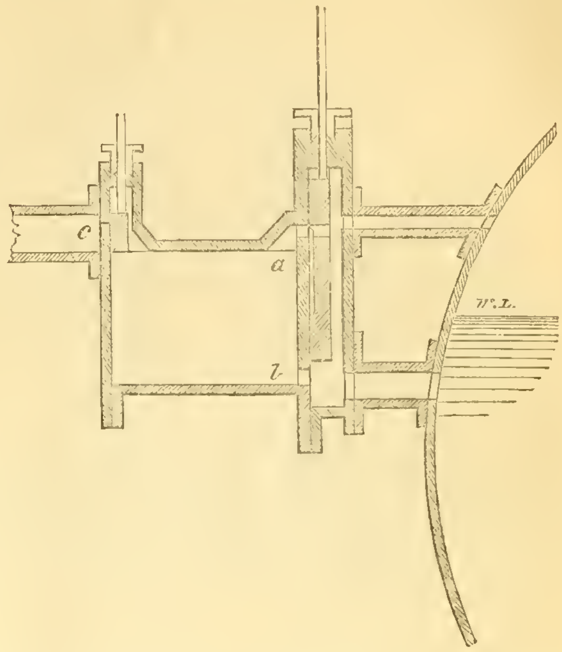
Parsonstown, Feb. 26, 1844.

An attempt is to be made this session to extend the patent law from fourteen to twenty-one years. It is indeed to be regretted that, whereas the copyright of authors dates from publication, when profit is supposed immediately to commence, the copyright of inventors expires too frequently before a profit can be realised.

SUPPLY OF WATER TO BOILERS.

Sir—In your *Journal* for last month there is a plan mentioned for supplying high pressure boilers with water, which I think might be effected in a more simple manner, thus:—

Let *a b c* be a small tank, placed by the side of the boiler, half above and half below the proper water level; let *a*, *b*, be ordinary slide valves connecting the tank with the boiler, *c* a valve connecting the tank with a reservoir placed above the level of the tank.



The action will be as follows:—The valves *a*, *b*, being shut, and *c* open, the tank will fill with water; then *c* being shut, *a* and *b* opened, the water will run out of the tank down to the level of the water in the boiler; the valves being again reversed, the same operation will be repeated, the steam in the tank being condensed by the admission of the cold water.

If the valves be connected with the engine, so as to be reversed at proper intervals, a self-acting and self-regulating feeder will be obtained; for it is evident the water in the boiler can never rise above the top of the tank, and if the water falls too low, a whole tank full will be admitted instead of half, thus quickly restoring the balance.

The valve *b* should be large, and the communication with the boiler not left open longer than necessary, in order to prevent the water in the tank becoming heated by the condensation of steam; a board floating loosely in the tank would prevent the steam coming in contact with the water.

An apparatus of this kind placed on the top of a locomotive would enable the boiler to be supplied by hand while the engine was standing.

I remain, Sir, your obedient servant,

Henry Carr.

Folkestone, February 8, 1844.

MAXTON'S LONG SLIDE VALVE FOR CONDENSING ENGINES.

By Mr. John Maxton, Engineer.

The advantages of this valve are,—that it may be used without a steam-chest, while it has all the advantages of a long slide valve in shortening the passages to the cylinder, it works with much less friction than the common long slide-valve, the pressure being equalized, and is much less expensive, and easier upheld, than the packed valve.

In fig. 1, the piston is represented as descending in the cylinder, the vacuum being formed under the piston by the passage A through the valve towards the condenser, the steam being admitted above the piston by the induction passage B, the steam at the same time having access to the portion of the valve below at D, which tends to press the

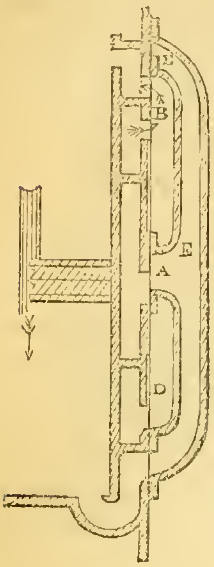


Fig. 1.

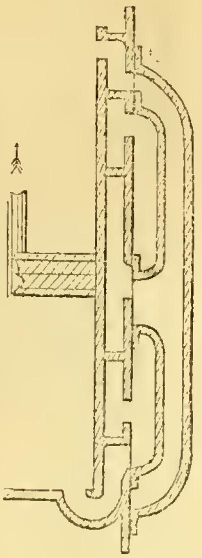

Fig. 2.

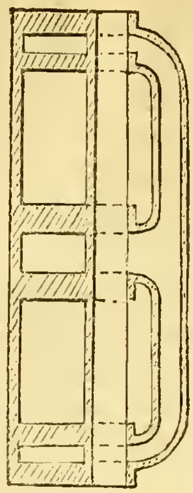

Fig. 3.

valve outwards from the cylinder, while the vacuum, acting on the inside of the valve E, draws it towards the cylinder, the valve being so proportioned that the vacuum must so far overbalance the steam, that the valve will keep close to the cylinder. In fig. 2, the piston is at half-stroke, ascending, and the position of the valve is reversed from that in fig. 1. Fig. 3 is a front view and section of the valve.

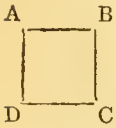
TUBES OF LOCOMOTIVE ENGINES.

Investigation to determine the diameter of the Tubes of a Locomotive Engine Boiler to produce a maximum effect.

IN treating this subject it appears rational to suppose that the effect of the hot air in passing through the tubes is directly in proportion to the extent of surface in contact therewith, and as the time of contact conjointly: that is, denoting the number of tubes by n, their diameter by δ, their aggregate surface by s, their united area by a, and the time of contact by t, supposing the length of the tubes constant, we shall have the following postulates.

$$t \propto a$$
$$a \propto n\,\delta^2 \qquad \text{A.}$$
$$\therefore\ t \propto n\,\delta^2 \qquad \text{B.}$$
$$s \propto n\,\delta \qquad \text{C.}$$
$$\therefore\ ts \propto n^2\,\delta^3 \text{ a maximum} \qquad \text{D.}$$



Let the parallelogram A B C D be the space which is to be occupied by the ends of the tubes, and let AB $= a$, and AD $= b$; also let the distance between the inner surfaces of two adjacent tubes be a given interval c, and because the same distance c must exist between the sides of the extreme tubes, and the ends A D, B C of the above figure, then $a-c$ must be divided into a certain number of equal parts, which will be regulated by the distance between the centres of two adjacent tubes, and let this distance be $(a-c)x$, x being a function of $(a-c)$, $\frac{a-c}{(a-c)x} = \frac{1}{x}$, the number of tubes in one horizontal row A B.

The tubes are so disposed, that the lines joining the centres of any three adjacent tubes form an equilateral triangle, consequently the vertical distance between the horizontal rows will be

$$(a-c)x\sqrt{\tfrac{3}{4}} \quad \therefore \quad \frac{b-c}{(a-c)x\sqrt{\frac{3}{4}}} = \frac{2(b-c)}{(a-c)x\sqrt{3}} =$$

the number of horizontal rows in A D, and

$$\frac{1}{x} \times \frac{2(b-c)}{(a-c)x\sqrt{3}} = \frac{2(b-c)}{(a-c)x^2\sqrt{3}} =$$

The whole number of tubes in A B C D $= n$.

Further the distance $(a-c)x$ is greater than the diameter of a tube by the interval c, therefore

$$(a-c)x - c = \text{the diameter of a tube} = \delta.$$

Let $\pi = 3{\cdot}1416$, then the aggregate circumference of all the tubes (and which may be taken to express the internal surface in consequence of the length of the tubes being constant), will be

$$\frac{2\pi(b-c)}{(a-c)\sqrt{3}} \times \frac{\{(a-c)x-c\}}{x^2} = n\,\delta \text{ or } s \qquad \text{(C)}$$

and the area of the tubes will be

$$\frac{\pi(b-c)}{2(a-c)\sqrt{3}} \cdot \frac{\{(a-c)x-c\}^2}{x^2} = n\,\delta^2, \text{ or } t \qquad \text{(A or B)}$$

Now by the postulate we have st a maximum, and substituting the values s and t as found above, we have

$$\frac{2\pi(b-c)}{(a-c)\sqrt{3}} \cdot \frac{\{(a-c)x-c\}}{x^2} \times \frac{\pi(b-c)}{2(a-c)\sqrt{3}} \cdot \frac{\{(a-c)x-c\}^2}{x^2} =$$

$$\frac{\pi^2(b-c)^2}{3(a-c)^2} \cdot \frac{\{(a-c)x-c\}^3}{x^4}, \text{ a maximum} = n^2\,\delta^3 \qquad \text{(D)}$$

All the above quantities, except x, are constants, and the second factor only contains the variable, therefore we have

$$\frac{\{(a-c)x-c\}^3}{x^4} = \text{a maximum}.$$

Differentiating and equating with zero, rejecting the denominator, we have

$$3(a-c)x^4\{(a-c)x-c\}^2\,dx - 4x^3\{(a-c)x-c\}^3\,dx = o;$$

whence $(a-c)x = 4c$.

But $(a-c)x =$ the distance between the centres of two adjacent tubes, which is therefore equal to four times the interval between their internal surfaces.

Further $(a-c)x - c = 3c =$ the diameter of a tube, which must be equal to three times the same interval.

It is obvious that the smaller c is taken, the greater will be the value of the expression $\frac{\{(a-c)x-c\}^3}{x^4}$; and, therefore, the tubes ought to be placed as near together as possible.

In order to exemplify the application of the principles herein developed, I have prepared drawings of the tubes of a locomotive engine boiler, such as are very commonly used, and also of one tubed according to the proportions just determined.

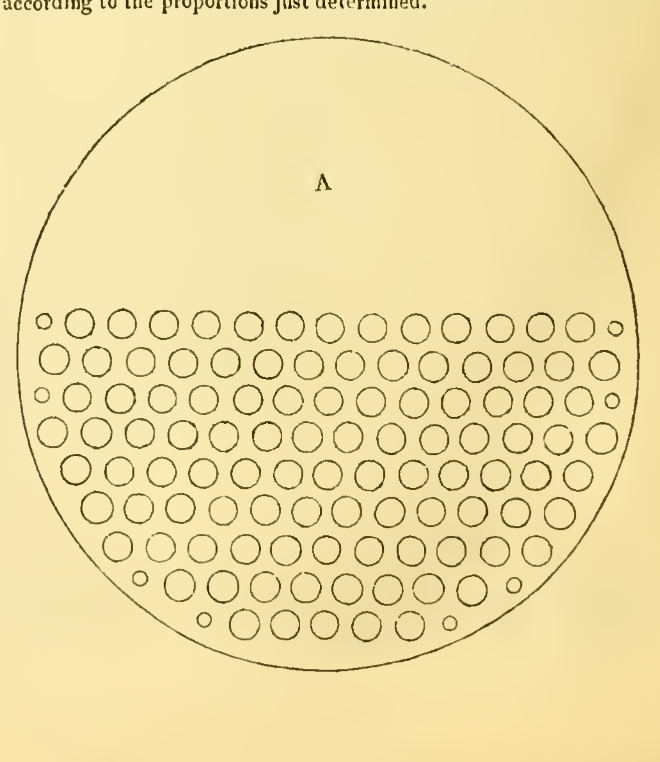


Table of the comparative evaporating power of three different methods of tubing:—

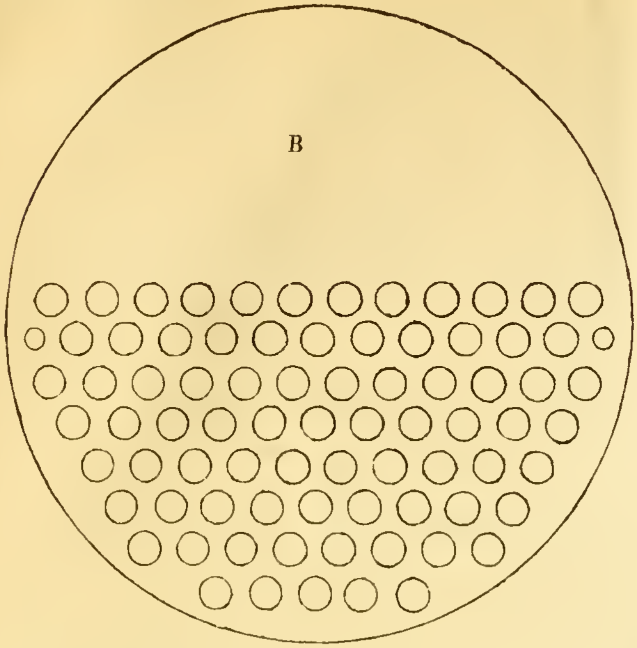
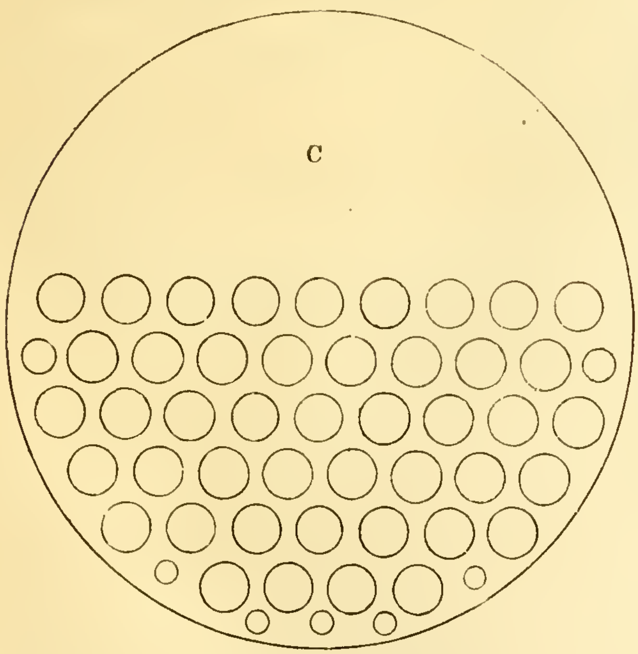


Reference to drawing		A	B	C
Number of tubes		103	78	45
Internal diameter of tubes	inches	$1\frac{5}{8}$	2	3
Distance between centres ..	,,	$2\frac{5}{8}$	3	4
Interval in tube plate ..	,,	$\frac{3}{4}$	$\frac{3}{4}$	$\frac{3}{4}$
Total circumference of tubes	,,	525·82	490·09	424·05
Total sectional area of tubes	,,	213·61	245·04	318·08
Product of circumference and area..		112,320	120,091	134,881

Comparison
A : C : : 100 : 120
B : C : : 100 : 112



It appears from the above, that the boiler which is tubed in the theoretic proportion is from 12 to 20 per cent. superior to the others.

Let us now determine the area of the tubes, as compared with the whole space, when the preceding theoretic ratio is adopted.

$\frac{a-c}{4c}$ = the number of tubes in one horizontal row A B.

$4c\sqrt{\frac{3}{4}} = 2c\sqrt{3}$ = the vertical distance between the horizontal rows

$\frac{b-c}{2c\sqrt{3}}$ = the number of horizontal rows in A D.

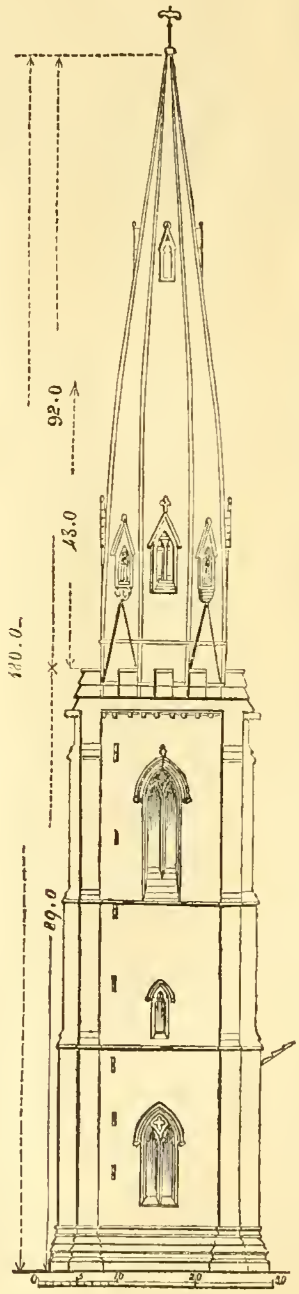
$\frac{a-c}{4c} \times \frac{b-c}{2c\sqrt{3}} = \frac{(a-c)(b-c)}{8c^2\sqrt{3}}$ = the whole number of tubes.

Diameter of a tube $= 3c$

$\therefore \frac{(a-c)(b-c)}{8c^2\sqrt{3}} \times \frac{\pi}{4}(3c)^2 = \frac{9\pi}{32\sqrt{3}} \cdot (a-c)(b-c) =$ the area of the tubes: from which it may be observed that the diameter of the tubes disappears from the expression, indicating that so long as the ratio between the diameter and interval remains the same, the aggregate area will be constant, let the actual diameter be what it may: and the value of $\frac{9\pi}{32\sqrt{3}} = 0{\cdot}51$. The area of the tubes will, therefore rather exceed the half of the space.

Manchester. Geo. W. Buck.

ENTASIS OF CHURCH SPIRES.



Sir—In a report of a recent meeting of the Royal Institute of British Architects, given in your journal of Jan. 27, I observed some remarks upon the question of entasis in spires, from which it appears, that the gentlemen who took part in the discussion had not recognised decided curved lines in any spire except that of Newark; I am happy to be able to instance, from the same district, a much finer and better developed example than the spire of that church, which, it is true, has a positive though slight entasis: the accompanying drawing, should you think it worthy of a place in your valuable *Journal*, and which is an elevation of the steeple of Gedling Church about four miles from Nottingham, will more clearly exemplify this assertion: the scale and measurements may be depended upon, as the latter were taken during some repairs at the summit of the spire. It will be perceived from this that the amount of variation or bulging from a straight line drawn from the base to the summit, is very considerable, being in the widest part not less than two feet; indeed the swell is so great as to prevent a person, standing upon the leads of the tower, seeing the weathercock, unless by leaning over the battlement: the curve extends 43 ft. from the top of the battlement, where it meets the straight lines of the rest of the spire, and forms a segment of a circle whose radius is about 270 ft.

The style of the spire is of what I should denominate the second decorated; circa 1320; and it is, perhaps, worthy of remark, that Newark is also of decorated date, although somewhat later than Gedling. It is situated at the north west angle of the nave; and consequently groups very picturesquely with the body of the church, which possesses many interesting features, and has a most exquisite early English chancel of rather unusual dimensions (50 ft. by 24 ft.): there are four niches occupying the alternate faces of the spire as indicated in the drawing; they contain male and female statues, in the attitude of prayer. One of the best preserved male figures is apparently clad in chain mail, with a low conical helmet; and wears either a jupon or cyclas, with a triangular or heater shaped shield, and a sword girt upon the thigh: this costume corresponds with the date to which I have assigned the erection of the steeple. There are also two canopied niches, containing good figures of saints, upon the western end.

The general effect of the spire is very imposing, its lofty altitude gaining additional elevation from its beautiful proportions and fine outline; which, together with the absence of all meretricious detail, and resulting simplicity of design, would, in my opinion, render it an admirable model for modern imitation.

I am, Sir, your obedient servant,

J. C. ROBINSON.

Nottingham, February 20, 1844.

MESSRS. BOULTON & WATT, ON THE STEAM ENGINE.

Through the intervention of a Correspondent we are enabled to lay before our readers a document of some importance—being not less than a copy of the instructions furnished by Messrs. Boulton & Watt to five, we are informed, of their principal agents, and superintendents, who were deputed by them to attend, in different parts of the kingdom, to the erection of the steam engines made by the firm, under the first conditions of the patent-rights granted to them.

In the history of the invention of the steam-engine, some authors have shown much laborious research, and have deemed it right to adduce as elementary discoverers, the names of Hero, Brancas, and other individuals; and have terminated this branch of their histories, with the inventions of Sir Samuel Morland, and the Marquis of Worcester. But we, ourselves, are of opinion that, in the history of the invention of the steam-engine, there are only three important elementary periods; viz., those of Savery, Newcomen, and Watt; and all of them took place within a century.

In taking a retrospect of the inventions of those eminently distinguished individuals, and of the times in which they respectively lived and brought them forward, we scarcely know to whom the greatest meed of praise is due—whether to Savery, for the invention of the steam-engine, and its first application to the arts of life; or to Newcomen, for the introduction of the cylinder, piston, beam, and pump-work generally, which still remain, as essential features of the invention; or to Watt, first for effecting the condensation of the steam in a vessel separate from the cylinder; and secondly, for his admirable contrivance of the parallel motion. For it was by this last that he was enabled to work the steam on both sides of the piston, and to reduce the action of the engine to that extraordinary precision of time and power, for which it is now universally celebrated, and by which it is adapted to the performance of the most delicate and rapid processes, even to the weaving of lace.

To James Watt, notwithstanding the profundity of his intellect and great inventive powers, much additional praise is due for his sound commercial talent; so ably aided and seconded, as it is well-known to have been, by his princely-minded partner, Mr. Boulton. And, perhaps, it was owing to this last mentioned circumstance, that the names of Messrs. Boulton & Watt spread so rapidly over the surface of the civilized world, as pre-eminently skilful mechanicians.

A document emanating from such a firm, even as a matter of history, is of some importance; but when the low state of the mechanical arts at that period is considered, and a knowledge of it is placed in juxta-position with the soundness of judgment, prudence, and foresight, displayed in the document, we cannot withhold our admiration of that commercial sagacity, by which they ensured practical success. There cannot be a question, that much of that success, and its consequence, the realization of great wealth, was produced by deep investigation of, and attention to, minute details, as thus exhibited; and it ought to convey to many of those who have embarked, or are about to embark, in the same arduous and honourable profession, a memorable lesson.

In giving the document to our readers, we shall not presume to disturb the meaning of the text, or attempt to enrich it by notes and annotations. But, at the conclusion, we shall take a retrospect of the whole, and bring the practical illustration of the steam-engine down to the present time.

TABLE OF CONTENTS.

General Directions for Building the Engine House, and Constructing some parts of the Engine.

1. Having fixed upon the proper situation of the pump in the pit, from its centre, measure out the distance to the centre of the cylinders;—that is, the length of the working beam, or great lever, and the half breadth of each of the great chains,[1] then, from the centre of the cylinder, set off all the other dimensions of the house, including the thickness of the walls. Dig out the whole grounds included, to the depth of the bottom of the cellar; so that the bottom of the cylinder may stand on a level with the natural ground of the place, or lower, if convenient. For the less height the house has above ground, so much the firmer will it be. The foundation of the walls must be laid at least two feet lower than the bottom of the cellar, unless the foundation be firm rock; and care must be taken to leave a small open drain into the pit, quite through the lowest part of the foundation of the lever wall, to let off any water that may be accidentally spilt in the engine house, or may naturally come into the cellar. If the foundation, at that depth, does not prove good, you must go down to a better, if in your reach; or make it good by a platform of wood, or piles, or both.

2. The foundation of the lever wall must be carried down lower than the bottom of the space left under the condenser cistern, to get at the screws which fix the condenser; and two short walls must be built to carry the beams under the condenser cistern. Two other slight walls must be built, one on each side, at a little distance from the cistern, to keep the earth from it, which would otherwise cause it to rot.

3. Within the house, low walls must be firmly built to carry the lower cylinder beams, so as to leave sufficient room to get to the holding down screws; and the ends of these beams must also be lodged in the wall; but the platform must not be built on them, until the house is otherwise finished.

4. The lever wall must be built in the firmest manner, and run solid, *course by course*, with thin lime mortar; and care must be taken that the lime has not been long slaked. If the house be built of stone, let the stones be long and large, and let many headers be laid through the wall; it should also be a rule, that every stone be laid on the broadest bed it has, and never set on its edge.

A course, or two, above the lintel of the door which leads to the condenser, build, in the wall, two parallel flat thin bars of iron, equally distant from each other, and from the outside and inside of the wall, and reaching the whole breadth of the lever wall. About a foot higher in the wall, lay at every four feet of the breadth of the front, other bars of the same kind, at right angles to the former course, and reaching quite through the thickness of the wall; and at each front corner lay a long bar, in the middle of the side walls, and reaching quite through the front wall. If these bars be 10 ft. or 12 ft. long, it will be sufficient. When the house is built up nearly to the bottom of the opening under the great beam, another double course of bars must be built in, as has been directed.

5. At the level of the upper cylinder beams, holes must be left in the walls for their ends, with room to move them laterally, so that the cylinder may be got in; and smaller holes must be left quite through the walls for the introduction of iron bars; which being firmly fastened to the cylinder beams at one end, and screwed at the other, or outer end, will serve, by their going through both the front and back walls, to bind the house more firmly together.

6. The spring beams, or iron bars fastened firmly to them, must reach quite through the back wall, and be keyed, or screwed up tight; and they must be firmly fastened to the lever wall on each side, either by iron bars, firm pieces of wood, or long strong stones reaching far back into the wall. They must also be bedded solidly; and the sides of the opening built in the firmest manner with wood or stone. The spring beam must always be laid eight inches, on each side, distant from the working beam, to give room for the side arches.

7. The house being finished, a wooden platform, of two and a half inch plank, must be laid on the lower cylinder beams; and the centre of the cylinder being accurately marked on it, four holes must be bored through the cylinder beams for the holding down screws; and four boxes, about seven or eight inches square, and as long as the stone platform will be deep, must be placed perpendicularly over them. Then the stone or brick platform must be built up to the level of the cylinder's bottom. It must be composed of the heaviest materials which can readily and cheaply be procured. A very solid pillar of stone or brickwork, laid in the best lime mortar, must be carried up directly under the cylinder, and must be, at least, of the diameter of the outside of the flanches; the rest of the platform may be filled up with heavy materials, bedded solidly in a mortar of clay and sand, and well beat into their places, so that they may never settle or yield.

[1] [N.B.—It may be necessary here to state, that as the instructions here given were for the first engines made and erected under the patent, they were applied to pumping only; that the engines were of the kind denominated "atmospheric," and that, as the parallel motion was not then invented, the circular motion of different parts of the beam were changed into the approximatively vertical, upward and downward, motion of the piston rod, and pump rods, by arch heads, or "arches," on the beams; and by suspending the rods to them by chains.]

8. The lever, or great working beam, is best when composed of one single log of seasoned oak, where that cannot be obtained, two may be used, or four, or more. The fewer logs it is composed of, so much the more durable will the lever be, or of so much smaller scantling may it be made. This beam must be fashioned and mounted. The diagonal stays, fastened to the arches, and on the lower log, or lower edge of the beam, will prevent the logs from sliding on one another, by the difference of the direction in which the chains act upon them, when the end of the lever is up or down. These stays must be let into the side of the beam, that the other diagonal braces may pass over them. The diagonal braces, which reach from the top of the king posts to the lower edge of the beam, are intended to prevent the logs from bending or sliding on one another. They are fastened to the beam, at their lower end, by means of a strong square bar of iron screwed at both ends, which passes through the beam, and serves to bind it together, laterally. They must nowhere else have any fixture to the beam. Their screws, at the top of the king posts, must be tightened from time to time, as required.

The gudgeon must be placed on the top of the beam, and must not be at all let into it; only the corners of the log may be taken off, to fit the saddle plate, and to prevent the saddle plate from sliding on the beam. One or two pieces of hardwood, about five inches broad, and a foot long, by three inches thick, may be let into the upper side of the beam, one inch deep, with their ends butting up against the saddle plate. They must be spiked down in their places; and both them, and the saddle plate, must be laid in a bed of tar and tallow, mixed and used boiling hot, which will prevent the wood rotting under them. A clamp of oak, four inches thick, and from four to six feet long, must be spiked on the lower side of the beam. This clamp must be rounded on the edges; its use is to prevent the beam straps from hurting or weakening the beam in that critical place. These beam straps must not be made out of thick bars, or lumps of iron; but must be made up by a number of thin or small bars welded together; and they, and all the other iron work of the beam, must be made of iron of the best quality. All the big pieces should be made up of smaller, or thin bars, in the way I have mentioned. Upon no account, whatever, let any holes be bored through the beam near the gudgeon, nor any thing else be done, which may weaken it there.

9. The arches for the plug tree and condenser pumps should be screwed to the beam by screw bolts, which should pass through the joints of the logs of the beam, if it be composed of more logs than one, and one bolt may generally pass above the beam; these bolts also serve to keep the beam together laterally; these arches should be made with a shoulder of two inches projection to rest on the upper side of the beam. The tails of the martingales of the plug tree, and the condenser pumps, must also be secured by bolts passing through the beam in some joint, if it can conveniently be done. The lower end of the king post should have a hollow in it, to fit the gudgeon on; but care should to be taken that it rests upon the gudgeon, and not upon the saddle plate. It should be contrived, that the tails of two of the great martingales should rest on the middle of each of the two logs which compose the thickness of the beam; that is, when the beam consists of four or more logs. The martingale screws should be strong, and should go quite down through the beam, as it is them that principally keep the beam together in the direction of its depth. Near these screws must be placed the keys, or pieces of hard dry wood; which, being half let into each log of the beam, prevent the logs from sliding one upon the other. These keys should never be above two inches thick; that is, one inch let into each log: they may be made in three pieces, the two outside pieces dovetail ways, and the middle one tapering; by driving up which, they are made to join themselves in their mortoises. Or they may be made of one piece, six inches broad at one end, and five at the other, so that by driving the whole in, it may check the sliding of the logs. If there are more sets of logs than two in the depth, the keys must be placed, alternately, on different sides of the martingale screws. Care must be taken, in placing the chains for the plug tree and condenser pumps, that all the heads of the chain bolts be next the beam, and that they be far enough off not to rub on the diagonal stays, or any other thing.

10. The great chains must be made of the very best Iron, and the martingales must be placed so, that the adjusting screws may lie parallel to the arches, and the upper surface of the head of the martingale be at right angles to them. The holes, in the martingales, should be quite easy for the adjusting screws; and a washer, thinned about the outer edges, should be quite easy for the adjusting screws; and a washer, thinned about the outer edges, should be put under the nuts. There should be a sufficient length of chain, to reach one link lower than the under end of the arch of the beam.

11. The cap and cross-bar, for the piston-rod, should be firm work, of good iron. The mortoise, in the cap, should be made exactly to suit the mortoise in the piston-rod; and the cutter, or forelock, to fit them both exactly; and the cutter above all things should be the very best of iron, as the whole depends on it. There is always a sufficient size given it in the drawings; so that, if it should fail, it must be the fault of the iron, or work-

manship. This cutter must be kept in its place by two cross cutters; and these again, by a thong of leather, passed through some holes in them.

12. It will seldom happen that the plug tree can be hung directly under its arch; you are to place them exactly in the places fixed by the drawings; that of the arch will always be found right in the general section; but the place of the plug tree and guide posts must be taken, by measuring from the nozzle, in the drawing of the working gear. A strong iron bracket with a stay must be fastened to the top of the plug tree, in such a direction that the point of the bracket may come directly under the arch. There must be a hole in the point of the bracket, to receive the end of an iron rod, reaching down from the chain; and the end of this rod must be screwed, for five or six inches, and have a nut on the lower side of the bracket, to adjust the height of the plug tree by.

13. There should be placed upon the spring beams, over the cylinder, two uprights, connected at top by a strong cape piece. These uprights serve to support a windlass, with a wheel and pinion; by means of which, and a pair of tackle pulley blocks hung to the cape piece, it will be easy to lift and put the cylinder, &c. in their places; and after the engine is completed, it makes it easy for the engine man to raise the cylinder lid, to pack the piston, without other assistance

The barrel of the windlass may be of oak, about six inches diameter; and must have a square gudgeon of iron driven quite through it; on one end of which, the toothed wheel must be fixed. The gudgeon may be from one and a half, to two and a half inches square, according to the size of the engine; and the wheel about two feet diameter, driven by a pinion five inches diameter; but these may be larger, or less, according to the weights commonly to be raised. It is necessary to mention to those who may look on a wheel and pinion as a superfluous expense, that there is no trusting to windlasses wrought by bars; and that many bad accidents have happened through the use of them, which obliges us absolutely to condemn them for this purpose.

14. The springs to receive, and, in some degree, to save the blow when the engine comes down too suddenly, are best made of a piece of a square dry elastic timber, reaching from the plummer blocks, to nine or ten inches beyond the catch pins; their size must be suited to that of the engine, from six inches square, to twelve, or fourteen. The ends next the catch pins must be sloped off on the under side, for four or six feet in length, according to the size of the engine; so that their points may be one inch distant from the spring beams, to which they must be bolted down, by a screw bolt at the end of the sloped part, and another at the end next the plummer blocks. The part of these springs which are struck by the catch pins, should be covered by a plate of iron, and that again by a piece of strong leather, to prevent the clattering noise they might otherwise make.

15. The utmost attention to dimensions must be observed, in constructing the masonry of the building; particularly in regard to heights; mistakes in them are productive of the worst consequences.

16. The condenser cistern must be made of best Dantzic three inch deal plank, if it can be got. If not readily to be got, any other good red deal, or oak, may be employed; but whatever kind of wood be used, be sure to cut off all the sap wood, otherwise the cistern will soon become useless. The best way of putting the cistern together is, by means of long screw bolts of iron, about three-quarters square, put through the planks edgeways, from top to bottom of the cistern. These screws may be eighteen inches distant from one another. The bottom may be put together in the same manner with screws; and then fixed down upon the beam, or beams: and be supported by so many more smaller beams, as may be necessary. If the cistern is not more than seven feet long, no uprights, on the outside, are necessary; only one, about six inches square, in each corner, in the inside; and in no cistern ought there to be any uprights on the sides next the wall. The joints of the planks should be plain joints and put together on a strip of coarse flannel, soaked with a mixture of tar and tallow, equal parts, and warm; or upon bullrushes. A large cock or a brass valve should be fixed in the bottom of the cistern, to let off the water occasionally; and a notch, about four inches deep, and eighteen inches broad, with a trough fitted to it, should be made in the upper edge of the cistern, to convey away the waste water. If surface water cannot be found to supply the injection, a small pump should be fixed, to bring up water from the main pump head into this cistern. In case the water from the pit is good, and is raised to the surface, the main pump may deliver it directly into the cistern; but if the water be subject to be muddy, or mixed with sand, &c. it will be best to put it into another cistern, to deposit some part of the matter first. If the pit water be vitriolic, or encrusting water, it becomes necessary to use every means to procure better water, otherwise it will destroy the condenser, &c.

17. In making the boiler, you should use rivets between five-eighths and three-fourths inch diameter. In the bottom, and sides, the heads of the rivets should be large, and placed next the fire, or on the outside; and in the boiler top, the heads should be placed on the inside. The rivets should be placed at two inches distance from the centre of one rivet to the centre of the other; and their centres should be about one inch distant from the edge of the plate. The edges of the plate should be evenly cut to a line, both outside and inside. It is impossible to make a boiler top truly tight, which is done otherwise. After the boiler is all put together, the edges of the plates should be thickened up; and made close by a blunt chissel, about one quarter inch thick in the edge, impelled by a hammer of three or more pounds weight; one man holding, and moving the chisel gradually, while the other strikes. All the joints, above water, should be wetted with a solution of sal ammoniac in water, or rather in urine; which, by rusting them, will help to make them steam tight. After the boiler is set, it may be dried by a small fire under it; and every joint and rivet above water, painted over with thin putty, made with whiting and linseed oil, applied with a brush. A gentle fire must be continued until the putty becomes quite hard, so as scarcely to be capable of being scratched off by the thumb nail; but care must be taken not to burn the putty, nor to leave off, until it becomes dry.

18. In building the brickwork of the boiler setting, no lime must be used where the fire or flame comes; but a mortar made of loam, and sand, and clay; but lime mortar should be used towards the outside. Pieces of old cart tyer, or other such like pieces of iron, may be laid under the chime of the boiler; between it and the bricks; which will prevent its being so soon burnt out there. The brickwork, which covers the boiler top, should be laid in the best lime; which will not hurt it there, but will preserve it. The mortar should be used thin; and the boiler top well plaistered with it; which will conduce greatly to tightness, if done some time before the engine be set to work. If your lime be not of the species which stands water, it will be well to mix some Dutch, or Italian terraso, or pan scratch from the salt works, with it; but in any case, the lime should be newly slacked. In carrying up the brickwork, round the flues, long pieces of rolled iron should be built in, in two or three courses, to prevent the brickwork from splitting. Four holes, at convenient places, should be made into the flues, large enough to admit a boy to go in, to clean them. One of them may be over the fire door; and another right behind the damper, in the backside of the chimney. This last, may be as high as the flues themselves are. These holes, when not in use, must be built up with nine inch brick work, and made perfectly air tight. Immediately above the brick work of the boiler setting, a hole must be left in the chimney, on the side next the boiler. This hole must be as wide as the chimney; and must have a sliding door fitted to it, to open it more or less, at pleasure; the use of it is to moderate the draught of the chimney, and to prevent the flame being drawn up it, before it has acted sufficiently on the boiler. A groove must be left in the brickwork, for the damper to move up and down in, easily; which should fit flat to the face of it. The damper may be made to move easily, up and down, by means of a wheel, on a beam, with a counterpoise equal to the weight of the damper. The best form of a fire door is two feet long, and one foot high, inside measure, to have leaves, made of boiler plates, hinged on the two sides, and over lapping one another, about an inch in the middle. The scantling of the frame may be three inches broad by two inches thick.

19. The gauge pipes may be fixed into the boiler top, in some convenient place; the lower end of the longest should reach within six inches of the top of the flues; and the shortest should be four inches above it. The feed pipe should reach two feet under the surface of the water in the boiler; and should have a valve, at its lower end, to prevent the water being ever forced up through it, by the steam. Its upper end should rise seven feet higher than the surface of the water in the boiler. It should be supplied with water by a pipe from the top of the hot water pump, regulated by a cock near the feed pipe.

20. If you have not land water that will naturally run into the condenser cistern, you must make a pool somewhere in the neighbourhood to receive the water from the hot water pump and reserve it for supplying the boiler and condenser cistern when the engine stands still on any occasion.

This pool must be at least forty feet long, and twenty feet wide, and to hold three feet deep of water; and pipes, or troughs, must be laid from its bottom, to the boiler feed pipe and cistern. That, at the feed pipe, must have a cock on purpose. It is meant, that the pool be simply dug in the earth; and be lined with turf, puddled; or otherwise made water tight. If no ground, within a reasonable distance, be high enough for the water to run from the bottom of the pool into the boiler, then a pool may be made o lower ground, and a hand pump be fixed up, to supply the boiler and cistere; but this ought to be avoided, if possible.

This concludes the first part of Messrs. Boulton & Watt's instructions. In our next *Journal*, we shall resume the subject, and give their "*Directions for Putting the Engine together;*" and also an engraving of the description of Engine referred to in these particulars.

Silver Mine.—We learn from Stockholm, that a silver mine, which is expected to be very productive, has been discovered near the town of Lindsberg.

AGRICULTURAL CHEMISTRY.

By Professor Brande, F.R.S., &c.

Lecture IV.—*Delivered at the Royal Institution, Feb.* 17, 1844.

(Specially reported for this Journal.)

Phosphoric acid, once considered unimportant, is requisite for most crops, but especially for wheat and grass. It is generally added to the soil in combination with lime, as bone dust, the earthy part of bone consisting almost entirely of phosphate of lime. Phosphorus, the base of phosphoric acid, is never found in a free state in nature, being obtained by distilling a mixture of phosphoric acid and charcoal. It is a pale yellow semi-transparent solid, remarkable for its easy combustibility, luminous in the dark, owing to its slowly burning. When set fire to and a tall glass jar placed over it, flakes of a beautiful white substance are collected, which is phosphoric acid, the phosphorus having combined with the oxygen of the air. These flakes will, in a short time, abstract moisture from the air, and become liquid. If this liquid be then added to a solution of lime, phosphate of lime, or bone earth, falls as a fine white insoluble powder. When bones are burned, it is this which is left as the white ash, the animal matter having been destroyed. But as phosphate of lime is soluble in acids, the animal part may be obtained in a separate state by digesting bone in weak muriatic acid; the bone remains in its original shape, but is then as flexible as cartilage, the whole of the earthy part being removed. In this state it is that bones are employed to make animal glue and portable soup. Formerly it was supposed that it was to this part that the virtue of bone manure was due; but it is found that bones are nearly as efficient after the animal part has been destroyed, as for instance, after they have been distilled for the manufacture of hartshorn, or ammonia. Since this has been clearly established there has been great demand for phosphate, search has been made to ascertain whether any large natural supply of this substance could be discovered, as it is frequently found in a mineral state. For this purpose Dr. Daubeny made a pilgrimage to Spain, and in Estramadura he found a large quantity known as Phosphnrite, from its giving off a pale blue light when heated; but as there is no water conveyance from thence, and the roads are bad, the expense would be too great. It is present in nearly every soil, and is even to be found in chalk, as the following analysis of the Brighton chalk will show.

100 *of Brighton Chalk.*

Carbonate of lime . . .	98·57
Carbonate of magnesia . . .	0·38
Phosphate of lime . . .	0·11
Oxides of iron and magnesia. . .	0·14
Alumina	0·16
Silica	0·64

In slate, phosphoric acid sometimes exists combined with alumina, and occasionally the surface of the slate is found covered with a crystalline mass of phosphate of alumina, or wavellite, as mineralogists term it. When this disintegrates, to form a clay soil, the phosphoric acid will get diffused, and thus become one of the elements of the food of the plant. In the chalk, which is agreed by most geologists to be the debris of organic matter, the phosphoric acid has, no doubt, had its origin from the shells of come of the lower animals. An interesting observation has been made on this subject, viz., that the shelly or bony structure of the lowest animals consists wholly of carbonate of lime; that as they increase in complexity of structure, a little phosphate of lime is found, and in that of the animals highest in the scale of creation, phosphate has entirely replaced the carbonate of lime. From this fact, the absolute necessity for phosphoric acid in the soil is evident; for the growing animal, browsing in the field, is c ntinually adding phosphate of lime to his increasing bone; from whence can it come? As he eats nothing but plants, it must be in their structure, and analysis proves it to be so: then, again, as the plant derives all it contains from the earth, air, and water, it must be in one or other, and the analysis of all fertile soils shows that it is invariably present. These remarks applying to phosphoric acid, are applicable to all the inorganic constituents of animals or vegetables. But it is also requisite that they should be in a soluble state, or the plant cannot take them into its circulation, and frequent disappointment has arisen in the use of bone dust, from there having been nothing in the soil to dissolve the phosphate of lime; it is by some imagined that plants excrete from their roots acid substances to render soluble the substances around them. Experiments have been made by dissolving the phosphate in an acid previous to mixing it with the soil, and very beneficial results have been obtained. The Duke of Richmond found that a much larger crop of turnips was thus obtained, and some agriculturists have stated that one pound of bone dust mixed with acid is as efficacious as 6 lb. without. The proportions advisable are, to take 100 lb. of bones, and after breaking small, to add to them about 50 lb. of sulphuric or muriatic acid, they being the cheapest, and about three cwt. of water, which will give a solution of subphosphate of lime and free phosphoric acid. In order to get it into a convenient form for application, it is advisable to sprinkle this liquid over some substance which will absorb it, such as saw-dust; if to this be added some silicate of potash, a most fertilising agent is obtained. A manure which is now being very extensively employed in this coutry, and the demand for which is daily on the increase, viz., guano, appears to owe its qualities principally to the phosphate and other salts which it contains. It is the excrement of sea birds, and is obtained in immense quantity. The amount of inorganic matter it contains may be ascertained by burning a known weight in a silver crucible, and weighing the ash which remains.

The quantity of inorganic material requisite to be added to the soil will depend upon two things, the quantity that the plant absorbs to form part of its system, and also upon what part of the plant is removed from the field, as it has already been seen how greatly the various parts of a plant differ in the quantity of their inorganic constituents. Hence is evident the importance of ploughing in all the parts of the plant not taken to market, especially the leafy parts. It is even, in sandy soils, found advisable to burn the plants which have grown there, such as heath and furze, and to return the ashes, which, by this means, in a few years render it fit for the growth of more profitable crops. The great difference in the quantity of the salts which various plants appropriate, will be rendered very evident by the two following tables:—

Salts, &c. in 1000 of the Ash of Seed and Straw.

	Wheat.	Wheat Straw.	Barley.	Barley Straw.	Oats.	Oat Straw.	Beans.	Bean Straw.

This will serve to explain why those plants which contain but few of these salts are said to form good fallow crops. It is remarkable, also, the invariable proportion in which they are present in the same plant, although grown in a different climate, and in a different soil. Sprengel analysed wheat from several districts, and found them, in this respect, exactly to resemble each other.

A question has arisen amongst vegetable physiologists whether one substance usually present in a plant, can be substituted by another, and it has been found to take place in some few instances. For instance, cases have occurred where plants which usually have one alkali present, when grown in a soil where that alkali is not present, have been found to appropriate another, but still preserving the same amount. Indeed, some plants, when growing in circumstances where they cannot obtain inorganic alkalis, will positively form organic ones, in order to carry on their functions; such is said to be the origin of the morphia, in poppies, to which organic alkali the properties of opium are due. It is well known that potatoes when stored up in a damp cellar, will throw out shoots to a very great length. Now when these are analysed, they are found to contain a vegetable alkali in great abundance, to which the name of solanine has been given, not an atom of which is ever to be found in the plant in its natural state. It has, in fact, formed this alkali from some of its other constituents, so that its germinations may proceed.

The efficacy of common salt as manure is most undoubted in many situations. To lands near the sea there cannot be any necessity for adding it, as the winds carrying the spray always give it a top dressing of salt, and those near the shore generally get too much. It is said by some to render the silica soluble, but one undoubted benefit it bestows is in killing the grubs and vermin which infest some crops to so enormous an extent. It is present in every soil. It is used in great quantities for the manufacture of soda, and distilled with sulphuric acid, yields muriatic acid.

The very large proportion of inorganic constituents that some plants contain, is occasionally rendered evident by accident. Thus hay, which contains 90 per cent of its weight, is frequently found, when a rick has caught fire, to be converted into a hard opaque glass, and a corn stack will burn to a complete flint. In the case of hay, this accident sometimes occurs, when it has been stacked before it is dry, by the heat which is evolved during the fermentation of its juices. There is a very admirable arrangement in nature for returning to the soil, every year the inorganic substances which it requires for its growth, but which it has not retained in its wood, and that is the autumnal fall of the leaf, which, as has been already seen, contains, of all other parts, by far the greatest quantity of salts. Thus they serve to go one perpetual round, now dissolved by the water in the soil, and absorbed by the roots, now flowing with the sap through every ramification of the tree, and at last forming part of the leaf, to be on the approach of winter, again deposited on the soil, to be again dissolved, absorbed, and perform the same functions; but in each circuit leaving part of itself as a permanent resident in the stem of the plant. Thus, then, we are led, by a consideration of these and other circumstances, to the only inference that can be drawn, that these inorganic constituents, in small proportion to the other parts as they may be, are nevertheless vitally essential; that no substance found in the ash of a plant can be considered as accidental but as constitutional, without every one of which be present in the soil, and in a fit state, it is useless to expect the plant to show, when the deficiency of the soil is known, what is requisite to be added, so as to make it suit each respective crop.

But it is time to pay attention to the organic part of the soil. This, which consists of the vegetable mould formed from the decay of the woody parts of the plants, is known by the name of humus. It may be traced in various stages, from the firm wood, to the yellow rotten wood, then to a brown, and lastly to a black earth, which is almost charcoal. On the banks of a stream, shaded by overhanging trees, the fallen beams may frequently be seen in the medium state, whilst at the bottom of the water, the dark brown mud is the best instance of it in its final state. When stirred it frequently gives off carbonic acid and carburetted hydrogen, arising from the decomposition of the woody fibre, or eremacausis, as it is the fashion to term it. There is no doubt that the presence of this is beneficial in the soil, though not to the extent that it was formerly considered. As it is very slightly soluble in water, it cannot yield much nourishment to the plant, and it is doubtful, except by the carbonic acid which it slowly evolves, whether it is of any other than a mechanical advantage to the soil. Indeed it is the opinion of many, that so long as the plant can get its inorganic parts from the soil, it can derive all its organic parts from the atmosphere. Vegetable matter, however, is found in all fertile soils, in the proportion of from 10 to 20 per cent. In boggy earth, it forms from 60 to 70 per cent. For the growth of rice, but little is required, for barley more, and for wheat more; about 12 per cent. is advisable. Water poured on good soil, should be very slightly coloured; if deep brown, it will be barren, possibly arising from the presence of an acid, rendering the vegetable matter soluble; this must be counteracted by lime or chalk.

Soils are classified and named according to the proportion of their principal constituents; thus some consist of pure agricultural clay, of which pipe clay is a good example, which consists of from 50 to 60 of silica, the remainder being alumina. This when stirred up with water, deposits no sand. Rivers, passing through clayey soils, carry with them an immense quantity, taking weeks to deposit the whole, and in some cases carrying it a long way out to sea. When a clayey soil contains

From	5 to 20	per cent. of sand, it is called a	strong clay.
,,	30 to 40	,, ,,	clay loam.
,,	40 to 70	,, ,,	loam.
,,	70 to 90	,, ,,	sandy loam.
	90	,, ,,	sandy soil.

When chalk is present in from 5 to 20 per cent., these are termed marls; and are sandy, loamy, or clayey, according to proportions. More than 20 per cent. forms a calcareous soil.

From 5 to 20 per cent. of humus constitutes a vegetable soil, and from that to 70 per cent. a peaty soil.

Lecture V.

Twenty years ago, when the agricultural chemist was requested to analyze a soil, he would consider he had done his duty when he had ascertained the proportions of the four earths, and the organic matter. Now, however, the case is widely different, and it has become one of the most complex operations, which can be performed only by an experienced hand, and which it is of no use for the farmer to attempt; for it is very doubtful whether, if he became an expert chemist, he would also be an expert agriculturist. Still, however, the knowledge of the use of the various tests set forth in these lectures ought to be possessed by every agriculturist, they are soon acquired, and will give very valuable information.

In order to classify soils, the usual mode of examination is as follows:—Weigh a certain quantity of soil, dry in air, then reduce it to powder, and dry it before a fire on paper, at as great a heat as the paper will bear without charring, then weigh it to ascertain the quantity of water lost; burn it in a crucible for the purpose of destroying organic matter, and again weigh it; then put in dilute muriatic acid, about 1,000 grains of the soil to a pint of water and two ounces of acid, which will dissolve the saline ingredients, dry it before a fire, and weigh it, then stir it up in a considerable quantity of water, and whilst the finest particles are suspended, pour off the water, and by this means the clay will be separated,

A soil may have every ingredient requisite for vegetation, and yet not be productive on account of its not being in a proper mechanical condition, and there are several particulars to be looked to in this respect, such as density, division, retention of water, capillary power, shrinkage, relation to heat, &c. All these demand consideration.

A soil should not be too dense, as it then offers too great a resistance to the growth of the plant, retains water too firmly, and, consequently, is always cold. The weight of a cubic foot of good soil should be from 50 to 90 lb. The state of division of a soil should be tolerably fine, though occasionally large masses are of use. It is the custom to gather off the large stones from a field, but during cold or dry winds they are of service by protecting the tender plants from the nipping of the one or the parching of the other. The state of cohesion of a soil should be between the looseness of sand and the plasticity of clay. This may be considerably modified by deep ploughing, by tilling, but particularly by draining. In very clayey lands, the best thing to do would be to add sand, but as that would be generally too expensive, the best substitute is drainage. The resistance to the plough varies very much according to the nature of the soil. It has been calculated that sand gives a resistance of about 4 lb. to the square foot, clayey ground about 8 lb., and a stiff clay about 25 lb.

Soils differ in nothing so much as their power of imbibing and retaining water. It has been found, by direct experiment, that exposed for twelve hours in damp weather, 1,000 lb. dried sandy soil gained 2 lb.; 1,000 lb. dried loam gained 21 lb.; 1,000 lb. dried clay loam gained 25 lb.; and 1,000 lb. dried pure clay gained 37 lb.

According to some experiments of Sir H. Davy, the same quantity of a barren sandy soil gained 3 lb. in twenty-four hours, whilst a fertile soil gained 18 lb. This will give some idea of the enormous quantity of moisture that would be absorbed from a moist air following a dry wind. Mr. Solly has made some experiments on increasing the imbibing power of dry soils, by adding to them some very deliquescent substance; for this purpose he used chloride of calcium with very good results, Connected with this is its retaining power. A quantity of water which would soak sand, would scarcely moisten dry clay. They have been found to vary as follows:—100 lb. of sand retained 25 lb. of water; loam, 40 lb.; chalk, 45 lb.; marl, 50 lb.; and agricultural clay, 70 lb. The moister the land, of course the more imperative it is to drain it well, as too much water keeps a soil cold, and prevents the air from getting to the plants.

Capillary attraction, or that power by which liquids crawl up small crevices, is exceedingly influential in agriculture, and is beneficial in two ways; 1st, by keeping the surface in a proper state of moisture, bringing up water from below, as fast as it evaporates above. This action may be illustrated by standing a lump of salt or other porous substance on end in a plate filled with a coloured liquid. It takes place very rapidly by using a tall glass cylinder, having a porous bottom, filled with sand. The densest chalk that can be procured will, in this way, become coloured several inches high in a few hours. In horticulture it is frequently taken advantage of by keeping a flower-pot in a saucer, into which water is poured. The second important use of capillary attraction is to bring up from the sub-soil a supply of those soluble substances of which the removal of the crops is continually depriving the soil. This may be thought but trifling, but when the immense amount of water evaporated is taken into account, it will appear far from insignificant. After a continuance of dry weather, the soil will frequently be covered with a perceptible film of the salts thus brought up, which by the first shower is diffused through the soil. In sandy lands the fertility depends upon this property. In tropical climates, where evaporation is so much greater, it is seen on a magnificent scale. In the deserts of Peru, for instance, the nitrate of soda thus annually brought to the surface is raked off, and exported in immense quantities, to be used for manufacturing, and latterly for agricultural purposes. In Africa, also, the neighbourhood of Tripoli thus furnishes a supply of a variety of carbonate of soda. These facts induce the inquiry whether it is not advisable to save the drainage waters, and after evaporating, by some means, to restore them to the soil, as doubtless they must contain these salts, which would be so beneficial to the crops.

The shrinkage of soils in dry weather seems to be in proportion to the clay or organic matter present. Clays and peats in drying shrink one-fifth of their bulk. This action is of great utility, by increasing capillary action, and by forming conduits, by which the superfluous water may run off. Of course this does not take place in sandy soils.

The absorption of heat by the soil during sunshine is very great, sometimes raising its temperature 30° or 40° over that of the air. When the air has been at 70° or 80°, the soil has been observed, during sunshine, at 100° or 120°. Black lands will rise rather higher in temperature than those of a lighter colour, but not so much so as might have been imagined; the greatest difference observed having been 10°. When a chalk was observed at 100°, a neighbouring black loam was at 110°. The difference of absorption of heat by different colours may be illustrated by placing pieces of phosphorous on three pieces of tin, one with its own surface, one coloured white, and the other coloured black, and placing a hot iron ball between them at an equal distance, to represent the sun. The phosphorus will be ignited first on the black, next on the white, and lastly on the metallic surface. Those soils which absorb the quickest, radiate the quickest, and consequently would be coldest at night.

The subject next claiming attention is the atmosphere, and which here introduces an important division of the subject; for as the soil has been considered as being the source of the inorganic part of plants, so the atmosphere is considered as yielding to the plant the whole of the organic part. Startling as this statement may appear, strong arguments will be brought forward to prove its plausibility. The composition of the atmosphere in 100 parts by measure is,

Nitrogen	77·5
Oxygen	21
Watery vapour (consisting of oxygen and hydrogen)	1.42
Carbonic acid (consisting of oxygen and carbon)	0·08
	100·
Ammonia (consisting of nitrogen and hydrogen)	a trace

These are the invariable proportions of its constituents, let the air be collected where it may, on the top of a mountain or in the depth of a valley, in Europe or in America. This extraordinary uniformity may be accounted for by the property of the diffusion of gases, by the action of currents, the earth's motion, winds, &c.

Nearly the whole of the organic part of plants is composed of the four elements, carbon, hydrogen, oxygen, and nitrogen. As all these substances can be found in the soil, that was supposed to be the source from whence the plant derived them. But recent investigations have shown that whilst vegetables impoverish the soil as regards the inorganic matter, they greatly increase the proportion of organic matter in the soil. A fir plant, growing on a dry sandy soil, is continually enriching it with humus, by the fall of its leaves and twigs. It is evident, then, that it must derive the greater part, if not all, of its wood from the air, and it is doubtful whether, for this purpose, the great bulk of the air, the nitrogen and oxygen, contribute any part, or whether it is not due to the water, carbonic acid, and ammonia, which, although present in so small a quantity, yet, as will be shown in a future lecture, is sufficient for the purpose. These may, by artificial means, be removed from the air, the water and ammonia by means of sulphuric acid, or chloride of calcium, and the carbonic acid by lime; and although the difference could not be detected in breathing or in the burning of combustibles, yet it has been destroyed as regards plants, because there is an entire absence of that which maintains vegetable growth, and without which plants cannot form their structures.

The proportion in which the nitrogen and oxygen exist in the air can be ascertained by abstracting the oxygen; this can be done by several means: if fine iron filings be powdered over the inside of a glass vessel, and this stood over water, the iron will combine with the oxygen, or become rusted, and the water will rise in the vessel to take the place of the abstracted oxygen. But it may be effected more rapidly by burning a piece of phosphorus in a portion of air confined over water; the phosphoric acid produced dissolves in water, leaving the nitrogen gas pure. If the properties of this gas be then examined, it will be found that it will neither burn nor support combustion or life, that indeed, it is totally inert. If it is wished to get oxygen gas pure, it cannot be obtained from the air, as there is no means known of removing the nitrogen. It may be procured by heating substances which contain a great quantity of it, and which will part with a portion of it readily. Such is black oxide of manganese; which is commonly employed on account of cheapness. For the sake of purity, chlorate of potash is best, or a mixture of the two. The properties of the gas thus obtained are the opposite of those of nitrogen, being very energetic, supporting combustion most vividly, and hurrying respiration to fever and death. Iron and zinc wire, heated at one end, and introduced into this gas, burned with great beauty, as do also charcoal and sulphur. Phosphorus burns with brilliancy, such that the eye can scarcely bear. From this it is evident that in the air it is the oxygen that is the acting principle, and that the nitrogen serves the office of detecting it, so as to make its action on substances immersed in it sufficiently slow.

The next and following lecture will be devoted to the consideration of the lesser, although as regards plants, the more important components of the atmosphere.

REGISTER OF PATENTS.

Under this head we propose to give abstracts of the specifications of all the most important patents as they are enrolled. If any additional information be required as to any patent, the same may be obtained by applying to Mr. LAXTON at the Office of this JOURNAL.

IMPROVED WINDOW SHUTTERS.

Archibald Horn, of Aldersgate Street. Zinc Worker, for "*Improvements in the construction of windows, and for other purposes.*"—Granted August 15, 1843; enrolled February 15, 1844.

Fig. 1.

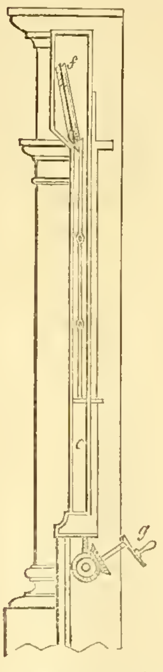

Fig. 2.

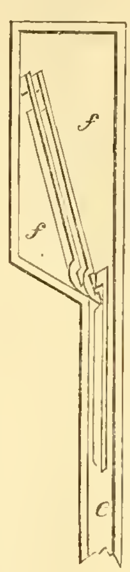
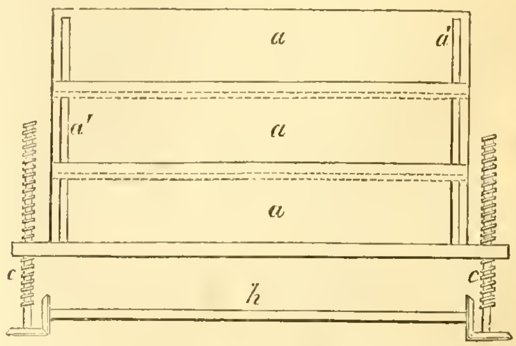


This invention consists in a novel mode of constructing shutters for closing windows and other openings, and consists in forming the shutters of thin plates of metal, strengthened at each end, and made to slide in vertical grooves at each side of the window or opening, and are successively deposited side by side in a box or chamber provided for their reception. Fig. 1, is a transverse section of a window, showing the application of this improvement; Fig. 2, is an end view of some of the plates, drawn on a large scale; Fig. 3, is a front view of the shutters, showing the method of raising them: *a, a, a*, are thin plates of metal, strengthened by means of transverse pieces of metal, *a′ a′* at each end, all of which are similar, with the exception of the lower one, which has a piece of metal, *b*, attached to its lower edge, having a female screw at each end, through which the screws, *c c*, pass. In Fig. 2, *e* is a portion of the grove, within which the ends of the plates slide, and *f f*, the box or chamber fur receiving such plates, which are su formed at their edges, or that part which forms the coupling, that as they are raised in the groove *e*, they will successively be disengaged, and each succeeding shutter will force the preceding one into the chamber *f*. It will be clearly seen, that on giving motion in one direction to the screws *c c*,

Fig. 3.



which is effected by means of a winch or handle, *g*, seen in Fig 1, which imparts motion by means of a bevel wheel to the horizontal shaft, *h*, that the metal plates or shutters, *a a*, will be raised in the groove, and the same will be disengaged successively until the whole, with the exception of the lower one, are deposited in the chamber; and on reversing the motion of the handle, the plates will be lowered, and in their descent will successively catch hold and successively draw each other down, and thereby form a plain metallic surface with lop joints. The patentee claims the mode of constructing and combining shutters in such manner, that they are successively caused to move into and out of the same grooves.

CHAIN CABLE.

JAMES BROWN, of High Street, Stepney, Middlesex, Engineer, for "*Improvements in tackle and apparatus for working and using chain cables in ships, and otherwise, and also certain improvements in tillers or rudders of ships and other vessels.*"—Granted August 16, 1843; enrolled February 16, 1844.

The first part of these improvements relates to a mode or modes of letting out, stopping, and raising chain cables; and secondly, to an improved steering apparatus. One of the improvements in the controller first described, of which Fig. 1, is a side elevation, and Fig. 2, a plan, is that the "shoe

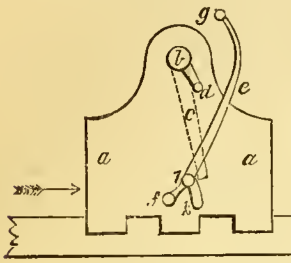


Fig. 1.

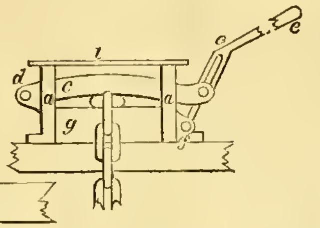

Fig. 3.

seat" or base of the frame is more deeply imbedded in the wood than is usual, and the anti-friction rollers hereafter described instead of working in fixed steps or journals in the ordinary manner, are dropped loosely in their bearings. *a a*, Figures and 2, is the framing; *b*, a shaft, supported at each end

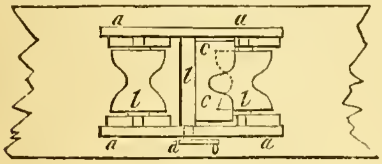

Fig. 2.

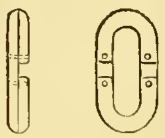

Fig. 5.

by the frame sides; *c*, is a leaf, having a slot or opening, as will be seen by the plan, and is attached to the shaft *b*; to the end of this shaft is also fixed a winch or handle, *d*, the object of which is to move or alter the position of the leaf when required; *e*, is a bent lever, moving upon its axis, *f*; this lever is connected by means of a handle, *g*, to a corresponding lever on the opposite side of the frame; *i*, is an iron roller, supported at each end by the levers *e*, and moving in a curvilinear slot *k*; it will be clearly seen, that when heaving the chain cable, the same will be allowed to pass freely in the direction of the arrow, in consequence of the leaf moving freely upon its axis, but it cannot return, on account of the end of the leaf coming against the iron roller *i*, which is shown in its elevated position, but on depressing the end of the level, the roller will be moved in the slot and away from the end of the leaf, and the cable will be at liberty to run off; *l l*, are two anti-friction rollers, which are dropped loosely in their bearings or journals.

Another modification of the above, consists in moving the iron roller by means of an eccentric. There are several other methods described for stopping and retarding chain cables, amongst which is the following, which is termed a box stopper, and is placed just over the chain funnel: *a a*, Fig. 3, is the frame firmly fixed to the deck timbers, and covered with a loose lid *b*; *c*, is a lever or nipper, attached at one end by a pin joint to the projection *d*; through the other end of this lever is passed a pin, which moves in the slot of the lever *e*; this lever is also attached in like manner to the projection *f*. The cable passes between the lever or nipper *c*, and the dead nipper *g*; thus by elevating the lever *e*, the pin of the nipper *c*, will be moved in the slot, and the same will be raised and the cable set at liberty, but on depressing the lever e, the nipper will retain the cable by one of the links, as shown. Another modification of this is shown, as being applied to the underside of the deck, which is termed an under deck controller. Fig. 4, is a sectional elevation of an apparatus for heaving the cable; *a a*, shows a portion of the frame side; *b*, a plate bolted thereon, which carries one end of an horizontal shaft *c*; upon this shaft is firmly fixed the working lever *d*, and also an arm *e*, to the extremities of which are attached one end of the connecting links *f f*, the other ends being attached to the levers *g g*, which levers work loosely upon the main axis *h*; *i i*, are two palls affixed to the levers *g g*, and taking into the ratchet wheel: it should be observed that there are two ratchet wheels and two sets of levers, this view only showing one half the machine, the section being taken through the centre. Between the ratchet wheels there is an indented wheel *k*, such indentures being made to receive each al-

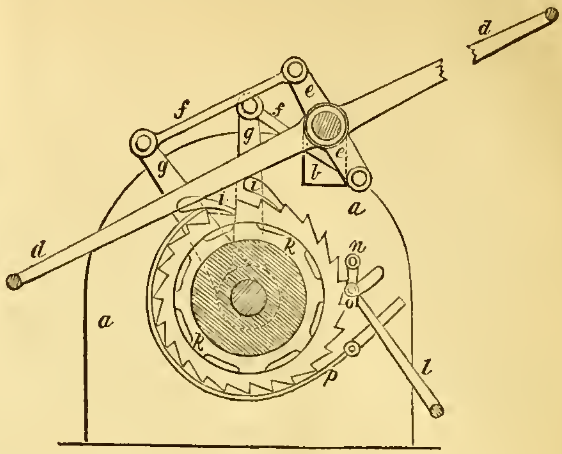

Fig. 4.

ternate link; the intermediate links of the chain pass into a groove; *l*, is a lever moving upon an axis *n*; to this lever is attached one end of cross bar *o*, which takes into the teeth of the ratchet wheels; *p*, is a friction band for retarding the motion of the barrel when letting out the cable. It will be clearly seen by the above, that on moving the ends of the lever up and down that a continuous rotary motion will be given to the barrel, and the chain will be hove in; when it is required to let out the chain it will be necessary in the first place to release the palls *i i*, after which the cross bar *o*, is released from the wheel by raising the lever *l*, which gives full liberty to the barrel.

Another improvement consists in constructing an improved link, which is intended to supersede the common shackle or swivel. Fig. 5, shows a front and edge view of one of these improved links, which are constructed in two halves or parts, each part having an opening, so that when put together, (which is effected by means of pins passing through holes in the link,) the openings are on opposite sides, and form one continuous link, which is said in the specification to have "all the strength of one continuous *solid* ring." We think if the patentee had said links or shackels, constructed as above, were something less than half the strength of a solid ring, he would have been nearer the truth, since the strength of the link is, by such opening, reduced to one half, minus the area of metal removed by drilling the holes for the reception of the pins. It will be seen that when it is required to disconnect the chains it will only be necessary to remove the pins and turn one of the parts half round, so that the two openings come together. There are other modifications of the above, which consist of hooks, the openings of which are closed by a piece of metal, so connected to the hook or hooks as to be easily removed.

The second part of the invention relates to a steering apparatus, and consists in the application of an additional pair of blocks, which are said in the specification to be attached by chains to the outer ends of the axis of the wheel, but in the drawings are shown as being attached to the end of the tiller, which is undoubtedly the proper place, the effect of which is said to cause the tiller rope to be always kept perfectly "taught" tight on the lee side. The specification sets forth twelve claims, which may be summed up in the general arrangement and combination of the parts described.

CORKING OF BOTTLES.

WILLIAM FLETCHER, of Morton House, Buckingham, clerk, for "*Securing corks in the mouths of bottles.*"—Granted Aug. 24, 1843; enrolled Feb. 24, 1844.

This invention relates to a mode of securing or fixing corks into the necks of bottles containing soda water and other aerated liquors, the mode of effecting which is as follows. Through the neck of the bottle and just below the rim there are two small holes in a right line with each other. These holes are intended to receive a metallic pin pointed at one end and turned round at the other, so as to form a ring suitable for withdrawing the pin when it is required to draw the cork of the bottle. When stopping or corking bottles containing aerated liquors, the cork is forced into the neck of the bottle in the ordinary manner; but in place of securing such cork by means of cord or wire passing round the neck of the bottle and over the cork, it is only necessary to insert the point of the pin into the small hole formed in the bottle neck, and force the same through the cork and through the hole in the opposite side of the neck, which will have the effect of holding the cork very securely in the neck of the bottle.

STEAM ENGINE, BOILER AND PROPELLER.

Peter Borrie, of Princes Square, St. George's in the East, Middlesex, engineer, and Mayer Henry, of Crutched Friars, in the City of London, merchant, for "*Improvements in steam engines, boilers, and propelling machinery.*"—Granted Aug. 3, 1843; enrolled Feb. 3, 1844.

The first improvement is for a rotary engine, and consists of a cylindrical case, within which revolves a cylinder having four longitudinal openings or recesses in its periphery, into which are fixed four sliding pistons, each opposite piston being connected together and acted on by springs. This cylinder is eccentric with the case, and turns upon its axis, which passes through the ends of the case and also through stuffing boxes. Steam is admitted at one side and near the upper part of the case, the force of which acting upon one of the pistons causes the interior cylinder to revolve, the steam escaping as the piston upon which it impinged passes the eduction port, which is on the opposite side, and in this manner the pistons are alternately acted upon, and rotary motion is obtained.

This engine differs from one for which a patent was granted June 7th, 1842, to Mr. John Woodcock, of Manchester, in this particular, that Mr. Borrie employs a double acting air-pump, which is worked from a crank fixed at one end of the main axis, and which may probably have some claim to novelty. Fig. 1, shows a section of this air-pump, which is open at both ends; *a a*, we will suppose to be the induction passages leading from the condenser, and each being provided with a valve opening inward; *b b*, are the eduction ways and which are also provided with valves opening outward; it will be clearly seen that the motion of the piston within the pump barrel *c*, will be double acting.

Fig. 1.

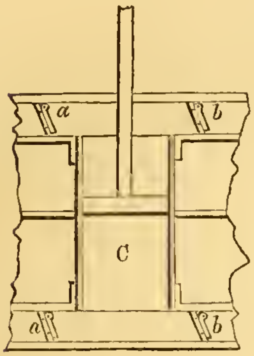

Fig. 2.

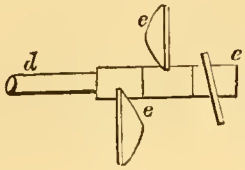

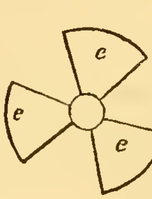

Fig. 3.

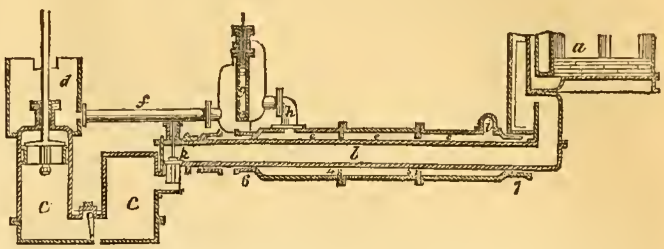
The patentee does not claim the application of this air-pump to the rotary engine as above described in particular, as the engine may be worked as a high pressure engine. The second improvement consists in the arrangement of two vibratory cylinders, inclined at an angle of about 45 degrees; three pistons of both cylinders are connected to one crank pin, from which pin is worked a double acting air-pump. The third improvement relates to tubular boilers; these boilers are constructed with a water space all around the fire he flame and heated vapours of which instead of passing from the fire box immediately through the tubes, pass underneath the tubes to the farther end of the boiler, and from thence through the tubes and to the chimney, (which is now generally done by most engineers with marine boilers.) The fourth improvement relates to a mode of disconnecting paddle wheels. And lastly to a stern propeller, of which we have given a side and end view; *d*, Fig. 2 & 3 is a shaft passing through the stern of the vessel; *e e e*, are three plates fixed on the end of the shaft, each of which are broader at the outer end, and are of a curvilinear or spiral form with regard to the axis. The patentees claim the general arrangement and combination of the several improvements described and set forth in the specification.

STEAM ENGINES AND BOILERS.

George Bennetts, of Gunnis Lake, Cornwall, civil engineer, for "*Improvements in steam engines and boilers and in generating steam.*"—Granted August 15, 1843; enrolled February 15, 1844.

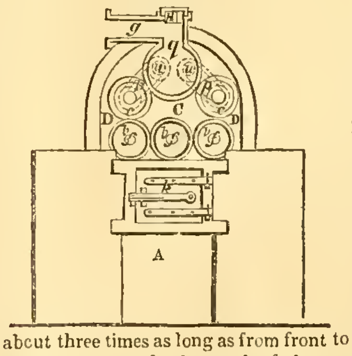
This invention relates to the construction and arrangement of certain apparatus in connexion with the engine and its boiler, for the purpose of rendering the steam which has been employed in working the engine, and is in its passage to the condenser or into the atmosphere available for heating the water, from which the steam is to be generated. And also in generating steam by injecting water in small jets into generators, which are maintained at such a temperature as to convert the water into steam on its coming into contact with the surface of the generator, whereby the cost and size of the boilers is reduced, and a saving of fuel effected. Fig. 1, is a vertical section

Fig. 1.



of parts of a condensing steam engine; *a*, is the cylinder with its piston rod, &c.; *b*, the eduction pipe; c c, the air-pump and condenser, all of which are well known; *e e e*, represents a vessel formed of three cylindrical pieces, bolted together at the flanches; at each of the places where these pieces join there is an internal projection, which is of such area as to allow only a thin sheet of water to pass at each stroke of the pump between these projections and the outside of the eduction pipe, which pipe passes through the vessel, and at the ends of the vessel where the pipe protrudes a steam tight joint is formed. This vessel should be capable of containing as much water as the engine will require to supply it with steam for eight or ten minutes; *g*, is a double acting forcing pump, connected at its eduction passage by means of the pipe *h*, to the vessel *e e e*, and at its induction passage by means of the pipe *f*, with the discharge cistern *d*; *i*, is a pipe leading from the vessel *c e e*, to the generators or boilers; *k*, is a valve, which the patentee places in pumping engines in the position shown in the drawing. This valve should be kept open during the time the engine is in motion, so as to offer no resistance to the steam in passing from the cylinder; but when the engine is at rest this valve should be closed, and the steam in the cylinder allowed to pass into the eduction pipe, where it will give out its heat to the water in the vessel *e e e*. This valve may alternately be opened and shut by any convenient means. The mode of action of this part of the invention is as follows. If the vessel *e e c*, is filled with water, and the pump *g*, set in motion, the water which it forces into the vessel at *h*, will force an equal quantity of water out of the vessel through the pipe *i*, into the generators or boilers, and the water thus forced into the vessel at *h*, will circulate through it for 8 or 10 minutes. until arriving at *i*, it is forced onwards into the generators or boilers, and during the time it has remained in the vessel *e*, will have taken up as much heat as the steam is capable of communicating, and the water entering at the part of the vessel next the condenser, is forced into a hotter position at each stroke of the pump, whilst the area of the vessel at four and five being contracted so as to allow only sufficient room for the water forced in by the pump to pass freely, prevents the water that has already passed these places from returning. By these means the steam which has been employed to work the engine will be available for raising the temperature of the water which is supplied to the boiler; and a partial condensation of steam may also be effected whereby less water than otherwise is required for condensing the steam in the condenser, and a smaller discharge pump than otherwise necessary will effectually free the engine from water and air, thus having a greater available power in the engine, at the same time economising fuel. Mr. Bennetts for this part of the invention claims the mode of using steam after it has performed its work, for the purpose of heating water when applied according to the means herein described.

Fig. 2.



The second part of this invention consists in a mode of generating steam by injecting the water upon the surface of metals raised to such a temperature as to convert such water immediately into steam. Fig. 2, is an end elevation, showing the arrangement of the generators, which will be sufficient to give an idea of this invention; A, is the furnace, from which there is a flue leading underneath the three generators marked *b b b*, and which are shown in the side elevations, (in the drawings of the specification,) as being about three times as long as from front to back of the fire place; the flue after arriving at the further end of the generators, turns upwards and joins the flue C, formed by the arrangement of generators, along which the gases and other vapours pass until they arrive at the end immediately over the front of the fire, whence they diverge and join the flue D D, whereby the gases are conducted outside the arrangement of generators, until they arrive at the further end, at which place the flue joins the chimney; *b b b, c c, q*, are the steam generators made of metal, sufficiently strong for the purpose; these generators are connected at both ends by pipes so as to form one continuous vessel; *f f f*, are three pipes, which extend as far into the interior of the generators *b b b*, as the further end of the fire place, these pipes are perforated throughout their length with a number of small holes, and are connected to a horizontal pipe (not shown in the drawing) which passes in front of the aforesaid pipes *f f f*, and extends to the water heating vessel *e e e*, Fig. 1, to which it is connected; *g*, is a pipe through which the steam is conveyed from the generators to the engine and to a safety valve.

The action of this apparatus is as follows. If the vessel *e e e*, Fig. 1, is filled with water, and the pump *g*, set in motion, the water which it forces into the vessel at *h*, will force an equal quantity of water out of the vessel through the pipe *i*, into the generators or boilers, and the water thus forced into the vessel at *h*, will circulate through it for 8 or 10 minutes, until arriving at *i*, it is forced onwards into the generators, and during the time it has remained in the vessel *e e e*, will have taken up as much heat as the steam is capable of communicating, and the water entering the generators through the perforated pipes *f f f*, will come in contact with the heated surfaces of the generators, and be thereby converted into steam, from whence it proceeds through the whole arrangement of generators to the engine. The water forced into the generators at each stroke of the pump only bears sufficient to supply the engine with one stroke of steam. The fire can be regulated by any of the well known means, care being taken not to overheat the generators, which ought never to be brought to a temperature approaching a red heat.

FURNITURE CASTORS.

John Charlton, of Birmingham, factor, for "*Improvements in castors for furniture*."—Granted August 17, 1843; enrolled February 17, 1844.

The specification, which consists of eleven skins of parchment, describes about 21 different kinds of castors for furniture, one of which consists of a cast iron socket, which may be subjected to the process of annealing, for the purpose of converting it into malleable iron, this socket is intended to receive the end of the table leg or other piece of furniture to which the castor is to be attached. Another cup or socket of brass is made to fit the external part of the iron one, so as to work loosely thereon; this latter cup is cast with two ears or projections, which support the roller in the ordinary manner, the two sockets being held together by a screw passing through the the bottom of the brass socket and screwing into the bottom of the iron one, the head of the screw being made sufficiently large to prevent the brass or external socket dropping from the iron one when the piece of furniture to which the castor is affixed is raised from the floor. There are several other modifications of this description of castor, among which there is one having its socket made in the form of half an egg. Another class or description of castor consists of a steel or iron spindle, made of a conical form at one end, which part is made to fit a conical recess formed in the underside of the socket, a hole being bored in the end of the table leg to receive such part. This spindle, which is shown in the drawing as being made in six or eight different forms, and applied to as many castors, has a collar or enlarged part in the middle, which is made to fit into a recess somewhat larger than the collar, and formed by a loose piece of metal, the edge of which is firmly fixed and held by a projecting piece on the bottom edge of the socket, the object of which is to prevent the spindle dropping out of the conical recess when the castor is lifted from the floor; and, to the lower part of the spindle is firmly rivetted the ears or projections which carry the roller. By this arrangement the weight of the piece of furniture is supported by the conical part of the spindle bearing against the socket, and that part just below the collar or enlarged part, which part fits in a hole (in the form of a bearing) bored in the centre and through the loose piece of metal, which holds the conical recess.

HYDRAULIC ENGINE.

Frederick Lipscomb, of Gloucester Place, Kentish Town, gentleman, for "*A hydrostatic engine, parts whereof are applicable to other engines and other purposes, and also improvements in railway carriages*."—Granted Aug. 17, 1843; enrolled Feb. 17, 1844.

The patentee having ascertained that the re-action produced by pressure upon a liquid is caused by the compression of the globules of air suspended in the liquid, which globules, by being compressed, have their elasticity increased in an equal ratio to their compression; and that re-action would not be produced in a liquid divested of air, constructs an engine which he denominates a hydrostatic engine.

It would only be a waste of time and room to give a descriptive account of this apparatus, and we will only remark, that if the patentee had paid a little more attention to the pressure of fluids he would not have speculated to such an extent in an engine he will eventually find incapable of moving a stroke. That part of the invention which relates to a break for retarding or stopping a train of railway carriages, consists in applying hydraulic pressure upon a liquid confined in a tube supported by guides at the end of the railway carriage; the pressure on the fluid has the effect of driving by means of a piston and intermediate gearing, the blocks or breaks against the wheels.

The next improvement consists in fixing a thin board or other material on each side of these wheels, which are wholly composed of metal, and used in the construction of railway carriages, the "sheet of wood" or other material being in size, or nearly so, to the space between the inside of the tire and the inside of the nave of the wheel, the unoccupied space between such "sheets" being filled with straw, tar, lashing, or other imperfect conductor of sound, for which the inventor claims the practical application of any of the imperfect conductors of sound in contact with such railway carriage wheels as are usually composed of metal, for the purpose of lessening the vibration of the wheel, thereby lessening the noise consequent upon vibration.

CLOTH FOR LINING WALLS.

John Collard Drake, of Elm-tree Road, St. John's Wood, Middlesex, Land Surveyor, for "*Improvements in lining walls of houses*."—Granted August 22, 1843; enrolled February 22, 1844.

This invention relates to a mode of lining walls of houses with a waterproof cloth, whereby they are rendered impervious to damp; for this purpose, the patentee prefers calico, on account of its cheapness: such fabric is to be coated on one side with a solution of india rubber, the process for making which is well known, and applied in the manner following. A number of strips of calico or other fabric, from three to four inches wide, are covered on both sides with india rubber cement or solution; these strips are affixed to the sides of the wall, by means of such cement, in parallel vertical lines, and at such distances apart, as to receive the edges of the pieces of fabric with which it is intended to line the walls. These pieces, which as above stated, are only covered with the solution on one side, are cemented to the strips already put up, with such cemented side to or next the wall, so that the plain side of the fabrics is free to receive a coat of paint; or the same may be papered in the ordinary manner. In constructing the walls of houses in the first instance, "stiles" or pieces of timber are inserted at convenient distances, and also transverse or cross pieces may be inserted, the space between being filled up with stucco or cement level with the face of the pieces of timber inserted, and to these pieces are affixed the strips of calico or other fabric, as before described. For the purpose of covering the wall according to this invention, the patentee makes use of a frame, for stretching the pieces of cloth before applying them to the walls; it consists of two bars of wood or wood and iron, or other metal, capable of being elongated by means of a screw, which connects them together; to the ends of each of these bars there is a cross piece, having a number of pins fixed in it; the ends of the cloth or other fabric are pricked or forced on to the pins, and the bar elongated by means of the screw, which causes the piece of fabric to be stretched previously to being cemented to the wall, in the manner hereinbefore described. The patentee claims the mode of lining the walls of houses, by the application of calico or other fabric coated at the back with a solution of india rubber.

BOTTLE STOPPERS.

Alexander Spears, of Glasgow, merchant, for "*Improvements on or appertaining to glass bottles proper for wine and other liquids*."—Granted Sep. 6, 1843; enrolled March 6, 1844.

This invention relates to a mode of stopping bottles containing wine or other liquid, and consists in making a screw plug or stopper of glass or earthenware, as may be required, to fit the neck of the bottle, and is effected as follows. The inside of the bottle neck is made with a female screw, into which is made to fit a screw plug or stopper, having an enlarged part or head equal in diameter to the external neck of the bottle, the head of the stopper being slightly hollowed underneath, and made to fit nicely upon the face or end of the bottle neck, which is about one-fourteenth of an inch in thickness. In bottling wine or other liquid it will be necessary to apply a little soft wax either to the end of the bottle or to the underside of the stopper, for the purpose of excluding the air, after which a strip of tin foil may be wrapped round the neck of the bottle and head of the stopper.

The specification describes certain arrangements of machinery for forming the screws within the neck of the bottle and also upon the stopper. The patentee claims the use of screw stoppers either of glass or earthenware with glass bottles, having corresponding screws in the necks thereof, and also the use of softened wax or india-rubber, which may be applied either in a semi-fluid state or in the form of a washer between the surface of the stopper and the top of the bottle; he also claims the arrangement of machinery for forming the necks of bottles and upon stoppers as described.

AN IMPROVED LAMP.

Pierre Pelletan, of Fitzroy Square, Middlesex, for "*Improvements in the production of light.*"—Granted September 6, 1843; enrolled March 6, 1844.

This invention has reference to a patent granted to Mr. Pelletan on the 2nd of May last, for improvements in the production of light, in which specification was explained the mode of producing light from volatile substances, and applied to a manner of mixing the spirit of turpentine or other less combustible matter with water, which were mixed in a generator in the proportion of from 4 to 10 of water to 1 of turpentine.

The present specification states that the above mixture will boil in a generator under atmospheric pressure at 212, (turpentine boiling at 272,) at which temperature (212) steam will be generated from the water, and will carry off with it, in passing through the turpentine, a portion of that spirit, so that the vapour which is allowed to pass through a burner is a mixture of of turpentine and water, and will burn with a bright white flame, but on attempting to increase its length will emit a large quantity of smoke, to obviate which the patentee employs a burner of peculiar construction, which forms the subject of this patent, and consists of a tube through which the steam passes to the burner; this tube has four openings at the bottom for admitting common air to be mixed with the steam; these openings can be regulated by a screw slide: the upper part of this tube is enlarged, and forms an annular space, into which the steam after passing through a perforated plate enters; it also passes through another perforated plate before leaving the burner: a current of air is admitted through four short tubes which pass in a horizontal direction through the annular space, or that part forming the burner, for the purpose of supplying the centre or middle of the flame with air, by which means a flame may be obtained as white and voluminous as may be required.

ON THE PHILOSOPHY OF VOLCANIC ACTION.

Volcanic action is the co-operative cause of numerous changes in the local disposition of the earth's surface, and in the character and qualities exposed to its influence; affecting not only those matters exposed to the direct action of heat, but also the surrounding strata. It is the minister of change, of production, and re-production: and while it insatiably devours entire beds of the earth, and amalgamates their organic and inorganic bodies as one grand result, thus obliterating for ever their former character and qualities; it gives liberty to their gaseous products, creates new and important compounds, causing matter to enter into new combinations; which, from their peculiar character and qualities, remain for after ages the unerring indicators of the magnitude and extent of its destructive powers: but, in the multiplicity of the phenomena, we must not forget, that there are limits to its extent, and that while so far as by awaking electrical action in bodies exposed to its influence, and thereby generating numerous beautiful results, it is still the humble and ineffectual imitation of that greater power, the SUN, whose universal and continuous operations give birth to the most stupendous as well as the most beautiful of natural products. Geologists, awed by the terrors of volcanic action and by the wide-spreading havoc it occasions, have in numerous instances been led to attribute to it powers of creation and disposition of matter, which it does not possess; and some of them go so far as to attribute to it the entire formations of the superficial crust of the earth, such as we now behold it, the material of every crystalline rock having, as they suppose, been elaborated within the interior, from whence it has issued in the exquisite beauty and peculiar order in which we now behold it: overlooking the simple fact that it is in the nature of volcanic action to destroy rock, which once destroyed, can never be reproduced in its primary state, its elementary constituents in decomposition and re-combination with bodies of other nature, giving results widely different from the body to which they previously belonged. We cannot shut our eyes to the almost endless diversity in the character and composition of crystalline rocks, their gradual transition into each other, the organic constitution of many of them, as proved by the configuration of their parts, as well as by their bituminous and other peculiar organic properties: nor can we doubt the evidence of our senses, when we witness in tropical regions both within and above the waters, the gradual consolidation into the crystalline body of calcarious and earthy matters uninfluenced by volcanic action and its attendant phenomena.

The high lands of South America are analogous to the low lands of the North, and exhibit the deserted bed of a primitive ocean; they are extensive *steppes*, bare and desolate, save a few saline plants; muriate of soda being comman to all of them, and also entering into combination with, and giving character to many mineral products. Enormous masses of white marble abound on the elevated savannahs of Cuba, which are principally composed of madripores, ocean marls, and the coverings of molluscous animals. Coal is found on the Peruvian heights, and the cinders ejected from some of the volcanoes evidence that abundance of this mineral exists within the lower beds: the sulphates are common in all these elevated regions, the high and dry climate is also extremely favourable for the development of electro-chemical action, as the abundance of inflammable products is favourable for the sustenance of internal fires.

The phenomena of the volcanoes in that portion of the globe vary in their nature, in conformity to the vast range through which the internal heat traverses, and also to the nature of the material: water, it is evident, being the grand essential necessary to produce intensity of action: this is sometimes abstracted from the neighbouring, or from subterranean lakes, and at other times it is supplied from the melting snows: sometimes it is abstracted from the neighbouring sea. The Jurago, being a small hill in 1760, in that year, on the 29th of September, it began to burn with furious explosions, ruining entirely the sugar works, and the neighbouring village of Guacana, and from that time continued to emit fire and burning rocks in such quantities, that the erupted matters, in six years, had formed themselves into three high mountains, nearly three miles in circumference. During the time of the first explosion, the ashes were carried as far as the city of Queretaro, 150 miles distant from the volcano; and at Valladolid, distant 60 miles from it, they were so abundant that the people were obliged to sweep their yards three or four times a day. In this exuded material we identify the well known madrepore limestone, and various kinds of felspathic rock. Humboldt, who probably never saw the historical record of this event, tells us, "that from his own observations, as well as from the testimony of those who were actual eye witnesses of the event, that a large tract of ground, from three to four square miles in extent was up-heaved, in a convex form, to the height of 550 feet, and that from the midst of this protuberance arose six conical hills, the least of them 300 feet in height, and the loftiest, Jorulla, elevated 1,600 feet above the level of the plain." To the shame of geology, this, and a silly woman's (Mrs. Maria Graham's) report of the elevation of the whole line of coast of Chili, for the extent of 100 miles by an earthquake, have been made the bases of systems of elevation, as incompatible with the operations of nature, as they are in violation of common sense. In support of this uplifting theory, Mr. Phillips observes, "Those who admit the uplifting of a whole island at once from the bed of the ocean (and who that is conversant with volcanic phenomena can question that such events have occurred) need feel no difficulty in admitting the testimony of the Indians, or the opinions of Humboldt, with respect to the fact of a mountain like Jorulla having been uplifted from the interior of the earth." This is the argument *ad absurdum;* for if the latter admission be made, the like admission may be required for elevating continents. Again, Humboldt damages the value of his statement, by adding that the whole mountain was composed of trachyte, as well as by several other similar sweeping assertions. The islands of Santarino and Sciacea were raised piecemeal by a succession of continuous and violent explosions, and many volcanic cones have been elevated in like manner.

Admitting, as geologists express it, the whole country of Quito is one volcanic hearth, still we find, that in all eruptions the ejected material is such as is palpably manifest the well-known constituents of the superficial beds of the earth. Combustion proceeding slowly through the beds formed during the eocene period, is at length awakened into action by the sudden intrusion of waters, the natural consequences follow, the generated steam and expanding gases rend the upper beds asunder, and deep-seated earthquakes extend to the distance of some hundred miles; the ejected material being the common minerals of the soil, sulphureous gases, sulphur, mud, and water, but very seldom lava; the torrents of water are generally supplied from the melted snows capping the heights of the crater. Cotopax became a volcano about the time the Spaniards arrived in Peru; an eruption occurred in 1743, which had been for some days preceded by a continual interior rumbling noise. The ignited substances that were ejected being mingled with considerable quantities of snow, which melted amidst the flames, were carried down with such rapidity that the plain from Callao to Latacunga was overflowed, and all the houses, with their wretched inhabitants, were swept away in the general and instantaneous destruction. The river Latacunga was the receptacle of this dreadful flood, till becoming swollen above its banks the torrent rolled over the adjacent country sweeping away houses and cattle: the eruption continued for several days longer, accompanied with terrible roarings of the wind rushing through the craters that had been opened. In May, 1744, the flames forced a passage through several other parts of the sides of the mountain, so that in clear nights, being reflected by the transparent ice, it exhibited a grand illumination. Mud is also ejected from some of the volcanoes of South America, and other portions of the globe, enormous beds of which after long exposure to the atmosphere become solidified as basalt; this is the distinguishing feature of the volcanoes of Java, which rarely emit lava. Vesuvius has also been known to emit torrents of mud; and, in 1755, Etna vomited forth immense quantities of salt water, with abundance of marine shells. "The volcano in the island of Tanna," says Pallas, "ejects a soft clay, of a bluish ash colour, which seems to be torn from the beds directly over the reservoir from whence the explosion proceeds: the volcanoes Skaptaa and Skaptaa Seyssel, discharge vast rivers of a muddy consistency, principally of the nature termed alluvial; and it is said that these streams in 1783 covered a space of more than 1,200 square miles; the lavas of Madeira and the Cape de Verd Islands are little other than mud, the scoriæ, ashes, tufa, &c., being such as to denote the nature of the inner beds from whence they were ejected. The island of Madeira consists of vast beds of commingled terrestrial and oceanic matters, of limestone rising from 2,000 to 3,000 feet above the level of the sea, and abounding with coral and marine shells. Where the internal fire exists among the older formations or mineral beds, the matters ejected are of analogous nature, being metallic scoriæ, fragments of crystalline rocks, &c. The volcanoes of Java, Sumatra, Sulpher Island, in the Loo Choo Archipelago, the Red Sea, Teneriffe, Vesuvius, and nearly all the great volcanoes of the earth, emit vast quantities of sulphur. During one eruption of Etna vast clouds of black sand or powder were ejected, which covered a space of fifteen square miles twelve feet thick. Lava, or streams of melted material, are occasionally ejected from the majority of the volcanoes of the earth during eruptions: this material is infinitely diversified in its nature, in conformity to the beds from whence it was abstracted; it is sometimes composed of the constituents of vegetable earths or aluminous clays, at other times it consists of lime, lime and magnesia, lime and soda, soda, lime, silica, and iron, in fact, it exhibits every possible variety, and every possible consistence, from a thin watery fluid to a ponderous molten mass, from the simplicity of chalk to the unity of compounds, which distinguish the crystalline rocks; the lava of no two volcanoes being alike. Even in the lava issued from the same volcanoes there is a marked difference. Thus Von Buch distinguishes on Vesuvius alone eighteen different kinds, and the old and new lavas of Etna are readily distinguished by their marked difference from each other. Lava is, in fact, the melted material of the inner beds, the chief constituents of which are silex, lime, chloride of sodium, alumine, and potass, which are well known substances belonging to the fossil and mineral kingdoms. Dr. Kennedy's analysis of lava from Etna is given as silica 52, alumine 19, lime 10, oxide of iron 15, soda, the constituents of oceanic soil, unmixed with aluminaries. The permanently elastic fluids given out of volcanoes are muriatic acid, sulphuretted hydrogen, sulphureous acid, and carbonic acid, the latter being chiefly given out from extinct volcanoes; all these substances are well known constituents of fossil soils, being exceedingly abundant both in their combined and their uncombined state: petroleum is also given out from some volcanoes in its unchanged state: in the Dead Sea this material is in its natural mineral state, being composed of animal matters, salts, and sulphur. "The sulphur," says Mr. Phillips, "is derived from the mutual decomposition of sulphureous and sulphuretted hydrogen, but this material is primarily derived from the decomposition of organic matter." Ammonia is evolved in abundance from many volcanoes, being a constituent of animal bodies, and a known constituent of almost all rocks.

The conditions of preservation of organic bodies are total exclusion from atmospheric and aqueous influence, but no sooner do they become exposed to the one or the other than change is the inevitable consequence, and as all change generates heat, so in changing masses the heat must not only in many cases be intense, but extensively manifest. The first effect of the waters upon these fossil beds, in which are combined all the elements of combustion, will be manifest in the earths and alkalis, which greedily abstracting the oxygen and the hydrogen thus set free by the decomposition of the water, will unite with the sulphur: again, in the decomposition of bodies thus chemically acted upon, much nitrogen gas is evolved, this being one of the chief constituents of animalized beds; and if muriate of soda be present, which it generally is, muriatic acid gas will also be given off; if the nitrogen unites in portions with hydrogen, ammonia is formed, and this gas is also evolved from the heated masses, as being one of their primary constituents: hydrogen and sulphur combining, form sulphuretted hydrogen gas, and if not recombined it evolves through the strata into the atmosphere.

The surface beds exposed to atmospheric influences soon oxygenize, but the fossils beneath the soil retain their primary conditions, or continue in a changing state, combining and re-combining for indefinite periods of time, with no other quantity of oxygen present than belongs to their primary condition, which is always insufficient to effect those permanent alterations necessary to effect the transition of metalloyds into the state of perfect metals. When we consider the nature of a fossil bed, we can readily conceive the intensity of action consequent on the accidental intrusion of water upon it. It abounds with silica, magnesium, calcium, and sodium, both of which latter alkalis are highly inflammable: sulphur is constantly generating within it, and if muriate of soda, as is the case in considerable quantities, the animal matter is partly converted into bitumen; under all circumstances it is a wonderful supporter of combustion, and if the carbonate unites with the soda, this compound acts as a flux with silica, and the accidental admission of water kindles the silica, which then burns with great intensity: again, the action of water upon potassium when this alkaline earth is present in the fossil bed, is sufficient to support combustion.

Against this theory of generated heat of combustion, it is urged that air as well as water must be present to support combustion, and in order to meet this difficulty, Sir Humphrey Davy was compelled to adopt the vague hypothesis, that the interior of the earth is cavernous, and that these caverns were natural reservoirs for the atmospheric currents supplied by apertures disposed as the surface of the earth. In all fossil and even in mineral beds vast quantities of azote exist in the latent strata, and when the heat is generated by electro-chemical excitement and increases to the heat of combustion, the electro-chemical disturbance continues to increase with the increase of heat. The accident of association, as for instance, the introduction of one of the inflammable gases produces atomic excitement in the chaotic mass, gaseous evolution of other gases, decomposition and re-combination of bodies with bodies, all of which in their expanded volume generate action and re-action accompanied by evolution of heat: it is a well-known law of chemistry, that every compound elastic fluid, and every consolidated body combines with its molecular particles a certain degree of heat pecular to itself, being capable of receiving an additional quantity of heat, without alteration of its physical condition; and, as Dr. Black expresses it, whenever a body changes its state, it either combines with caloric or separates from caloric; these phenomena are manifest in fossil beds, extensively excited compounds united by slight affinity are immediately separated, the gaseous products exchange place, disposition, and association, act and re-act upon the several bodies among which they are disposed, or with which they are brought in contact; and in the general decomposition which ensues the azote of the fixed air is extricated, contributes to assist and maintain silent combustion. We cannot conceive any locality wholly free from fixed air, it is a component of all the most ponderable rocks, it is disposed in bodies composing the earth, and it is one of the chief constituents of animal matter; we have, therefore, good grounds for believing that during the heat of combustion, azote in sufficient quantities is extricated from the strata acted upon to support, maintain, and when other causes are favourable, to extend that combustion. On the other hand, after eruptions have taken place, and the open crater is formed, a large and continuous supply of air is drawn in by this funnel: communications with the atmosphere is sometimes maintained through the medium of the funnels of extinct volcanoes: air is sometimes communicated through cavernous apertures: it is also communicated with the intruding waters which always hold a certain quantity of air in mechanical combination.

"All the phenomena," says Professor Phillips, "which are concomitant upon volcanic action, seem to admit of explanation, if we will only suppose salt water, and afterwards air, to find admittance into cavities in the interior of the earth, whence they come in contact with the metals, and the earthy or alkaline metalloyds combined with sulphur there existing." It cannot be denied that chlorine is an abundant material of the earth, even in beds the most distant from the sea, and from their elevation most assuredly not subject to the intrusion of salt water: it is also a well known fact, that all volcanoes are disposed near the sea, and where there are exceptions to this rule, as in Central Asia, they are disposed in the vicinity of the salt lakes, the relics of a former sea, and consequently an oceanic soil: salt beds, and consequently saline waters, abound in all quarters of the earth, and most particularly so in fossil soils, where chlorine abounds under numerous forms and combinations, with many bodies having little affinity, and in some beds, being manifest in its gaseous state. Again, as I have previously observed, air is always present with water, and in its latent state. and consequently when combustion is generated by the intrusion of saline waters in fossil beds, in their primary condition, the alkalis being in their uncombined state, air is liberated in sufficient quantity to sustain the internal fire. It cannot for a moment be contended, that spontaneous combustion will not be elicited from mixed bodies buried within the earth, for the artificial volcano distinctly proves that all the phenomena of volcanic action may be truly imitated.

The earth is deriving a large and continuous supply of oxygen and azote from the atmosphere, and the phenomena consequent thereon are variously manifest in different regions of the earth: in the vast expanse of deserts in Asia and Africa, the virgin soils greedily imbibe air as well as rains and dews, the oxygen entering into combination with the marine exuviæ, the hydrogen uniting with the sulphur, and escaping to the surface as sulphuretted hydrogen. This gas, so inimical to the existence of man, is continually evolved in those parts of the desert which have become covered with rank vegetation: beneath the rainless regions the sulphureous gas is principally evolved: on the other hand nitrogen readily unites with the supporters of combustion, becomes a component of many earthy bodies, and is a proximate cause of the generation of nitrates. Chlorine freely evolved unites with sulphur and phosphorus and forms an acid, and this acid is again decomposed by the uncombined alkalis, deposited as a neutral body, on or in the surface of the earth, it is the subject of incessant change, separating and recombining as local influences may determine. Chlorine and oxygen are the only gases which emit light under any circumstances: chlorine has a most powerful attraction for oxygen, decomposing water and other substances, of which hydrogen is an element, when at a red heat. If chlorine be liberated from its combinations in calcarious fossil beds, and is retained in its cavities, the phosphorous, which abounds in these beds, uniting with it, will take fire and exhibit the phenomena of spontaneous combustion; the heat thus produced, and communicated to the sulphur and iron, or other metals, or undecompounded alkaline earths, with water, the heat is strengthened and increased, and must of necessity increase, so long as the causes of effects produced are in operation. In the heat thus produced, the electric matter, in its latent state, is liberated, and intense electric action is generated, which is followed by a sequence of events favourable to the development and continuous support of combustion.

Spontaneous combustion takes place under numerous combinations. In the union of ammoniacal and muriatic acid gases, much heat is evolved: mixtures of the inflammable gases with oxygen generate heat: again, heat generated in the sulphates, combustion takes place: the nitrates and chlorates in deflagration with metallic bodies, or with sulphur, phosphorus, &c., undergo a great enlargement of volume producing light and heat: nitre, sulphur, and charcoal, present similar phenomena. Sulphuric acid decomposes marble with evolution of great heat and falling on caustic lime the heat is increased. All the materials of combustion above enumerated (except charcoal) are common to, and form the chief components of, virgin or fossil soils, and being present are capable, under favourable circumstances, of generating and supporting the heat of combustion. Hydrogen with caloric forms gas sixteen times as light as common air; insoluble in most substances, but capable of dissolving sulphur, phosphorus, carbon, oils, &c., and thus forming different species of inflammable gas: it decomposes several metallic oxides and acids with simple or known radicals: its continuous decomposition and re-production within a confined medium is considered sufficient to maintain silent combustion and evolution of heat for an indefinite period of time.

BOULTON, WATT & CO.'S NEW SAFETY VALVE.

The above sketch represents a new arrangement of safety valve, adopted by Messrs. Boulton, Watt & Co. for tubular boilers, when required to bear a load of more than 5 lb. on the square inch.

The two objects kept in view in such cases, were—1st. to diminish the size of the lead weights put upon the valve—objectionable not only on account of expense, but also of the space taken up in the valve box—without at the same time lessening the area for the escape of steam; and 2nd. to provide the means of taking off any part of the weight upon the valve, at any period of the vessel's passage, with the greatest facility.

The first of these is effected by the application of the double beat or Cornish valve, in which the upper part A, rests upon the seat B by the two surfaces C C, being loaded with the weights D D D, upon the spindle E. The steam has access from the boiler to the space G G, where it increases in elasticity, till pressing upon the rim H H, its

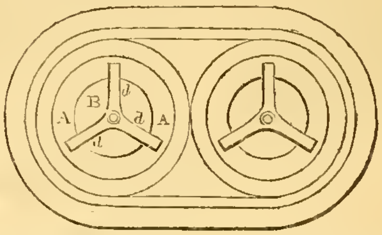
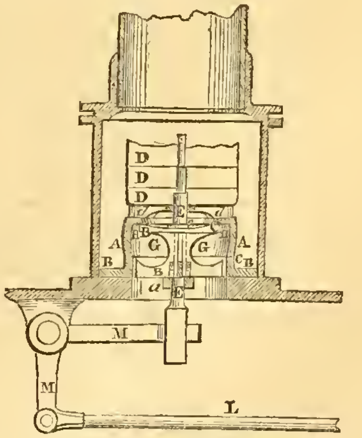
power overcomes the weight of the valve, and the part A, rises from the fixed seat B, leaving two openings for the escape of the steam at the points C C. This area is much greater than in the ordinary valve, while the part to be loaded is only the rim H H, reducing the weights to about one sixth of those otherwise necessary; *a*, is a small stuffing

Fig. 2.



box which screws into the seat B, to prevent the passage of steam round the spindle E. The sides of the rising part A, are made convex, to give a greater passage for the steam when the valve is open.

Fig. 3.



The second object, viz., taking off one-third or two-thirds of the weight when desirable, is done by the graduated spindle E, acted upon by the rod and lever L and M, which are worked by a screw handle on the front of the boiler, raising the upper, or two upper weights, and making the load 15 lb., 10 lb., or 5 lb., as may be required. If the rod L, be drawn still farther, the collar *e*, rises to the arms *d d*, and raises the valve and weights together when necessary to let the steam escape, the engines being at rest.

Feb. 20, 1844.

OBITUARY.

GEORGE MADDOX.

We have to take some reproach to ourselves for not having before spoken of one who, if scarcely known to the public as a professional man, was an honour to his profession, and most sincerely and devotedly attached to his art—to a degree that, perhaps, rather retarded than at all advanced his immediate interests, causing him to postpone all other considerations to his love of art—an enthusiasm which continued unabated to the very last.

The whole of his long life may be said to have been one uninterrupted course of study, not merely in architecture, but in art generally; therefore, long as it was, it offers very little in the shape of matter-of-fact biography, although if treated *auto-biographically*, and so as to record mental habits and their formation—feelings and opinions, the most studious and an almost recluse life, may possess a higher and even stronger interest for the few, if not for the many, than one marked by variety and adventure. The power and originality of mind were not wanting, which would have enabled the subject of our memoir to give the world a memoir of himself, fraught both with interest and instruction—most certainly the last, if only by embodying in permanent form his own opinions and views of art, and thereby becoming a valuable store of criticism.

As to what we are able here to say, it is so very slight and imperfect that it does not deserve the name of "memoir" at all, since it amounts to little more than a mere "memorandum" of the man, without even the skeleton of a biography, in regard to facts and dates.

George Maddox was a native of the town of Monmouth, where he was born in 1760, and where his father was, we believe, a builder by trade. On the expiry of the time of his apprenticeship with his father, he came up to London, where he afterwards obtained an engagement with Soane as his assistant. How long he actually continued with him, we are unable to say, but we believe for no very great length of time; certain it is that he ultimately quitted him in disgust,—which is so far from being at all surprising, that it would have been infinitely more so, had one of such independence of mind as was Maddox, tamely brooked the tyrannical temper, and the wild and wayward caprices of the other. Though this may have been a somewhat imprudent step in its consequences, there was, no doubt, enough to justify it, more especially as there is strong reason for supposing, that not temper alone, but also ungenerous conduct, on the part of Soane, caused the rupture between them; and, whether justly or unjustly, at all events the character of the latter gives strong probability to such suspicions. He was next connected with the Pantheon, in Oxford Street, and in such a manner as to be seriously involved in the pecuniary affairs of that property. About the same time a most promising prospect that was opening itself to him, was suddenly cut off by the loss of a patron in the then Duke of Cumberland, brother to George III., whose death caused the project of building an Opera House in Leicester Square to be abandoned, just as all but the final preliminaries had been arranged. The edifice was to have been upon a scale then, and even now, unprecedented in the metropolis; Grecian Ionic in style, with a magnificent portico, whose columns would have been about sixty feet high. What became of the design for it, we are unable to say; but it does not appear to have been preserved. The same is, unfortunately, the case with those of many buildings which he actually did execute, and which, although, being for the most part only private houses, and those upon a moderate scale, they were not of a kind to obtain general notice, have much in them highly deserving of attentive study, being most carefully studied themselves; and containing many original and valuable ideas, nor least of all so, in regard to detail. At any rate, a selection of some of them would have formed an instructive publication, as would likewise some of his original compositions for capitals, and other ornamental details in the Greek style; to which, for want of any other, the not particularly recommendatory epithet of "*fancy*" capitals, &c., must be applied, although they were singularly happy in idea, and true to the sentiment of Grecian prototypes,—felicitous conceptions meditated, and afterwards wrought out, *con amore*.

Enthusiastic as was his admiration of classical architecture, more especially of Grecian, Maddox was by no means an advocate for merely copying the extant examples of it, much less for treating them in the jejune, spiritless, and mechanical manner we generally find them. He was, in fact, an artist in the most comprehensive sense of the word,—perhaps to a degree that was rather prejudicial than the contrary, to his immediate interests, since he was too much wrapt up in art, to attend to *that* of making his way in the world, and pushing himself forward as he might have done, without thereby compromising his integrity.

Cheap and vulgar praise he scorned, and no doubt felt that few could appreciate his ideas. This last must certainly have been the case in regard to the architectural subjects, annually sent by him to the Society of British Artists. As pictures in oil, they were of all others almost the least calculated to attract notice in an exhibition room: "Portraits of cabbages," as he himself used to say, would have had a fairer chance of being looked at. And his required to be not only looked at, but carefully looked into, to detect all the varied beauties of detail, and the fresh and valuable ideas with which they abounded. In truth, they were quite out of their element in such miscellaneous exhibitions, more especially as there was nothing in their mere titles to call attention to them, and being generally of small size, and not of a kind to strike at first sight, they were apt to be overlooked, or else merely glanced at, by those who could have done justice to their merits.

Besides being a very superior architectural painter in oil, Mr. Maddox showed great ability with his etching-needle, and some time before his death had made considerable progress with a series of etchings, about forty in number, of groups of architectural fragments and ornaments. Unfortunately infirmity and suffering prevented his finally completing them for publication, as he intended; yet it is to be hoped that even now they will not be entirely lost to the world, but impressions of them published from the coppers as left by himself. This, we hope, will be done, if only for the sake of his widow, who, it pains us to say, has been left almost entirely without resources, since for many years previous to his death he had no other means of subsisting than teaching pupils, and occasional employment from others in making designs and drawings; occupations precarious almost at the best, and frequently interrupted of late years by severe and protracted attacks of illness. The last of which terminated in his death, Oct. 7, 1843 in the 83rd year of his age.

LUIGI CANONICA

Is another octogenarian whom art has lately lost, and still more recently, for he died at the beginning of the present year, some time in the month of February, at Milan, aged 82. Like his eminent contemporary, Luigi Cagnola, whom he survived just ten years, it was the good fortune of the Cavaliere Luigi Canonica to be employed on some of the more important *monumens* of Milan. After the celebrated *Arco della Pace*, by the former, the *Arena*, by the latter, is one of the modern architectural *lions* of that city, although it is not every English tourist—not even those among them who are architects also—that has condescended to bestow any notice on either, at least not beyond what the ordinary "Guide-book" supplies. That the "Arena" should have obtained so little of their attention, is indeed surprising, because it affords a good opportunity for comparison with ancient structures of the same kind. We meet, however, with some description of it, in a work entitled "*Notes Abroad, &c.,*" which, we may remark, deals far more largely than usual in architectural criticism, and occasionally speaks out more than rather freely in regard to some of our architects here at home.

"In the arena," says the writer, "Canonica has given us an imitation of an ancient amphitheatre, upon a still larger scale than any similar work of the Romans, it being an ellipsis of about 800 by 400 feet, dimensions that would give it a superiority even over the Colosseum. In other respects, however, it must be confessed that it falls very far short both of that and the edifice at Verona, for there are not more than eight rows of *gradini*, which do not rise above twenty feet; which want of height, together with the much greater extent of open area, causes it to assume altogether a different character, and appear little more than an inclosure surrounded by a single *præcinctio* of seats; whereas in all the ancient amphitheatres the external walls are exceedingly lofty, and consist of tiers of arcades. Here, on the contrary, there is only one series of semi-circular arches, disposed at a considerable distance from each other, with a plain square-headed doorway beneath it (each?), and the summit is finished by a balustrade. Nevertheless the whole is a work of great magnitude, and was completed within a comparatively short time." (It was commenced in 1805.) "The principal entrance is at one extremity through an arch, with two fluted Doric columns on each side of it, supporting an enriched entablature, and a pediment, filled with sculpture, placed against a podium, or low unbroken attic. This frontispiece rises much higher than the external wall, the impost of the arch itself being on a level with the top of the balustrade. There is also on one side, namely that adjoining the Piazza d' Armi, a raised loggia (*Pulvinare*) of eight Corinthian columns of red granite, containing seats for the Viceroy and his suite, with a saloon behind it, whose windows open on the piazza. This unique structure was erected by order of Buonaparte as a place of public amusement and recreation for his Milanese lieges, where they might be gratified not only by horse and foot races, for which it is exceedingly well adapted, but also aquatic exhibitions and rowing matches, as the arena can be laid completely under water in a very short time. A festival of this last-mentioned kind was given on the occasion of the birth of the King of Rome."

To this account we need merely add that, notwithstanding there are so few rows of seats, they are computed to be capable of accommodating no fewer than 30,000 spectators. We ought to observe, however, that the dimensions stated by the writer whom we have quoted, do not pretend to accuracy, we therefore give them according to what we have found them stated to be in metres; annexing, in order to afford readier means of comparison, those of some ancient ancient amphitheatres:—

Milan, Arena	780 × 380 feet
Rome, Colosseum	615 × 510 feet
Verona, Amphitheatre	450 × 360 feet
Pola, do.	436 × 346 feet
Nismes, do.	400 × 320 feet

If we have spoken somewhat at length of this work of Canonica's, we shall not do so in regard to any of his other buildings, and for a most cogent reason, having, unfortunately, no materials for description; and it has even now cost us no little trouble to ascertain the names of those we here enumerate. Among those erected by him at Milan are the *Teatro Ré*, the *Teatro Carcano*, and the *Teatro Filodrammatico;* also the *Casa Canonica* his own mansion, and the *Palazzo Belloni.*

Canonica has been spoken of with high commendation by the writer of an article in the Quarterly Review, on the "Palladian Architecture of Italy," more especially with reference to the last-mentioned structure, "the front of which," it is there said, "is, perhaps, for its size, the most beautiful of any private building in Italy. It consists of a rustic basement story, with a balustrade, on which rests a disengaged colonnade of six fluted Ionic columns, with an unbroken entablature, and above it another balustrade with statues." We also find him mentioned as the architect of three other theatres, at Brescia, Mantua, and Parma; at least the last was designed by him, though executed by Bettoli. Canonica possessed a considerable fortune, and has made some munificent bequests, leaving by his will 174,000 fr. (about £7,000) to the Primary Schools of Lombardy, and 87,000 fr. (about £3,700) to the Milan Academy of Fine Arts, the interest of which is to be devoted annually to the education and support of some young artist—architect, sculptor, or painter.

FOUNDATIONS ON SAND.

The subject of foundations on sand has latterly attracted a good deal of attention here, and particularly on account of Mr. Perring's discovery that many of the buildings in Egypt were built on such foundations. At page 80 of this volume of the *Journal* it is said, "It seems that the stony surface of the desert had been made level by a layer of fine sand, and confined by a stone platform 14 ft. 6 in. wide and 2 ft. 9 in. thick, which supported the external casing, and the pyramid (that of Dashhour) was built on upon the sand which is firm and solid." Other examples of the same kind were met with by Mr. Perring, and it seemed that the sand, when retained in its place could be depended upon. We have, therefore, thought it would be interesting, while public attention is directed to the subject, to notice what has been done on this system in France. It seems to have been first adopted, in 1822, by M. Devilliers, C.E., when employed on the canal of St. Martin, where he used it extensively. It is to be observed, however, that it is the only system employed in the Dutch colony of Surinam, and was suggested long since by Captain Rosmy but not applied.

We have no account of M. Devilliers' works, and the process seems to have remained in abeyance until 1830, when Captain Gauzence, of the French Engineers, employed it for the support of the portico of of the Guard-house of Mousserolles, at Bayonne. This plan is represented in Fig. 1, where A represents the front of the portico, B the façade of the guard-house, and C the sand foundation.

The soil was a slippery greasy clay, extending to a considerable depth, and it was at first proposed to lay down a platform of wood as a basis. Capt. Gauzence's suggestion however having been adopted, the soil was dug out to about a yard below the substructure and filled in with sand well rammed. On this were laid two courses of Ashlar masonry, and then a course of dressed stone, forming the surbase. Before finishing the columns, one of them was laden with ten tons of lead without any sensible effect being produced. The structure was finished in October, 1830, and no settlement has taken place since, though each column is computed to carry a weight of ten tons, and a wall of the same guard-house, otherwise built, has settled a good deal.

Fig. 1.

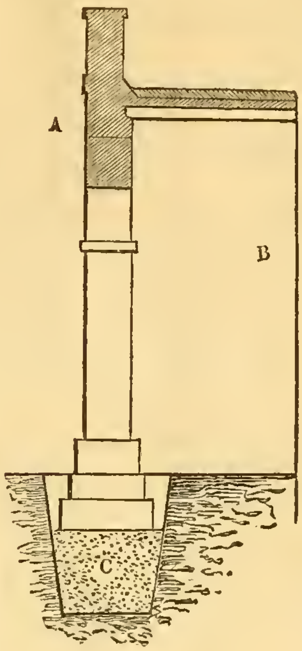


Fig. 2.

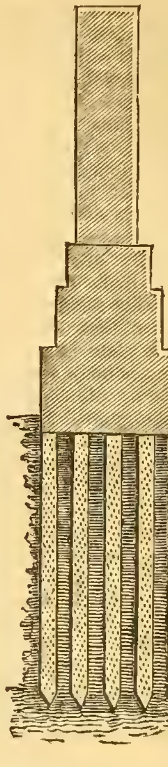

Fig. 3.

The same plan has been successfully pursued in some of the fortifications of Bayonne, where buildings had to be placed on made ground. In 1836 a sand foundation, about 2½ ft. thick, was employed, with an equally satisfactory result, for the quay wall of a small harbour on the coast of Brittany.

For the construction of the artillery arsenal at Bayonne another plan has been adopted. The soil is of the same greasy kind before described, while it is quite impossible to use wooden piles, for not only is wood very dear in the neighbourhood, but at high water a stratum of water penetrates the soil, which rapidly rots wooden piles or platforms. Colonel Durbach therefore proposed to employ what have been termed piles of sand. The forge department is surrounded by square piers united by a wall, and in fig. 2 we have a section of one of the piers, the weight of which, and of the carpentry supported, is about 35 tons.

The foundation piles are so arranged that each bears only two tons. The process adopted was to drive into the ground an ordinary wooden pile about 7 in. square and 6½ ft. long. This was then drawn out, and the hole filled with sand. The surface was then levelled, the sand well rammed in, and the masonry raised upon it. To draw the wooden mould pile, an ordinary machine was used, to which a chain was attached in the manner shown in fig. 3.

In 1833 Colonel Durbach's plan, with some modification, was employed by M. Mery, C.E., in the canal of St. Martin, at Paris, for the construction of a lateral culvert, which passed through ground of bad quality, in which a quantity of water was infiltrated. Instead of sand, which would have been washed away, sand mortar was used, made by mixing one seventh of hydraulic lime with six sevenths of sand, which soon consolidated.

With regard to the sand to be employed, it is recommended that it should be moderately fine, of equal grain, and not earthy. It must be moulded and rammed in layers of about 8 in. or 9 in. thick, which is an important point.

The theory of this process is not known, but it is supposed that the pressure is equally distributed on the sides as well as on the base. Some curious circumstances as to the pressure of sand are to be observed in connexion with blasting, where it is found to produce the most efficient tamping.

IMPROVED TWO CYLINDER ENGINE.

(With an Engraving, Plate IV.)

DESCRIPTION of a 20-horse high pressure engine, with two cylinders, in the establishment of Messrs. Geo. Forrester & Co., Liverpool.

This engine is represented in the accompanying engraving; Fig. 1, being a side elevation; Fig. 2, a ground plan; and, Fig. 3, an end view of the same.

The improvement consists in an arrangement of *two* cylinders (instead of one of double the area), which are placed side by side upon an independent foundation plate, in a horizontal position, with a space of sufficient width to allow a connecting rod to work freely between them; the piston rods of both cylinders are connected together by a cross-head at one end, from which the power of the combined cylinders is communicated directly by a long connecting rod to the crank shaft at the other. Each cylinder is provided with a separate slide valve, both valves being connected together, and worked by one valve shaft and eccentric motion. The feed pump is placed at the front end of the foundation plate, at the same level as the cylinders, and is worked directly from the main cross head of the engine, to which the pump ram is attached. Steam of 35lb. pressure is used in the boiler, and the supply is regulated by an atmospheric governor (Hick's patent), which is attached to the throttle valve, placed in the leading steam pipe to the two cylinders (as shown in the drawing).

The object of the above arrangement (as will be seen) is to lessen greatly the dimensions and weight of the engine, the length occupied being little more than half that of the ordinary engine, whilst all the working parts are rendered more accessible, and their simplicity is such as to render it both durable and easy of attention. An important feature in this arrangement is that of the crank shaft being very close in position to the seat of the cylinders, whereby the strain of the engine is confined to a very limited portion of the foundation plate, the power of the combined cylinder not being transmitted through any portion of the framing at their front end, but only through that part intervening between them and the crank shaft which is placed immediately behind them. The engine being thus perfectly self-contained requires no foundation, except a bed of brickwork or timber to raise it to the requisite height, whilst the reduced space it occupies renders the expense of the engine house, or preparation for it, comparatively small.

REVIEWS.

GEOLOGY.

1. *Geology, introductory, descriptive and practical.* By DAVID THOMAS ANSTED, M.A., F.R.S., Professor of Geology in King's College, London. London: Van Voorst, 1844. Part I.

2. *A History of British Fossil Mammalia and Birds.* By RICHARD OWEN, F.R.S., Hunterian Professor at the Royal College of Surgeons. London: Van Voorst, 1844. Part I.

The study of geology, whatever interest it may possess for the follower of abstract science, has immediate claims upon the engineer, being intimately connected with his practical pursuits, and recognised as an imperative part of his professional course and taught in the public schools. In the design of grand works of internal communication in the drainage of the open country, in the search for water, in the industrial application of the mineral resources of a district, the engineer experiences the necessity for a well grounded acquaintance with the principles and details of geology. In the laying out of a line of canal or railway, he must ascertain what materials he has in the locality, which can be used with a due regard to economy and durability, and from inattention it has often happened that materials have been at much expense brought from a distance, which were to be found in equal abundance and perfection on the spot. It lies with the skilful engineer to point out such deposits of brick earth, lime, ballasting sand, and other mineral productions as may become a source of increasing traffic to the line. For the supply of a steam engine or factory he will frequently find a difficulty in obtaining the requisite supply of water, and he has to determine on the practicability of obtaining it from the underlying strata. He may also have to construct absorbent artesian wells, for the purpose of carrying off impurities. In the supply of water to large towns, geological knowledge is of much avail, for the engineer has not merely to avail himself of surface sources, but he must ascertain how far the supply of water is likely to be permanent, and what means exist of increasing the surface supplies. He may also be threatened with opposition as interfering with the supply of water to other purposes, and to vested interests. The question of bringing water from the Colne, so ably discussed by Mr. Robert Stephenson, was mainly one of geology, *(Civil Engineer and Architect's Journal*, Vol. VI., p. 350.) In the course of works, too, many geological questions arise, not merely as to the nature of the substrata influencing the foundations and the power of sustaining an embankment without bulging or spewing, or as to the extent of a deposit of wet sand or quicksand, but in a variety of ways. Thus in the important case of *Ranger* v. *the Great Western*, one of the allegations was that a particular rock was improperly and unfairly described, the description of Pennant stone intimating that it was a soft rock, whereas it was a hard rock, and that the trial pits on one of the sections were unfair, because they did not show the substratum of hard rock, and of which no mention was made in the specification, whereas it ought to have been known to the engineers that such a substratum was to be found within a certain depth, and that thereby the contractor was misled. In this specific instance judgment was given in favour of the engineer; but it shows how much care it behoves the practitioner to employ. Indeed the geological features often influence a contract; bricks are directed to be made on the spot; thus Mr. F. W. Simms, C.E., had the superintendence of a tunnel, constructed on the South Eastern Railway, through a difficult geological formation, and at the same time he had the direction of large brick works in which he introduced several valuable improvements, *(Civil Engineer and Architect's Journal*, Vol. VI., p. 348.) The use of stone upon the line requires a good deal of consideration, and also the use of any material for embankments, or ballasting. The danger of mixing some soils is well known, witness the case which occurred some time ago of pyrites taking fire on the London and Birmingham Railway, and embankment, sleepers, and rails being seriously injured. The use of light sand employed on the Croydon Railway for some time until gravel could be reached, was found highly inconvenient for ballasting, the passengers complaining much of the quantity blown into the carriages, and the maintenance of the line being very troublesome. An intimate acquaintance with the different strata is in fact of the greatest importance, one material will stand with one batter, one with another, and so on, and an engineer removed from one geological district to another, will often find himself at a loss, when he attempts to avail himself of his previous experience in his new locality. Thus a northern engineer will frequently not duly allow for the nature of the chalk and London clay formations of the southern districts. Tunnels are projected in the chalk as a homogeneous and compact mass, and fissures are met with, and springs of water. The London clay, too, presents the greatest difficulties, and baffles all calculation; works may stand very well for two or three years, or for longer periods, then they swell with water, extensive and sudden slips take place, and there are no means of stopping them. It cannot be said that the slips on the Croydon Railway are yet remedied; and certainly Mr. Gibbs was as little to blame for their occurrence, as Mr. Cubitt is for not having been able yet to check them, although so much of the clay has been removed, and large buttresses of gravel have been substituted. So at last the London clay has begun to show its character in the Camden Town cutting of the London and Birmingham Railway, and Mr. Watson's ingenious plan of draining (described at pages 49 and 61 of the present volume) has been obliged to be adopted as the only efficient means of checking the evil, though strong retaining walls strengthened by iron girders, present a barrier sufficient to contain any other material. The treatment of slips has become a new branch of engineering, requiring a most skilful application of the various modes and appliances of draining, while as yet the means of so constructing the original works as to prevent slips is far from being in a satisfactory state. The engineer avails himself of previous experience, he finds works standing in several localities with a certain batter, and yet his own works may crumble to the ground, though he has faithfully followed the exemplar. One element with regard to the slope, at which any material will stand, has, in our opinion, been passed over, and that is the height. It may happen that clay or chalk may stand very well with a certain batter at 20 ft. high, and yet that it may not stand with the same batter at 40 ft., 60 ft., or 80 ft. We think it very likely that a law prevails modifying such results, and it would be very desirable to have the subject investigated.

We need scarcely allude to the advantages which an engineer will derive from his geological knowledge in laying out any grand line of works, the adoption of such a course as to avail himself of the natural passes and levels, and not to come in contact with the natural difficulties. So too with regard to many operations; thus the grand experiment of Mr. Cubitt in removing large quantities of the Dover chalk

END ELEVATION

rocks by gunpowder remains a subject of controversy; for although he has undoubtedly removed the material in an economical manner, it may be very much doubted whether he has not so shaken the remaining rock, and so extended its fissures, as to threaten him in subsequent years with serious slips, which may be productive of much embarrassment. So also the application of the artesian well system requires caution, for by want of care the well may be carried down to a limited reservoir only, when any other well being carried down to the same natural tank will diminish the supply to the previous well, and require both to be carried to a greater depth. The theory of artesian wells is satisfactorily established, but its application is in many cases matter of great controversy, as in the instance of the Trafalgar Square well, and it is necessary that the engineer should be well instructed so as efficiently to conduct his operation, and satisfactorily to defend its propriety. We may remark here *en passant* that the progress of the artesian well system is one of deep interest to the engineer, and with regard to which many valuable experiments are going on: thus at Naples the supply of water from the exterior is scanty and expensive, and a well is being bored in the King's garden to try for water at a lower depth: so too in the desert of Egypt a similar experiment is contemplated by the Pasha, the result of which will have an important bearing, and if successful, will alleviate one of the great difficulties of the Indian transit. An acquaintance with the inferior strata of water is indeed of the greatest value, for it will sometimes happen that water will abound below, which cannot be retained on a sandy surface, or it may exist in a state of greater purity, filtered through loose strata, while on the surface, it may be so mixed with extraneous matters as to be unfit for use. A better acquaintance with this subject may lead to some relief of the great droughts suffered by some districts of Australia, and which materially impede the progress of our colonies there. To return to the railway and canal engineer, it will sometimes happen that in cuttings he will come on deposits of septaria, which are extensively used in the manufacture of Roman cement, or on coprolites, which have been pointed out as a copious source of manure, and likely to be so employed, or he may come on some calcareous formation, the qualities of which being duly ascertained may be of great value for agricultural purposes or in the composition of cements.

In mining the possibility of reaching coal or ironstone is often left to the investigation of the engineer, and the educated engineer will not do now what was formerly done, bore for coal in the tertiary deposits. He has, too, as we have before observed, to make himself well acquainted with the geological character of the district in which he is engaged, and he has thus the opportunity of ascertaining its mineral resources, and of suggesting the necessary means of exploitation. The opening of the coal and lime works by the Messrs. Stephenson on the line of railway in Derbyshire, has not only been a means of affording great benefit to the district, but of bringing in considerable profit to the projectors. An investigation into the supply of ironstone, the presence of the requisite flux, and the accessibility to fuel is requisite to determine the formation and establishment of an iron work, and its successful prosecution. Indeed, various are the occasions on which geological skill will be found one of the most valuable attainments of the engineer.

In hydraulic works this knowledge is indispensable, one coast differs from another, rivers from rivers, and a well grounded acquaintance with the natural operations going on in the locality and elsewhere must be the chief guide to the engineer. Here the *vis medicatrix naturæ* is of the greatest utility, nature cannot be contended with, she must be humoured, and her powers turned to account. The most elaborate piers and jetties may be erected, but if the backwater be poured in at right angles to the tide, a deposit must take place. So too, an ill considered disposition will make a costly harbour a mere shingle trap, and the extension of piers and jetties only results in the carrying of the bar further out out to sea. Here, too, is a department where much is to be studied and much is to be done, at present it decidedly remains the domain of empiric practice, and harbour is made after harbour, and hundreds of thousands spent after hundreds of thousands only to result in failure. A careful examination of results would show a most lamentable condition of this branch of engineering science, for few indeed are the works which have proved effectual. This, too, must be the case so long as Mr. A. or Mr. B. is directed to improve Mudport Harbour, in the teeth of his repeated failures, for here a man is not tried by the efficacy of his cure but by the polish of the instruments he has employed in maiming or destroying his patient. His harbour is barred in a calm, and inaccessible in a gale, but what matters that, his north pier is an admirable specimen of constructive skill, his pier wall is faultless, and his lock gates magnificent, and so he goes on, and people talk about back water, scouring power and shingle, and when they have bothered their own heads and other person's, there is an end of the matter. So long as your engineer can employ a ballast engine, and dredge away the obtrusion, he gets one or two feet more water, and people are satisfied, not considering that he has applied a mere palliative and not removed the evil. The only remedy we can suggest under the circumstances, is to leave the design of harbour works open to public competition. The result we think would be to give the young engineer an excitement to study this branch, to give due effect to local experience, and to bring nautical knowledge to bear, while the public would feel much more deeply interested, the plans would be judged by a much more jealous tribunal than they now are, a great degree of valuable information would be obtained, and the basis laid for the scientific pursuit of hydraulic engineering; as it is, we consider, the grand defect undoubtedly to be an ill acquaintance with natural operations, and an inattention to the proper application of natural resources.

We may make the same remarks with regard to embanking, which as a scientific study, is in its infancy. Some thousand acres have been recovered on the Lincolnshire coast, but it has been by brute force rather than otherwise, and the means of applying natural resources to the recovery of the numerous available sites on our coasts have been totally neglected, though nothing would be more easy than the reclamation of very large districts, if adequately treated. We shall have occasion, in alluding to the force of water, and the amount of solid matter held in suspension, to show what an immense power is available if properly directed. We may remark with regard to any hydraulic construction, that careful study is required, the contour of nearly every coast varies, and consequently the set of the currents, which form the chief disturbing forces. This will be recognised at once, if we compare the eastern coasts of England with the west or with the south. Each has its peculiarities; and it is quite absurd to set an engineer at work in one locality, even on the ground of his success in another. How differently do the tides and currents set in the straits of Dover to what they do elsewhere: then again look at the tidal current acting in St. George's Channel, where at one end it has a broad entrance, and at the other is confined within the narrow space between Port Partrick and Donaghadee. How different is this from the long line of current sweeping for several hundred miles along the east coast.

Were there no other motive for the study of geology by the engineer, yet the unique opportunities he has for making new discoveries ought alone to incite him. In the bowels of the earth extraordinary phenomena meet his eye first, unexpected faults, slips, and novel fossils; in his cuttings and in his tunnels, he has the means of perceiving the order and superposition of strata, their depth, their extent, and the organic remains which characterise them, and under circumstances which other geologists vainly seek. It is with pride we point to many engineers, who have availed themselves of these opportunities, as the collection of railway sections in the Museum of Economic Geology will show, and who have rendered great service by many valuable discoveries and important communications.

With so many members of the profession devoting themselves to colonial pursuits we cannot too strongly recommend to young men the importance of geology. As the medical man is called on in the colonies to find supplies of drugs and medicines, by the use and substitution of local plants, so the colonial surveyor has to discover adequate materials, and to point out the resources of the district in which he is employed. By such exertions his value to the community of which he is a member, and his importance are enhanced, and by well directed investigation he may much increase the produce of the colony, and find many advantageous means of investment on his own account. The discovery of coal in a colony is recognized, as a most valuable service, and its exploitation, either immediately or indirectly, gives employment to the engineer, increases his professional income, and affords a permanent source of occupation.

We have now before us two works produced by Mr. Van Voorst, a circumstance, which to those who know his publications, will be alone a sufficient recommendation. Each work appears in parts. Mr. Ansted is Professor of Geology at King's College, and he gives abundant proof in every page of his qualification for the task he has undertaken. The arrangement of his work, and his treatment of the subject rather differ from the course usually pursued, but they are such as to give the student a clear and well grounded acquaintance with the study. Mr. Ansted carefully eschews all theory at the commencement, and begins his description of the strata with the palæozoic, instead of with the tertiary, as is frequently the case. His style is simple, and his great endeavour is to give the learner a clear idea of what is before him. It is a book written, not as such works too often are written, for the learned man, but for students, in which the writer enters as it were into the mind of his reader, anticipates his difficulties, and by making himself acquainted with them is more easily able to remove them. This is the great skill in the art of teaching, as in all persuasive arts, to think not of yourself and your own ideas, but how you can best communicate the subject to those whom you are addressing. The mere inculcation of a fact is nothing, you must make the student apprehend it and comprehend it. In attaining this end, we think Professor Ansted has well succeeded, and he has produced a work, which of all those which have appeared, is best calculated to be of service to the learner. We must not, however, be misunderstood, this is no cram book, no creation of paste and scissors, the anything good enough for the public; but carefully elaborated, every fact duly weighed, the knowledge and experience of the author brought to bear, and the latest researches recorded, even to the current period.

Professor Owen is an authority in every department of comparative anatomy, known for his close and ingenious research, the extent of his discoveries, the originality of his views, and the keenness of his discrimination. Those who heard his masterly paper before the Geological Society on Koch's Missourian, can well appreciate his powers, the skill with which he disarticulated the skeleton, showed its true character, and reconstructed it as the Mastodon. It did certainly appear extraordinary that men of science should not have recognised the false articulation, when the posterior extremities were made to join on to the *caudal vertebræ;* the turning of the tusks upwards, and the raising of the skeleton on the fore legs were shown to be characteristics impossible and false. His paper on the Amphitherium in the work before us is no less admirable. The British Fossil Mammalia are arranged not according to any geological peculiarities, but according to their natural classification, beginning with the Quadrumans, and we have perused this first part with deep interest, and strongly recommend it to all who are desirous of making themselves acquainted with this important branch of geology, so necessary for the accurate discrimination of strata, and so valuable in its bearing on the higher branches of the science.

We can scarcely conclude these remarks better than by extracting the preliminary observations of Professor Ansted on the power of water.

"It requires but little study to discover that every one of the most common and daily operations of nature is concerned more or less in the formation of stratified rocks. Every shower of rain that falls in a hilly or mountainous district, every brook or river that pursues its course through a greater or less extent of country to the sea, or is swallowed up before reaching the sea in some mightier stream than its own, every lake or pool that receives the waters of a river loaded with the particles of muddy soil over which it has passed, and pours forth at its opposite extremity a transparent stream cleared of impurities, every wave that dashes against a projecting rock on the sea coast, or washes into a hollow bay, tearing and grinding away the solid cliff:—each one of these, together with other not less powerful though less frequently recurring agents, is concerned in the formation of new strata, and in effecting changes in the physical conformation of the globe scarcely less remarkable than those with which the geologist has to deal, and which will hereafter be described. A few instances of the actual extent of the effect thus produced will form a useful and interesting introduction to a description of geological facts analogous to them.

"Of the many constantly recurring phenomena, which, owing to their perfect and undeviating regularity, attract but little notice from the casual observer, there is none perhaps more remarkable than the quantity of solid matter held for a time in mechanical suspension in the water of rivers and brought down to be deposited at the mouth of the stream, or spread over the bed of the ocean. The vast amount of mud thus conveyed by running water is occasionally seen in the extensive deltas, or tracts of swampy land, at the mouths of great rivers, such as the Rhine, the Po, the Nile, the Ganges, &c.; in each of which cases the river divides into so many channels before reaching the sea, that its actual character and apparent magnitude is completely lost.

"The origin of these vast deposits of rich alluvial soil must be sought for entirely in mud brought from the high lands or the plains through which the river passes, and held in suspension so long as the water is in rapid motion, but which sinks to the bottom when the current is checked. To obtain some notion of the actual quantity of solid matter thus continually brought down from the high land to the sea, an experiment was made some years ago by Mr. Leonard Horner, on the waters of the Rhine, the calculations founded on which possess considerable interest. Mr. Horner found that in the month of August, when the river was unusually low, one cubic foot of water taken fairly from near the middle of the river, near Bonn, supplied rather more than 21 grains of solid matter, and that in the month of November, when the water was turbid, about 35 grains of residuum were obtained. Now, taking the average of these two observations, and considering the Rhine at Bonn to be 1,200 feet wide, to have a mean depth of 15 feet, and to run with a mean velocity of 2½ miles per hour, it appears that nearly 400 tons of solid matter would pass down the stream per hour; and that in the course of one year, between seven and eight thousand millions of tons would be carried along, the greater part of which must be deposited in Holland before reaching the sea, in consequence of the slow and meandering course of the river through that flat alluvial country. In the course of 2,000 years, the Rhine may thus have brought down enough material to form a stratum one yard thick, extending over an area more than 36 miles square.

"But the delta of the Ganges far surpasses in magnitude that of any European river; and is on the whole, perhaps, the most extensive and remarkable of all those at present forming of which we have any accurate data. The head of this gigantic delta commences at a distance of 220 miles in a direct line from the sea, and the base of it is 200 miles in length; the whole triangular space occupied comprising upwards of 20,000 square miles, every part of which has been formed by deposition from the river and its tributaries.

"The quantity of mud and sand carried by the Ganges into the Bay of Bengal is however, notwithstanding the vast deposit which previously takes place, still so great, that during the rainy season when the stream is turbid, the sea does not recover its transparency even at a distance of 60 miles from the coast; and the quantity of mud held in mechanical suspension is so great, that a glass of water taken out of the river when at its height, is said to yield one part in four of mud. Calculating from the dimensions of the river and the rate of the current, Major Rennel has shown that during the flood season the weight of the mud thus brought down daily, and deposited either within the limits of the present delta, or at the mouths of the different branches, must be as much as 450 millions of tons, a quantity which is perhaps more readily understood by expressing it as equal to about 74 times the weight of the Great Pyramid of Egypt, supposing that to be a solid mass of granite.

"Another instance of a vast amount of solid matter conveyed by a river, and spread out upon the bottom of the ocean, is seen in the distribution of the sediment of the great river of the Amazons. At the point where the current formed along the coast of Africa, (a current which crosses the Atlantic to the continent of South America,) meets the stream of the Amazons, it runs at the rate of about four miles per hour. The stream of the river, however, preserves part of its original impulse, and its waters may be recognised by their muddy colour, and are not wholly mingled with those of the ocean at a distance of 300 miles from its mouth. An immense tract of swamp is being formed along the coast of Guiana by the deposit of the mud thus brought down by the Amazons, and the shallow sea along that coast is rapidly being converted into land.

"The power of water when in motion of transporting not only mud, but heavy bodies of considerable magnitude, is another point of considerable interest in geology, and one that requires to be stated in some little detail, because there are certain popular fallacies concerning the motion of heavy bodies, which tend much to confuse and mislead the judgment on this subject.

"We are accustomed to consider weight as an absolute quality of certain bodies, which we therefore call heavy. Now this quality of weight, as the word is commonly applied, is in fact only relative; and in this relative sense, a piece of wood is no more heavy when immersed in water than a balloon filled with hydrogen gas is in the air, each being lighter or of less weight than an equal quantity of the element in which it is placed, and which it displaces. In all cases, the actual weight of that quantity of the fluid which would have occupied the space filled by a solid body, must be deducted from the actual weight of the body before the relative weight,—the only part which resists motion,—can be calculated.

"Speaking accurately, therefore, bodies of all kinds are heavier in air than they are in water, and are consequently moved with greater facility in the latter, than in the former fluid. It should also be borne in mind that the power which water possesses, of transporting heavy bodies, increases in an enormous ratio with the increase of rapidity of the current; and with these considerations, we shall be able to account for, and understand statements on record, otherwise almost incredible, of the effects produced by water in rapid motion.

"As a recent instance of effects of this kind, and one occurring in our own island, I quote an account of an extensive flood, which spread simultaneously over a large tract of country, in Aberdeenshire, in the early part of August, 1829. The total length of river flooded on this occasion could not be less than between five and six hundred miles, and the whole of the river courses were marked by the destruction of bridges, roads, crops, and buildings.

"Speaking of the river Nairn, Sir T. D. Lauder relates, in a detailed account of this flood that a fragment of sandstone rock, fourteen feet long, three feet wide, and one foot thick, and which could not have weighed less than three tons, was carried down the river a distance of two hundred yards.

"A bridge over the Dee having five arches, and a waterway of two hundred and sixty feet, which was built of granite, and had stood uninjured for twenty years, was carried away by the flood, and the whole mass disappeared from the bed of the river.

"'The river Don,' says Mr. Farquharson, describing the effects of the same flood, 'has, upon my premises, forced a mass of four or five hundred tons of stones, many of them weighing as much as two or three cwt., up an inclined plane, rising six feet in eight or ten yards, and left them in a rectangular heap, about three feet deep on flat ground.'

"The gradual wearing away of solid rocks, by the action of water passing over them, is another cause constantly tending to destroy existing inequalities of the surface, and deposit the materials in beds at the bottom of the sea. In one instance on record, a torrent of hard blue lava, ejected from one of the craters near the summit of Mount Etna, had crossed the channel of the Simeto, the largest of the Sicilian rivers, and had not only occupied the channel, but crossing to the opposite side of the valley, had accumulated there in a rocky mass. The date of this eruption is supposed to be 1603; and, at any rate, it is one of the most modern of those of Mount Etna; but now, after the lapse of little more than two centuries, the river has cut a passage for itself through the lava from fifty to one hundred feet wide, and in some parts from forty to fifty feet deep.

"But the power of marine currents, and the ceaseless dash of the waves of the ocean, are much more striking in their effects than the quiet action of a river. As instances of this, the condition of the various promontories of chalk, on the south coast of England, and the opposite coast of Normandy, is too well known to require more than a passing allusion; but on the northern and more exposed shores, both of the main land and the western Islands of Scotland, this power is exhibited on an extremely grand scale. In what is called the Grind of the Navir, in the Shetland Isles, the sea is constantly widening a passage it has cut for itself, through cliffs of the hardest porphyry, tearing down huge fragments of rock, and depositing them at a considerable distance. In this way, from time to time, islands have been separated from the main land, and the islands themselves split, as it were, into shreds; until at last even these bare bones, the skeleton of what was one land, have also been swept away, the last victims to the restless violence of moving water.

"The ordinary force of marine currents is also, under some circumstances, very remarkably shown. During the erection of the well-known Bell Rock lighthouse, at the mouth of the Tay, six large blocks of granite, which had been landed on the reef of the Bell Rock at low water, were, on one occasion, removed by the force of the sea as the tide rose, and thrown over a ledge to the distance of twelve or fifteen paces; an anchor weighing about twenty-two hundred weight being, on the same occasion, thrown upon the rock.

"Along the whole of the eastern coast of England the waves are ceaselessly occupied in washing away the different projecting headlands that stretch into the sea. In various places in Yorkshire, Norfolk, and Suffolk, houses, churches, and even whole villages, are, from time to time, swallowed up, and the advance of the sea is sometimes extremely rapid. At Sherringham, in Norfolk, a house was built in 1805 at the distance of fifty yards from the cliff, which, however, has receded so rapidly, that in the year 1829, after the lapse of less than a quarter of a century, there remained only a very small garden between the house and the sea, as much as seventeen yards of cliff having been swept away in the course of the five last years only. In the harbour of the same port (Sherringham) there is now at one point a depth of twenty feet of water, where, less than fifty years ago, there stood a cliff fifty feet high; and a little further to the south, where the cliffs are composed of alternating strata of clay, gravel, loam, and sand, large tracts of land are not unfrequently swallowed up by the sea, being undermined by the waves, or by springs of water rising and penetrating between the beds. Many other extensive landslips have occurred, from time to time, on the south coast of England, and also on the western coast, where the county of Cheshire has suffered a loss of many acres of land between the Mersey and the Dee, by the gradual advance of the sea upon the abrupt low cliffs of red clay and sand."

Illustrations of Baptismal Fonts. London: Van Voorst. Parts II., III., and IV.

We were pleased with the first number of this work, but we are still more gratified with its progress. Now that ecclesiastical architecture is carried out in its details, that it is considered not enough to design the shell of a church, but it is required that its parts and its fittings should be in some degree appropriate, great convenience will be felt in having accessible manuals for study and reference. Mr. Weale has done much good in publishing so many examples of stained glass, brasses have been taken up by the Camden Society, and fonts by the present publisher. Pulpits, moreover, will be found not unworthy of notice; abroad, especially in Holland and in Belgium, many beautiful specimens of carved pulpits exist, which may be advantageously studied here. Indeed a record of the many admirable specimens of carving in wood and in metal would be highly valuable, as for instance, Grinling Gibbons' works, which, we believe, have never yet been published, though recognized on all hands as masterpieces of art. In London, especially, we have many admirable specimens of this artist, which, with the growing taste for ornament, might be advantageously studied.

Of course in a work on baptismal fonts, the delineations are the grand thing, description amounts but to little, and we are consequently restricted in our notice of the work. We can but describe its general character, which seems to be that of careful and accurate delineation, at the same time that a highly artistical effect is produced, and the result is a work valuable for reference, and ornamental in the library. We are glad to see that it is in contemplation to give a classed index at the end of the work, so that the several specimens of Norman, Early English, and Decorated may be bound together, and more conveniently referred to. The publisher has also very prudently given a list of those gentlemen who have communicated drawings, which is very long, and we regret to see includes the names of only four architects. The metropolis has only contributed one architect, and we think this, to some extent, a reflection on the profession, for it is to be supposed that in the course of their studies they must necessarily have examined the many admirable works of antiquity in their several neighbourhoods, and have formed drawings of them. This argues but little for the love of art, and zeal for diffusing knowledge, existing among the great body of architects. The amateurs far out-number the architects, and the clergy are upwards of thirty in number, showing a laudable zeal for the promotion of art, and for the honour of the edifices in which they respectively officiate. In fact, the number of ladies who have contributed drawings seems to be about as large as that of architects, while the drawings communicated by the ladies are much more numerous. This is not creditable to the architects, and we hope it will be remedied. Indeed if any charge can be rightly laid to the door of the architects we fear it is that of a want of public spirit. They are never forthcoming on any great occasion, they give nothing to the public they can avoid, and publish little of any value. The greatest jealousy exists as to communicating accounts of their works and designs, and notorious examples frequently occur of public servants setting the public voice at defiance, and refusing to submit their designs for important edifices to open and candid scrutiny. The publishers complain that the architects, though a richer body, do not subscribe adequately to professional works, but that they are beaten hollow by the engineers, in the proportion of three to one. It is also to be observed that at the Royal Institute of British Architects the greatest deficiency of original papers is evident, and the managers are obliged to get up papers on antiquities, and on books published by other people. The most valuable papers in their "Transactions" are by Professor Willis, and other laymen. Yet, under such circumstances, a morbid jealousy of the acquirements and interference of amateurs, and of the criticism of the press, exists on the part of many members of the architectural profession, when it is evident that there are small grounds for the assumption of professional superiority, and that it is of the greatest importance that the public voice should be brought to bear as an excitement to exertion. It may, too, be safely pronounced that the majority of works treating of architectural antiquities have emanated from laymen. In what other profession can such a state of affairs be found? Surely not in engineering, in medicine, at the bar, but all going unequivocally to prove a want of disposition on the part of architects to comply with their responsibilities as members of a noble and enlightened profession. We say this with no desire of offence, but because we feel the facts strongly, and are desirous of seeing a remedy applied to such a state of affairs by the vigorous exertions of the profession. The architectural profession is in a serious position, the public voice has virtually proclaimed it inefficient in the performance of its public duties, and has required a greater originality of design, and a more intellectual treatment of details. A spirit is abroad among the clergy, and among the educated and intelligent of the community, which exacts much more intellectual labour than architects have been accustomed to afford, and it becomes them to comply with the reasonable demands of the public

It should be recollected that Michael Angelo, Philibert de l'Orme, and Sir Christopher Wren, not to enumerate other names, were not originally architects by profession, and yet they have produced works, which whatever technical defects they may possess, yet by their originality they have obtained fame in all times. As it is, the movement for the restoration of Gothic architecture has been entirely extra-professional, the great zeal manifested for it now is by the clergy, and in this, as in other departments, it is but a short step from the theory of the amateur to his practical exertions. If the architects once teach the public that their professional title is but a name, farewell to all their glory, and we cannot say that such a result is either impossible or far distant. One thing is very evident, that architects, as was observed at the Institute on a recent occasion, are behind the age, and they must bestir themselves strenuously.

To return to the "Illustrations of Fonts," we are pleased to find such a long list of drawings already received, promising a valuable and extensive series, and also that the editor has formed a considerable list of fonts lying in a desecrated state, and also of those once desecrated, but now restored, the publication of which is promised in a forthcoming number. We strongly suspect that the editor is a clergyman, for the vigour and energy he displays are not characteristic of the architectural profession. We are pleased to find noticed in the numbers already published so many instances of the restoration of desecrated fonts, showing a laudable and energetic spirit on the part of the clergy. Indeed it appears that the clergy have been most earnest in affording information, whenever applied to.

The number of Norman fonts is considerable, several of them from Cornwall, which we believe are rather later in date than is generally assigned to the Norman period, for Cornwall was much behind the Saxon parts of the Island. At Keysoe, in Bedfordshire is an early English font having an ancient inscription as follows:—

" +TRESTVI :KEPARHIC IPASSERVI
PVRLEAL MEWAREL PRIEV : KE
DEVPARSA GRACEVE RREYMERCILIFACE AM.

which forms a distich running thus in modern French:—

Restez ; qui par ici passerez
Pour l'âme de Warel priez :
Que Dieu par sa grace
Vraie / or Voir } merci lui fasse. Amen."

Now we are inclined to give a different reading of the last line. It is tolerably evident that it cannot be either VRAIE or VOIR, neither agree with the sense or the orthography. The word is VEURREY, and it is probably some irregular inflexion of the verb *vouloir*, perhaps *voudra, veuillera, or veuillerait*, contracted to VEURREY. The two latter lines according to us would read—

" Que Dieu par sa grace
Voudra merci lui fasse."

A Hand-Book for Plain and Ornamental Mapping, and Engineering Drawing, used by Surveyors and Civil and Mechanical Engineers. By Benjamin P. Wilme. Part V.

We have before had occasion to allude to the utility of this work, and are glad to see that Mr. Wilme continues his labours so usefully; we must, however, remark that we do not approve of the colouring in every instance as adopted by Mr. Wilme; for example, in one of the plates, stone ashlaring is shown of a tint usually introduced for brick-work; again, we must observe, that sufficient pains have not been taken with the plate of "Signs used in Mapping," many of them are drawn very carelessly; this should not be the case with a work that is professedly to be an examplar of reference.

PROPOSED SUPPLY OF WATER AND RAILWAY AT BERLIN.

(From the Allgemeine Preuszische Zeitung.)

Since railways have been conducted through mountains and over deep valleys, proposals for gigantic works have been listened to with less doubt and astonishment. A project is now spoken of for Berlin, which, if completed, would be one of the most magnificent hitherto possessed by any capital.

It is well known that Berlin is not yet provided with water-works like London, Paris, and other cities, for the purpose of extinguishing fires, cleansing the streets and other objects. It has been found, after many enquiries, that those arrangements which have been adopted in places where nature supplies water from elevations, cannot serve as models for our flat country. Subterranean conduits are nothing more than the gradual extension of works separately undertaken and executed without regard to the future. In places where a perfect system for the supply of water has to be established at once, to its whole extent, aqueducts give a more perfect means of conduction than pipes, which always occasion a continual disturbance of the pavement of the streets. Aqueducts, however, would be too expensive for Berlin if they were not at the same time directed to another and more important purpose, viz., the introduction of railways into the city. At Paris a circular road is intended to be formed round the city, for the purpose of connecting the different lines of railway. For Berlin it is proposed to introduce, instead of a circular line of rails, a system of viaducts, passing through the centre of the town, where, by crossing each other, they will connect the termini of different roads. This mode of uniting our railways will have many advantages over the circular plan, which would interfere with the outlets from the town. Luggage cars will, by this arrangement, be dispatched between Leipzig, Breslau and the Baltic, without being unloaded at Berlin. These railways within the town will, however, besides the principal object of their adoption, supply the place of cabs and omnibusses, like the Blackwall and Greenwich railways of London;—they will connect the distant parts of the town with each other, and lessen the distance to the centre. The small stations, which will have to be constructed for each of these railways, as near the centre as possible, and to an equal height with the viaducts, and according to the models of the Blackwall, Greenwich, and Eastern Counties railways of London, will cover a considerable portion of the building expenses, as the lower parts of these structures will be used for waiting rooms, workshops, meal and corn halls, and other purposes. For the completion of this grand design, the railway viaducts will also be aqueducts, for the supply, in any direction between the different parts of the town, of high-service water for extinguishing fires, watering the streets, &c. The viaducts will rise with the common gradients of 1 in 100, or, supposing wooden rails to be employed, of 1 in 20. The required height will be gained after their entrance upon the waste lands in the town, and they will be maintained at the height necessary for the supply of the water, which will be raised by steam engines from the river or from wells. The water may be further distributed from the aqueducts through stone pipes, which, from the cheapness of the material, may be placed on both sides of the street; and as there will be little necessity for repair, there will be few occasions to interrupt the traffic. A greater width will be required for the railway viaducts than for the aqueducts, and this surplus space will save the necessity of constructing large reservoirs for the head of water, the formation of which would be very expensive in the absence of high grounds.

But Berlin, with the slight fall of its site, wants a greater quantity of water, for the purpose of cleansing its streets, than cities with a considerable descent. This will be economically supplied by using the water raised by a steam power of 1000 horse, in its descent, for the purpose of machinery in manufactures and workshops, an arrangement which we cannot now more minutely describe. Thus the intended works will unite a complete supply of water, the shortest possible connexion of the railways terminating in Berlin, an omnibus communication with the different parts of the town, and a distribution of steam power similar to the supply of gas or water.

GEOLOGICAL SUBMARINE RESEARCHES.

At the Royal Institution, Feb. 23, Professor Forbes gave a lecture *"On the light thrown on Geology by Submarine Researches."* Having alluded to the researches of two Italian naturalists, Donati and Soldani, who dredged the Adriatic about the middle of the last century, Prof. Forbes entered on the important inferences which he had derived from similar investigations in the Irish Channel, and in the Archipelago. His first conclusion was, that marine animals and plants are grouped, according to their species, at particular depths in the sea, each species having a range of depth appropriated to itself. Prof. Forbes illustrated this assertion by a diagram, indicating the plants and animals respectively inhabiting what he termed the *littoral* zone, which extends immediately from the coast—the *laminarian* zone, where the broad-leaved fuci are most abundant—the *coralline*, in which there is an assemblage of mollusca, especially bivalves and corals, and the *deep sea coral*, so called because in it only we find examples of large corals on the British shores. Prof. Forbes next alluded to the fact of the number of species diminishing according to depth, so that by gaining an accurate knowledge of the Fauna and Flora, appropriated to various sea-bottoms, the naturalists can infer their depth—no plants are found below 100 fathoms, and the probable zero of animal life is at 300 fathoms. Sedimentary deposits below this depth are consequently destitute of organic matter. This circumstance bids the geologist to be cautious in inferring that any stratum was formed before the creation of animals, on no other account than that it is devoid of organic remains: he should rather conclude from such deficiency, that the stratum was deposited in very deep water—Prof. Forbes next remarked that British species are found throughout the zones of depth in the Mediterranean Sea; but that in that sea, the proportion of northern testacea in the lower zones greatly exceeds that in the upper, so that there is a representation of climates, or parallels of latitude, in depth. The fourth proposition advanced by the Professor, was, that all varieties of sea-bottom are not equally capable of maintaining animal life. The sandy parts are usually the desert ones. Hence the scarcity of fossils in sand-stone: though traces of worms (which inhabit the sand) are found in ancient sand-stones. As each animal is not able to live, except on its own locality, those marine animals, as the scallop, which are gregarious, deteriorating the ground when they increase beyond a certain extent, die; then the place becomes silted up, the ground changes, and another race occupies it. This fact explains the phenomena of distribution of organic remains in rocks—*i. e.* their being grouped together in separate strata, fossilliferous strata alternating with those which are free from organic remains.—Prof. Forbes proceeded to observe, that such animals as are common to many zones of depth, are those which have the greatest horizontal range in space, and are generally those which are present in the tertiary deposits; and thus it is that the most generally-distributed fossils are such as are found in the greatest number of formations; because these are necessarily the most independent of destroying influences. But, on the other hand, as the elevation or depression of strata to a very small extent would destroy the species peculiar to any zone, or to the zone above or beneath it, it becomes an important inquiry how this destruction is compensated. In dealing with this question, Prof. Forbes announced a most important law in zoology, one altogether new to ourselves—viz. *That the mollusca migrate.* He discovered by his own observation, that this is the case even with the limpets, the most fixed of all species. This migration occurs in their egg-state, when the ova are strung together, and floated over the ocean, from shore to shore. In the larva state they are swimmers. In fact, they commence their life in a form closely analogous to that which is permanent among the pteropods. But, though in this state they can live in any zone, they cannot arrive at perfection except in the peculiar zone to which they are adapted. This accounts for the very imperfect shells of prematurely dying mollusca being found at a low depth. Professor Forbes concluded his communication by noticing its bearings on the views of the most eminent geologists of our time. 1st. With regard to Mr. Lyell's principle of distinguishing tertiary strata by the per-centage of recent species in each. This is confirmed by Prof. Forbes's investigations; only in using Mr. Lyell's criterion, the element of depth, which gives climatal character in living animals, must be taken into account. 2nd. Prof. Forbes next noticed that Sir H. De la Beche had hypothetically anticipated, what his researches established, the representations of climates and depth, ten years ago. 3rd. He lastly ascribed to Viscount d'Archiac and M. de Verneuil, the credit of having announced (what he had observed and mentioned in the course of his communication) that species which are found in a great number of localities, and in very distant countries, are always those which have lived during the formation of several successive systems.

SULPHATE OF BARYTES.

A correspondent of the *Athenæum* observes that there is a beautiful white' as all artists know, made from the earth called Barytes. The pigment is called "constant" or "permanent white." If the "quick," or "setting," properties of lime, are not essential to the art of fresco painting, or stuccos and washes in house decoration, I would suggest the use of the sulphate of barytes instead. It is, in itself, a most brilliant white, and from the experience of artists, is known to mix with most colours, without altering their properties. It may not be generally known, that this earth (in the sulphates) is found in large veins in different parts of the county of Montgomery, and is thrown out in large quantities by the miners in the lead mines. It is found, also, in Shropshire (bordering on Montgomeryshire) in the hills called Stiperstones, in a mine called Snailback. It is a mineral which was considered of little use in the county of Montgomery till the last few years, when a person, of the name of Maguiness, rented a vein of the sulphate of barytes, and converted old flour mills, at Pool Quay, (in Welshpool) into mills for grinding this beautiful mineral, which is of a dazzling white when ground. It is put in barrels, and shipped in great quantities for America, where it is used in the composition of china. This sulphate of barytes is indestructible, uninfluenced by damp, foul air, time or light, and seems to be a substance, both from its durability and extreme beauty, peculiarly fitted for house decorations, when the vehicle is not oil. The carbonate of barytes is, as all chemists know, of a most poisonous nature, but the sulphate, being insoluble, is perfectly harmless. It has been used, since Mr. Wedgewood first applied it, in the composition of china, but it seems a pity that such a beautiful substance should be applied solely to that use and the pigment used by artists, if it can be applied more generally in paintings, where water and size are the vehicles, and in house decorations. The New Houses of Parliament will afford scope for its use, if these suggestions prove practicable.

The annual exhibition of the works of art was opened at Paris on Friday the 15th instant. The catalogue comprises 2423 articles, or 826 more than in 1843—namely, 1808 paintings and pictures, 348 miniatures, water colours, paintings on porcelain, &c.; 24 works of architecture, 133 of sculpture, 89 engravings, and 21 lithographs.

ST. STEPHEN'S CATHEDRAL, VIENNA.

In the *Journal* of last January we gave an abstract of a paper by Mr. Higgins, read at the Royal Institute of British Architects, on the recent restoration of the spire of St. Stephen, at Vienna *(the Dom-Kirche)*, respecting which a correspondent of the *Athenæum* has forwarded the following communication:—

"As some recent interest about the *Dom-Kirche* of Vienna seems to have been created among both your readers and writers, perhaps a few notes, taken on the spot, and before the 'cast-iron' restoration, will prove acceptable also; they pretend to no other merit than those advantages may give them, for I had no intention of printing my pocket-book, when filling it with such brief, hurried, and meagre memoranda. The Great Tower of St. Stephen's is steeple-capt, very high and noble, but the top leans much from its original position; it is carried up by canopies and pinnacles, the former on an outer plane of decoration, like net-work hung over the spire itself: the crocketting (as usual throughout German Gothic) is inelegant, has a *larded* look, and reminds one of holdfasts instead of ornaments. *Mem.* crockets should never appear stuck on but growing out of, what supports them. The west front is Lombardesque in character, being decorated with small animals—a phase of Byzantine, or rather Romanesque; its portal (the 'Giant's Gate') consists of several round-headed arches under a pointed one, but this last perhaps altered from circular, and all sustained by slender columns, which, as well as the superincumbent arches, are wrought over with lozenge reticulation, or platted over with reeds, not with zigzag nor any other peculiar Norman or Saxon embellisment. The east end has a double apse, one part of which forms the choir, and both parts are polygonal in ground plan. The choir is battlemented with trefoil arcs, the nave with a parapet of flowing open-work. Buttresses run *through* the cornice quite round the church, and rise into crocketted pinnacles, many of which are now deficient. The nave has several gables on its sides, now filled up, except one of beautiful tracery. The roof is tiled in lozenges and letters, made by diversified colours—another German techtonic fashion that should become English too, as our monotonous red roofs present the ugliest bird's-eye view possible. Correspondent to the great steeple-tower at S.E. stands an intended but unfinished duplicate at N.W.; besides these there are two smaller towers, octagon, and set over gable ends, which appear on the west front. North and south of these towers run the aisles, exhibiting a much more modern character, as the towers themselves have a Normanesque air. Thus two lines of corbelling (a table supported by trefoil arcs with bosses for corbel-heads) adorn the lowermost story, while above these are three plainer lines (the common Norman table on small arcs without any heads beneath them). Outside the church, at its base, some curious tombs, like rectangular mantel-pieces of reeded mouldings, which another triad of reeds, but curvilinear, interpenetrates, where it meets their jambs and crosses, arch-wise or *rhumb*-wise, their lintels. Interpenetration could not well push its preposterous ingenuity further; Nuremburg doorways often present similar examples of it—to be avoided. St. Stephen's Cathedral is neither whitewashed nor painted within, but impressive from gloom, and the fine, soft chiaroscuro produced by darkness stamping itself in visible masses upon the grey columns and walls, yet leaving portions of both to dawn here and there through it. Sundry additions of varied Gothic, such as chapels, screens, &c. enrich the effect. Transept narrow and short; chancel of deep-tinted wood, well carved, and harmonizes well with the edifice, both as respects character and colour. The columns all massive, composed of numerous rounds and hollows, rise picturesquely from altars at their basement (*these*, however, are low-classic). Except in the choir, whose nave and aisles have the same height, this church does not bear out Mr. Whewell's assertion that it exemplifies a late system of Gothic vaulting, for the nave is highest elsewhere, though but by a little; generally, the interior has neither the elevation, lightness, nor openness he attributes to edifices thus constructed; it has his last characteristic indeed—absence of a clerestory. The choir exhibits plain diagonal ribs on its roof, all the rest of the church complex intersections. With regard to the windows they *had* mixed geometrical and flowing traceries; those in the body have now modern sashes and square panes: those in the side chapels of the apses are mostly built up, but some retain their old rich painted glass, very splendid, yet very sombre."

THE ISTHMUS OF PANAMA.

Mr. Wheelwright lately read a paper at the Geographical Society showing how an easy line of communication might be made between the Atlantic and Pacific Oceans, over the Isthmus of Panama.

Mr. Wheelwright, from his long residence in that part of the world, was perfectly acquainted with the country. After discussing some of the routes that had been proposed as lines of communication, whether by canal or otherwise, between the Atlantic and Pacific, Mr. Wheelwright gives the decided preference to the line between Chagres and Panama, the line in fact which had been explored and described by Colonel Lloyd. The Chagres river cannot easily be ascended by sailing vessels for various reasons, but properly constructed steamers of six or seven hundred tons burden may cross the bar to ascend as far as the confluence of the Trinidad, at all times and seasons. From a height, at the junction of the Trinidad, the line pointed out by Lloyd is distinctly seen to be free from any continuous heights, and from another elevation at Gorgona, on the Chagres, the line, which runs about five miles to the westward of the latter town, is again seen to be uninterrupted but by small isolated hills. The road from Gorgona to Panama, good in the dry season, is muddy after the rains, though always practicable, and an omnibus might be driven along it by merely clearing away the trees. This road passes over the head waters of streams flowing into the two oceans, and such is the level, that the traveller cannot perceive any division between them. The level nature of the ground thus established, Mr. Wheelwright is of opinion that, whatever ulterior plan may be decided upon, a road should first be constructed as near the level line as possible, both with a view to future labours, which such a road would great facilitate, and for the purpose of an immediate intercourse between the two oceans. This road should commence at the junction of the Trinidad with Chagres, to which place the steamers would ascend without stopping at Chagres: thus no risk from climate would be incurred, and the whole detention on the Isthmus would not exceed a few hours—goods could be transported with celerity and easily at a trifling expense. Excellent timber, and a most useful liana are abundant, as are also provisions, which are cheap: labour is likewise cheap, and coal, when wanted, is found in great abundance, and of good quality, extending across the Isthmus from Boca del Toro to St. David.

RAILWAYS.

RESOLUTIONS ORDERED BY THE HOUSE OF COMMONS TO BE PRINTED, MARCH 4, 1844.

Ordered, 1. That in each case where bills are now pending to authorize the construction of new lines of railway, competing with one another, such bills be respectively referred to one committee.

2. That the committees for the consideration of such bills be specially constituted.

3. That bills now pending to authorize the construction of new lines of railway, which will compete with existing railways, be in like manner referred to committees specially constituted.

4. That such committees be composed of five members, to be nominated by the Committee of Selection, who shall sign a declaration that their constituents have no local interest, and that they themselves have no personal interest, in the bill or bills referred to them, and that they will not vote on any question which may arise without having duly heard and attended to the evidence relating thereto; and that three shall be a quorum.

5. That a select committee be appointed to consider which of the pending railway bills shall be deemed competing bills, according to the foregoing resolutions.

6. That such select committee be composed of five members, of whom three shall be a quorum, and that the committee have power to send for persons, papers, and records.

7. That such of the standing orders as relate to the composition of the committees on private bills and the orders consequent thereon, be suspended, so far as regards competing railway bills pending in the course of the present session.

J. H. LEY, Cl. Dom. Com.

CARRINGTON BRIDGE, NOTTINGHAM.

SIR,—In your last paper, No. 84, page 90, there are some observations on this bridge referring to the flatness of the arch in the cast iron ribs, which have a versed sine of 5 ft. in a span of 70 = 1 in 14; the arch is stated, by the writer, to be the flattest he is aware of.

I beg, therefore, to inquire of you, or such of your readers as may be able to answer the question, what is the span and versed sine of the cast iron bridge over the river at Boston, Lincolnshire. It is now upwards of 30 years since I saw it, but (judging only from memory of the latter, and from the drawing given in your *Journal* of the former) I think Boston bridge must be the flatter of the two, but I believe it it not so large a span. But of Boston bridge some of the ribs were fractured when I saw it, and when I fancy it had not been long erected.

I am, Sir, your obedient servant,
A SUBSCRIBER.

March 2, 1844.

STEAM NAVIGATION.

Mr. Blake, the master builder at Portsmouth Dock-yard, is ordered by the Admiralty to prepare plans for constructing another 50-gun frigate, of the same tonnage (2,000) and dimensions as that already ordered to be laid down here. They are to be named the *Leander* and *Shannon*.

The *Prometheus* steamer, Lieutenant Pasco, arrived at Devonport on the 11th March, from her voyage with the *Penelope*. She was disabled in one of her boilers before she reached Madeira, where she remained six days. Soon after she left Madeira for this port her other boiler became damaged. On the 17th March she arrived at Portsmouth. She will proceed to Woolwich to be repaired.

The *Vulture* first class steam-frigate was undocked at Sheerness on the 13th March, and now remains in the basin.

The *Dædalus*, 42, a frigate of the old school, same dimensions as the *Penelope*, was ordered from Sheerness to Woolwich to be cut down to a flush-deck corvette, to mount 18 32-pounders, of 56 cwt.

The *Penelope*, 22, Captain W. Jones, left Lisbon on the 5th March for the coast of Africa. Every letter received from her officers and crew brings fresh complaints of the miserable discomforts experienced by them, and pronounces her an utter failure as a first-rate steam frigate.

The coating of the bottom of the *Shannon* frigate, at Sheerness, with the marine glue is just completed.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

March 4.—WILLIAM TITE, Esq., V.P., in the chair.

A paper was read "*On the Architectural Nomenclature of the Middle Ages,*" by the Rev. R. WILLIS. This paper is a portion of a work on which Professor Willis has been for some time engaged, and in which he proposes to ascertain the architectural terms of the middle ages, and to trace the origin of many technical words in use at the present day. The Itinerary of William of Worcester contains many examples of such terms as were in use in the fifteenth century, especially in a detailed description of the churches of St. Stephen and St. Mary Redcliff, at Bristol—but although this document has long been in print, nobody hitherto appears to have thought of comparing the descriptions with the existing buildings—a process to which they have been submitted by Professor Willis with satisfactory results, the coincidence being found perfect. By this means, the names of several mouldings have been fixed beyond a doubt. With regard to the terms applied to the members of classical architecture in the present day, few are found of classical origin in any language in Europe, the architects and writers of the Renaissance having generally applied the terms in common use, with the exception of Alberti, who affected to call everything by a new name, and invented for himself a Latin nomenclature which has never been adopted. Of the Vitruvian terms, few have been retained, since his early translators, being for the most part practical men, and writing for practical men, having naturally made use of their own mediæval words, applying them to the classical mouldings. In fact, the names of mouldings to be picked out of Vitruvius, who has not written expressly on the subject, are neither complete nor very intelligible, and a distinction is to be made between the names he applies to mouldings derived from their form, and those which are due to their place or mode of combination. These terms Professor Willis calls the *sectional* and *functional* names, and much obscurity has rested upon the words used by Vitruvius from inattention to this point. The nomenclature in use in England at the present day is of a very mixed character, and has arisen from the different media, Italian, French, or Dutch, through which a knowledge of the great masters reached us during the seventeenth century.

March 18.—E. B. LAMB, Esq., in the Chair.

The following papers were read—

1. "*Some observations connected with Hampton Court Bridge, and the adjacent parts of the River Thames,*" by C. PARKER, Esq., Fellow. It appears, that as late as the year 1750 there was no communication between Hampton Court and the opposite bank, except by a ferry; for we learn, by an act of parliament about that date, that J. Clark, who possessed the manor of East Moulsey (from the reign of Charles II.) was empowered to erect a bridge across the river, from East Moulsey to Hampton Court. The bridge was erected from the designs of S. Stephens, by B. Ludgator, and was opened in December, 1753. That bridge, however, did remain up long; for having been built too slight to stand, or to resist the concussion of the passing craft, it was subsequently taken down. On its removal, the present bridge was erected, and although it has been repaired several times, the original form of its construction is still preserved. It is built of oak, supported by ten piers of the same material; the length is about 350 feet, and the breadth 18 feet. In 1841, it appeared that material alterations had been made in the current of the river, by the construction of Moulsey Lock, about the year 1817, and subsequently (about 1833) the construction of two wooden embankments, projecting from the north bank of the river, by which the width of the stream was reduced one-half. These obstructions had caused such an alteration in the direction of the current and the rapidity of the stream, as to occasion, not only a disruption of the banks and the bed of the river, but likewise much injury to the bridge itself, from the craft being frequently driven with violence against the piers. Extensive repairs were in consequence found necessary. The main piles were strengthened

with additional ones, the decayed portions were removed, and the whole bound together with wrought-iron chain-bars. Proper precautions were taken to retain the chalk in the piers, and the gravel of the platform was reduced in thickness 18 inches, in order to lighten the superincumbent weight; and the structure, though still presenting a somewhat disjointed and sunken appearance, is now firm and compact.

2. "*On the Chancel of Ringwood Church, Hants*," by Mr. F. J. Francis. This chancel, 50 feet long and 22 feet broad, is (as appeared from the drawings exhibited) a fine specimen of the early pointed style; and, although, like the rest of the church, it has suffered from continued neglect, spoliation, and bad taste, enough remains to prove, that the ancient builders had bestowed on it no ordinary portion of ingenuity and skill. The peculiar feature is the number of windows which it contains, there being a series of eight lofty, narrow lancet windows on each side, with deep splays, some of which bear traces of painted decorations, with a fine triple lancet at the east end, making a total of nineteen. The peculiar features of the style are well carried out in all the details. The caps and bases of the slender Purbeck pillars, which separate the splays of the window at the east end, are in the purest taste; indications of similar pillars are to be found between the windows on the north and south side.

THE ROYAL SCOTTISH SOCIETY OF ARTS.

February 12.—Professor Traill, M.D., F.R.S.E., President in the chair.

The following communications were made:—

1. (Part II.) *Observations on, and Improvements proposed in, the Ventilating and Warming of Factories.* By Robert Ritchie, Esq., C.E. Mr. Ritchie continued his exposition of the modes in use for warming and ventilating factories. He showed the diversity of opinion which exists on the subject of ventilation, some being in favour of an *upward*, and others in favour of *downward*, withdrawal of the vitiated air. He also showed, from the opinions of many scientific men, the advantages, as regards salubrity, to be derived from not separating the *ventilating* from the *warming* process, &c.

2. *Account of a Cheap and Portable Self-Register-Tide-Gauge.* Invented by John Wood, Esq., of Port-Glasgow. Communicated by John Scott Russell, M.A., F.R.S.E., C.E. One of these tide-gauges and examples of its work were shown. This is a very beautiful, simple, cheap, and portable tide-gauge. It can be packed in a box of about two feet square, costs about 2*l.* only, and registers by a pencil on a cylinder of paper the total rise and fall of the tide for a month at a time. By a simple addition, costing only 20*s.* more, where there is a clock at hand, it can be made to register the state of the tide at every period of time. The machine was much admired for its simplicity and cheapness, and was referred to a committee.

3. *On the Naphtha or Camphine Lamp, and its expense compared with other sources of Light.* By Andrew Fyfe, M.D., F.R.S.E. The lamp was exhibited. After describing the construction of the lamp, Dr. Fyfe alluded to the nature of the oil used, which he said seemed to be a preparation of turpentine, if not turpentine itself, and then afterwards to the comparative expense. From different trials he had made, comparing its light with that of gas, he found that the expense would be as about three to one, compared to that of an equal light from the gas as supplied to Edinburgh. Of course, if the gas were more expensive, or the quality inferior, then the comparative expense of the lamp would be less. As compared to lamps with common oil, the expense was as about three to five for whale oil, and as about three to eight for sperm oil. Accordingly, though the lamp was more expensive than gas, yet, in those places where gas could not be got, the lamp was much more economical than lamps with sperm or even with common oil.

4. *Account and Description of a Self-Registering Dynamometric Apparatus*, constructed in Paris for the Hydraulic Experiments of Mr. Scott Russell, by M. Morin, Chef de Bataillon of Artillery. With diagrams of its work, and some account of its results. By Mr. Scott Russell. The apparatus was exhibited. It is a very scientific and expensive apparatus, requiring the greatest care in its construction, as the springs, on bending, show on the register equal strains in equal spaces traversed by the pencil. It is particularly useful in hydraulic and railway experiments, registering correctly the strains and forces at all parts of the voyage or journey. It has several very beautiful adaptations and adjustments, and requires little attention from the engineer observing. The whole work is carefully recorded on a roll of paper which is taken off and preserved at the end of the journey.

5. *Autographic Apparatus for obtaining accurate Drawings of the Forms of Surfaces or Double Curvature;* with Autographic Projections and Drawings, illustrated by Practical Examples. By Mr. Scott Russell. Referred to a Committee.

February 26.—Mungo Ponton, Esq., F.R.S.E., in the Chair.

The following communications were made:—

1. (Part III.) Observations on, and Improvements proposed in the *Ventilating and Warming of Factories.* By Robert Ritchie, Esq., F.R.S.S.A., Civil Engineer, Edinburgh. In this part of his paper Mr, Ritchie stated the general principles upon which all approved modes of warming and ventilation must proceed; and in particular the combination of the two, so that the air of the chamber shall not only be warmed, but a constant influx of pure warm air, and the extraction of the vitiated air, shall be effectually secured, in order that the health of the operatives in large factories may be promoted.

2. Description, with a Drawing, of a *new Method of constructing the Dwellings of the Poorer Classes,* in order to ensure a more comfortable home, and better ventilation. By Mr. Anthony Bower. In this paper it is proposed to construct the dwellings of cast-iron as being cheaper than stone or brick, and to ventilate them by a common double concentric shaft or chimney, into the centre portion of which the fire flues are carried, and into the outer portion are carried the ventilation flues—the beams supporting the floors being cast hollow, and the ventilation going on through them. He proposes to make the tops of the houses flat, to allow of drying clothes thereon, and he collects the rain water in cisterns at the roofs for washing the clothes.

3. Description and Drawing of a Water-Meter. By William Fraser.

4. On a *Reversing Locomotive Steam-Engine*, with Reversing Box, and Pivot Valve. By Mr. Daniel Erskine. A Working Model in German Silver was exhibited in action. This was a very beautiful application of Mr. Erskine's reversing box and pivot valve to the locomotive steam-engine. The reversing was performed in the most simple and instantaneous manner, by moving a handle. The model was exceedingly well executed by Mr. Erskine's own hands, and did its duty well, either on a straight or circular railway.

ROYAL INSTITUTION.

March 1.—Mr. Fownes delivered a lecture "*On the Chemical History of Sugar.*"—After a slight description of the properties and distinctive characters of the more important of the sweet principles of the vegetable kingdom, the lecturer proceeded to discuss the subject of the practical manufacture of raw and refined sugar from the juice of the cane. The sugar-cane itself, originally a native of India or China, was introduced into Sicily, by the way of Egypt and Syria, at a period antecedent to the Crusades. It was carried, in 1420, by the Portuguese to Madeira, and subsequently, by the same people and the Spaniards, to Brazil and to the West India Islands. The process of sugar making in the British West India colonies has probably undergone but little change for two centuries or more, except in the improvement of the machinery for crushing the ripe canes and extracting the juice. he tempering with lime, clarifying by heat, and quick evaporation in a series of open pans, still remain. Under the most favourable circumstances a large quantity of molasses is always produced; and as we know from the experiments of M. Peligot that nothing but crystallizable sugar exists in the juice of the cane, this production of treacle must be ascribed to an alteration of the sugar from the high temperature of the liquid in the open pans towards the termination of the boiling. The excellent plan now adopted by the refiners of the raw or Muscovado sugar, for concentrating their purified and bleached syrup by evaporation in vessels from which the air is exhausted, patented in 1813 by the Hon. C. E. Howard, was then described and illustrated, and its adoption in the sugar islands, for concentrating to the necessary degree the clarified cane juice, strongly recommended. Under this system the product of sugar would be greatly increased, and its quality much improved, while little uncrystallizable syrup would be produced. This is, however, but a part, although an essential one, of the improvement of which the sugar cultivation and manufacture are susceptible. The East India sugars are made in part from the juice of a palm; the crude product, or *jaggery*, is subjected to a kind of refining process before exportation. These sugars are softer and less crystalline, and inferior in sweetness to those of the West Indies. The cause of the latter fact is to be sought for in the quantity of *grape sugar* they contain, which, indeed, is found more or less in every sample of raw sugar, having been produced in the first boiling at the expense of the crystallizable portion. For the purpose of detecting the presence of the grape sugar recourse may be had to a beautiful experiment of Trommer, described in the "Annalen der Chemie und Pharmacie," for 1841, p. 360. The sugar to be examined is dissolved in water, mixed with a solution of sulphate of copper, and then a large excess of caustic potash added. The blue precipitate at first thrown down is re-dissolved with intense purplish-blue colour by the excess of alkali. So far, both cane and grape-sugar behave alike; but on heating the liquid to the boiling point, the cane sugar solution undergoes but little change, while that containing the grape sugar yields a copious precipitate of brilliant red suboxide of copper. It was suggested that this experiment might possibly be put into a form applicable to the *assay* of sugars, in which the proportion of grape sugar—that is, worthless sugar—should be inferred from the quantity of suboxide of copper produced from a given weight of the sample. The cheaper kinds of raw sugar, chiefly consumed by the poor, are sometimes cruelly adulterated by an intentional admixture of grape sugar, manufactured on a large scale for the purpose from potato-starch. This is a fraud which should be suppressed.

INSTITUTION OF CIVIL ENGINEERS.

March 5.—The President in the Chair.

The first paper read was a description by Mr. J. T. Syme, *of the bridge over the river Whitadder, at Allanton.* This bridge, which was executed at he expense of Miss Boswall, of Blackadder, from the designs of Messrs.

Stevenson & Sons, of Edinburgh, consists of two arches of 75 ft. span each, with a versed sine of 11 ft. 6 in., the centre pier being 32 ft. 1 in. long and 10 ft. in breadth, making the distance between the faces of the abutments 160 ft.; it was constructed of soft red sandstone, and the abutments were built up solid, the greater part of the masonry being ashlar; the total cost of the bridge was stated to be £6058.

An account of the building of *Wellington Bridge, over the river Aire*, at Leeds, by Mr. J. Temperley, was also read. This bridge was executed from the designs of the late Mr. Rennie about 20 years since; it crosses the river where it is 100 ft. wide and 6 ft. deep; it consists of a segmental arch of 100 ft. span, with a versed sine of 15 ft., constructed of stone from the quarries of Bramley Fall, which are about four miles from the bridge; the abutments are built in radiating courses, external faces, which are horizontal, the whole being well bonded together: the total quantity of masonry is 80,000 cubic feet. The method of forming the foundations, as well as of the coffer-dams, and centre was given in detail, and it was stated that the total cost of the bridge was only £7250.

Mr. G. Rennie made some clear and consise remarks on the ancient arches, of which traces have been discovered, by the recent researches of travellers; alluding to Perring's account of ancient arches discovered at Thebes, the bricks of which bore the name of Sesostris, which would carry back the knowledge of the arch to a period of upwards of 3000 years. He noticed also the size of the stone lintel among the Greeks—the etruscan arches found in Italy, and also the more modern but very bold arches still remaining in Italy, Portugal and Spain.

A paper by Mr. F. Nash was then read describing *a new kind of girder*, composed of a number of diagonal bars of wrought iron abutting against each other, with cast iron transoms; these latter supporting the pressure and the former the tension. This mode of construction has been recently introduced in France; and the paper after describing a number of preliminary experiments on small girders, gave the details of the proofs, to which four girders placed side by side with a bearing of 74 ft. 8 in. had been subjected, by order of Mons. Teste, the Minister of Public Works, Paris. From this it appeared, that with a load of 62 tons, the deflexion in the centre was $1\frac{3}{16}$ in., and that the girders resumed their original position on the weight being removed, after bearing it for a month. In order to test the effect of a sudden shock, a cart loaded with $4\frac{1}{2}$ tons of iron was caused to break down suddenly in the centre of the bridge, without producing any prejudicial effect beyond crushing the flooring planks. The weight of these four girders was stated to be $20\frac{1}{4}$ tons.

March 12.—The President in the Chair.

The discussion upon the knowledge of the properties of the arch possessed by the ancients was renewed, on the presentation by Mr. Page of drawings of two arches standing near some Cyclopæan remains at Cape Crio, (Cnidus). There was no positive evidence of the date of these arches, but from their being built without mortar, and the massiveness of their construction, it was agreed that they were probably of the same period as the Cyclopæan work among which they were situated.

The failure of the *Pont de Boverie, at Liège*, which sunk so much and cracked on the piers to such an extent as to oblige it to be taken down, was fully explained by Mr. Rennie, who presented a drawing of it. Mr. B. Green also exhibited a design for the proposed stone bridge of eight circular arches for connecting Gateshead with Newcastle-upon-Tyne, at a high level. He also exhibited some beautiful specimens of ornamental bricks, made by Mr. Barnes, of Newcastle.

The first paper read was an "*Account of the harbour of Pulteney Town*," (Wick, Caithness, N. B.) This harbour, which was designed by Mr. Telford for the British Fisheries Society in 1803, and for which the first part of the works was executed between 1865 and 1811, by Mr. Burn, at an expense of £16,400. The success of the herring fishery, and the consequent increase of the shipping frequenting the port, rendered a more extensive harbour essential, and in 1823, other plans, which received the approval of Mr. Telford, were carried into effect by Mr. Bremner. The various extensions of the works were given in great detail, with the ingenious methods employed in their execution, as also the account of the devastation caused by the sudden inroad of the sea upon the unfinished work of the pier, when 100 ft. in length of the pier head was swept away in one tide, besides doing much damage to the other parts of the works. The ruined works were secured for the remainder of that year by binding them together with chain cables, and in the succeeding summer the works were completed, and have stood so ever since. Some interesting observations were made as to the relative action of the waves upon long and short slopes of the sea faces of piers, and the author's experience evidently leads him to prefer a slope of about one to one for works which are exposed to a heavy sea.

The various ingenious methods adopted by the author for conquering the difficulties before him, excited great interest, which was kept up by the next paper, also by Mr. Bremner; it was a "*Description of casks used in floating large stones for building sea walls in deep water.*" These casks, which were strongly built of fir staves, hooped externally with iron, and supported inside by radiating bars, like the spokes of a wheel, were used instead of crane barges, for conveying stones of 30 to 40 tons weight, for securing the foot of the sea walls of Banff Harbour, which had failed. Two of these casks, of 445 ft. cube each, were used to convey stones of 30 tons weight, by passing the two chain cables, which were wound round them, through the eyes of the leweses which were fixed in the stone at low water, at which time the chains being hauled down tight, when the tide flowed, the buoyancy of the casks floated the stones, and they were towed by a boat over the place where the stone was to be deposited—the lashing being cut away, the casks were let go, and the stone fell into its seat. This method was found to succeed perfectly in weather that would have destroyed any crane barges, and the works of Banff Harbour were thus secured from further degradation, and were subsequently entirely restored at a comparatively small cost. The drawings and enlarged diagrams gave fully the details of this method of working.

A model of Farani's railway switch was exhibited, and its self-acting motion, in guiding the carriages into the sidings or on the main lines, as required, was shown by the inventor. These switches were stated to have been used on the Grand Junction Railway for some considerable time.

March 19.—The President in the Chair.

In the recapitulation of the conversation of the meeting of March 12th, there were read some interesting remarks by Colonel Leafe, on the knowledge possessed by the Greeks of the properties of the arch: he contended that numerous examples still existed of their having used it, but from the solidity of their constructions, the nature of the materials they employed, and the architectural character of the edifices, which were chiefly temples, the arch was evidently less employed than among the Romans, who used different and less solid materials.

A description was then read "*of the formation of the Town-lands of Musselburgh, on the Firth of Forth*," by Mr. James Hay. This was a curious instance of an extensive tract of nearly 400 acres of land, being formed by an alluvial deposit, in about 300 years. The river Esk, when swollen by rain, is stated to bring down quantities of the detritus from the hills, which, with the soil washed from the banks of the low lands, is arrested when it meets the tide, and is thrown upon the beach; this, being mingled with large boulder stones, become fixed; the sand is blown over it by the heavy north winds, to which the shore is exposed, and thus this large tract has been formed. The diagrams showed the several lines of high water at various dates, and that nearly the entire town is built upon land thus recovered from the sea without the aid of art.

The next paper read was "*a description of an hydraulic traversing frame at the Bristol terminus of the Great Western Railway*, by Mr. A. J. Dodson, Assoc. Inst. C.E. The action of this machine, the object of which is to transport the railway carriages from the arrival side of the terminus, to the departure side, or to any one of several intermediate lines, was thus described: an opening being made in the train, the apparatus is pushed on to the line of rails, and the carriage required to be moved, is run over it when the frame is quite down, it being then sufficiently low to allow the carriages to pass freely over. As soon as the carriage is brought directly over the apparatus, a man works a pump, acting upon four hydraulic presses, which raise the frame until both sides are in contact with the axles of the carriage wheels, and raise the flanges of the wheel clear of the rails; the whole apparatus, with the carriage suspended upon it, is then easily transported to any of the lines of rails, when, by unscrewing a stopper, which allows the water to flow back from the presses into its cistern, the carriage is lowered on to the rails, and the apparatus is rolled over ready for re-commencing the operation, the whole transit not having occupied more than one minute and a half. The action of the apparatus (which was made by Mr. Napier, York Road) was stated to be very satisfactory, and its cost to have been about £220.

An account was then read *of the Landslip in the Ashley cutting on the Great Western Railway*, by Mr. J. G. Thomson, Grad. Inst. C.E. The cutting, which was described, is situated about five miles on the London side of Bath; it was made through a mass of detritus from the neighbouring highlands, consisting of sand, oolitic gravel, vegetable matter, and stones of the great oolite, lying upon the blue lias clay and marl. The whole district was extraordinarily full of water, and appeared to have defied all attempts to drain it; this accumulation of water softened the clay, turning portions into soft silt, and when, by cutting away a portion of the foot, which was situated on a slope, the support was taken away, the whole mass was set in motion, and every attempt to resist it was fruitless. The details of the attempts at driving water headings, sinking pits, which collapsed and were obliged to be filled up with stones and fagots, and all the other engineering devices that were adopted, were given with great minuteness, and when being aided by some well executed drawings, gave an interesting account of a good specimen of one of the difficulties to be encountered by the railway engineer, in the ordinary course of his labours.

The paper was an example of that which has been so frequently insisted upon at the meetings of the Institution, namely, the advantage to the civil engineer of a knowledge of geology, by which his progress would be safely made under such circumstances.

March 26.—The PRESIDENT in the Chair.

The paper read was by Mr. C. H. Gregory, engineer of the London and Croydon Railway; it treated of "railway cuttings and embankments, with an account of some 'slips' in the London clay." An outline was given of the general principles which regulate the formation of railway cuttings and embankments, illustrating the manner in which these works are affected by the geological character of the earths employed, or that were cut through. The paper then gave a detailed history of some heavy slips in the London clay, which had occurred under the observation of the author, on the London and Croydon Railway, and described the means adopted for clearing the railway from the immense masses of clay with which it was covered, to a depth of 10 to 12 feet, and for enabling the passenger trains to run without hindrance, during the time of repairing the damage. The cause of these slips was then fully considered, and it appeared evident that in nearly every case they proceeded from the combined action of air and water, the latter entering in rainy seasons by the cracks formed by the drying action of the former, until the mass of upper yellow clay being detached, moved by its own weight, and sliding upon the blue clay, the surface of which was rendered semi-fluid by the percolated water, was precipitated into the cutting. The means adopted for preventing the recurrence of such events were fully considered, particularly the introduction of gravel buttresses and rivetments through and at the foot of the slips, a system which had been perfectly successful.

In the discussion which ensued the means adopted were generally approved; many instances were given of the use of similar gravel buttresses on other railways; the importance of extensive surface drainage and of freeing from water the slopes and embankments, was insisted on; the interesting question of the 'creep,' or presumed rising of the floor of old mines was examined, and it was contended that, in almost all cases, it was the roof, or upper rocks that sunk down. The case of the village of Wallsend was instanced, which place had been sunk vertically between 16 and 24 inches, in consequence of the excavation of the coal from beneath it, by the mines under the direction of the late Mr. Buddle.

The further discussion of the question was adjourned until the next meeting, April 2, when the monthly ballot for members was announced to take place, and the following papers will be read:—

"Account of the Railway from Amsterdam to Rotterdam, and of the principal works upon it." By Le Chevalier F. W. Conrad, M. Inst. C.E., translated from the French, by C. Manby, Secretary.

"Description of the Piling Machine used at Montrose Harbour Works." By G. T. Page, Assoc. Inst. C.E.

"Account of a series of experiments on the comparative strength of solid and hollow axles." By C. Geech.

EDGE'S WATER-METER.

Read at the Society of Arts, March 20, 1844.

Fig. 1.

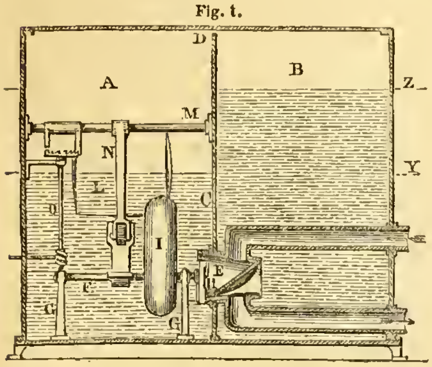

Fig. 2.

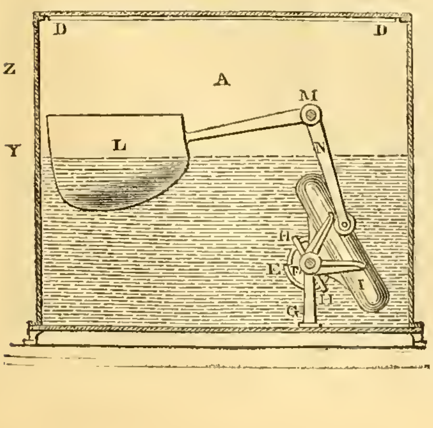

For many years past the want of a machine to measure liquids, while being transmitted through tubes, seems to have occupied public attention, and more recently water companies, and practical engineers, have become desirous of the existence of such an instrument; the former to ascertain the quantity of water supplied, (more particularly to their large consumers,) the latter to ascertain the amount of water passed into their steam boilers, and by inference the amount of steam generated, the comparative advantages of different fuels, and the attention of the engineer to his duty.

It was with a view to supply the wants of the two latter classes, that the present machine was invented; although there is no doubt that if modified in a particular way, it would as effectually answer the purposes of the former. Before entering upon a description of this machine, it may be as well remarked that several others for the same purposes have been from time to time brought before the public, without much success; these however are liable to one of two very important faults, either that they cannot measure liquids while acted upon by pressure, or that they will measure any air which may pass through them, as if it were liquid. These objections are entirely overcome by the present arrangement, and also, it is believed, a greater degree of accuracy and simplicity is obtained. The annexed engravings show the meter for the measurement of water, for which purpose it is now being tested in several parts of England, and also at Mr. Edge's manufactory, Great Peter-street, Westminster.

Fig. 1 is a sectional elevation showing the chambers A and B, and the machinery therein.

Fig. 2 is a section of chamber A, taken at right angles to Fig. 1.

The outer casing is rectangular, and is made of cast iron; this however may be varied to zinc or tin plate if the pressure of the liquid be not too great. This case is divided in the middle by a partition C, thereby forming two chambers A and B, communicating through the slit D in the top of the partition C. In the partition C there is a four way cock E, the larger end of which opens into chamber A, and the smaller into chamber B; the water is conducted to and from this cock by means of tubes, shown by arrows passing through chamber B. This cock transmits the liquid to and from the chambers A and B, in the same manner as the slide valve conveys the steam, to and from the cylinder of the steam engine. Parallel with the centre of the cock E, is a spindle F working in the upright standards G G; this spindle carries a driver H, which acts upon projections on the plug of the cock E, and it also carries a metal cylinder I, hermetically sealed, in which is a heavy metal ball K, less in diameter than the cylinder, so that it may roll freely in it. In the upper part of chamber A, there is a float L working upon the axis M, which carries a pendant arm N, having upon the end of it a friction pulley. As the float rises and falls by the action of the water, this arm vibrates, and acting alternately upon the inner sides of the two teeth on the spindle F, causes the lower end of the cylinder I, (in which is the metal ball) to be raised, the ball rolls to the opposite end of the cylinder; and by its weight moves the spindle F suddenly round, which motion is communicated to the plug of the cock E, thereby causing a change of inlet and outlet.

The action of the meter is as follows. The water enters the inlet pipe, and (from the peculiar position of the plug of the cock) passes into the chamber A, until it has risen to the dotted line Z, the float will by this time have been raised to its highest position, and the pendant arm N will have raised the lower end of the cylinder I by its action upon one of the teeth on the spindle F. The ball will then suddenly roll to the other end of the cylinder, causing the spindle to move round, which motion is conveyed to the plug of the cock, and its position being reversed, the water then passes into the chamber B through the four way cock. Now the air which was in chamber B and the upper part of chamber A, becomes compressed, and its expansive force acting upon the surface of the water in A, expels it through the outlet by the four way cock, until the water falls to the dotted line Y Y, when the float will also have fallen, and by its action upon one of the teeth on the end of the spindle, have raised the opposite end of the tube, causing the metal ball to roll to the other end, which force being conveyed to the plug of the cock by the driver, suddenly moves it into its original position. The water will again rise into the chamber A, and acting on the compressed air expel the water from B, through the four way cock. Thus each chamber receives and discharges distinct portions of water; the pressure exerted to fill the one, being communicated by a column of air to discharge that in the other. Each stroke being equal to the area of the chamber A, from dotted line to dotted line, (minus the bulk of the float and other machinery in that part of the chamber). It may here be remarked that the bulk of chamber B has nothing to do with the measurement; for B can only receive as much water as A discharges, and can only discharge as much as is received by A. The only exception to this rule, is when an additional pressure takes place, at this time a longer stroke is given, which is again repaid by a short one, which exactly compensates for it when the pressure is removed.

Upon the axis M, there are two teeth taking into a crown wheel, similar to a clock escapement; thus the vibrations of the axis M, give rotary motion to the upright spindle O; from thence to the counting apparatus which is of a novel description.

WESTMINSTER BRIDGE CONTROVERSY.

Mr. Barry has brought forward a new design for a Westminster Bridge. The structure proposed is to be of iron, and of five arches, the old bridge having thirteen arches. The design is made to harmonise in style with the Palace of Westminster, and has a very light appearance. Mr. Barry proposes to improve the navigation, to give greater waterway, and greater roadway, while the expense is estimated at £185,000, and it is supposed the cost of repairing the old bridge will be double the sum, and the property of the Bridge Commissioners is considered to be ample for securing the outlay, thus making no demand on the public purse. The span of the proposed arches is, centre arch 160 ft., two second arches 157 ft. each, and two end arches 133 ft. each. The roadway is much lower and much broader. The breadth of the river will be considerably curtailed by the embankment, a space equal to two arches of the old bridge being taken in at each end. The plan of a temporary timber bridge to carry the traffic during the removal of the old bridge and erection of the new is shown.

MARINE BOILERS.

Sir—As a subscriber and careful reader of your highly respectable and well conducted *Journal* from its commencement, I have, in conjunction with many others, derived much pleasure and considerable advantage from the manner in which many subjects of science and art have been treated; but nothing has pleased me more than the plan you have adopted in the number for this present month, (viz., page 90 and plate III,) of giving working drawings and particulars of marine engines and boilers, and I sincerely trust nothing will intervene to hinder your carrying out a plan so important to every one connected with practical mechanics and commerce.

The specimen of boiler you have given is certainly a good one and will, I have no doubt, if generally adopted, be found very superior to those of ordinary construction; but with all due deference to your judgment and sources of information, there are several bad parts, or rather some that might, in my estimation, be improved. In the first place, I do not approve of the straight sides which you have adopted, because they are in practice found to be very weak, and hence must be *heavily* stayed, to prevent the change of form and liability to leakage from the fluctuation of pressure to which they are subjected. To remedy this defect I would make the shell slightly curved in all directions, which could be made to occupy a mere fraction of more space, and would, from their improved or arched form, prevent that vibration that I complain of. The next point I would call your attention to, is the uptake from the furnace at the back end of the boilers, where the water is permitted to go direct up between the outer and uptake shells without any external fire doors, and in the event of bursting one or more of the iron tubes, which is often the case, (at least in railway locomotives, the tubes being only soldered, except for a short distance behind their insertion plate, where they are welded,) how could you stop the leak at the back end without extinguishing your fires? Now had you introduced a fire or tube door at the back end, same as front, you could with ease plug the burst tube or tubes up at once, and hence the only difference in the working of the boilers would be the loss of the heating surface of the said tube or tubes. There are other minor points that might, in my estimation, be improved, such as the curving the furnace tops and bottoms, &c.; but I must not trespass further upon your notice, as all these, and perhaps more, will readily occur to the practical man: yet however valueless these remarks may be in themselves, if every one who was capable of correcting the mistakes that occur in mechanical works would condescend to do so, they would lead to that interchange of thought which by rubbing against each other produces the sparks of excellence.

I am, Sir,
Your most obedient servant,
J. H. S. C.

Newcastle-on-Tyne, March 11th, 1844.

[Our correspondent is evidently a locomotive engineer, accustomed to steam of very high-pressures, and consequently spherical and cylindrical boilers. It is not intended that steam of a higher density than 10 lb. per square inch should be used in the boilers delineated in our last number, which pressure would not affect their form if they were stayed in any tolerably efficient way, and which would not be so heavy as the additional plate, water and space, which would be necessary if shaped in accordance with the suggestions of J. H. S. C. The "*fraction* of additional space," required by curvilinear shelled boilers, is not so small as he thinks; we could illustrate this, but it would be too lengthy for a note. We do not understand what he means by the "vibration" of rectangular boilers. Doors in the back uptake, for the removal of defective tubes would not be safe for marine boilers, the heat would be so intense as to seriously affect the safety of the vessel, and the most effective surface would be decreased. Nor do we see the necessity of it, for we are not acquainted with the failure of a single tube in any marine boilers of this description. The tops of the furnaces are made elliptical, the bottoms nearly square, to admit as large a portion of atmospheric air to the grates as possible, for it is not always convenient to raise the gates to get the required area. In courtesy we answer the questions put to us, although the remarks of our correspondent will sound strange in the ears of marine engineers.—Editor.]

VULCANIAN ARCHITECTURE.

(From the Athenæum.)

A paper on the restoration of St. Stephen's Spire, Vienna, read at the Institution of British Architects, (see the *Journal* for January last), has even a more than architectural interest; it serves to illustrate the progress of human knowledge, and to show how compatible is a vast deal of movement with very little advancement. There may be progressions in various provinces, but retrogressions in perhaps as many others; and the sum of the former, *minus* the amount of the latter, would exhibit zero for the surplus oftener than most people imagine. Human knowledge, if thus considered, will appear to expand somewhat like a gridiron pendulum, whose alternate bars contract while their companions lengthen, so that the whole remains, a prodigious time, of the selfsame dimensions. Human intellect, again, if it does march, marches at about the pace of my Uncle Toby, putting one foot before the other without advancing an inch. Contrary to Swift's maxim, we hold that a specimen brick *may*, by times, tell no little of the structure from which it was taken; and we think the one above, taken from the Temple of Architecture, tells a lamentable tale respecting its present condition. It reveals rather more than a Babylonian tile does of Belus's Tower, and in far less cryptic characters. The imperial architects, it would appear, have raised St. Stephen's dilapidated spire to its ancient stupendous height, not by means of lawful masons' work, but blacksmiths'—they have *restored* the pyramidal part (above one-third of the whole altitude) not with stone, but iron! Exquisite and appropriate finish—just as Samoyeds might tip the imperial sceptre, if they got hold of it, with a fish bone! Barbarians—so our super-civilized contemporaries call them—built up that epitome of the sublime and beautiful—to which Cleopatra's Needle *was* a needle—than whose topmost stone no loftier above earth's surface did mortal hand ever lay (except what said barbarians posited also); yet modern "progressives," either through want of genius, pure artistic taste, masonic power, or—the fatalest among all defalcations—want of *inspiring will*, tremble at a like attempt, and instead of a proper apex, put upon the stone frustrum of the tower an enormous iron fool's cap—fit emblem of their deserts who ordained it! This forging a steeple implies, we allow, some progress in the arts, but a retrogression too, far greater, because in a nobler province. The sun of mental enlightenment, we suspect, about which flatterers of themselves along with their age, hold such stentorian discourses, gets almost as many new spots, year by year, as it gets rid of: it shone, perhaps, throughout the "Dark Ages" pretty much as it does at present, save that our metaphorical Dan Sol "tricks his beams" a little better. Spirits of the Old Free Masons, hear this—a foundry for Gothic Architecture! Spires to be cast like lamp-posts: pinnacles, canopies, crockets, finials—all the delicate and decorative details of your exquisite style to be made per pattern, and moulded per gross, like cheap stoves, irons, fenders, snuffer-dishes, inkstands, metal buttons, and brads! Ready made cathedrals will no doubt soon be ordered from the mine's mouth for European cities, like palaces for Timbuctoo! Vulcan, the god of blacksmiths, will become the god of architects: England, above all other lands, bids fair to make his anvil her chief altar, and, as the Lipari Isle of yore, to resound his name and his hammer throughout her subterranean dominions—

> Vulcani domus, et Vulcania nomine tellus,
> Huc tunc Ignipotens cælo descendet ab alto!

We do not, by these remarks, mean any impeachment against the merits of iron applied to common domestic, or even public structures, nor, indeed, to divers *un*common, where the more heterogeneous the materials the more suitable they would be: but we would denounce with the force of an interdict, if possible, the adoption of this illegitimate substance in superior edifices, as radically subversive of true architecture—professionally and nationally disgraceful. Let us, therefore, enter our humble caveat against the Vulcanian School being commended for imitation among our countrymen. Some connoisseurs might deem an iron or a leaden, or a wooden, yea, a leathern steeple on Westminster Abbey middle tower better than none, and the mongrel addition to St. Stephen's, at Vienna, may stand excused by such an alternative; nevertheless, a vicious principle once admitted, furnishes a precedent to be followed when its origin has been forgotten, because mankind has a natural leaning towards the corrupt in fine art, as well as in morals. The school abovesaid does not count its sole disciples amongst the successors of the *Huns*, nor confine itself to the Carpathian wizards of the Danube; even those learned martinettes, the Prussians, sanction it; even their heaven-born *baumeister*, Schinkel, entered himself a pupil! Berlin iron-work having obtained great vogue for its quincaillerie and brittle bijouterie, insect-brooches, and animalculous breast-pins, ladies' clasps, purses, filagree trinkets, puppet statues, and chimney-piece articles of virtù—being proper enough, too, perhaps, for coarse or concealed masses of construction—was brought into most abusive use for prominent architectural features—nay, whole national edifices. The *Kreuberg Denkmal*, by Schinkel himself, and Luther's canopied shrine, at Wittenberg, are examples. We consider this pseudo-masonic system only another version of imitation stone work; as to principle, not one jot above lath-and-plaster edification: a system brought about among architects by modern middle-class taste—by the self-same low-minded satisfaction with surface effects which gazes enraptured at mock-marble and scagliola columns, "compo" entablatures, *papier-mâché* balustrades, and similar factitious substitutes—which loves them better than the genuine materials, because more applicable to profuse bedizenment, and easier distorted into novel monstrosities. Found, if needful, a new kind of architecture upon the native character of iron, such as its essence can pervade, its attributes warrant, its powers embrace; let some forgetive brain, in Falstaff's sense hammer out a solid, sterling system of Vulcanian Architecture, and we shall praise it; but none of your hybrid abortions, begot between metallurgy and masonry, that cohere still worse than the brass and clay of Nebuchadnezzar's image! It may be said, what imports the substance, so as the appearance is agreeable? how should molecular constitution of parts affect their integral masses, whose forms and proportions are alone very important? A reply seems almostl superfluous; yet we give it. Besides that bad faith, when appearances do not fulfil their promises, always offends a well-regulated mind—besides that the inward or thorough worth of materials enriches the spectator's imagination—besides that their untractableness overcome enhances his pleasure, as the quantum of skill, toil, and time employed upon all productions augments their value—besides this, we are much disposed to maintain that there exists a bond, indissoluble though indefinable, between beauty of end and legitimacy of means—that the nature of the constructive material suggests, demands, nay, often *commands* the style of construction; and that, if the former become debased, the latter will degenerate also. We are persuaded the PARTHENON could never have arisen had the Greeks built their temples of cast iron; no, nor the beautiful Tripod Monument, had their Corinthian capitals been moulded out of the very nicest potter's clay in the Ceramicus, and their columns been the very best stock-brick, covered over with plaster of *Paros!* No more, we affirm, than the Phidian Minerva could have sprung from "Coade's Stone," as the customary stuff of sculpture, or little wooden lozenges given birth to the rude grandeur of the Appian Way, and such specimens of cyclopean road-making. Such things we will admit possible when beavers can build another Waterloo Bridge with Thames mud and their tails! Augustus, it was said, found Rome brick, and left her marble; yet see how the inveterate use of brick debased the Roman style of architecture, until the native properties of that material absorbed those of the finer one, and brought forth a style (the arcaded) favourable to their full development. The spirit of the material, as it were, transfuses itself throughout the creations therefrom: the meanness of a material enters into the soul of the artist; understanding by meanness—not commonness (for Grecian and Etruscan fictile vases of most refined elegance are often mere earthenware), but—poor and pitiful mis-adaptedness to the given purpose; this it is which would render an El Dorado, though built of ingots, or Aladdin's palace, though walled with gems, mean architecturally beside a simple Greek fane, whose blocks begot its massive character; and which, on the other hand, permits a Gothic church of grey stone or rubble itself, to rival Pentelic temples. We shall, perhaps, have the Vulcanians cite King Solomon as patronizing cast metal pillars. What then? Were either Jews or Gentiles enjoined brazen architecture thereby? Must architects, till the pillars of the world give way, bow down before the brazen images of *Jachin* and *Boaz?* Had these enormous objects no loftier aim, no deeper, where all was symbolic? Briefly—how much does any one know about them?

But hypothesis, reasonable or fanciful, aside, it is amongst the plainest principles of art, we submit, that every material should be made to do its own work, and not the work of another, unless their qualities have a close similitude. Tempera may sometimes do the work of fresco, oils of either; yet, perhaps, we might date and deduce the downfall of painting from what many persons derive its perfection—Van Eyck's discovery—the substitution of a smooth and luscious medium, whose appropriate productions are small, elegant, and epicurean, for simple water or *size*, best adapted to the most gigantic efforts, the sublimest and severest trials of the pencil. We would push this principle farther and contend that no material, while doing its lawful work, should be made to *seem* as if doing the work of another. Real art rejects all such artifices—virile taste despises all such puerilities. Even when the imitation is unintended, its existence proves either the imitator's faint perception of distinct principles, or his feeble hand, which fails to obey his clear convictions. Look at Henry the Seventh's Chapel; observe its numberless minute, slim, canelike mouldings, its lath-and-rafter-like ribs and braces, its bird-cage delicacy of screen-work, its panelled surfaces throughout—little distinguishable from *panel*, indeed—does it not seem rather a colossal specimen of joiner's craft than anything else?—a carved, morticed, and dovetailed construction of box-wood than a structure of stone? Dexterous, we grant, polydedalean (if you please so to call it) in mechanism, fanciful as a frost-work palace in effect; but cast your eyes on the Abbey Choir next it, and behold what a mere bijou, an architectural trinket, it looks compared with the massive grandeur of this! This proclaims itself at once, genuine masonry, and thus far, if no farther, much excels its florid neighbour whose embattlements and enrichments might pass for petrified carpentry. A coral grove may be curious, precious, and beauteous; yet all amateurs (but old children, who still cling to their corals) would prefer an oak forest. The Abbey Choir, we sometimes imagine, turns a huge shoulder of contempt upon the little fretted and frittered appendage behind it, perchance acknowledging about the same relationship to it which Fingal's Cave does to the mermaiden of Staffa's stalactite grotto. Indeed, the Lancet, or Early English style, under this view, surpasses, we think, the Decorated (by many persons deemed the perfectionated) Gothic, as well as the Florid, or decadent. For, beyond dispute, those double-curved and contorted outlines—those ramified cusped and tressured foliations—those antler-spread traceries, make stone pretend to be what it is not—a flexous substance, make it ape live timber, molten ore, or some pliable compost. Now, though we may consider stone ductile or plastic in statuary and decorative details of architecture, yet, where it forms a principal feature, and marks an architectural style, it should have itself a pure architectural character; it should resemble mason-work, should pronounce itself *stone*, and suggest no adventitious substitute. Thus, a crocket or a corbel may imitate a leaf or a lion's head, because a positive leaf or lion's head stuck upon the place would not de-characterize the edifice; but a window or a parapet should not, strictly speaking, weave its mullions like a vegetable branch, nor twist its bars like iron-work, unless the edifice be built of timber or metal. Even were the Greek Corinthian capital taken from a flower-pot, we see that the core is a stone cylinder, and does not pretend to be a stem of acanthus. These remarks are submitted for a very different purpose from that of disparaging the Decorated Gothic, which we admire and revere: but the true and strict laws of art demand our veneration still more. They, alone, ever and anon dunned into the ear, will fright the isle out of her improprieties, if this be possible. She finds licenses enough placarded on every church-wall, through the whole breadth of its flank and length of its steeple: "plenary indulgence" for unchasteness in architecture! absolution without either confession or repentance!

Akin to the above principle is another, sinned against as with a cart-rope, with the very loosest libertinage, ever since the "Renaissance," or it might rather be called the *Decadence*, of pure architecture, seeing that the pointed style is pure architecture, on its own picturesque grounds. But this aforesaid transgression, like an original sin, vitiates a whole species of techtonic productions, though it may leave a certain divine spirit about them still,—we mean Italian edifices. More or less throughout these, pillars, entablatures, and pediments are made to perform the part of mere decoration, instead of staminal and horizontal support, and protective shelter, their true business. A colonnade along the entire front of a house supports what?—a cornice! And what does the cornice support?—*sparrows*. Tiers of little portico-façades, called windows, adorning the same front, what do their pediments protect?—spiders beneath their eaves, migninionette boxes in their balconies, bytimes also glaziers and chambermaids who stand outside to mend the panes or clean them! Yet this at best elegant debasement of the Classic style entitles its professors to pronounce the Pointed "barbarous," and to boast their wonderful progress beyond the architects of the Middle Ages. Again, let us inquire, did the gods ever commit such gross acts of artistical bad faith as the Italian school,—disguising, under a thin surface of cut stone, masses of quite a different nature, almost always of a comparatively worthless one, which yet constitute the veritable erections? Excuse this as we may, it must be denominated mongrel architecture. Some of the very grandest efforts in modern constructive art are obnoxious to that name. St. Paul's cupola, despite its many merits, is a much less genuine production than Salisbury steeple; whilst its outward appearance bespeaks a "Pantheon hung in the air," what sublime elements compose it? Timber and lead! The whole dome, exterior and interior, consists of no less than four distinct materials,—stone, brick, wood, and metal,—thus being a specimen of mason's, bricklayer's, carpenter's, and plumber's work, mixt together share and share alike, rather than what it seems and ought to be, part of a masonic edifice. So far forth, it can just as little call itself a legitimate feature, as the iron palisade which fences (we wish it could screen!) that accumulation of architectural absurdities—Buckingham Palace. Wren was no "Goth"—his Westminster Abbey towers attest this!—but he ranks amongst the very greatest modern architects; he wrote well too on his art, yet asperses a skill he attempted to rival and failed to reach—the power of "spiring-up," with an "affectation of height and grandeur."* St. Bride's steeple became unsafe, though it had never been half the height of Strasburg Cathedral, nor stood half the time! Bow's, somewhat about St. Bride's altitute, may stand better,—perhaps much because it employs both within and without Gothic props and principles.

We return from our not altogether irrelevant digression, and repeat—iron should no more pretend to supplant or represent the beautiful stone-work of pointed edifices, than stone the reticulations and convolutions of chain-work. Frivolous minds or very green experience alone can relish either. Certain Neapolitan statues by one Corradini, a popular sculptor (that is, stone-carver), which exhibit their forms under nets or veils wrought upon the solid marble, our travelled gentlemen and ladies pronounce miracles—and such they are—miracles of the vilest taste and paltriest ingenuity. Cast-iron architecture, Classic or Gothic, is still worse, because no miracle, good or bad, at all; it goes to destroy the art, as a *fine* art, and will do it if patronized, by substituting machine productions for man's immediate handiwork. Let us assure ourselves of this,—whatever removes the artist's own hand from his material, removes his *spirit* from it also, and just to the same distance. Many mechanic helps between it and him will prove just so many artistic obstacles; his manufactures will augment, but deteriorate. Of the architect at least well may it be sung,

> Ay me what perils do environ
> The man that meddles with cold iron!

We have been more serious upon this matter than perchance it deserves; indeed, why should we care much about domes or spires, when Heaven's stupendous cupola stands for ever above our heads, when those numberless crag-pinnacled steeples, built by the Supreme Architect, from the Spitze-horn down to Derbyshire Peak, are within sight of eye or of mind? These will suffice, let man do what he may! But we have said all we have said, because Truth is the greatest of all utilities, being useful even where it illumines perishable, unimportant objects, as its virtue remains in the soul!

* V. Parentalia. These "senseless artificers" (he thus stigmatizes them elsewhere) never like him built a prodigious and prodigal second story as a mere mask to smuggle in foreign conveniences. Such are the concealed flying buttresses which support St. Paul's spine and haunch.

GREAT WESTERN STEAM SHIP COMPANY.

The last meeting of the shareholders of this company seems to have been regarded by the directors with some misgivings, for, contrary to the usual practice of respectable companies, the press were excluded. It is not unnatural that the directors should have been so desirous to keep their proceedings in the background, for a most unsatisfactory tale does their report relate. It is a supplement to the many similar narratives by them of arrangements misconceived, of reckless and meddling experiments, of serious and embarrassing failures, and of vexatious delay. The *Great Western* having been slightly injured in one of her recent voyages, affords an eligible opportunity to Mr. Experimenter Guppy to alter her paddle-wheels, and try some of his new views upon her, although she is acknowledged by the directors as having, with her ordinary paddles, proved the fastest ocean steamer. Had the company a number of boats, a lucrative traffic, and large dividends, so far from disapproving of any experiment of the kind, we should have considered it highly laudable, we should have praised the public spirit of the directors, and awaited with complacency the failure or success. Here, however, is a company with only one boat running, the success of the company a matter of doubt, and so far from the managers doing what is safe, "letting well alone," they are rushing heedlessly and recklessly into experiments, which may turn out well, but which just as likely may end in loss to the company. On such grounds we see these proceedings with regret, for we have no confidence in the management.

As to "the Great Postponed"—we beg pardon—the "*Great Britain*," she is not forthcoming yet, and her advertised days of starting cannot be complied with, fur ludicrous to detail, this "*monstrum, horrendum, informe* (we believe we may add, in compliment to the board), *ingens, cui lumen adæptum*," this mighty whale among the minnows, cannot get through the lock-gates. We beg to recommend for the figure head Sterne's starling, if prepared with a Guppyan profile, and a profuse repetition of the motto, "I can't get out." Anything so extremely preposterous, so ridiculous to every one but the poor shareholders, has scarcely ever been known, but it is avowed by the directors that they built the vessel without making themselves duly acquainted with the dimensions of the gates, subsequently calculating on the Dock Trustees allowing them to pull down one side of the gates to let her out. This the Dock Trustees refuse to do, although the company are willing to go to an expense of £300 for the purpose. Nay, the Directors have gone so far as to offer a thousand pounds towards the permanent enlargement of the dock-gates, and even this has been refused. The conclusion is, that the way now proposed for getting her out is to construct three or four iron pots or tanks to be put under her keel, by which it is expected she will be raised some three or four feet! and so to be carried through the gates on stilts. We should not, however, be surprised, at the rate the company are going on, if like other *detenus*, she were only got out of custody by being whitewashed, for management so careless, and expenditure so profuse, we have rarely ever witnessed. In addition to this, there is another mess with the Dock Trustees, for through miscalculation, the water in the dock had to be lowered eight feet, in order to allow "the Great Postponed" to be floated. The trustees claim some £800 compensation, and the directors resist, so that a snug law suit is likely to be manufactured on this score. As to the conduct of the Dock Trustees, we cannot speak in favour either of its immediate or ultimate policy. A parcel of Bristol hogs could hardly have done more to injure the city than have these trustees, they exacted dues from the *Great Western* when she could not get through the gates, and though they received £2,500 dues upon her, besides those upon her cargoes, they were not satisfied till they drove her permanently to Liverpool. Indeed all that the enterprize of a few energetic individuals has projected and done for the city of Bristol promises to be destroyed by the pigheadedness of its inhabitants. Bristol now occupies a very low rank in the list of ports, in consequence of the disadvantages she labours under in not being able to supply a return. The Great Western Cotton Works, which would have had the effect of locating an important manufacture on the spot, have not been adequately supported, the Great Western Steam-Ship Company have been driven away, and their yard is to be shut up, and thus the only chance Bristol had for retrieval, by becoming a great steam port, has been irretrievably destroyed. Indeed, even as to the trade she has, it is likely before long to be seriously affected, for the Great Western Railway Company cannot afford to lose traffic if the people of Bristol can, and they will undoubtedly promote docks at Pill and elsewhere, to which all the Irish, and Welsh, and Somerset steam tonnage will be removed, and which will have superior facilities for the conduct of all traffic. So much for greediness.

Meanwhile, however we contemplate the proceedings of the directors, they inspire us with equal distrust of their prudence and capacity. At first they were to have trunk engines, then they altered them; first they adopt a particular system of screw, and then they alter it. The worst of it, however, is, that they are already engaged in making the screw, while they have been making trials elsewhere, in consequence of which they are going to change the form again, of course at great expense and with great delay. The next thing we suppose will be to do away with the absurdity of straps for working the screw, and to substitute cog-wheel gear, and next the incumbrous flue boilers will have to be exchanged for tubular boilers. "Never ending, still beginning," the whole performances impress us with the idea that they can be meant for nothing but to provide snug berths for some parties who want such provision.

The directors also ask the shareholders to arm them with the power of retaining the yard and workshops, and tendering for Government and other contracts. Whatever may be our views with regard to the general policy of such a measure, we must say that the directors have made out no case for such confidence to be reposed in them, and the shareholders can only anticipate a profuse expenditure, a great deal of meddling and bungling, and a great delay in getting returns, if any should ever be forthcoming. Who, too, will trust parties with contracts who have not as yet shown that they have practical experience on the subject, and who have *pro tanto* failed in everything they have undertaken?

A general meeting of the proprietors of the above company was held on Thursday, March 14, at Bristol. The following is an abstract of the Directors' Report:—

"The receipts by the *Great Western* for 1843 have amounted to £33,406 0*s.* 4*d.*, and the expenditure has been only £25,573 4*s.* 3*d.*; the receipts for 1842 having been only £30,830 8*s.* 2*d.*, while the expenditure was £28,615 7*s.* 1*d.* To the improved state of things in the United States much of this is to be attributed, a good deal to the close attention to expenditure; but your directors believe still more to the circumstance of Liverpool having been altogether the rendezvous for your business on this side the Atlantic."

The report then states that the *Great Western's* last winter voyage to New York, by way of Madeira, had been rendered unprofitable, the carelessness of the New York pilot having allowed her to touch the ground, in consequence of which that vessel had to be surveyed and repaired at her Majesty's dock-yard at Pater, at an outlay of £606, in addition to which it was calculated that a loss of £1,500, in passengers, had been sustained by the unavoidable delay, and change in the times of sailing. She had been subsequently docked in Bristol, and "thoroughly examined," when, according to the directors, it was "impossible to over rate her condition." The pilot at New York had been suspended on the representation of the company, and the underwriters at Lloyd's had signally marked their sense of Captain Hosken's merit in bringing home the vessel. "The *Great Western* has run nearly 240,000 miles, at a higher average speed than had been attained by any other sea-going steamer—10¾ miles per hour." In September last the company's engineer reported that the boilers, which had done duty for six years, might, at an outlay of £1,000, be made to last for one, or, at most, two seasons longer. Under these circumstances the directors thought it better to have new boilers, the estimate for which is £3,000, which are now being rapidly put up on board, are known by the name of tubular, and require only half the space of the old ones, by which the stowage of the ship, for either coals.

or cargo, has been increased to the extent of upwards of 200 tons. She is also to have new paddle-wheels, which are nearly finished, and in progress of fitting in place. The directors observe:—

"Mr. Ashton, the well-known shipbroker and auctioneer, was employed to effect a sale of your works, either by private contract or by auction, and your directors regret to announce ineffectually. The time is now fast approaching when they will be closed, unless parties come forward to take them off your hands. Situated as your premises are, with water-side frontage, ample space for building, a graving dock of the first-class, and in other respects a more convenient engineering and ship-building establishment than any in the kingdom, your directors long since expected that they should be able to communicate to you that the mechanics and other able hands, who before their establishment were many of them strangers to Bristol, would not have had occasion to turn their backs upon the city; they still trust these hopes may be realized, and that the time will not arrive when it will be advisable to sell the tools and the materials piecemeal. Your directors have, on more than one occasion, suggested to you the good effects to be anticipated from your arming them with authority to tender for Government vessels, or otherwise to work for the public. The opportunities have been numerous, and if they had been authorised to have accepted some of them, Bristol, they think, would by this time have become a steam-ship building port of the first class, and your establishment, in all probability, in a flourishing condition, instead of being, as it has a prospect of being, on your hands, subject to an outlay for rent, taxes, and maintenance, of not less than £400 per annum."

Prince Albert's visit and the undocking of the *Great Britain* are then briefly alluded to, it being stated that "the whole of the expenses of that auspicious occasion were defrayed from the fund arising from the sale of tickets, or from visitors to the works." The report then goes on to state that, "for the purpose of opening the bank fronting the dock in the most inexpensive way," the Great Western Steam-ship Company had obtained the permission of the Dock Company to lower the water in the float six feet. Circumstances, however, had rendered it necessary to lower the water "considerably below the six feet asked for;" and on the 13th December, nearly six months after the event, the Dock Company made a claim for £312 17*s.* 10*d.* for damage done to the ship *Augusta* in consequence of the lowering of the water. The payment of this sum had been resisted, and the "not acceding to this demand, the directors have reason to fear, has operated injuriously upon the consent of the dock board to the passage of the *Great Britain* through the locks." The report then goes on to speak of the *Great Britain.*

"The size of your ship *Great Britain* was not finally settled until the year 1839. At your annual meeting, in 1840, her dimensions were made known to you, and a model was laid before you. Before, however, the final settlement of her power and capacity, deputations from the public bodies had been for months sitting in committee, with the view of arriving at some conclusive recommendation to the city, by and through which it was anticipated that the trade of the port would be relieved by arrangements with the Dock Company, and its locks thrown open for the ingress and egress of a larger class of steam vessels than those which are of necessity, your directors believe, confined to Bristol only; and one of the resolutions which were reported to your town council on that occasion as the result of the indefatigable exertions of the gentlemen composing that Committee was, 'that it is essential to the trade of the port that the entrance to the floating harbour should be made wider'—at the same time your consulting engineer, Mr. Brunel, was employed by the council to survey the harbour and rivers, and did, after completing the same, hand in estimates for widening the old locks, or forming a new one. The *Great Britain's* beam and form were a good deal affected by the width of the locks, which were supposed to be 45 feet nearly all the way up and down; on measuring, however, your engineers have since found they are much narrower, even at the average high water mark. The great buoyancy of iron ships is such, that to gain draft of water, which in then as well as in the present state of knowledge of ship-building was supposed to be necessary to give stability and the other qualities necessary for a sea-going steamer, the usual form of steam-ship building had to be abandoned, and the breadth towards the bottom considerably contracted; capacity, conseqently, had to be looked for above rather than below the water line. This and other considerable advantages led to the adoption of the form in which the *Great Britain* is built, her widest part being far above the line of flotation; and they have great pleasure in stating that she has been visited by most of the eminent ship-builders and engineers of this and the neighbouring kingdoms, and her construction and form not merely highly approved of, but greatly admired. About the middle of the year 1841, your engineers reported to your directors that a great saving would follow putting the boilers on board in dock, and at the same time they were informed that it was not likely the ship would be allowed to occupy nearly a whole side of Cumberland basin for so long a time, as it was then discovered would be necessary to complete her equipment; and in 1842 your directors reported to you that the most economical way of getting the machinery on board would be through an aperture in her side while in the dock, by which the necessity of floating her would be avoided. Your directors were fully aware that by this decision they would have to seek the consent of the dock directors for a temporary removal of two or three of the upper courses of stones of the lock, and the unshipping of the gates of either one or both sides for a few days, which they were assured by your consulting engineer, who acted in the same capacity for the dock directors, would be a matter comparatively inexpensive in execution, without risk, easy of accomplishment, and in no way likely to inconvenience the trade of the port."

The report then proceeds to detail the unsuccessful negotiations with the Dock Company, respecting the facilities afforded for getting the *Great Britain* into and out of Cumberland basin; the directors observing, that they had not anticipated such a termination to the negotiations, more especially as "the actual dues on the *Great Western*, received by the Dock Company, have amounted to £2,500, while those upon her several cargoes, which the directors have no means of computing, must have been considerable." The consequence of this want of agreement between the two companies is that, instead of getting the *Great Britain* into Cumberland basin on the 21st inst., and out of it for Kingroad on the 4th April, it is "the painful duty" of the directors to inform the Steam-Ship Company, that they anticipate so much delay from the plan which they are now driven to adopt, that they think it will be impossible to keep the advertised dates of the sailings of the *Great Britain.* The Report then goes on to state:—

"The expenses for experiments on the *Archimedes* have been reported to you. Your directors regret that she was taken away before they were completed. A three-armed screw made for her at your works, was tried by Mr. Guppy, on the French man-of-war *Napoleon*, a vessel of more than double the power of the *Archimedes*, and with it a high speed was attained; and your directors believe with a screw of proper size on a similar plan, she is at this moment admitted to be the fastest man-of-war afloat. Your consulting engineer's services have been engaged by the Lords of the Admiralty to report upon screws, and for this purpose her Majesty's ship *Rattler*, of 800 tons and 200 H.P., has been placed at his disposal. Her experiments have been frequently attended by one or other of your officials, as were also experiments, three years ago, upon her Majesty's ship *Polyphemus*, a sister vessel, with paddle wheels. In her a speed of nine knots was attained in Southampton water. The late results of the *Rattler* have been nine and a half, better than half a knot over the speed of the *Polyphemus*, as well as of another sister vessel of the same power, and in the same place with paddle-wheels—her Majesty's ship *Prometheus* in the Thames. Your directors have been induced to dwell upon this subject, not merely in consequence of its importance, but because of garbled statements of speeches in the House upon the navy estimates, or of assertions not founded on the real facts of the case, having led many of the proprietors to seek for information at your office. Your consulting engineer and Mr. Smith, the patentee, are acting with the most perfect understanding, and the speed of the *Rattler* has been improved with every alteration of the screw, the principle, your directors believe, remaining the same. Your directors greatly regret that it became necessary to put the *Great Britain's* screw in hand before the experiments in the *Rattler* were concluded. They will not quit this subject without reminding you that it has never been asserted that a higher rate of speed is expected to be attained in perfectly smooth water, with a screw than with paddles; but that it has numerous advantages over the paddle for long voyages on the ocean, and that the averages are likely to be better; and as certain authorities have asked what the speed of the *Rattler* is or what about 11 statute miles per hour is to 15 or 16, or even more, which is reported to have been attained by fast boats on the Thames, the Hudson, and other rivers; you are to recollect that the power in her Majesty's ships is seldom more than one horse to four tons, while in the fast river boats it is about as one to two tons, or even less, and that few, if any of them, would be safe at sea in bad weather, from the slightness of build and disproportion of weights. The *Elberfelt*, recently caught crossing the Channel, is a case in point. If your directors are rightly informed she was built for the Elbe, of iron one-eighth thick, and did not draw two feet of water. The accounts of the company are appended to the report, and after reserving the sum of £430 13*s.* for the reduction of the preliminary expenses of the company, and £767 in reduction of stock, a dividend has been declared of 2*l.* 10*s.* per share, or 7½ per cent. on the original cost, or 9½ per cent. on the reduced cost of the *Great Western*, which will become payable on the 15th inst., free of income tax, leaving a balance of £1,511 9*s.* 1*d.* to be carried to the reserved fund, making the amount, with interest, £13,139 3*s.* 4*d.* in reduction of the original cost of the *Great Western.*

Subjoined to the report is a statement of accounts, in which the following is given as the

COST OF THE "GREAT BRITAIN."

	£	s.	d.
Hull, engines, and boilers . . .	£66,790	3	10
Fittings	8,908	13	8
Masts, rigging, boats, pumps, cables, and stores .	2,110	9	4
General expenditure, including screw experiments	19,344	17	6
	£97,154	4	4

THE PROPOSED NEW BUILDING ACT.

We have now in the House of Commons another bill "*For better Regulating the Building of the Metropolitan Districts, and to provide for the Drainage thereof.*" The bill that we noticed last year, and which was read a second time in the House of Commons last session, proved an abortion. The present bill appears to have been got up with great labour and care, and with some few alterations may prove acceptable; the principal fault is, the bill is too verbose; however, we are not disposed to be too nice, knowing the difficulties the framers must have had to contend with; we shall for the present only give an outline of the bill, with a few extracts of the most important parts.

It is proposed to extend the building act district the same as in last years' bill (see *Journal*, Vol. VI., p. 214), and it is also proposed to empower her Majesty in Council to extend it to any place within 12 miles of Charing Cross.

It is proposed to alter the mode of rating the building into classes as set forth in Schedule C hereafter shown; the third and sixth class of buildings are to be erected under the joint supervision of the district surveyor and the official referees.

Power is to be given to the Commissioners of Works and Buildings (heretofore called Commissioners of Woods and Forests) upon the recommendation of the official referees to modify any of the rules prescribed by the act.

Two architects are to be appointed by the Home Secretary of State to act as official referees, with a salary of £1000. each, to whom are to be referred many important duties; in fact, they may be considered as judges: it is therefore essentially necessary that they should not be allowed to practise as architects privately, and that a clause ought to be inserted to that effect; and we think the importance of the office demands that both the referees and also the registrar (another officer to be appointed with a salary of £1000.) should have one public office, and it would be still better, if it were part of the same building as that of the Commissioners of Works and Buildings, thus uniting all under one roof would give importance to the department.

We shall now defer making any further observations, but shall carefully watch the progress of the building, and report if any important alterations should hereafter be made. The following are the clauses to which we have referred. The numbers refer to the bill.

11. And, for the purpose of preventing the express provisions of this Act from hindering the adoption of improvements, and of providing for the adoption of expedients better adapted to accomplish the purposes thereof; be it enacted, with regard to every builing, of whatever class, so far as relates to the modification of any rules hereby prescribed, that if, in the opinion of the official referees, the rules by this Act imposed shall be inapplicable, or will defeat the objects of this Act, and that by the adoption of any modification of the rules hereby prescribed, its objects will be attained either better or as effectually, it shall be the duty of such official referees to report their opinion thereon, stating the grounds of such their opinion, to the Commissioners of Works and Buildings; and that, if on the investigation thereof it shall appear to the said commissioners that such opinion is well founded, then it shall be lawful for the said commissioners or any two of them to direct that such modification may be made as will, in their opinion, give effect to the purposes of this Act; and that although such official referees shall be of opinion that such modifications are not requisite or admissible, yet if any party interested present to the official referees a representation, setting forth the grounds whereon such modification is claimed, it shall be the duty of the official referees, and they are hereby required to report such representation, as well as their opinion thereon to the said commissioners, with the grounds of such their report and opinion and that thereupon, if the said commissioners think fit, it shall be lawful for them or any two of them to direct the official referees to make such order in the matter as may appear to them to be requisite; and that, with regard to such application, so far as relates to the payment of the costs thereof, it shall be lawful for the said commissioners to direct such official referees to make such order relative to the costs of such reference to them, as to the said commissioners shall seem fit.

75. And now, for the purpose of providing for the appointment of competent official referees to superintend the execution of this act throughout all the districts to which it is applicable, and also to determine sundry matters in question incident thereto, as well as to exercise, in certain cases, a discretion in the relaxation of the fixed rules and directions of this act, where the strict observance thereof is impracticable, or would defeat the object of this act, or would needlessly affect, with injury, the course and operation of this branch of business; be it enacted, with regard to the official referees, so far as relates to their appointment, to their qualifications, and to the tenure of their office, that it shall be lawful for her Majesty's Principal Secretary of State acting for the Home Department, and he is hereby empowered to appoint two persons, being architects, to be official referees of metropolitan buildings, and from time to time, as he shall think proper, to remove such official referees, and in their place to appoint other persons so qualified.

76. And be it enacted, with regard to such official referees, so far as relates to their functions generally, that it shall be the duty of such official referees, and they are hereby required to superintend the execution of this act, by the several district surveyors already existing, or hereby authorized to be appointed, and to perform the several matters to them respectively assigned by the provisions of this act, and to determine all questions referred to them, whether expressly by this act, or at the instance of any one or more of the parties concerned.

77. And be it enacted, with regard to the official referees, so far as relates to their jurisdiction, that if any doubt, difference or dissatisfaction, in respect of any matter within the limits of this act, arise between any parties concerned, or between any party and any surveyor, or between any two surveyors, as to any act done, or to be done, in pursuance of this act; or as to the effect of the provisions thereof; or as to the mode in which the provisions and directions of this Act are or ought to be carried into effect; and particularly as to whether the requirements implied in terms of qualification, applied to sites, to soils, to materials or to workmanship, or otherwise, and denoting good, sound, fit, proper or sufficient, are fulfilled in certain cases; or as to the district in which any building, matter or thing is to be deemed to be situate, especially in cases where such building, matter or thing is partly in one district and partly in another; or as to the expenses to be borne by the respective owners of premises parted by the same party-walls, or the proportions thereof; or as to the proportions of the expense to be borne by the occupier, or by the owners of premises, in respect of any work executed, or any other matter whatever; then it shall be lawful for any party concerned, and he is hereby entitled, to require the official referees to determine such matter, but so that such requisition be made in writing, and that it sets forth, either generally or otherwise, the matters in respect of which the determination of the official referees is required; and that the determination of such referees, or of one of such referees, with the assent of the registrar of metropolitan buildings, as to all or any of the points in difference on which such referees shall make their award, and as to the costs, charges and expenses of such reference, shall be binding on all parties to such reference.

78. And be it enacted, with regard to the official referees, so far as relates to their authority in respect of any reference to them, and to the effect of their award upon the rights and interests of the owners and occupiers of property, that it shall be lawful for such referees and they are hereby empowered to exercise all such powers as arbitrators as they would have had in case they had been appointed under an order of her Majesty's Court of Queen's Bench at Westminster; and that if such award be given in writing, and be sealed by the official seal of the registrar of metropolitan buildings, it shall be as effectual as if made under an order of reference by such court, and shall be enforced by the said court in all respects as if made under an order of such court; and that it shall be binding and conclusive against every person, body politic and corporate, including the Queen's Majesty, her heirs and successors, claiming any estate, right, title, trust, use or interest in, to or out of the said premises or any part thereof, either in possession, reversion, remainder, or expectancy, and against every other person whomsoever.

79. And be it enacted, with regard to such award, so far as relates to the effect thereof as evidence of the matter thereof, that if on the trial or hearing of any cause or matter in any court of law or equity or elsewhere, any copy of an award, signed and sealed with the seal of the said registrar, be produced, then it shall be the duty of all judges, justices, and others, and they are hereby required to receive the same as *primâ facie* evidence of the matters therein contained.

81. And be it enacted, with regard to such official referees, so far as relates to the regulation of the business of their office, that when any matter is by this Act required, directed or permitted to be done by the official referees, the same may be done by any one of them, with the assent of the registrar of metropolitan buildings, unless express provision to the contrary be made, and if done by any one of them with such assent, it shall be as valid and effectual as if done by all of them; and that, subject to such restrictions and regulations as may be made in that behalf by the Commissioners of Works and Buildings, it shall be lawful for the official referees to appoint any one of their number, under their hands and the seal of the registrar of metropolitan buildings, to make any inquiry or any survey which shall appear to them either necessary or expedient in order to enable them to determine any matters in reference.

82. And, for the purpose of duly recording relaxations of the requisitions of this Act, made in pursuance of the provisions hereof in that behalf, and of providing for the revision from time to time both of such relaxations and requisitions, and of providing against the partial exercise of the powers of this Act, and for the more effectually providing for the due recording of the acts of the official referees, and for exercising a due control thereon; be it enacted that it shall be lawful for the Commissioners of Works and Buildings, and they are hereby authorized and required to appoint a registrar of metropolitan buildings; and that such registrar shall hold his office during the pleasure of the said commissioners; and that, subject to the provisions of this Act, it shall be lawful for the said Commissioners to make rules for regulating the execution of the duties of the office of the said registrar; and that it shall be the duty of such registrar to keep a seal, and to affix such seal to all documents made by the said official referees, and required to be sealed; and to keep all the documents and records relating to the business of their office, and to register the same: provided always, with regard to such registrar, so far as relates to the affixing the seal of office to any document, that if it shall appear to the said registrar that any such documents are contrary to law, or not complete in any of the requisite forms, or beyond the competence of the said official referees, either with regard to the provisions of this Act or any rules or regulations prescribed for their guidance, by the said Commissioners of Works and Buildings, then it shall be the duty of the said registrar to refuse to affix the seal; and that thereafter, if the said official referees shall so require, it shall be his duty, and he is hereby required to report the matter and the particular grounds and reasons for his refusal to the said commissioners; and that upon the receipt of such report it shall be lawful for the said Commissioners to authorize the said registrar to affix the seal or to confirm his refusal; provided always, with regard to such office of registrar, so far as relates to the execution of his duties in certain events, that if such registrar be ill or otherwise unable to discharge the duties of his said office, or if he be absent, then it shall be lawful for the said Commissioners of Works and Buildings to appoint some other person to act in his behalf, and to assign to such person such part of the remuneration of the said registrar, or otherwise to remunerate him as the Lords of the Treasury shall appoint in that behalf.

87. And be it enacted, with regard to such official referees and registrar,

so far as relates to their remuneration, that it shall be lawful for her Majesty to grant to each of such official referees and the said registrar a salary not exceeding *one thousand* pounds by the year, in four equal quarterly payments; and that if any such official referee or such registrar shall be appointed, or shall die, resign, or be removed from office, in the interval between two quarterly days of payment, then he shall be entitled to a proportionate part of the salary for the period of such interval during which he shall hold such appointment.

SCHEDULE (C.)—PART I.—(*See* § 5.)—Rules for determining the Classes and Rates to which Buildings are to be deemed to belong for the purposes of this Act, and the Thicknesses of the Walls of Buildings of such Rates.

CLASSES OF BUILDINGS.—For the purposes of this Act, all buildings of whatever kind, subject to the provisions thereof, are to be deemed to belong to one or other of the following three classes; that is to say—

First Class.—If a building be built originally as a dwelling-house, to be occupied, or intended to be occupied as such—then it is to be deemed to belong to the first, or dwelling-house class.

Second Class.—If a building be built originally as a warehouse, storehouse, granary, brewery, distillery, manufactory or workshop, or be occupied or intended to be occupied as such, or for a similar purpose—then it is to be deemed to belong to the second or warehouse class.

Third Class.—If a building be built originally as a church, chapel, or other place of public worship, college, hall, hospital, theatre, public concert-room, public ball-room, public lecture-room, public exhibition-room, or occupied or intended to be occupied as such, or for a similar purpose, or otherwise used

SCHEDULE (C),—PARTS II & III.—(*See* § 5.)

Conditions for determining the Rates to which Buildings are to be deemed to belong, and the Thickness of the External and of the Party Walls thereof.

Class.	In reference to Height.	In reference to Area.	In reference to Stories.	Rate of Building.	Requisite Thickness of External Walls of each Rate of the First Class.	Requisite Thickness of Party Walls of each Rate of the First Class.
First or Dwelling House Class.	1. If the building be in height not more than 22 ft.,	- - If the building do not cover more than 4 squares,	- - If the building do not contain in height more than 2 stories,	- - It is to be of the 1st or Lowest Rate of this Class.	- - And the thickness of the external walls must be, at the least, 8½ in. from the top of the footing to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 13½ in. from the top of the footiog to the top of the wall.
	2. If more than 22, and not more than 33 ft.,	- - or if it cover more than 4, and less than 6 squares,	- - or if it contain 3 stories,	- - It is to be of the 2d Rate.	- - And the thickness of the external walls must be, at the least, 13½ in. from the top of the footing to the under-side of the gutter-plate; and at the least 8½ in. from the under-side of the plate to the top of the wall.	- - And the thickness of the party-walls must be, at the lea-t 17½ in. from the top of the footing to the under side of the second floor; and, at the least, 13½ in. from the under-side of the second floor to the top of the wall.
	3. If more than 33, and not more than 47 ft.,	- - or if it cover more than 6, and less than 8 squares,	- - or if it contain 4 stories,	- - It is to be of the 3d Rate.	- - And the thickness of the external walls must be, at the least, 17½ in. from the top of the footing to the under-side of the second floor; and, at the least, 13½ in. from the under-side of the second floor to the under-side of the gutter-plate; and, at the least, 8½ in. from the under-side of the gutter-plate to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 17½ in. from the top of the footiog to the under-side of the third floor; and, at the least, 13½ in. from the under-side of the third floor to the top of the wall.
	4. If more than 47, and not more than 65 ft.,	- - or if it cover more than 8, and less than 10 squares,	- - or if it contain 5 stories,	- - It is to be of the 4th Rate.	- - And the thickness of the external walls must be, at the least, 17½ in. from the top of the footing to the under-side of the third floor; and, at the least, 13½ in. from the under-side of the third floor to the under-side of the gutter-plate; and, at the least, 8½ in. from the under-side of the gutter-plate to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 22 in. from the top of the footing to the under-side of the second floor; and, at the least, 17½ in. from the under-side of the second floor to the under-side of the fifth floor; and, at the least, 13½ in. from the under-side of the fifth floor to the top of the wall.
	5. If more than 65, and not more than 82 ft.,	- - or if it cover more than 10, and less than 12 squares,	- - or if it contain 6 stories,	- - It is to be of the 5th Rate.	- - And the thickness of the external walls must be, at the least, 22 in. from the top of the footing to the under-side of the second floor; and, at the least, 17½ in. from the under-side of the second floor to the under-side of the fourth floor; and, at the least, 13½ in. from the under-side of the fourth floor to the under-side of the gutter-plate; and, at the least, 8½ in. from the under side of the gutter-plate to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 22 in. from the top of the footiog to the under side of the third floor; and, at the least, 17½ in. from the under-side of the third floor to the top of the wall.
	6. If more than 82 ft.,	- - or if it cover more than 12 squares.	- - or if it contain more than 6 stories,	- - It is to be of the 6th Rate, and of the 3d Class.	- - And the thickness of the external walls must be, at the least, 4 in. greater than is hereby required for walls of the 5th rate.	- - And the thickness of the party-walls must be, at the least, 4 in. greater than is hereby required for walls of the fifth rate.
Second or Warehouse Class.	1. If the building be in height not more than 12 ft.,	- - If the building do not cover more than 6 squares,	- - If the building do not contain in height more than one story,	- - It is to be of the First or Lowest Rate of this Class.	- - And the thickness of the external walls must be, at the least, 8½ in. from the top of the footing to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 13½ in. from the top of the footing to the top of the wall.
	2. If more than 12, and not more than 22 ft.,	- - or if it cover more than 6, and less than 10 squares,	- - or if it contain two stories,	- - It is to be of the Second Rate.	- - And the thickness of the external walls must be, at the least, 13½ in. from the top of the footing to the under-side of the gutter-plate; and, at the least, 8½ in. from the under-side of the gutter-plate to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 17½ in. from the top of the footing to the under side of the second floor, and 13½ in. from the under-side of the second floor to the top of the wall.
	3. If more than 22, and not more than 30 ft.,	- - or if it cover more than 10, and less than 18 squares,	- - or if it contain three stories,	- - It is to be of the Third Rate.	- - And the thickness of the external walls must be, at the least, 17½ in. from the top of the footing to the under-side of the second floor; and, at the least, 13½ in. from the under-side of the second floor to the under-side of the gutter-plate; and, at the least, 8½ in. from the under-side of the gutter-plate to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 17½ in. from the top of the footing to the under-side of the third floor, and, at the least, 13½ in. from the under-side of the third floor to the top of the wall.
	4. If more than 30, and not more than 50 ft.,	- - or if it cover more than 18, and less than 26 squares,	- - or if it contain five stories,	- - It is to be of the Fourth Rate.	- - And the thickness of the external walls must be, at the least, 17½ in. from the top of the footing to the under-side of the third floor; and, at the least, 13½ in. from the under-side of the third floor to the under-side of the gutter-plate; and, at the least, 8½ in. from the under-side of the gutter-plate to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 22 in. from the top of the footing to the under-side of the second floor, and, at the least, 17½ in. from the under-side of the second floor to the under-side of the fifth floor, and at the least, 13½ in, from the under-side of the fifth floor to the top of the wall.
	5. If more than 50, and not more than 65 ft.,	- - or if it cover more than 26, and less than 35 squares,	- - or if it contain six stories,	- - It is to be of the Fifth Rate.	- - And the thickness of the external walls must be, at the least, 22 in. from the top of the footing to the under-side of the second floor; and, at the least, 17½ in. from the under-side of the second floor to the under-side of the fourth floor; and, at the least, 13½ in. from the under-side of the fourth floor to the under-side of the gutter-plate; and, at the least, 8½ in. from the under-side of the gutter-plate to the top of the wall.	- - And the thickness of the party-walls must be, at the least, 22 in. from the top of the footings to the under-side of the third floor; and, at the least, 17½ in. from the under-side of the third floor to the top of the wall.
	6. If more than 65 ft.,	- - or if it cover more than 35 squares,	- - or if it contain more than six stories,	- - It is to be of the Sixth Rate, and of the Third Class.	- - And the thickness of the walls must be, at the least, 4 in. thicker than is hereby required for walls of the fifth rate.	- - And the thickness of the party-walls must be, at the least, 4 in. thicker than is hereby required for walls of the fifth rate.

or intended to be used, either occasionally or constantly, for the assemblage of persons in large numbers, whether for public worship, business, instruction, debate, diversion, or resort—then it is to be deemed to belong to the third or public building class.

Rates of Buildings.—And the buildings included in the said classes are to be deemed to belong to the rates of those classes, according to the conditions of height, area, and number of stories set forth in the following tables; which conditions are to be determined according to the following rules:

The Prince of Wales Steamer.—This fine vessel made a trip down the river on Tuesday, the 26th March, previously to going on her station between London and Margate, for the ensuing season. She is an iron vessel built last year by Messrs. Miller, Ravenhill & Co., the well known engineers, who also constructed the engines, which were originally a pair of side lever engines, taken out of another Margate steamer. During the experimental trip the Prince made several trials in Long Reach, to test her capabilities as to speed, which may be calculated at not less than 12½ knots through the water. She ran down below the Nore and could find no competitor with whom to try her comparative speed; on her return she again tried her speed at the mile distance in Long Reach, when she met the *renowned* Princess Alice, with the tricoloured flag flying at her mast-head, notifying the presence of Belgian royalty on board. The *Princess* had been announced to have outstripped all vessels she came near. This was a fine opportunity to test the capabilities of the annular engines of the *Princess* and the beam engines of the *Prince*. The helm of the *Prince* was ordered to be brought about, but before the vessel was fairly turned, her sister, the *Princess*, had got a-head full a mile; nothing daunted, the *Prince* moved on, when it was very soon discovered that he was making way fast upon the *Princess*, and in about 30 minutes he went right a-head of her (not very gallant to her highness). All on board of the *Prince* pronounced it a decided victory of at least one-and-a-half to two miles per hour faster than the *Princess;* we may, therefore, pronounce, without fear of contradiction, that the *Prince* is the champion of the river, until any other vessel is found that will eclipse her. This we must own was to us a fine trial: here we had the skill of one of the first builders of iron vessels, Messrs. Ditchburn and Mair, with the annular engines, of the celebrated firm of Messrs. Maudslays and Field, against the iron steam vessel and engines of the *Prince of Wales*, both constructed by Messrs. Miller, Ravenhill, and Co., another firm equally celebrated for the excellency of their workmanship and the success of all their vessels.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM FEBRUARY 26, TO MARCH 28, 1844.

Six Months allowed for Enrolment, unless otherwise expressed.

Isabella Larbalestier, of Noble Street, Falcon Square, furrier, for "Improvements in making certain skins resemble the sable fur."—Sealed, February 26.

Richard Kitson, of Cleckheaton, card manufacturer, and John Garthwaite, of Leeds, flax spinner, for "Improvements in wire cards for carding cotton, wool, silk, flax, and other fibrous substances, and for producing tow and yarns from line and tow-yarn waste, which comes from the spinning frames commonly called hard waste."—February 27.

Charles Newington, of Ticehurst, Sussex, esq., for "Improvements in apparatus for ascertaining and indicating the time at which a person is present at a particular place."—February 27.

Thomas Harbottle, of Manchester, gentleman, for "a machine designed for manufacturing boot soles, taps, and also for riveting leather hose, traces, and for other purposes, to which the same may be usefully applied."—February 27.

William Clegg Gover, of Chester Square, Middlesex, gentleman, for "A method of casting off the sash lines and weights from the window sashes, and of taking out the window sashes from their frames without removing the beads."—March 1; two months.

Joseph Crawhall, of Newcastle-upon-Tyne, rope manufacturer, for "Improvements in machinery for manufacturing ropes and cordage."—March 2.

John Stevelly, of Belfast, professor of natural philosophy, for "Improvements in steam engines."—March 2.

Henry Dunnington, of Nottingham, manufacturer, for "Improvements in the manufacture of fabrics produced in warp and lace machinery."—March 4.

Peter Ward, of West Bromwich, Stafford, practical chemist, for "An improvement in combining matters for washing and cleansing."—March 4.

Samuel Atkinson, of Manchester Street, Gray's Inn Road, Middlesex, turner, for "Improvements in the construction of wheels for carriages."—March 4.

Bernard Peard Walker, of North Street, Wolverhampton, clerk, for "Improvements in machinery for making nails."—March 6.

Thomas Foster, of Streatham, Surrey, manufacturer, for "Improvements in preparing composition of India rubber, and other matters for forming articles therefrom, and for the coating of surfaces of leather, and woven, and other fabrics."—March 6.

William Henry Barlow, of Leicester, civil engineer, for "Improvements in the construction of keys, wedges or fastenings, for engineering purposes."—March 6.

William Fairbairn, of Manchester, engineer, for certain "Improvements in machinery used for propelling vessels by steam."—March 7.

Charles Townend, of Manchester, fustian manufacturer, for "An improved process, or manufacture, whereby cotton fabrics are aided and made repellant to water and mildew, and any unpleasant smell is prevented in such fabrics."—March 7; two months.

Alexander Angus Croll, of Brick Lane, Middlesex, superintendent of the gas works, and William Richards of the same place, mechanical inspector, for "Improvements in the manufacture of gas for the purpose of illumination, and in apparatus used when transmitting and measuring gas."—March 7.

Wilton George Turner, of Gateshead, Durham, doctor in philosophy, for the "Manufacturing of salts of ammonia and compounds of cyanogen, from a substance never before applied to that purpose."—March 11.

Charles Harrison, manager of the Coed Talon and Leeswood Iron Works, Flintshire, for "Certain improvements in the manufacture of cast iron pipes and other iron castings."—March 14.

Charles Roberts, of High Holborn, Middlesex, boot maker, for "Improvements in the manufacture of boot and shoe trees, lasts, and stretchers."—March 14.

William Godfrey Kneller, of Wimbledon, Surrey, chemist, for "Improvements in the preparation of zink, and in combinations of zink with other metallic bodies."—March 14.

Henry Pershouse Parkes, of Dudley, Worcester, manufacturer of chain cables, for "Improvements in the manufacture of flat pit chains."—March 14.

Samuel Cunliff Lister, and James Ambler, of Bradford, York, manufacturers, for "Improvements in machinery for applying fringes to shawls and other articles."—March 14.

Frederick Stephenson, of High Street, Birmingham, comb manufacturer, for "Improvements in bookbinding, and apparatus for cutting books or other folded paper, part of which improvements is applicable to pen holders."—March 14.

John Browne, of New Bond Street, Middlesex, esq., for "Improvements in urinary utensils."—March 14.

William Bown, of Leicester, glove and mit manufacturer, for "Improvements in weaving elastic fabrics."—March 14.

John Tatham, of Rochdale, machine maker, and David Cheetham, of the same place, cotton spinner, for "Certain improvements in machinery or apparatus to be employed in the preparation and spinning of cotton wool and other fibrous substances."—March 14.

Moses Poole, of Lincoln's Inn, Middlesex, gentleman, for "Improvements in steam-engines, steam-boilers, and furnaces or fireplaces." (A communication.)—March 14.

Emanuel Wharton, of Birmingham, engineer, for "Improvements in steam-engines, which are in whole or in part applicable to other motive engines, and to machines for raising or impelling fluids."—March 14.

Thomas Seymour, of Riding House Lane, Great Portland Street, Middlesex, gun-maker and John Seymour, of Wellington Street, Gray's Inn Lane, lock-filer, for "An improved safety-bolt and tumbler for the locks of certain kinds of fire-arms."—March 14.

William Henry Burke, of Tottenham, Middlesex, manufacturer, for "Improved machinery for cutting Indian rubber and other elastic substances into balls and other solid figures."—March 19.

William Saunders, of Bush Lane, London, chemist, for "An improved apparatus for modifying temperature in the condensation of vapours, and in the cooling or heating of liquids and fluids."—March 19.

Hugh Inglis, of Kilmarnock, Scotland, mechanic, for "Improvements upon locomotive steam-engines, whereby a saving of fuel will be effected, which improvements are applicable to steam vessels and other purposes, and to the increasing the adhesion of the wheels of railway engines, carriages, and tenders upon the lines of rail, when the same are in a moist state."—March 19.

William Bates, of Leicester, fuller and dresser, for "Improvements in the dressing and getting up of hosiery goods manufactured from lamb's wool and other yarns, and in machinery for raising the nap on the same, and in the construction of legs and other forms or shapes for stockings and other articles of hosiery."—March 19.

Jules Thiebeauld de la Cronée, of Pinner's Court, London, merchant, for "An improved apparatus for, or method of purifying, clarifying, and refining, vegetable extracts." (A communication.)—March 19.

André Drouet de Charlieu, of Sablonière Hotel, Leicester Square, gentleman, for "Improvements in rails for railways, and in wheels for locomotive carriages." (A communication.)—March 20.

William Isaac Cookson, of Newcastle-upon-Tyne esquire, for "Improvements in apparatus for burning sulphur in the manufacture of sulphuric acid."—March 20.

John Holland Butterworth, of Rochdale, Lancaster, cotton spinner, for "An apparatus applicable to preparation machines used in the spinning of cotton and other fibrous materials."—March 20.

Moses Poole, of Lincoln's Inn, Middlesex, gentleman, for "Improvements in dyeing." (A communication.)—March 21.

John Butt, of Maldon, Essex, draper, for "Improvements in candlesticks."—March 22.

John Harcourt Quincey, of Old Street, City Road, gentleman, and John Johnson, of Cursitor Street, lamp maker, for "Improvements in the manufacture of lamps, and shades for lamps and other lights." (Partly a communication.)—March 25.

William Pollard, of Newcastle-upon-Tyne, gentleman, for "Improvements in the manufacture of ammonia."—March 28.

James Hardy, of Birmingham, Warwick, gentleman, for "Improvements in the process of welding tubes, pipes, or hollow rods of malleable iron by machinery."—March 28.

Joseph Maudslay, of the firm of Messrs. Maudslay, Son, & Field, of Lambeth, Surrey, engineer, for "Improvements in steam engines."—March 28.

Alfred Richard Johnson, of the firms of Messrs. Johnson & Co., Regent Street, and Messrs. Griffiths & Johnson, Old Bond Street, Middlesex, hatters, for "Improvements in hats."—March 28.

Joseph Cooper, of Hoxton, Middlesex, gentleman, for "Improvements in the purification and clarification of sugar, which improvements are also applicable to the purifying and clarifying of other articles of commerce."—March 28.

Robert Davison, of Brick Lane, Middlesex, civil engineer, and William Symington, of East Smithfield, Middlesex, civil engineer, for "A method or methods of drying, seasoning, and hardening wood and other articles, parts of which are applicable to the desiccation of vegetable substances generally."—March 28.

Robert Mollett, of Shacklewell, Middlesex, gentleman, and Jesse Bridgman, of Hackney, Middlesex, gentleman, for "Improvements in separating the fatty and oily from the membraneous portions of animal and vegetable substances."—March 28.

Charles William Spicer, of 28, Portman Square, Middlesex, esquire, for "An invention called the nautilus, or portable life preserver and swimming belt." (A communication.)—March 28.

Charles Hector Francois Dumontier, of Rouen, France, engineer, for "Improvements in the construction of lithographic and autographic presses." (A communication.)—March 28.

A New Propeller.—An invention has been made by an ingenious mechanic of Edinburgh, of a new mode of giving motion to vessels, doing away with paddle-wheels and boxes, as well as the Archimedian screw. It is a simple revolving cylinder, placed midships, which acts as a windlass, and makes a rope of the sea; in fact, the velocity acquired is in proportion to the quantity of water discharged by the agency of the cylinder, through a discharging nozzle at each side of the vessel, and what is curious, the discharging nozzle can be turned by a simple operation on deck, so as to stop the vessel, make her move backward or round as on a pivot, within her own length, without even the knowledge of the engineer, or the assistance of the rudder, as no stoppage of the engine is necessary for the purpose. The convenience is a smaller consumption of fuel, and the capability of the broadside carrying an entire armament.—Scotsman.

Copper Balloon.—A balloon composed of copper is so far completed, that it is now exhibited to the public: this immense globe is formed of sheets of copper, united and soldered. The object proposed by this experiment is to resolve the problem of the practicability of the employment of metals in the construction of balloons.—Paris Paper.

THE TIMBER ROOFS OF THE MIDDLE AGES.

Remarks on the Timber Roofs of the Middle Ages, by THOMAS MORRIS, *read before the Institute of British Architects.*

(With an Engraving, Plote V., containing Roofs of the following buildings.)

Fig. 1. Westminster Hall.—2. Nursted Court, Kent.—3. Old Basing Church.—4. Guard Room, Lambeth.—5. School House, Coventry.—6. Hall Croydon Palace.—7. Conway Castle.—8. Eltham Palace.—9. Wolsey's Hall, Hampton Court.—10. King's College Chapel.—11. Chapel, Croydon Palace.—12. South Wraxall.—13. Westminster School.—14. Crosby Hall.

THE timber roofs of the ancient regal and baronial halls, which form so prominent and characteristic a feature of our national mediæval architecture, merit, in an eminent degree, the attention of all to whom the science of construction is an object of interest; and although other avocations have precluded the present writer from going into the subject in that full and perfect manner which it is calculated to repay, and which its importaoce fairly demands, he trusts he may be able to furnish a few observations, to serve, perhaps, as a stock on which the results of other and more successsul efforts may be at a future season engrafted. So little, indeed, has yet been done towards giving a connected form to the history and principles of English carpentry, that he who would shrink with conscious inability from attempting so comprehensive a project, may yet hope to find not utterly valueless such mere gleanings as the present.

It will not be thought requisite to carry the subject back to that remote period of Anglo-Saxon history when the carpenter (as well as other artificers) was considered, if not a positive vegetable, at least part of what we are accustomed to call the plant of an estate, transferable from owner to owner with the land, as we read that "when the brother of Godwin gave to a monastery a certain manor, he included its appendages; that is, his overseer and all his chattels, his smith, carpenter, fisherman, miller, all these tenants, and all their goods and chattels."

The artificers of the early Saxons appear to have been for the most part either monks or slaves—they were nothing more than sheer necessity made them—they lived and died poor, unhonoured, and unimproved! "The habits of life were too uniform, its luxuries too few; its property too small; its wants too numerous, and the spirit of the great mass too servile and dull," says Mr. Sharon Turner, "to have that collection of ingenious, active, respected and inventive men who make and circulate our internal and external commerce with eager but not illiberal competition; or to have those accomplished artificers and manufacturers, whose taste in execution equals that of the most elegant fancy in its invention."

"In the monastery," says the historian, "were to be found smiths, carpenters, millers, illuminators, agriculturalists, and fishermen." The carpenter was at that time the *treow wyrhta* (the tree or wood workman.) The Anglo-Saxon verb used in speaking of building is commonly *getymbrian*, "to make of wood," and it is known to every architectural antiquary that many early churches were constructed of that material—one at Greensted, in Essex, still remains.

As we approach the time of the Norman conquest, matters became ameliorated, and this was an advantage concomitant with the establishment of Christianity and the influx of Italian clergy. The most durable materials were sought for and applied in ecclesiastical works, and to our architects for several centuries previous to the date of any large wooden roof,

> "The art was known,
> By pointed arch and shafted stalk,
> The arcades of an alleyed walk,
> To emulate in stone."

This art they practised with such admirable skill and effect, that their works have been not unfrequently considered beyond the pale of modern imitation. To these architects who had previously and progressively roofed our edifices with stone, from the simple adaptation of the *more Romanum* in buildings of Anglo-Saxon and Anglo-Norman dates, to the masterly example in the Chapter House at York, who had clothed with so much invention and taste the bold framework of mathematical deduction, are we indebted for the wooden wonder of Westminster. The span of Gothic groined roofs seldom exceeded 35 ft.,[1] while the Great Palatial Hall was double that width. Numerous obstacles to a stone roof must therefore have presented themselves; the builder was thrown upon the resources of his art, but he proved himself his craft's master, and a novel and elegant application of that great element of lightness and beauty, the arch, was the consequence. The former ponderous and friable material was exchanged for one equally susceptible of the nicest equilibriation, and greatly superior in tenacity and tractibility. It was one of the grandest innovations recorded in the annals of English art.

Westminster Hall, Anno 1399.—(Fig. 1.)

Our first consideration (in respect of dimensions if not of date) is due to the roof of Westminster Hall, where the distance between the sides is 68 ft., and the length 240 ft. This length is divided into twelve bays, giving a distance of 20 ft. between the principals or points of pressure and support. At these intervals an arch of great strength and boldness is thrown from wall to wall, setting down on stone corbels, and rising about five-eighths of the span. The curve, from the springing to the vertex, is divided into three nearly equal spaces, but the intermediate points are made to approximate somewhat more closely, in order to facilitate the disposition of the load; and additional stiffness and protection is afforded by the well-devised framework within the arch. It will be seen that the uppermost of these points falls immediately under the middle of the rafter, where the weight is collected by a massive purlin, and carried by an auxiliary arch to the queen posts, and by them conveyed to the hammer beam, a timber which possesses the property of a lever rather than a tie. The point of intersection with the arch (Fig. 1*) is its fulcrum or centre of motion, and the force exerted at the inner end, which represents the weight of the upper half of the rafter, forms a well adjusted counterpoise to the pressure on the pole plate or beam at the foot of the rafter connected with the outer end of the hammer beam. These forces combined follow the direction of the arch, which discharges its load fairly on to the walls; and the outward thrust is so perfectly counteracted by the disposition of the parts, that the flying buttresses of the exterior seem called for, rather as a set off to the casualties of practice than any imperfection in the principle. This appears, indeed, the light in which they were received by the builders, for there seems to have been little attention to regularity even in their original disposition.

This *chef d'œuvre* was completed in the year 1399, when Richard II. kept his Christmas at Westminster, and is said to have entertained 10,000 guests daily, but as that number could barely manage to stand in the hall, it is clear the whole party did not dine together. This was no doubt a circumstance of annoyance to the hospitable monarch who is said to have exclaimed that it was but a "mere dressing room in comparison with what he wished to have!"

Eltham Palace, 1480.—(Fig. 8.)

To the decorated period Mr. Rickman has, I think, erroneously attributed the roof at Eltham. Its characteristics are certainly those of well developed perpendicular. It is a bad imitation of the Westminster roof, the chief arch being an obtuse pointed segmental one, which of course exerts a very considerable pressure against the upper part of the walls, and the hammer beams and brackets are but ill calculated for supporting any part of the load that may be thrown upon them. The designer seems to have taken little pains to obviate a lateral strain, trusting, in this respect, to the resistance afforded by the walls and buttresses. The principal rafters are of large dimensions, and are stiffened by horizontal struts under the purlins. The arched rib relieves the hammer beam of much of the weight at its inner end, and there are no longitudinal arches springing from them as in the foregoing example. The clear span of this roof is 36 feet.

On investigation, I find my previous surmise as to the date of this roof supported, and its erection satisfactorily attributed to Edward IV. The cognizances of that monarch are of frequent occurrence in the masonry, and documentary evidence exists of his having at great cost repaired his house at Eltham. His third daughter (Bridget) was born here in 1480, and in 1483 he celebrated Christmas in a most sumptuous style—2000 persons being regaled daily at the festive board.

Wolsey's Hall, Hampton Court, 1520.—(Fig. 9.)

The roof of the Great Hall at Hampton Court (temp. H. 8) covers a space of 40 ft., (which is the same as at Christchurch, Oxford, and Trinity College, Cambridge,) and is, perhaps, the most elaborate we possess.

As a scientific system of framing, it cannot enter into rivalry with that at Westminster, which will be readily felt, when we consider that the admiration it attracts is directed to a mere casing and not to the actual skeleton. This gives it the character of a ceiling rather than of a roof, but it is to the timbers that our attention must now be

[1] The Chapter House at York is 57 ft. in diameter, but the building is octagonal, and the points of support, therefore, more frequent, and the resistance to a pressure from within greater than in a continuous vault. The nave of York Cathedral is also of the great extent of 48 ft.

devoted, and here we do not recognize that masterly arrangement, that perfect equilibration, which should at once proclaim it to be "By its own weight made steadfast and immoveable," a line that may be applied to Westminster Hall, with equal truth, force and beauty.

In the present instance a considerable thrust is exerted laterally upon the walls, rendering buttresses necessary to its stability. Still there is much ingenuity in the frame work, and the pressure is made to exert itself at an angle of about 70°, being as near to a vertical direction as the scheme of the roof would perhaps admit of. The principal rafters may be said to partake of the property of an arch, and being concealed, their ruder construction does not form a very material disadvantage.

The forces are made to exert themselves upon the hammer beam; but with respect to the manner in which this timber is supported, a marked difference is observable; a difference, indeed, that causes a complete change in the constructive principle and ultimate transmission of the load. At Westminster we have seen the great arched rib proudly spanning the entire width of the hall, and forming the grand support of the whole roof. The hammer beam, as has been shown, is poised with the greatest precision upon a point in the arch, and the weight thrown perpendicularly on the walls at the springing; but at Hampton Court this principle is not carried out, for the hammer beams with their struts support the arch! In estimating the lateral thrust of such a piece of framing, the simplest method seems to be to compose the forces acting on the hammer beam, and draw the resultant, A B, through the bracket and the walls to the ground. We thus have the elements of a lever, the external edge of the wall being the fulcrum or prop. The weight of the wall collected at half its thickness from the fulcrum, as the resistance to be overcome, and the point where the resultant cuts the ground, shows the position of the counteracting force.

In this point of view the ancient massive rubble wall had certain advantages over the light and compact mural works of the moderns. In conveying the forces from the hammer beam to the wall, the bracket is presumed to be of adequate strength; but it ought to include a straight (or more strictly a parabolic) line from the bottom of the queen-post to the corbel, to prevent a cross strain, and the line of the composed forces should pass on the outside of the corbel, otherwise the hammer beam would be liable to be depressed. The form of these brackets being just the reverse of that which the mathematician would prescribe, the introduction of the bolt, an object which is regarded by the carpenter with extreme jealousy, became an act of only due precaution.

Roof of Westminster School.—(Fig. 13.)

This exhibits very closely the anatomy of such as Hampton Court, and was selected by Tredgold as a general type of these works. The deflexion of the hammer beams and derangement of the queen-posts consequent on an excessive loading of the inner ends of the brackets, is quite apparent. The hammer beams of the opposite sides are now connected by bars of iron, a most unsightly and I fear equally ineffectual remedy.

King's College Chapel.—(Fig. 10.)

This roof, which has been very accurately delineated by Mr. Mackenzie, is curious, from the degree of care bestowed on its form and finish, considering its destination as a mere covering to the very beautiful masonry beneath. It illustrates the practice of first roofing in buildings to be vaulted with stone. "There are," says Rickman, "buildings in which, though the upper roof is shown, there is preparation for an inner roof; such is Chester Cathedral, where only the lady chapel and the ailes of the choir are groined, and the whole of the rest of the church is open; but on the top of the shafts is the commencement of the springing of a stone roof.

It is in perfect consistency with the usual order of events to suppose that roofs were constructed with principals of a simple arched rib antecedently to those of more complicated forms and grander dimensions; and at Conway Castle (1284) (Fig. 7) there are appearances which have induced me to suppose that the purlins and other timbers were supported by a series of stone arches and gables, serving the purposes of principals.

Guard Room, Lambeth Palace, 1450.—(Fig. 4.)

This is a very elegant roof of a simple wooden arch, but its precise date is not recorded. It has the lofty two-centred and bold tracery of early perpendicular work, and there is in Brayley's illustrations a memorandum under the date 1452, that on account of the great infirmity of Archbishop Kemp a convocation was adjourned from St. Paul's Cathedral to the Manor of Lambeth, and held in the High Great Chamber, *(altâ camerâ majori,)* which he supposes to be the room in question. It is said to have been the restoration of a still earlier guard room. Though now plastered over there is every reason for concluding that the rafters were originally exposed to view.

Hall and Chapel, Croydon Palace, 1450.—(Figs. 6 & 11.)

These furnish examples with the four-centred arch; and at the Moat House, at Igtham, Kent, is a very bold simple arch which when accompanied by spandril tracery, and the upper part occupied by king-posts and the other timbers, must have produced a very fine effect.

The Roof of the Divinity School, Oxford, may be instanced as a specimen of the arched rib, with pierced tracery in the spandril, supporting a ground ceiling with pendants and elaborate tracery.

In Rickman's work on "Gothic Architecture," is mentioned a roof at Willingham Church, Cambridgeshire, where stone ribs rise like the timber ones, the intervals are pierced, and the slope of roof is of stone; it is high pitched, and the whole appears of decorated character (1307 to 1377).

In smaller examples we often meet with arch-formed timbers serving (otherwise than for ornament) as auxiliaries to the principal rafters, and give no change of direction to the weight. Instances of this are found at South Wraxall (Fig. 12), the Vicar's Hall, Wells, and many other places.

Nursted Court, Kent, 1330.—(Fig. 2.)

At Nursted Court, situated about four miles due south from Gravesend, is a roof of singular interest, doubtlessly anterior to that of Westminster Hall, and attributed, with great probability, to Stephen de Gravesend, Bishop of London, who became possessed of the manor in 1338. In this example the portion of the weight which at Westminster thrown on the inner end of the hammer-beam, is here at once conveyed by a series of arches and posts to the ground. Mr. Carlos says, "The interior of the hall was distinguished by the singular construction of its roof, which was sustained on pillars standing within the area, in this respect differing from the generality of ancient examples which have reached our day, it is however highly probable that Westminster Hall was originally divided after the same manner. The roof appears to have been sustained on a frame work composed of two principal beams and two purlins, and supported by four oaken pillars disposed on two ranges on each side of the area, the beams being converted into arches by the addition to their soffits of arch formed timbers. It is illustrated in the "Gentleman's Magazine," for April, 1837, where there is a notice of a similar roof at Balsall Temple, Warwickshire. The School House, at Coventry (Fig. 5), is another example.

Crosby Hall, 1470.—(Fig. 14.)

Another class of roofs of considerable antiquity, but perfectly distinct in principle from those yet considered, based on the property of the triangle to resist racking or change of form, is met with in several of our colleges, at Crosby Hall, and in many later buildings. It is in roofs of this kind that timbers possessing the nature of a tie, or for which a flexible substance, as a rope or chain, might be substituted, are first advanced in English work, all beams in the former examples being either compressed or subjected to cross strains. This roof was well adapted for the oranamental ceilings of the sixteenth century, when the custom of concealing the timbers prevailed, and formed an easy transilience from the steep inclination of the old roof to the flat unbroken plane of "modern instances."

Gothic roofs, then, (using the term generically, in contradistinction to those with level ties) admit of an obvious and definite analysis into four classes, to one or other of which any roof may be referred. Three of these have the arch for their basis, and the science of equilibriation is called into direct action; the fourth has in itself a countercheck to lateral pressure.

The first class comprises roofs with simple arched ribs as at the Guard Room, Lambeth; the Moat House, Igtham; Ackwell Manor House, &c.

The second class comprehends those examples that have a grand arch spanning the entire width with axiliary timbers, by which part of the weight is suspended from the intrados as at Westminster, Eltham, Boddington, Iuxon Hall, Lambeth, &c.

The third class consists of such as have the arch supported by brackets, as at Hampton Court, Westminster School, &c.

The fourth class, or angular roofing, includes such as are formed of two intersecting triangular frames, in which the tendency to press out the walls is counteracted by the longitudinal stress upon the connecting beams, as at Crosby Hall.

In this latter class we arrive at a point where it becomes difficult to trace the principle of construction, and to determine with exactitude the object of the cross beams. In some instances their use as struts is apparent as at Old Basing Church (Fig. 3), in Hampshire, in others their usefulness as ties can hardly be questioned, as at Crosby Hall. I mention this ambiguity, because the original application of oblique or inclined ties has been attributed to Mr. Revett, an architect of the last century, and known to the republic of letters as the editor of the third volume of Stuart's "Athens." On the one hand it must be confessed that in the older roofs we can hardly be said to meet with timbers in a state of tension. On the other, if we reflect how decidedly the attention of artists was in Mr. Revett's time averted from our natural relics, we shall cease to be surprised if their just pretension met with neglect, and, in some cases, misappropriation.

OBSERVATIONS ON ARCHITECTS AND ARCHITECTURE.

By Henry Fulton, M.D.

No. 8.

The Farnese or Italian astylar seems likely to gain the ascendant in this country, and, perhaps, all things considered, it is well that it should do so. In the mind of every man of taste the Greek style is inseparably connected with a state of purity which rejects all adulteration, and (whether fortunately or not for the development of our own powers) our climate and customs require so many changes from the original, that in the adaptation of the style, it too often loses all its value, and becomes flat, stale, and unprofitable. Exceptions there are to this in favour of a few temples and isolated buildings, where the style may still be exhibited to advantage; and unpardonable indeed is the architect who does not seize on such opportunities when within his reach; as these must be relied on to maintain and hand down to posterity the true principles of the art.

But although the use of the Greek style, as defined by its orginators, must, for the reasons stated, be in a great measure abandoned, yet unless the love of it and a full and entire perception of its beauties pervade the whole soul of the architect, it would be better for us mortals that his proper calling was to build pigeon boxes or hen coops rather than National Galleries, Museums, Royal Exchange interiors, and club houses. If, in the chances of life, Canova had been cast away on some barbarous island in the Pacific, would he not, if obliged to cut jade into idols, have carried out, even with such materials and for such purposes, those principles of his art which he had acquired by studying the works of Phidias? If our masters—aye, our masters, for we must agree with Sir Joshua, who says, "From the remains of the works of the ancients the modern arts were revived, and it is by their means that they must be restored a second time. However it may mortify our vanity, we must be forced to allow them our masters; and we may venture to prophecy that when they shall cease to be studied, arts will no longer flourish, and we shall again relapse into barbarism," if the architects of the time of Pericles were now permitted to appear amongst us, would they not carry into the designs for our modern buildings the same principles which guided them in designing those structures which *ought* to be the admiration of the world?

Now it is precisely the lack of this feeling and perception, and not the difference of climate and wants which causes the failure of some modern architects. Take the ancient models to pieces, select, appropriate and combine *ad libitum*, but remember the principles, and do not deviate one iota from them. Invent, if you please, and treat your own inventions as you please, but do not take the same liberty with the inventions of others. Do not take a Greek cornice for the purpose of breaking it up into trifling parts, without reflecting that the Greeks themselves obtained grandeur and simplicity by its integrity, and that the same results may not follow a contrary practice. As Sir Joshua Reynolds aptly says, "however contradictory it may be in geometry, it is true in taste, that many little things will not make a great one;" if this be true in painting, much more is it applicable to architectural outline. Do not stick a Greek portico up against a building, because it will then have the appearance of not being part of the original design, but rather an after-thought, which may be easily removed elsewhere, and all the compositions of the Greeks had a monographical character, which gave their most elaborately finished works all the charms of simplicity. If a portico be required on the side of a building, or in any case where it cannot be made to extend the entire front, why not recess it *in antis*, and thus preserve integrity of outline? In truth we have both bill stickers and portico stickers all engaged in the laudable occupation of disfiguring our public and private edifices.

Do not let your pediments have the appearance of having been sliced off from some smaller edifice; that is, let the entire extent of the front be crowned with a pediment, or if that may not be, let there be none at all, for if you place more than one in the same line, as in the river front of Somerset House, for instance, then the composition must have the appearance of being so many separate edifices, and not as one design.

Windows we must have, although, as far as the Greek style is concerned, they are evils, still they are necessary evils, yet it is by no means necessary to make the evil greater and more apparent by means of incongruous ornament, if indeed we may use the word ornament to express any thing when it ceases to be ornamental. Why then do we find two little columns surmounted by a little pediment, which only appears to be made part of the building by an awkward process of grafting? Little columns and little pediments are little things and little in the acceptation of the term, when it implies mean or insignificant; they must have magnitude or they cannot have importance. The proportion generally given for windows is that the height shall be twice the width: in the Traveller's Club the columns of the windows are 10 ft. 3 in., and the interspace between the columns 5 ft.; taking the columns to be ten diameters high, this would give us no less than six diameters from centre to centre; in fact, with a little stretch of imagination, these windows look like the porticos of model temples let into holes in the wall, the centre columns being removed for the purpose of showing the muntons of the sash lights. In considering the subject of intercolumniation, I had recourse to my old friend Palladio, not for the purpose of seeing what he did, for I expected no ally in that quarter, but to see what he said, which may have some weight with those who take his works as their standard. He says, "The intercolumniation may be of one diameter and a half, or of two, of two and a quarter, of three, and sometimes more, but the ancients never exceeded three except in the Tuscan order. Great care must be taken to keep a due proportion, because if small columns are made with large intercolumniations, it will very much diminish the beauty of the former." It is moreover the invariable practice to diminish columns even when engaged, which in the case of windows must leave the opening wider above than at the bottom.

The apex of a pediment should be the crowning stone of the composition, the highest point in the picture; how is this character preserved in windows which have wall and cornice, and, it may be, other windows and pediments above them?

But perhaps it may be asked, "do you require merely a plain opening in the wall?" for my part, I can contemplate a plain cleanly finished, unornamented window, without feeling the same horror which arises from one of the ornate description first alluded to, or the shouldered and balustraded ones which are presented to us in great variety; but there is no necessity for leaving these openings destitute of all ornament, for moulded architraves may in almost every case be supplied with advantage. The Roman arch gives a good form of window, particularly for the ground floor; but it must be quite plain, without even a dropping keystone, which, indeed, looks like the consequence of a mistake on the part of the workmen, who may have accidentally placed the piers or jams too far asunder, and hence the dropping of the keystone. Mathematicians consider the circle as the most beautiful of all figures; the dropping keystone destroys its arc.

The Egyptians, by covering their walls with hieroglyphics, sought to convey and perpetuate information and instruction to the people, and their labours have survived the knowledge of the characters in which they were written. Some architects now-a-days cover their edifices not with graven precepts, but with scored lines, which have neither wit nor worth, excellence nor meaning. The New Zealander thus tatooes his face as the American Indian puts on his paint, that he may bear the distinguishing marks of his tribe; but it will scarcely be urged that tatooing is of the same use in distinguishing one class of buildings from another. Mr. Leeds, in his criticism on the Traveller's Club, says, "Rusticating of different kinds contributes in no small degree to variety and character in this style. Contrary to the idea the term itself at first suggests, so far from producing rudeness, coarseness or negligence, it is not incompatible either with richness or delicacy of finish." For my part, I can distinguish no difference, unless it be that in some examples there is more paring and frittering away than in others. "There is no beauty in straight lines," such as these which break up the surface without giving any breadth of shadow. A few lines are easily drawn on paper, but much labour is given to workmen, and consequently not a little expense entailed on those who are to pay; and for what? to make open joints for the reception of dust and moisture, without having a redeeming feature.

Columns are the most ornamental part of classical architecture, and yet they are quite unfitted for ornament, nor has the attempt to appropriate them for that purpose ever succeeded; the explanation of this seeming paradox is that their beauty principally arises from the exquisite variety of light and shade which they afford when properly insulated; but when engaged doing any thing else or doing nothing, we feel the want of that they do not give, and the more sensibly because they seem only to recall its absence to our memory. Engaged columns give the substance but not the shadow.

We must also notice the introduction of those bloated, stunted, pot-bellied, corpulent things called balusters, (although we regret they do not merit being designated by more elegant terms.) A critic in the March number of a contemporary journal speaking of the Gresham Club, (noticed in Observations No. 7,) says, "That the great merit of club architecture is to make a good kitchen;" and in place of giving any remarks on other points, gives in commendatory terms an account of the "lifts" for the dishes to pass to and fro, and the washing of plates; all this is no doubt very satisfactory to the readers of that journal, and german to the guzzle-ability and gull-ability of the civic members of the club, as well as creditable to the ability of the architect himself, however it may excite the risibility of others. In the façade of this club we have these architectural wall-*flowers* introduced no doubt as emblems of the fat contented state, which the culinary arrangements of the kitchen may probably produce. Sir Robert Smirke has placed these *gouty* columns (as they have been called) on the College of Physicians, for the more humane and noble purpose, as emblems of swathed *podagra*, to remind those who are afflicted with one of the most painful maladies which the pleasures of the kitchen bring, that here they may be relieved. Where it is not necessary to set forth on the elevation by means of these pigmy columns either the bane or antidote, if a screen be requisite, the iron founders furnish many examples in much better taste, more Greek and not less classical. In the Travellers' Club, for instance, both may be compared, and we can recommend this without the imputation of flattery because we bestow our praise to its back and not to its face.

Balustrades might be made highly ornamental and appropriate on gastronomic principles for "Club architecture," if instead of dwarf columns with their capitals reversed, specimens of fat inflated humanity were designed and placed in the same position.

It is the practice of some architects to treat their antæ and pilasters either to foliated or voluted capitals; now the true and legitimate use of a pilaster in a composition is to connect columns with the walls, that the transition be not too violent, and these connecting links should partake of the nature of both; which can be best obtained by neither fluting, diminishing, nor giving them capitals other than suitable mouldings.

Old women and children (it may be remarked without disparagement to the taste of some persons who do not rank as either) invariably prefer the Ionic and Corinthian orders to the Doric. This latter order is plain and severe, and can only recommend itself to the eye by its well adjusted proportions. It would almost appear that its inventors had felt this, and laid down an unerring rule, which, like the laws of the Medes and Persians, properly admitted of no change, namely, that two metopes, and two only, should intervene on the frieze between centre and centre of each column. It is true there is one instance of the contrary, but it forms the exception, not the rule, and it is an example rather to be avoided than magnified and taken as a precedent. I am very far from holding the opinion that the proportion of frieze just mentioned should not *in any* instance be deviated from, for even so much as the entire space of a third metope may be given and the eye shall scarcely detect it if the index be not given in the form of triglyphs. In the basement story of Carlton Terrace, facing St. James's Park, an instance of what I mean may be seen. But in the name of good taste, what innate beauty is there in a triglyph? Is there any form or figure in architecture more devoid of beauty? Yet as used it is the index either of beauty or deformity; it is either the index of a well proportioned arrangement, or the indication of a struggling and weak one, which can neither permit the eye nor the imagination to be deceived. In the Roman or emasculated Doric (which is no more a specimen of the noble order from which it is said to have been derived, and whose name in part it bears, than the unhappy modification of the *genus homo* is a fair example of the class whence he is taken, and whose garb he wears) triglyphs are of the same advantage as false curls are to the shrivelled and withered face of an old harridan, which, as the index respectively of due proportion and youth, only renders deformity, debility, and decripitude the more apparent: and although the age and infirmities of the ancient dame, even when thus indicated, may excite our sympathy, yet the Vitruvian epicene and fabled personification of the other sex has no claims on the extension of our gallantry.

An example of faulty metopical arrangement may be seen in the portico of the University Club, as it appears in Leeds' "Illustrations of the Buildings of London;" there are two columns flanked by coupled antæ, and the triglyph is not placed over the centre of the internal pilaster, and there are three metopes on the frieze above the centre intercolumniation; these incongruities and irregularities would not have been so evident if the frieze had been altogether naked or enriched with sculpture instead of the triglyphs. The Universities have some reason to be dissatisfied with such an attempt at a classical portico.

It neither was the practice of the ancients, nor is it of modern architects to introduce triglyphs into Ionic or Corinthian compositions, yet there seems no reason for not doing so, when the arrangement of the columns admit of it: but we have ancient examples in abundance, and too seldom followed, of sculptured friezes without triglyphs in all the orders.

The first and somewhat distant view of an edifice should give a bold unbroken outline; all ornament should from such a point of view appear softened into a mass, merely soliciting a closer inspection: and when to obtain this the spectator advances, the eye ceases to take in the outline, or to feel that it is all interrupted by the most highly finished or minute sculptured details: but if instead of these, broken entablatures, polytriglyphs, senseless rustic lines, and a spongy-looking surface meet his view, better nothing existed to incite a close examination. Of all the ancient architects, the Egyptians first, and after them the Greeks, alone seem to have been aware of the advantages of these principles. On these the beauty of a composition depends; without them an edifice may be ornate but not ornamental; convenient but not symmetrical; well constructed but ill designed; the work of a skilful builder who understands his trade, but not the production of an accomplished architect who aims at the highest walk in his profession; it may induce the groundlings to stare, but it must force the judicious to grieve; the censure of one of which ought, in the allowance of an architect to o'erweigh a whole crowd of others.

It cannot be denied that disappointment often arises when a structure is finished, an event which was not expected when the drawings of the design were in the first instance submitted for inspection. Employers seldom look at a design except as a picture, and they are ignorant of what the result may be in the solid. Unfortunately architects are obliged to minister to this state of things, particularly in cases of competition, and I believe that few are the instances where the most highly finished and tasty drawings have not been the successful ones; and when once these receive the fiat of approval, the architect is naturally loth to suggest any alteration. A geometrical elevation appears a cold stiff production to every eye that cannot realize its erection, hence the architect is tempted to set it off to the best advantage, and to give it pictorial effect by the introduction of light and shade, to procure which he must often break up his composition. In short, the efforts of the architect may be directed to produce a design on paper as the primary object; the erection of the edifice itself being altogether of secondary importance, and instead of his conception being (if I may so speak) in stone, it is on paper, and must be viewed from very different points of sight. The architect's whole thoughts are centered on the draught, on the ornamenting of which he spends the might of his mind, careless it may be of the effect, which must result in the solid, from his projecting lines which ornament his picture; and as drawings are generally to the subject what an inch is to ten or twenty feet, features scarcely observable are, when thus magnified, rendered unsightly.

It would be most desirable, in all cases, if models were prepared, instead of, or in addition to drawings; it is true some expence would be incurred by the practice, but in many cases it would tend to save expence. Buckingham Palace, for instance, a great part of which was taken down whilst the works were in progress, I believe more than once; and in others, the National Gallery, for example, it might save us a world of regret and disappointment. This is an inventive age, and as soon as the demand for models shall arise, we shall have suitable materials discovered for their construction.

It is said of Fuseli that on seeing a student in the Royal Academy staring at vacancy, he asked him what he was looking at, "Nothing, Sir," was the reply; "See something," retorted Fuseli, "I always see the subjects I am about to paint;" so it should be with an architect, he ought to think of the solid, and in this respect *building castles in the air* may not be an unprofitable occupation, as regards the advancement of his taste. Drawings ought merely to be the memoranda for the assistance of his own memory, and the means by which he wishes to demonstrate to others the subjects of his thoughts.

Some of our readers may be disposed to think that many of the observations in these papers are so trite and self-evident as to be uncalled for; I wish they could show me from modern practice that they were unnecessary; I wish they could bring forward the erections of the last ten years in refutation of what is here urged; then, indeed, the labours of "a mere amateur" would be superfluous, and I should gladly lay down my pen, and give myself up to the contemplation of the beauty of revived architecture. Mr. Gwilt and others have written and spoken with a righteous horror of the interference of "idlers," but let Mr. Gwilt and the rest not confine themselves to writing and speaking against amateurs, let them also write and speak openly against what those amateurs say. A certain clique are too generous, too candid, too much occupied with ideas of their own importance, to attack, even in self defence, an anonymous assailant: let us see what reply they can give to one who does not shelter himself in ambush, to one who although fully sensible of his want of powers to set forth things as he could wish, yet yields to none in a desire to promote a love and knowledge of the art, and who is thoroughly persuaded that the best method of doing so, both for the interest of the profession and the furtherance of the art itself, is to give the public the means of obtaining information. If the writer of these papers should have succeeded in the attempt to promote this, then he has written as he would; but if his endeavours have been marred by lack of ability then he has written as he best could, and he hopes that others more highly qualified may be induced to come to his assistance, point out his errors, and supply that which is deficient.

It has been too much the practice in all ages to meet suggested improvements and proposed deviations from established notions, with other than open and candid argument. Daring is the man who attempts to run counter to the prejudices of his age; *parva componere magnis;* Galileo was put into the Inquisition for asserting that the earth moves round the sun; and Harvey lost his practice as a physician for attempting to demonstrate the circulation; still we can now say with Florence's eldest son,

"The starry Galileo with his woes."

"It moves," as he said, when a ray of light entered between the bars of his prison and fell on a diagram of the Copernican system scratched on the walls of his dungeon. And although worse than monkish bigotry (considering the quarter from whence it came) assailed our own Harvey, still from its citadel, the heart, life's current flows and returns in the very circle which he pointed out. If the immortal conception of the Greek architects, buried amidst the rubbish of false taste, must lie neglected and dishonoured, let Resurgeram be graven on its tomb, for assuredly against us also it shall hereafter rise in judgment.

II. Mr. Gwilt in his Encyclopedia, 'expresses the laudable desire "to form, guide and correct the taste of even the *mere* amateur," and he says that "York Stairs, another of Inigo Jones' examples exhibits a pureness and propriety of character which appear afterwards unappreciated by his successors, with Wren at their head." Will Mr. Gwilt, the learned author of the Elements of Architectural Criticism, have the kindness to state what form, figure or feature of this erection "exhibits pureness and propriety of character?" I am sure the pleasure and instruction he can afford by doing so, will be shared with me by all the readers of this Journal, (I hope a numerous class) who desire to have their taste formed, guided and corrected.

Clonmore, Dublin, April 1844.

PROGRESS OF ART.—WESTMINSTER REVIEW, No. 80.

While the Quarterly, and the Foreign Quarterly Review, both of which used at one time to be rather frequent with architectural topics, together with others bearing upon the fine arts, now never touch them, the "Westminster" here gives no fewer that *four* articles of the kind, occupying one-third of the entire "Number." Architecture therefore seems to have turned up "trumps" in that *quarter;* and whether they be small or high trumps, it holds a most remarkably strong hand of them. The one which may be considered the ace of them, is played off first, viz., that entitled "Progress of Art," which, we may observe, in lieu of the writer's initials, has only a mystifying, * ?, attached to it. That the writer should not have cared to afford any clue to his name, is not particularly surprising; since he does not take a very flattering view of the Progress of Art, either among ourselves or in other countries,—in fact, he considers the Progress to be in some respects a backward and retrograde one,—to be one not of advance but of falling back upon antiquated forms and models, excellent in their time, and admirably adapted to the spirit of it; yet our time is not theirs: Europe is not China: the lapse of comparatively very few centuries has wrought a complete change in the European mind,—and not only in our social and outward habits, but in our mental ones likewise. Nought does it avail to say that such ought not to be the case, if such it really is; consequently it is for those who contend that things ought to be otherwise, to show how they can be made so. Surely Art has not yet gone through every possible phase of it,—has not yet revolved through the whole of its great Platonic year.

We must not, however, allow such vain questions—hardly less useless than perplexing—to detain us; neither can we pretend to notice here what the writer says in regard to the state of painting and sculpture at the present day; accordingly to his comments on architecture, little flattering, or rather, exceedingly unpalatable as some of them are, we confine ourselves. Be they truth or untruth, it is important that architects themselves should be fully aware what sort of opinions get abroad relative to themselves and their art. They may, indeed, shut their eyes and their ears, but they cannot compel the public to do so likewise, therefore it is as well for them to keep a sharp look-out, or they may chance to find the tide rushing in upon, and taking them by surprise when they are quite unprepared.

"Though the whole nation," says the writer, "have and always have had an interest, not only in the private edifices, but in the public buildings erected throughout the kingdom,—while the knowledge and enjoyment of the sister arts have been confined to the affluent and the educated, still architecture is with us at present in a worse position than either of the others, its professors have less title to the name of artists, and its best productions can only claim as their highest praise to be correct copies, or at most, successful adaptations of some other buildings erected in former times, for purposes totally different from anything we at present require. The cause of this, we believe, will be found to lie, even more directly than in the other arts, in the system of copying, to the exclusion of all original thinking, or, indeed, of common sense; and the reason why this should be so fearfully prevalent in architecture will be found to be principally in the anomalous system in which not only the patrons of art, but the artists themselves, have been educated in England."

We have next some severe but just remarks on "gentlemanly education" in this country, and the insufficient system pursued at the great schools and the two universities, with some lustily dealt blows at the latter for their utter neglect of art. Then, after some stringent remarks on the miserable sort of professional education which young men receive in this country, when placed as articled pupils to architects, the writer comes to some of the late, and of the living "notabilities" in the profession. Among the former, Soane, Nash, Wilkins, are fairly enough estimated by him,—we might say, rather favourably than the contrary, for considering the number and the kind of the opportunities afforded them, not one of the three achieved what he might have done; each of them was, besides, too much of a mere mannerist, and seems to have worked with a very limited stock of ideas. Mannerism, monotony, and penury of ideas, still more strongly characterize a *distinguished* living celebrity, who, as far as he has any character at all, may be described as the utter "negation of an artist." As such he is spoken of here,

"Sir Robert Smirke has adopted a safer plan than any of these men; his fame rests entirely on the sound masonry of his buildings, and the only attempt he makes at artistic effect is putting up as many Ionic columns as his employers will allow, One drawing made long ago has served for all his porticos, now about to be brought to the acme of perfection in the British Museum, where forty-four of these useless Ionic columns, placed in various rows, are to form the façade."

This is assuredly sufficiently expressive of contempt, in itself, yet we fear, will be taken, both by Sir Robert and many others besides, as very mild reproach. It is, indeed, by far too much so for so very great an offender—one who has injured art most seriously, and that not so much by his own miserable abortions, which might well be left to contempt, as by robbing it again and again of some of the fairest opportunities that have been afforded to architecture among our public and national edifices, nay absolutely nullifying them. If Pecksniffs there must be in the land, at all events let them not be thrust into high places. The man himself might have been a very respectable "*carcase builder,*" but as an architect is the poorest maudlin imaginable: still in his merely being so there would be nothing very remarkable, but that being so, he should have been allowed to go on to the extent he has done,—to commit failure after failure, is indeed most wonderful and supremely mortifying; and withal shows what kind of encouragement is bestowed in this country on architecture itself, and how far the patronage it receives is judicious, discriminating and sincere.

If towards Sir R. Smirke, the writer in the "Westminster" has been somewhat more lenient than many others, he has not been sparing of criticism towards one who has hitherto been accustomed to have to listen to it only as applause or even homage—we mean Charles Barry. That gentleman would perhaps have been better satisfied, had his works been more briefly mentioned; still he can bear to hear the truth as well as any body; while as to the writer, if he has touched one or two vulnerable points in the architect's greatest work, somewhat ungently, it shows that he is not over-awed by a reputation which seems to carry all before it. After a few strictures on Mr. Barry's club houses, the reviewer goes on to say—

"The Parliament houses are, however, the great architectural undertaking of the present day. Since the rebuilding of St. Paul's nothing so splendid has been attempted in Britain, and indeed, since Versailles, scarce anything on the Continent can compare with them. We have also the satisfaction of knowing that the design is the best of our best architect, and that instead of the grudging economy that is said to have spoiled so many of our undertakings in art, the expenditure here has been not only liberal but lavish; for had we been content with a plain, honest brick building, with stone dressings, such as would have satisfied our fathers or ourselves a few years ago, we might have had all the accommodation the present one will afford, and better arranged, for £150,000 or £200,000, whereas the estimates for this one already amount to £1,200,000, and it will not be finished under a million and a half. Here then is at least a million of money spent on pure æsthetic ornament, a sum that would have restored to their pristine beauty (if we wanted Gotbic) every cathedral or church in the kingdom, or would have established schools of art and design, with collections of art, in all the principal cities in the kingdom; this it has been determined to expend in realizing the design of one architect, and already the nation are beginning to tire of their bauble before they have got it, and to think they have paid too much for what they begin to find out will not be satisfactory when finished.

"The river front is now nearly completed, and as Mr. Barry declares it to be the best part of the design, we may safely assert that the new buildings, though clad in the very prettiest and best selected Gothic detail, will, when finished, be as much like the bold, meaning, purpose-like buildings of our ancestors as the very pretty Swiss peasant girls and very polite brigands and Albanians of our ball-rooms are like the rough originals.

"Every building of our ancestors expressed in every part the purpose for which it was erected, and with a degree of richness or simplicity suited to its destination; here, with the idea of producing a grand uniform whole, every part has been made externally to look exactly alike. The speaker's house is the counterpart of that of the usher of the black rod, and though the latter is obliged to share his residence with a librarian, that is not to be discovered from the exterior; and equal magnificence is displayed in the apartments allotted to the clerks of the House and all the inferior offices. Indeed, whether it is the great conference hall or the public libraries or committee rooms,—whether it is the Queen's robing room or a librarian's bed room, each is externally the same; and whether the room is fifty feet by thirty, or only fifteen feet square, the stories throughout are of the same height, unless indeed, as has been suspected, some of these fine looking windows are to be cut into two by concealed floors, a falsehood no Gothic architect ever was guilty of, and a meanness which two honest windows would never exhibit.

"It is needless to point out at what an enormous sacrifice of expense and convenience this has been effected; but what is worse, it is not only not Gothic, but is an attempt at the same silly pretension which induced Nash, in the Regent's Park terraces, to group together a number of small houses into one design, to make them look like a palace. The truth peeps out at every corner there, and so it does here; and if any one will take the trouble of clothing any of them in Gothic detail, Chester Terrace for instance, he will be surprised how nearly he has re-produced the river front of the Parliament Houses."

Long as is the foregoing extract, we must immediately follow it up by another still longer:—

"It must always appear strange how an architect could have gone so much out of his way to obtain this uniformity, and produce a prevalence of the horizontal lines over the vertical, for not only is this utterly abhorrent from Gothic in every case, but here, where he had a front about eight times the length of its height to deal with, all his ingenuity should have been exerted either to break the horizontal lines, or by bold projecting masses (as at Versailles), to prevent the eye following them, and thus take off the low street-like appearance the building now has; but, as if to make this still more apparent, the towers, instead of being parts of the river front, so as to give it height, are placed behind it, and disconnected, as if by contrast to make it still lower. It is lucky for the architect's fame that the land front, in spite of his worse judgment, will be broken and varied by the projections of Westminster Hall and the law courts, and will thus much surpass the river front; but it is painful to see the great tower placed so as by its mass to depress and overpower the Abbey and Henry the Seventh's chapel. It would have been difficult to invent anything that could be more prejudicial to them than this feature, which, if admissible at all, should have been placed where the speaker's house is, at the angle next the bridge. Had this been done, we should not have had the architect coolly asking for £120,000 to rebuild the superstructure at great temporary inconvenience to the public, and permanent detriment to the navigation of the river, and this merely because he forgot the existence of the bridge in making his design, or had not wit enough to know how to counteract the effect of it on the building. It is besides here, where there is a great thoroughfare and a fine open space (it is understood that the houses in Bridge Street are to come down), where processions and shows can be seen from the square, the bridge, and the river, that the Queen's and Peers' state entrances, with the Peers' House, should have been placed; not as they now are, in a back street of Westminster; and had this been done, and the south end devoted to the Commons, there would have been good grammar and good taste in building that part of a plainer and less pretending style than the north, half devoted to royalty and the peers. This would have been more appropriate to the confined situation, and the saving of expense as great as the additional convenience.

"If, however, the exterior shows all these defects, and many more, which it would be tedious to point out, the interior is far worse, which will be easily understood when it is stated that one-fourth of the whole area is occupied by eleven large and seven small courts; and as these are all entirely surrounded by high buildings, they will be at best but damp, ill-ventilated well holes, whose floors the sun will seldom see. They increase the expense of the building to an extent not easily calculated, not only by spreading it over a quarter more space, but they actually present more lineal feet of stone-faced wall than the whole exterior of the new building put together.

"Had the architect adopted one great court, with a glazed roof, running behind the river front, and divided into four compartments by the two houses and the central hall, these compartments forming four halls might have been surrounded by three tiers of arcades, something similar to the galleries of our old inn court yards, thus affording easy and cheerful access to all the apartments, and doing away with the tunnel-like corridors which at present occupy half the building. If, in addition to this, he had raised the roof of his ground floor about ten feet, and lighted it with good honest windows, instead of the loopholes which at present scarce admit light to render it habitable, a much smaller building would have afforded far more accommodation.

"It is not easy to conceive anything that would, architecturally speaking, have been more magnificent than this range of halls, extending at least 700 feet in length, and broken by the arcades supporting the houses and central hall, so as to take off every appearance of narrowness; and had something like fan tracery been adopted for the roofs, but with the fairy lightness that cast iron would have enabled the architect to introduce, and the interstices glazed with coloured glass, we might fairly have challenged the world to produce anything like it. In these halls, too, might have been placed the memorials of our great men; one court might have been devoted to our literary men, another to our men of science, whilst the others would have been occupied by our heroes and statesmen. Their statues might have stood in the centre, and their illustrious deeds have been painted on the walls.

"By bringing the ground floor into use, it would not only have given the building more height, which it much wants, but have provided space, in conjunction with the halls, for coffee rooms, committee rooms, waiting rooms of all sorts; and by adopting four covered courts instead of the open ones, so much space might have been attained that the building might have been set back fifty feet from the present line of front, and a good broad terrace road obtained, from which the river front might have been seen; at present it is entirely lost, and cannot be seen near enough to be examined from a boat; the present terrace, of thirty feet wide, is too narrow to admit of the building being viewed from it, besides not being accessible to the public."

The terrace is, in fact, not only too narrow, but much too low: it ought to have been raised twelve or fifteen feet more, or to about the same level as the foot of the bridge; that front of the building being still of the same height as at present, consequently loftier than those on the west side. Of course this would have caused material alteration of the plan within, because the principal floor rooms towards the river, must have been on a proportionably higher level than the rest; yet so far from being attended by inconvenience, that circumstance might have been made to contribute not a little towards interior effect, the ascent to those rooms being arranged somewhat after the same manner as will now be that leading up from Westminster Hall into St. Stephen's Hall.

Beyond the two last-mentioned portions of the future "Palace of Westminster," we apprehend, the scheme for fresco-painting and other decoration can hardly be carried out,—at least not so that the public can derive much advantage from it. No provision has been made by the architect for what was not contemplated neither by himself nor any one else, when he first formed his plans. The fresco painting scheme has been entirely an after-thought, and hardly practicable to anything like the extent that has been talked of. Little less than preposterous is it to suppose that decoration of the kind can be adopted for corridors, which, great as will be their extent, will be merely passages of communication—not at all too wide even for that purpose, and with no more light than what is absolutely necessary; yet, it is to be hoped that, come when they may, our English frescos will endure to be seen to advantage without being shown in twilight.

After Barry, Pugin comes in for some share of the critic's notice and animadversion, for while it is admitted that he not only understands the style he follows, but enters into the spirit of it, he is charged with wrong-headed enthusiasm, in endeavouring to dress us all up in the costume of the fourteenth or fifteenth century.

"It might please some enthusiastic persons," says the writer, "that we should give up our science and civilization, and return to the barbarous ignorance and simplicity of those days; but it requires no great sagacity to foresee that, so far from retroceding, we cannot even stand still, but must advance; and although, because we have no other art to admire, we are now wild after correct copies of old churches, it is quite evident that neither the symbolism nor the monkish superstition of the middle ages can have any permanent hold on an enlightened people."

So, too, think we: neither religious feeling, nor feeling for art, is likely to be in the slightest degree benefitted by the ecclesiastical mummery now so largely affected, and accompanied with no small share of hypocrisy on the one side, and of stupid credulity on the other.

SUGGESTIONS CONNECTED WITH THE ANTIQUITIES IN ASIA MINOR.

[The Government determined in 1843 to send out a fresh expedition to Asia Minor, under Mr. Fellowes' direction, to procure further marbles, and to investigate more thoroughly the antiquities of the neighbourhood of Xanthus. The Trustees of the British Museum appointed Mr. Hawkins, Jun., to assist Mr. Fellowes in his architectural researches among the monuments of the country; and the Council of the Royal Institute of British Architects having been applied to for instructions and suggestions to aid the travellers in their investigations, Messrs. Donaldson, Vice-President, Angell and Scoles, were requested to draw up a paper on the subject; the following memoranda were furnished to Mr. Hawkins.]

Most of the monuments in this country are either of the time of the successors of Alexander, or were erected during the Roman dominion. But if there be any of a remoter period they are of very great interest in connexion with the history of art and the usages of the earlier times.

Those of the higher antiquity will doubtless be of ruder execution, and the proportions not so graceful as the later ones of the Alexandrine period. The monuments of this latter epoch will generally be found to be purer in conception and execution than those erected either previously or subsequently; but not so refined as those of *Grecia Propria* of the time of Pericles. Under the Roman rule the wants and luxurious habits of the people increased, and some of the Roman usages were adopted. In these buildings, therefore, there will be found greater intricacy of plan, and frequently a mixture of brick and stone or of brick and marble construction, and the use of the arch more frequent. Examples of the early use of this important feature will be very interesting.

The edifices of the ancients in Asia Minor were frequently subordinate one to another; and their Agoræ, Temples, Theatres, Stadia, Gymnasia, &c., form very interesting groups. It should, therefore, be an especial study of the architect in Asia Minor to observe these combinations, and to mark the reference which one building has to another.

The temples will generally be found to be placed in the centre of a peribolus, which will have the usual propylea. Observe also the circumambient porticos, if any, of the peribolus; whether the inner range of columns, if there be two, be higher than the outer one. Remark, likewise, if there be any arrangement immediately in front of the temple, as for an altar, canopy, pedestals, seats, &c. The interior arrangement of the cella will doubtless be found peculiar in some examples, as for instance in that of Apollo Didymeus at Branchydæ, near Miletus. There is no complete plan of an Asia Minor temple known; those at Magnesia, Teos, &c., being so encumbered with ruins as to preclude investigation, without more means for excavation and removal of blocks than usually possessed by ordinary travellers.

There are many particulars still required respecting the ancient theatres, especially as regards the scene, *proscenium*, *pulpitum*, orchestra. For the lower portions of the theatres are generally piled up with the ruins of these parts. Observe whether the floor of the *pulpitum* be of stone or has been of wood. Remark whether there be any traces of the chambers or recesses for the echeia in the κοιλον or cavea as mentioned by Vitruvius—also the decorations of the scene—of how many orders it consisted, whether it had three or five doors, and any subterraneous passages, and how constructed.

Details of the arrangement of an Agora are desirable, showing the disposition of the shops and general form of the whole, whether square or oblong? Did there exist honorary pedestals or other monuments in the area? Were there two orders of columns one above the other? What temples or other edifices had immediate connexion with the agora? Its propylon—was it traversed by a road?

If any roadways still exist, observe whether they are paved with oblong blocks or polygonal stones—are there stepping stones in the streets as at Pompeii?

Some of the palestræ, gymnasia or baths were of large proportions, as those of Alexandria Troas, and Ephesus already published. But more particular details of such edifices are required; as not only plans but elevations and sections and mode of construction.

Remark also any aqueducts or triumphal arches—take details of the water channel or gallery (specus) and observe, if they have any coating of a strong stucco or cement, or whether they have merely a natural calcareous deposit resulting from the water itself.

So complete have been the illustrations of the details of Greek buildings in the several works on Grecian architecture, that mere details of mouldings and parts are now of less consequence, unless there be any striking peculiarity in them. But the general arrangement of edifices and the disposition of the halls, porticos, vestibules and various chambers in any group demand the especial attention of the traveller, which should be directed to these desiderata and also to the general plans of cities. The walls, towers and other warlike defences and fortifications may afford great novelty, particularly the entrance gates.

Sometimes there are burial places outside the towns at some distance with tombs, sarcophagi and other funeral constructions in a group; at others these sepulchral erections line the roadways leading to a city. Remark how the summit of the tombs was finished, and whether there be signs of a pedestal or statue on the top.

Carefully note all indications of colour on the architecture of this country—and if possible put at once on the drawing corresponding tints—if not write them down—and try to scrape off some of the colour and preserve it in a packet, carefully inscribed with the name of the monument, date and place whence taken.

If any temples should be discovered with the columns still standing endeavour to ascertain whether their axes be perpendicular or inclined either towards the cella or outwards.

In any cases where it may be practicable to excavate and clear away the accumulated earth from the ruins, care should be taken to note down and observe the precise situation of all the fallen blocks, previously to removing any of them, and an endeavour should be made on the spot to design a satisfactory restoration. In some instances the ruins of temples may be found prostrated in almost symmetrical order, and the columns, entablatures, pediments and acroteriæ, may be traced in regular succession. A careful examination of the situation of the fallen masses will also assist materially in ascertaining the causes of the destruction of the edifice, which in many cases will be found to have been occasioned by earthquakes, or by the hands of the conqueror.

All blocks of an irregular form, and which throw any light as to the construction of the masonry, should be measured, and a perspective sketch made of them, after the mode adopted by Mr. Cockerell, as shown in his contribution to the additional volumes of Stuart's Athens. The mortice holes for the insertion of timbers, cramp holes, the mode of tooling, the manner of working the beds, and all points relative to the construction will be found of great use. Observe also as to the mode supposed to be adopted for raising the masonry, for instance, the grooves at the ends of blocks or any other similar contrivance. Examine the description of marble or stone, and ascertain, if possible, the quarries from whence it was brought; these are often in the immediate neighbourhood of the cities and should be visited. Remains of unfinished columns and entablatures may sometimes be found in them. Notice the mode adopted by the ancients in disengaging the blocks from the rock—if by wedges, by fire, by sawing, &c. Where practicable, examine the foundations and lower courses of the buildings; notice the method and age of the construction, as it frequently happens that temples (as in the case of the Parthenon) have been erected upon foundations of a prior date to the buildings themselves. Any Cyclopean remains and works of the heroic ages, which may be discovered, should be carefully examined and described as subjects of paramount interest.

It will sometimes happen that fragments, wanting for the purpose of completing the restoration, may be found built up in an adjoining modern building, or in the walls dividing the fields.

The forms and construction of modern buildings should not be altogether overlooked. The resemblance between the modern constructed wood huts and the representation of beams and timbers in several of the ancient monuments is highly curious, and without doubt many ancient forms and modes have been handed down with but trifling alterations from century to century.

Marble doors are common in Asia Minor in the tombs. The mode of hanging them by pivots or other means should be noticed.

At Antiphellus are numerous curious tombs—a reservoir, theatre, &c., worthy of a visit and attention.

Among other indications of the site of an ancient city the existence of wells is often a guide to travellers in their researches. Tanks for the reception of water from the mountains also exist; and at Antiphellus (now Castelarizzo) is a circular reservoir, which also had the advantage of preventing the town below from being inundated.

Thomas L. Donaldson, V.P.,
Samuel Angell,
J. J. Scoles.

THE PHILOSOPHY OF TERRA FIRMA.

Having devoted the preceding chapters to a brief outline of the chief primary Causes of Effects manifest within the primitive ocean, and the phenomena of primitive earths of exclusive oceanic origin, I will now pass on to the consideration of earths of *Terra Firma*, elaborated by animals and vegetables, as produced by secondary causes, by the moving force of waters, and atmospheric affections, produced and still producing by a regular unbroken sequence of events, being the continuance of the one great chain of life, and still ascending in the scale of development. The primitive soils of the ocean, or more plainly speaking, those which are the exclusive products of the ocean, are silicates, and the earths of calx, and soda, forming sands and pebbles, marls of varieties, limestones, calcarious matters, salts, sulphates, muriates, carbonates, nitrates, and other characteristic fossil and mineral bodies: these several matters being (separately, and under numerous combinations,) the foundations of Terra Firma, and being the secondary and co-operative causes of all terrestrial phenomena embracing the living, fossil, and mineral kingdoms.

Professor Brande, in his lectures, given in this *Journal*, has told you that the presence of alumina is necessary for the generation and maintenance of almost all vegetable species; but he has not, neither can he inform you, under what conditions aluminous earths are formed. The oceanic earths of which I have previously spoken, have no aluminous clay, nor traces of this earth in their composition, unless they have been subjected to those influences by which this earth is generated. The island, and the district apportioned to the main continent, have not only no alumine, which is absolutely necessary for the maintenance of species, but the soil when first elevated above the waters, is wholly inimical to land vegetation, abounding with bitter acrid salts, mechanically and confusedly mixed with the alkaline earths. The conditions of change are atmospheric influences, thus the virgin lands disposed within the hot rainless regions continue bare and desolate for a long unbroken succession of ages, but where the rains fall or the lands are periodically or for any prolonged period of time covered by the freshes, the acrid salts rapidly disappear, contending acids and alkalies uniting, form neutral bodies, and the soil rapidly acquires the generating power. Again, there are secondary causes of fertility, such as sea birds resorting to the newly formed land, or masses of vegetable matter being conveyed there by the tides, or thrown thereon during storms. The species first generated on these desolate soils are uniformly species of mangrove, being aquatic plants, nurtured and fed by saline waters, containing much soda, and sinking within the waters in consequence of their consolidated nature: with these we find rank coarse grasses almost wholly composed of silica, and thorny shrubs of a dry brittle nature: neither the one, or the other, produce the black vegetable soil common to older strata, their chief constituents similating with ocean plants. In the course of time, the soil undergoes a change more favourable to vegetable existence, the dung of aquatic birds and vast quantities of fish brought by them and continually spread upon the soil contributes to increase this favourable disposition, and if rain, only occasionally fall, new species more exclusively belonging to the earth simultaneously or in succession make their appearance; acacias, gum trees, aromatic shrubs, replacing the trees and plants and grasses of a more decided character, as the former occupants die away, or diverge into new species, in conformity to the change of soil and local influence. The law of nature in spontaneous generation is climate and association: the deserts being disposed within rainless regions continue bare and desolate, except in those regions where the rains fall, where rivers and fresh waters spread over the soil, or where these waters find their way by percolating through the porous beds: on the other hand the countless islands of the Pacific derive a rapid fertility from the rains that periodically fall, as well as from each other by a variety of secondary causes, such as the conveyance of vegetation from the one island to the other, by the sea, by birds, and by man:—the generation and increase of vegetable earth depends therefore upon the generation and increase of vegetable species.

Soils of Terra Firma are the resolution of ascesent vegetables generally combined with variable proportions of animal matter; of a black colour; eagerly combining with the atmospheric volumes and with water, by which combinations various known products are generated; they are bibulous, reducible to dust, inflammable, and combustible, converted into clay, and from thence by transition into schist, again decomposing and passing into earths and ochres: sometimes passing into coal. Chemists by the tortuous means of fire produce from pure vegetable earth a definite compound, which they term *humus*, but the student must bear in mind that this compound is artificial, not existing in the natural state, and can only be obtained by causing the separation of those acids, which are part and parcel of the soil, and by oxydating the remainder by means of heat of fusion.

While the living inhabitants of the ocean are continuously occupied in generating consolidated gaseous and volatile products, the architects of Terra Firma, awakened into existence and local action, become in time equally effective elaborators of earths of other qualities than those previously existing; and in climates favourable to vegetation the earths gradually accumulate, forming vast aggregate masses in union with those oceanic products which they abstract from the ocean soil, or that are united with them by the moving force of waters. Of the numerous varieties of animal and vegetable existences peculiar to the earth, to fresh water lakes, streams, rivers, and even to the air, but very few retain their primary form on the cessation of vital action; of those few, some enter into the fossil state, but the great majority are either devoured by animals and pass through the digestive process, or they decompose, their atomic particles and peculiar compounds being received by the earth, the general parent and nursing mother of all—disseminating and combining with each other, and with oceanic substances, as the accident of locality and local influence may determine; the result of change being earths, fossils, and minerals, and also aggregate masses, termed mineral beds: the results produced by purely atmospheric influences, varying from the results manifest in oceanic beds, the material of the animal and vegetable structure being peculiar to the element under the conditions of which it lives, and is enabled to propagate its kind. We have seen the polypes existing by sufferance only, of latitude, dip, and inclination, and such, in fact, is the general law of nature, applicable to all living forms of the earth; and as the polypifus flourish most, and as all oceanic creatures are most abundant beneath tropical waters, so do we find animals and vegetables most abundant in those lands situate within the tropics which are favoured with excess of heat and moisture: many individual species having scarcely any limits to their growth or the multiplication of kind. Time, under all circumstances, is necessary for the full development of species, as it is for the full development of the earth: generations elapse ere the coral reef rears its head as an island or main portion of a continent: generations elapse ere the forest tree attains its maturity of growth, multiplies its species, and thereby generates those vast beds of vegetable matter and clay which meet the view in local portions of the earth. We have, it is true, no hills or mountains of bone, the reliques of terrestrial species; but we have masses of vegetable matter equalling in extent many of the coral formations of the deep. Beneath the Equatorial Band, in those localities which favour the rapid generation, destruction, decomposition, and change of organic bodies, these depositions of vegetable earth cover many thousand square miles of the surface of the earth, and contribute in many places to fill up the unfathomable depths of the ocean, being carried therein by rivers of vast magnitude. The trees of the forest possess, it is true, greater longevity than any known animal species, they stand for ages ere they become impaired by time or general accident, but during this prolonged period they are active agents of change, absorbing carbonic acid and atmospheric air, and thus adding to their consolidated structure, producing foliage, fruit, and flowers periodically—nay, perpetually changing—the leaves, flowers, and fruits falling to the earth, and adding to the vegetable earth previously formed, their volatile products dissipating and finally entering into new combinations, and being the proximate Causes of new Results. Again, vegetables constitute the food of ruminating and granivorus animals, of locusts, and varieties of the insect tribes, of worms and other creeping things of the earth, and of many of the birds of the air: man draws largely upon it for his subsistence, and myriads subsist upon vegetable alone; all adding, by the digestive process, to the animal matter of which they are composed, and also to the earth in the form of soil, cast out at the draught; and, added to the soil, unite with and become a portion of numerous consolidated bodies. Again, the roots of plants continually decay, and are as continually regenerated and extended; thus under whatever form or disposition vegetable matter is deposited on the earth, it adds its portion to the earth, and thereby increases the general sum of inorganic matter.

Animal and vegetable species of Terra Firma maintain their existence on the same tenure as species of the ocean: vegetables exist by the carbon elaborated by animals, as well as by the elements of air and water; they also abstract matters from the soil in which they exist; and they propagate by seeds or separation of parts: animal species are generated, are enabled to exist, and multiply their species by devouring animal or vegetable species: thus it is, in and throughout universal nature an interminable war is carried on, the strong devouring the weak, the weak preying upon and existing by the strong, death and the digestive process of the living continually adding to the soil, and the soil abstracting matter continually from the atmosphere and the waters; the fossil kingdom enlarging as species generate and decay; the mineral kingdom increasing in every vibration of Time, as generations rise and decay, and as matter composing the beds of earth changes in its character and qualities. As the naked polypes elaborate silica, as stony polypes, crustaceous, and molluscous animals elaborate calx and soda, so the vegetable species elaborate the elements of potash, many peculiar acids, and a variety of vegetable products, so animals elaborate oils, animal matter, iron, &c.; the elements of the one, and the elements of the other, uniting in death and contributing to form beds of the earth, in which, although every organic form is obliterated, individual character exists sufficient to enable man to identify its previous condition as a product of the earth. Place a bed of black mould by the side of a bed of chalk, how great is the contrast, how diversified the material, trace each to the fountain head of production, and the like phenomena are observable, countless species, differing from each other in form and character uniting in death, and producing ONE RESULT: blend the one with the other, after subjecting them to climate and consequent chemical action and change, and the results are the varied beds and mineral aggregates of this earth.

"It is generally considered," says Professor Brande, "that lime is elaborated by animal species;" such, indeed, is the expressed opinion of Linnæus and other writers, but it can scarcely yet be said to be the general opinion of geologists. Still, qualified as this admission is, it leads the way to admissions still more important—to a knowledge of facts still more essential to the elucidation of the enigma of nature: it is also admitted that vegetable earth is produced by the decomposition of vegetables, that much of its material is abstracted from the compounds air and water, and much more is formed by the digestive process of animals which feed upon it. The vegetable body, springing from a basis of vegetable and animal matter, is found, on ultimate analysis, to consist of the elements of air and water, and of carbon, the latter constituting the bulk of the vegetable body: the union of these compounds in definite proportions, determining, of necessity, the character of the plant, and the link in the chain of vegetable life extending in a graduated scale from the tremellæ, which have neither form nor size defined, nor appearance of organic structure, to the fungi, mosses, lichens, grasses, plants, and, finally, to fruit and forest trees.

In all climates we observe the first manifestations, the gradual increase, and the vast local accumulations of vegetable earth: the pulverulent lichens, requiring no vegetable soil in the first effort of vegetative life, clothe the barren rock, and in the gradual decay of portions of the roots and minute branches an exceedingly fine earth is formed, gradually accumulating and concealing the rock on which they grow from view: by this continuned increase the plant is eventually destroyed by a too rich soil, it perishes, and in its place foliaceous lichens, plants of larger growth, spring up, destroying all that remains of their humble predecessors, and these in turn give place to mosses. In the plains the acrid grasses and plants yield gradually to species of a more succulent and generous nature, and terrestrial animals always follow in the wake of the vegetable creation. The fossil kingdom is inimical to vegetable life, but as the mineral kingdom forms by and in the decomposition and recombination of these bodies, so the vegetable kingdom, when favoured by warmth and moisture, increases in extent and variety. Humboldt has remarked that in the Canary Islands, Guinea, and the rocky coasts of Peru, the pioneers of vegetable life are succulent plants: in the Pacific, vegetation forms very rapidly, from a variety of causes, and favoured by heat and moisture: in the deserts, as previously observed, the earth remains barren and unproductive age after age, and every region of the earth presents not only mineral and geographical features peculiar to itself, but also peculiar vegetation: "Thus," as Lamoreaux remarks, "the bason of the Atlantic, the west sea of the Indies, comprising most of the Gulf of Mexico, the East coast of South America, the Indian Ocean and its gulfs, the shores of New Holland and the adjacent isles; the Mediterranean and the Red Sea, all have a marked vegetation of their own, differing from each other."

In form, in matter, and in motions, Nature is equally variable: the production of one day disappears in the next; the etherial fluid becomes æriform, vaporous, or aqueous; the aqueous becomes consolidated as rock. Again they change, and again and again, as locally affected, without regard being had to their usefulness or to their utility, All things are Produced, all things are Producing, all things are perpetually changing in their parts and qualities. A stratum is formed to-day, it is destroyed on the morrow; the ocean retires before the earth; the earth is overwhelmed by the flood; the innumerable phenomena constituting earth being necessarily produced by uniting and contending motions, and uniting and contending matters, originating in one and in many causes.

In the changes continually taking place among inorganic bodies, elementary principles, and gaseous compounds, the like difficulties stand in the way of the man of science when he attempts to generalize upon particular phenomenon. Life departing, the passive clothing of life becomes a portion of the soil to which it is accidentally consigned, and the subject of new forces, the nature of the influences exercised upon it, determining the nature of the ultimate result. A forest is prostrated by tempest or by flood, and the wreck covering perchance several leagues, becomes gradually or suddenly entombed in the earth: it is then, the nature of the earth, and the peculiar influences to which it is exposed, determines the character the embedded fossil remains will assume: thus within an earthy soil, they quickly decompose, becoming a portion of that soil; imbedded in saline earths, they are preserved from decomposition, and become mineralized as coal; imbedded in peculiar clays, they perchance mineralize as slate; or, under other circumstances, become siliceous bodies, or proximate causes of the production of basalt; the ultimate result always depending upon the nature of the material in its mixture, and upon the elements to which they are subjected, and by which their changes are directed and governed, the organic body in death becoming the subject of new and peculiar disposition in its atomic parts and qualities, decomposing, or consolidating, as the accidents of circumstance may determine, their primary qualities being for ever lost in their new dispositions. Again, in the more complex organizations and combinations of nature, we see the folly of generalizing upon single phenomenon; for particular fossil species may be found in certain strata which bear a striking analogy to each other, but the Causes of Effects thus manifest may widely differ from each other; thus land animals may be, and often are found in oceanic beds: found, for instance, in the chalk and lias of England are often the relics of elephants and other terrestrial animals, formerly carried therein by running streams: and, again, oceanic animals are abundantly found in terrestrial strata, not only as primarily forming these strata, but also generally diffused through terrestrial earths by the moving causes of flood and fire: the accidents of a day, of an hour, may in a few fleeting moments have produced this complicated state of affairs: but, if the primary causes of many terrestrial vegetable species being locally generated and produced, forming noble forests, verdant savannahs and plains still exist, it follows as a necessary consequence, that the sum of terrestrial earth as vegetable soil still continues to increase; for in all bodies decomposition and recombination is rapidly going on, and all aluminous earths are the results proceeding therefrom. In the rainless regions, particularly the great deserts of the earth, immense local areas are nearly or wholly devoid of life, and as a necessary consequence vegetable earths are not to be found unless deposited in the line of rivers, in deltas, and narrow valleys, such as the Oasis; and this alone is a great testimony that the earths which cover the valleys are not produced as is generally asserted by the disintegration of ancient rocks, for the nature of the silt of rivers is always consonent to the nature of the soil, thus in some streams it is almost wholly composed of salts and vegetable earths, whereas in the absence of vegetable earth the matters held in suspension are such as charaterize the fossil soil, as magnesia, carbonate of lime, soda, iron, mucilagine salt, sulphuric acid, and other compounds belonging to fossil soils only. On the other hand, in local areas of the globe favourable for the development and increase of vegetable species, vegetable earths abound also, the local extent of production of the one depending on the increase of the other, for even when deposited in the beds of lakes and running streams, it is necessary that the ratio of increase be continually such as is consonent with the increase and decomposition of organic bodies from whence the supply is obtained. Thus it is, primary or fossil soils uncovered with vegetable species, and exposed to the action of running waters, suffer degradation to a very great extent, the hills and mountains become intersected with ravines, and beds of rivers are carried below the adjacent soil: the mountain ranges of Arabia and other parts of Asia, of Africa and Australia, suffer degradation to a vast extent during the monsoms or rainy season, the abstracted material being carried into and spread over the valleys and plains, or otherwise over the bed of the ocean from whence it was primarily derived, but in those places where vegetable species abound, the earth is protected from abrasion, and not only so, but the decomposed vegetable bodies carried by the waters into the valleys prevents any further decomposition.

It is an error generally embraced in the present day that the earth receives no increase, but merely changes in its parts and qualities, and that the sum of consolidated matter and of the waters continue the same for ever. This, although in conformity to the opinions of ancient philosophers, is as entirely at variance with the nature of things around us, as it is to facts coming under the cognizance of even common observers. From the waters in the union of oxygen, hydrogen, and nitrogen, aided by light and heat, species are produced, derive their increase, their several capacities and powers, and are enabled to propagate their species: the union of these elements in varying proportions of necessity produces varying results: and, again, with these results, thus generated by the living, the several elements of bodies, and decomposed portions of bodies, again and again unite, producing a further and indefinite series of resclts. Some of the cryptogamia, for instance, derive their nourishment and increase from the atmosphere alone, and thus consolidated matter, termed vegetable earth, is production in incessant decay and reproduction of these plants; quantity being produced from the continued generation of atoms in the unity of these atoms, and quality being produced from the varying mixtures of matter with matter, the earth obtaining increase by the processes of generation, dissolution, and change. Every organic body in the ocean abstracts by its mechanical or chemical operations a certain portion from the waters, the oxygen and hydrogen uniting according to the forces of affinity and motion, ammonia, carbon, and other proximate elementary bodies being produced, previously no existence, and when formed maintaining their integrity of character under numberless combinations, and being incapable of returning to their previous state. In like manner terrestrial species abstract from the waters and the atmosphere—a portion of this abstracted material is again returned to these elementary compounds, but another portion is retained by the body which is thereby enabled to maintain its position as a thing of life, to develope its parts, and to propagate its species. The earth teems with countless myriads of animals and vegetables, and life is sustained in and throughout the whole by incessant absortion, and consequent abstraction of atmospheric air, a fourth body carbon being the result, more concentrated in its nature and of greater specific gravity, and consequently having a greater tendency to consolidate; and the carbon generated by animal life is greedily absorbed and condensed in *form* and *body*, by vegetable species of simple organization and of simple elementary qualities.

The laws of nature, in production and reproduction, are regulated by the force of circumstances; orders are produced by local action and re-action and local influences; genera and species diverge therefrom by local action, accidentally or casually manifested; the genera, order, or species produced, the multiplication of like from like, depending entirely upon the accident of circumstance, over which they have no defined control: thus under favourable circumstances, and in the absence of destroying agents they rapidly increase and multiply, the trees become a forest, the polypes form chains of hills, and locomotive animals assemble in shoals—flocks and herds, or swarms, obscure the face of day. Under less favourable circumstances they become the sport and prey of hostile species, or of the elements; thus the forests are laid low, the flock and herds are destroyed by disease or by carnivorous animals, innumerable enemies thin the shoals of fishes, and storms destroy the gathering insect tribe; brought into being they become immediately the sport of circumstance, destroying and destroyed: the frog feeds upon the insect tribe, the serpent feeds upon the frog, the cormorant and the wild hog feed upon the serpent: each of these has its enemies, and last of all comes man, before whose wishes and desires Death marches terrific, mowing down all in his way. The law of nature is war!—war!—species arranged against species—life against life;—such is of *necessity*, otherwise the ocean water would become stagnant with the living and the dead, and terrestrial earth would for ever remain a desert.

There is, it is true, apparent harmony in the economy of nature, both in the ocean and on the earth, proceeding from the local distribution of animals and vegetables, arranged in groups and families, and also in the local disposition of inorganic matter, which, although produced by many, contains elementary principles and proximate principles, similating and in common with all: but, upon a close examination and analysis, we find that all aggregate masses of matter differ widely from each other, and, although the general aspect of the mineral compound may be such as to enable us to classify and arrange them, still there is a marked difference in the composition, structure, and qualities of aggregates bearing the same name. Motions and matter similating and prolonged to a certain period of Time, produces an apparent but no real regularity of disposition of strata, this apparent arrangement proceeding from similar Causes, by a series of dispositions of like qualities, and of like compound atomic particles, the matter thus brought together, producing ONE RESULT, the stratum thus formed having qualities peculiar to the class to which it owes its origin. In the union of matter inert there is no fixed law, for countless organic bodies of the animal and vegetable kingdoms are confusedly united together after the functional operations of life have ceased, and the nature of these bodies, and of the elementary principles with which they unite in the mineral kingdom, determines the nature of the strata; thus some, in union and general decomposition, form clay—others marls, varying in their qualities, according to thei r mixtures—others sands, or limestone, or other kinds of rock, or compound bodies. In all these Changes the Causes of effects produced may be many, but the result is ONE; the material of the stratum may differ in its local distribution, but the difference escapes the cognizence of the senses as we review the ONE WHOLE.

In the union of particles and proximate principles, of which terrestrial earth is composed, crystaline and cemented masses are produced, and even the ætherial and volatile principles loosely disseminated in the atmosphere, and in the earth, decomposed by the action of light and heat, unite in quantities with the particles and aggregates of matter: thus the bulk of earth receives a continued accession to its parts and quantities; the waters and the air enter into the composition of fossil and mineral aggregates: this being the case, it is not necessary to ensure the continual increase of the earth and decrease of the waters and the atmosphere, that the elementary constituents of organic bodies should be preserved together as one whole after the functions of life have ceased and the body has mingled with the dust; for were the leaves of a forest to volatilize entirely, even then, the volatile principles in their ultimate recombinations become constituents of the rocks, earths, metals, or gaseous products.

This difference in quantities and qualities would have no existence did Nature act by unerring rules: a compound aggregate mass of inorganic matter is naturally formed, but the object for which it is formed, or the intents and purposes of it application, are alike uncertain: there are peculiar kinds of rock, which man can severally and usefully employ, but, at the same time, it will be acknowledged that there is no necessity for any one particular kind of rock, for man could do without it, the earth could do without it, and its absence would very often be an advantage to production and re-production, and more particularly to man, whose brief career is passed in rendering nature subservient to his wants and purposes. Again, strata are produced, but there is no necessity for strata having peculiarity of form, composition, and character, for the use of a thing does not constitute its necessity, even admitting for a moment that it is useful; and this applies even to the precious metals, for, however desirable gold may be in our eyes, still it must be acknowledged there is no necessity for gold—man perhaps would be happier without it.

The stratum forms by the mere accidents of union of matter with matter; it disunites once more, and is irrevocably separated by the accidents of flood or fire, and new results are produced by the mere accidents of union. In all the changes manifest in this planet, Life is subservient to the building of consolidated matter, and this consolidated matter is in turn subservient to life, the accidents of *production* and the accidents of *destruction* equally affecting both. The laws of Nature are the laws of Forces, which regulate the distribution of Forces and consequent Action, and the union of bodies proceeds from the forces of affinity and cohesion which invariably govern the disposition of matter uniting with matter: thus, bodies unite with bodies, similating, or bearing relationship to themselves. Again, aggregates unite by the force of specific gravity and lateral pressure, or upon the cessation of motion, or the disposition of those forces imparted. It is from these necessary consequences of matter united, uniting, and contending with matter, that rocks, strata, and other compound mineral bodies are produced.

Philosophers of the present day have placed a record before us, facts the most astounding, of vast aggregate masses of terrestrial earth, being formed of minute animalcula: thus Ehrenberg speaks of his discoveries of chalk, earths, tripoli, and other compounds, being wholly composed of animal life: "At Swienemude in the Baltic," he observes, "where about two millions and a half of cubic feet of mud were recently removed in one year, one third of that entire mass consisted of microscopic animals. The Moors of Leinburgh present accumulations of fossil infusoria 28 feet in thickness. In the peaty layer of Berlin tunnel-shaped deposits of eggs reach in some places to the depth of 60 feet; there is no doubt," he says, "they are still alive, and capable of increase." The like phenomena are mentioned by American writers as manifest on that continent. M.

Fossil Oak in a Freestone Quarry.—A few days ago, some workmen engaged in excavating freestone from a quarry near Darlaston, discovered an oak tree, nearly 15 feet in length, in a complete fossil state, imbedded in the freestone. This matter is worthy the attention of geologists, it being a very rare occurrence that such specimens are found in freestone.

PROFESSIONAL POLICY.

Sir,—There is by far more truth than there ought to be—perhaps, not quite so much as there might have been—in the reflections thrown out against architects, in page 123 of your last No. Taken as a body, they do show themselves to be both too supine and too self-confident; and they seemingly take no other interest in their art, than what is suggested by a concern for their own personal and immediate interests. It would be folly to look for either among them or any other class of persons, such Quixotic public spirit as would induce them to neglect the latter for the former; still they might manifest something like a disinterested affection for art for its own sake,—supposing they really entertain any; or if they do not, they might, out of mere policy, assume some appearance of liberality of feeling, and might also pay some deference to public opinion. On the contrary, by doing nothing towards the encouraging extra-professional study, they appear rather desirous to check it, and to show themselves determined neither to countenance, nor to pay any attention to what is done or said by any section of the general public.

Science can shift for itself, because its services cannot be dispensed with; but art stands in a widely different position: it depends upon public sympathy and favour, upon a general disposition to encourage it,—which is likely, it may be presumed, to be in proportion as a taste for art is generally diffused and cultivated. If they do not perceive this, architects must be very obtuse; if perceiving it, they do not shape their course accordingly, they must be very disinterested—disinterested at least as far as their art is concerned. But what they do not perceive or now shut their eyes to, they may ere long very sensibly *feel*. Indeed, they might have found out ere this some of the consequences which are resulting from their own negligence and supineness. By standing aloof, and refusing to take any share in the task of enlightening the public on the subject of their art, architects not only betray an unworthy jealousy, but by their own incommunicativeness and silence, they actually surrender up to laymen and extra-professional writers a very important influence—that derived from the power of promulgating their opinions unchecked, and of guiding public taste, whether in a right direction or a wrong one. And though, individually, some of the writers of this class may be feeble enough; as a body they are not to be despised.

If no one else, Mr. Gwilt is, perhaps, now fully sensible of this, because so far from awing—as he, no doubt, flattered himself he should do—Reviewers, Amateurs, *et hoc genus omne*, into silence, his sneers and reproaches seem to have stirred up their blood, to have rendered them more daring and active than ever. He has certainly made himself conspicuous by rendering himself obnoxious, and a mark for their shafts, some of which are likely to remain sticking in him; neither does the poor "stricken deer" meet with any show of sympathy from the rest of the herd, whose maxim on such occasions is, *sauve qui peut*.

Another circumstance which does not say much for the *con amore* feeling with which architects apply to their art, is that, notwithstanding the extraordinarily great numerical increase of the profession, as far as they are concerned there is less encouragement than ever for architectural publications. Were it not for purchasers of a different class, there would scarcely be any sale at all for them. It is the same, too, in regard to works of the same kind imported from the Continent: not one copy in twenty—perhaps not even a single one, finds a purchaser among professional men; it may therefore be questioned whether the latter are even aware of the existence of many foreign publications of the sort, unless they happen to have seen them on the library table of some amateur. It may be that those among the profession who can best afford to purchase expensive architectural books, are those who least of all need them for any information or instruction to be derived from them. Still it might be presumed that whether they have actual occasion for them or not, they would be glad to possess them, just as they do pictures and other productions of art: nay, even if only in evidence of their own affection for *their own* art, and of their willingness to encourage it in every possible shape. But,

> pudet hæc opprobia *tantis*
> Et dici potuisse et non potuisse refelli,

—such is not the case: some of those who can afford to do most in the way of bestowing such encouragement on architectural literature and illustration, are precisely those who show themselves most niggardly; and that, sometimes to a degree quite incredible. Shocking as it may be to say all this, it is still more shocking that there should be any occasion for saying it at all; and to think of suppressing it is perfectly useless, because if it does not reach the public through one channel, it will through another, and the attempt to keep it back will only cause it to burst forth at last with all the greater violence.

As to myself I own that I might honour professional men much more than I now do, did I honour architecture much less.

I remain, &c.,

Censor.

AGRICULTURAL CHEMISTRY.

By Professor Brande, F.R.S., &c.

Lecture VI.—*Delivered at the Royal Institution, March* 3, 1844.

(Specially reported for this Journal.)

The great bulk of a vegetable consisting of carbon, hydrogen, oxygen, and nitrogen, the question arises, are these contained in the water, carbonic acid, and ammonia of the air, and the table given of the composition of these answers in the affirmative; the carbon is in the carbonic acid, the hydrogen in the water and the ammonia, the oxygen in the water and the acid, and the nitrogen in the ammonia. But it may be said that there is carbon in the soil as humus; true, but not in a fit state to act as food for the plant, which would starve when surrounded with these four elements, if they were not in a state of combination proper for its consumption. Carbon is of no use to the plant without it be combined with oxygen as carbonic acid, nor hydrogen without it be combined with oxygen as water, or with nitrogen as ammonia, nor nitrogen except, with hydrogen, it exists as ammonia. These gases are all evolved during the decomposition of animals. In a similar condition is man, for though he requires little else than the elements they contain for his life and growth, yet it is of no use offering him, water, carbonic acid, and ammonia as food; for him these must be elaborated by the plant into gum, starch, sugar, gluten, fibrin, &c. Thus it is seen that the plant feeds upon unorganised matter, but organizing it, converting it into its own tissues, it renders it into a proper condition to become the food of the animal, which, in its turn, converts it into its own substance; and then, to complete the circle, when the animal dies, his decomposing body passes again into those gases which are the proper food of plants.

First, as regards the water. This is always present in the air in large quantities as moisture, but is very variable, depending principally upon temperature and pressure, the supply being always kept up by the evaporation continually taking place. The greater the heat the greater the evaporation, and the more water the air can take up. When the air has not, for its temperature, the proper quantity of moisture, in passing over a field it deprives the crop of some of its water, by increasing too much the evaporation from the surface of the leaf, and is called a parching wind. When, on the contrary, the air is very moist, plants take water from it. Capillary action takes place continually in the juices of a plant, and the evaporation at the surface of the leaf, like that in the soil, causes the thin sap which rises into the leaf to go out of it thick and syruppy. This will serve to explain why the leaf contains so large a per centage of ash.

When water is cooled down to a temperature of 40°, it begins to expand, and continues expanding till, at 32°, it freezes. This expansion takes place with gigantic power, rending asunder the hardest rocks into which water has infiltered, and bursting leaden and iron pipes with facility. Phials, and thick iron tubes, filled with water, may be heard to burst if immersed in an artificial freezing mixture. In this manner the frost acts in disintegrating the soil. In passing from the liquid to the solid state, water gives out heat until it is solid, heat which was not previously sensible to the thermometer, termed latent heat. This heat, which is always evolved when liquids become solid, may be rendered evident by crystallizing a solution of a salt, such as sulphate of soda. If a hot saturated solution of this salt be corked up in a flask whilst steaming, the vapour condensing forms a partial vacuum, and the solution remains liquid; but so soon as the air is admitted, crystallization takes place rapidly, heat is evolved. and owing to the expansion, the liquid rises up the neck of the flask. This may be considered to represent what takes place during the freezing of water. Water is useful also as a solvent of air, as it will take up 1-36th of its bulk. The air which rain or snow contains has been found to have more oxygen than is in the atmosphere, as though they had a greater attraction for the oxygen than for the nitrogen. The proportion is increased from 21 to 32 per cent. It also has from one to six per cent. of carbonic acid. Thus it supplies to the plant air of much more favourable composition than the atmosphere. It also carries down with it a portion of ammonia, which gives to it the feeling of softness. This is of use to the plant, and though 1,000 gallons of rain water is nothing to be evaporated from a field, yet the amount of ammoniacal salts left behind is by no means trifling.

As in the passage from the liquid to the solid, water gives out heat, so in vapourising, or in the passage from the liquid to the gaseous state, water abstracts heat. Wet cloths are frequently wrapt round the head for thi purpose, the water evaporating carries with it heat, which it renders latent, taking it from any substance near it. It is essential for its change of condition, and yet can not be detected by the thermometer; deprive it of it, and it is again liquid. By absorbing its vapour as quickly as formed under an air pump receiver, water may be frozen, owing to the abstraction of heat by its own evaporation. It is from this cause that a wet soil is always a cold one, for when the sun does shine on it, its warming influence is neutralized by the action of evaporation.

These are the effects on plants from mere change of form. But as water is decomposed largely by plants, its composition must be next considered. In 100 parts, water consists by weight of

Oxygen	88·9	=	8
Hydrogen	11·1	=	1
	100·		9

or, by measure, two of hydrogen to one of oxygen; consequently oxygen is 16 times heavier than hydrogen, which is the lightest of gases, being about 1-15th of the weight of air. Resins, with which some trees so abound, have an excess of hydrogen in them. Now this can only come from the water which they decompose, and consequently we find that plants are continually liberating oxygen, no doubt principally from the water of which they have appropriated the hydrogen.

The best method of ascertaining the composition of water is to decompose i ; and if for that purpose electricity is employed, the advantage is gained of being able to collect the products separately. In analysing the air, only one of its components could be obtained, and that only by removing the other. But by bringing the poles of a galvanic battery into water, the electric current causes the hydrogen to separate from the oxygen, and each is evolved at a different pole, all the hydrogen at the negative, and all the oxygen at the positive pole. By placing glass vessels over the poles the gases may be collected, and it will then be found that the hydrogen will occupy twice the bulk of the oxygen, but if it be weighed, it will be found to be only $\frac{1}{8}$ of its weight. A lighted taper immersed in the hydrogen is itself extinguished but ignites the gas, which burns, if in contact with air, with a pale blue flame; immersed in the oxygen, its combustion is much more rapid and brilliant. These gases, when mixed and ignited, explode with great noise, and re-form water. But the best method of effecting this is to screw on to the top of a bell glass filled with the mixed gases, a Cavendish's apparatus, which consists of a strong glass vessel, through each side of the neck of which passes a platinum wire, which wires nearly meet in the interior; having previously exhausted this of its air, let the gases enter into it; then, after closing the stop-cock, without removing the apparatus, send an electric spark through its platinum wires from a Leyden jar, which will cause the gases to unite, and the water formed will trickle down the sides of the Cavendish; by again opening the communication, more of the gases will rush into the partial vacuum that is formed, and it may thus be repeated till all the gases are combined. It will thus be found that nine ounces of water can be decomposed into eight ounces of oxygen and one ounce of hydrogen gases, which may then be reconverted into nine ounces of water. Thus electricity is employed to decompose and to recompose water.

Next with respect to the carbonic acid. The base of this, carbon or charcoal, has been very highly recommended for its good effects when applied as a top-dressing. This was once attributed to the plants feeding on it in some way or other, but that idea is now discarded. It appears as though its action was principally due to its absortion of ammonia. Many substances possess this property of absorbing moisture and gases, but none to so surprising an extent as carbon. If a piece of fresh-burnt charcoal be exposed to the air, it will shortly be found to have increased considerably in weight, owing principally to the water it has abstracted from the air. But this property varies according to the source of the charcoal, as the following table exhibits:—

After one week's exposure of

Charcoal from	Lignum Vitæ,	it had gained	9·6	per cent.
"	Fir	"	13·	"
"	Box	"	14·	"
"	Beech	"	16·3	"
"	Oak	"	16·5	"
"	Mahogany	"	18·	"

But this property of charcoal is shown more remarkably with respect to the gases, many of which are rapidly absorbed to the extent of many times the bulk of the charcoal:—

1 volume of charcoal absorbs of

Ammonia	90 volumes		Carbonic oxide	9·42 volumes
Hydrochloric acid	85	"	Oxygen	9·25 "
Sulphurous	65	"	Nitrogen	7·5 "
Sulphuretted hydrogen	55	"	Hydrogen	1·75 "
Carbonic acid	35	"		

On this account charcoal is frequently employed to sweeten putrid water, by filtering it through it, and it is, after this operation, better fitted as manure than previously, as the substances it withdraws from the water are beneficial to vegetation. In this manner peat waters might be filtered, and the charcoal employed as manure.

But no property of carbon is so important to vegetation as its affinity for oxygen, being by that means converted into gas, and so brought to the plant in a fit state for food. In this manner it has derived its carbon, which in many plants forms nearly one half of their weight. Not that carbon, when pure and uncombined, shows any tendency, at ordinary temperatures, to combine with oxygen, but when in combination in the animal frame, or in the vegetable tissue, by respiration and decomposition, then carbon is readily converted into the gaseous acid. This being wafted over the surface of the leaf is by it, with the assistance of solar light, decomposed, its oxygen being again set free, its carbon, uniting with the elements of water, sometimes forming woody fibre, sometimes gum, with an excess of hydrogen, forming resinous substances, with excess of oxygen, forming acids.

Lecture VII.

When carbon in any state is heated to redness, it entirely passes off as carbonic acid gas; and if this be performed in a jar of oxygen instead of air, the combustion is rapid, and the whole of the oxygen is converted into carbonic acid. If the properties of this gas be then examined, it will be found to extinguish a lighted taper, and if an animal be inserted in it, it will be deprived of life. Air containing one tenth of it causes drowsiness in man, followed by torpor and death; its action is then like that of a narcotic; but when pure, it suffocates instantly, causing spasm of the glottis. The oxygen is combined with the carbon in this gas with so great an affinity, that it almost baffles the chemist's art to separate them. He is obliged to have recourse to his most energetic means in order to do that which the minutest plant is doing so constantly, so easily, and so largely. Phosphorus has not the power of abstracting the oxygen, but if burning potassium be inserted into this gas, decomposition is effected, potash formed, and carbon liberated, which may be rendered evident by diffusing it through water. Carbonic acid is heavier than air, in the proportion of 15 to 10, owing to which it may be poured from vessel to vessel like water, this being rendered evident by the extinction of a taper. It may even be transferred by letting down a little bucket into a jar of the gas. But after a time it will be found to have vanished, for it possesses a property common to all the gases, heavy or light, of mixing with each other till they are perfectly blended. Also heat, by expanding it, causes it to ascend, and it may thus be expelled from a vessel by inserting a red hot ball. Owing to these properties, it is, that it gets diffused in the air so evenly, and its injurious accumulation prevented. Many substances absorb carbonic acid, as is proved by dipping a sponge in caustic alkalies and placing it in a jar of the gas over water. In a short time the water will rise and fill the vessel. Lime, also, rapidly absorbs it, losing thereby its causticity, being converted into chalk. From this chalk it may be again driven by the action of a stronger acid, and this is the readiest means of producing it. The difference of action of this gas and oxygen on a combustible body may be beautifully illustrated by inserting a taper with a long wick, just blown out, into a tall glass jar, the upper part of which contains oxygen, the lower carbonic acid; the glowing wick is ignited on first insertion, on lowering it to the region of the carbonic acid it is extinguished, raising it up to the oxygen it is relit, and with care this may be repeated many times.

Water at the common temperature and pressure absorbs its own bulk of carbonic acid, but will dissolve more exactly in proportion to the pressure given. It is in this manner that water is so strongly impregnated with it to produce soda water, it communicating to liquids a peculiar agreeable pungency. Its solution reddens vegetable blues, proving its acid quality. Plants can decompose it as readily when it is dissolved in water, as when in air, the action taking place at the surface of the leaf. It is the peculiar characteristic of animals to produce carbonic acid, of plants to absorb and decompose it. The enormous increase of carbon in plants in a short time, is truly surprising, and many experiments have been performed, the precautions taken being such that the plant could derive carbon from no other source than the carbonic acid of the air. Grown in calcined clay and water, seed peas have been found to increase in three months as follows:—

Original Weight.		After 3 Months.	Increase.
Carbon	515	2376	1861
Hydrogen	59	281	222
Oxygen	440	1650	1210
Nitrogen	46	101	55
	1060	4408	3348
Ashes	12	33	21
	1072	4441	3369

Seed wheat grown in sand and water, in three months, increased as follows:—

Original Weight.		After 3 Months.	Increase.
Carbon	460	880	420
Hydrogen	58	105	47
Oxygen	441	810	369
Nitrogen	35	37	2
	994	1832	838
Ashes	6	6	
	1000	1838	

But the quantity of carbon thus abstracted from the air being so enormous, and the carbonic acid being present in it in so small a quantity, the question arises, is the air competent to supply such a demand? To ascertain its probability, a few calculations are required, the data for which are well established. The average weight of a crop per acre is about 1½ ton, and as on the average one-third of the weight of a plant is carbon, the total carbon in the crop may be reckoned as about 10 cwt. per acre. The weight of the air is about 15 lb. per square inch, and taking the weight of the carbonic acid present as 3 in 1000, and 63 grs. of carbonic acid to contain 17 grs. of carbon, it will be found that the air on each acre contains about seven tons of carbon, and therefore, if the whole earth were cultivated, it could only support vegetation for 14 years. But as no proof exists that the quantity of carbonic acid in the air is lessening, and as it is being removed so enormously by vegetation, whence can come the supply which maintains the equilibrium. There are at least three sources that can be pointed to as supplying vast quantities of carbonic acid, viz., animal respiration, volcanoes, and combustion of fuel.

1. After respiration, the quantity of carbonic acid present in the air, will be found to have increased a hundredfold, it forming one-fifth of the expired air. It will not then support either life or combustion. Passed through lime water it renders it turbid, from the formation of carbonate of lime. It is calculated that the carbonic acid exhaled from the lungs in 24 hours contains from 5 to 8 oz. of carbon, or from 100 to 160 lb. in the year, the difference depending upon the amount of exercise taken.[1] With increased exercise more carbon is consumed in the system, and more heat produced, exactly analogous to the consumption of carbon in a charcoal fire, carbon when being oxidised always evolving heat, whether it takes place quickly or slowly. Animals, such as horses and cows, would, from their bulk, be expected to exhale at least twice as much as man, but it has been shown by Boussingault, that they exhale very little more than man. The inhabitants of Great Britain being taken at 20 millions, and supposing that other animals expire about the same quantity of carbon, it will be found to amount to about two million tons, or sufficient for about four millions of acres of cultivated land.

2. Volcanoes, both active and extinct, are continually pouring into the air torrents of carbonic acid. From one in the neighbourhood of Coblentz, it is reckoned that 90,000 lb. of carbonic acid are daily evolved.

3. The combustion of 20 millions of tons of coal, which is the annual consumption of Great Britain, adds to the air 14 millions of tons of carbon, and as each acre of vegetation is reckoned to require half a ton, this alone is sufficient for 28 millions of acres, or nearly seven-eighths of the arable land, as it is considered that there are about 34 millions of acres in cultivation.

By such means as these, then, is the carbonic acid restored to the atmosphere as fast as it is abstracted by plants, and thus the balance is maintained.

With regard to the ammonia. This is always present in the air, and is carried down in some quantity by rain. It is considered to be the source whence the plant derives its nitrogen, and not from the air. When its constituents, nitrogen and hydrogen, are mixed together, they do not combine, nor can they be made to combine directly, but it is formed invariably during the decomposition of substances containing these two gases. If horn shavings or other animal matter are heated, ammonia is evolved, and it is even given off during the burning of a cigar and the distillation of coal, thus having both an animal and vegetable origin. It will neither burn nor support combustion, is rapidly absorbed by water, and being an alkali, renders turmeric paper brown, and restores the blue to liquids that have been reddened by acids. It may be made to combine with excess of oxygen and then is converted into nitric acid and water; in this manner nitrate of ammonia is formed during lightning, and Faraday considers it likely that the points of trees, being silent dischargers of the electricity of the earth, in this way contribute to the formation of nitrates in the air. Rain water, evaporated along with an acid to prevent the ammonia from volatilizing, will be found to contain nitric acid, sulphuric acid, and ammonia, thus supplying to the plant its necessary ingredients. The quantity of nitrogen in plants varies, but is always present, even when the soil contains none, and therefore in such cases must come wholly from the air, as must also be the case with wild plants and trees. Boussingault, to whom science is much indebted for the laborious manner in which he has investigated these subjects, testing theories by practice on a large scale, found that in five years' rotation of crops the nitrogen as well as the carbon, was present in greater quantities than the soil could possibly yield. A crop of Jerusalem artichokes, which gave 23,500 lb. to the acre, contained 38 lb. more nitrogen than the soil could have given.

The quantity of nitrogen that various crops contain, and its proportion to the carbon and other constituents, is well seen in the following table:—

	Hay.	Red Clover Hay.	Potatoe.	Wheat.	Wheat Straw.	Oats.	Oat Straw.
Carbon	458	474	440	461	484	507	501
Hydrogen ..	50	50	58	58	53	64	54
Oxygen	387	378	477	434	390	367	390
Nitrogen	15	21	15	23	3	22	4
Ash	90	77	40	24	70	40	51
	1000	1000	1000	1000	1000	1000	1000
Water	158	210	759	145	260	151	287
	1158	1210	1759	1145	1260	1151	1287

Although the quantity of ammonia contained in rain water is very small, one pound containing but a quarter of a grain, yet when the total annual quantity of rain that falls is considered, it will be found to yield a considerable amount of nitrogen to the plant. The average number of inches of rain that falls in Great Britain is about 22 inches and four-tenths, which will give a weight of 117 lb. to the square foot, or 5,096,500 lb. per acre, and at a quarter of a grain of ammonia per pound, is equal to about 120 lb. of nitrogen. Nitrogenous substances are useful to plants, not only as forming part of their substance, but as acting as a stimulant, enabling it to draw the same substance in greater quantity from other sources; in a similar manner salt, muriate of lime, and other substances, are supposed to act, as by their agency the gluten or nitrogenous part of wheat is always increased.

It has thus been shown that plants require two classes of food, organic and inorganic. The inorganic must be rendered soluble, and must be the same as are found in the ashes of plants, which are separated from the other parts by burning. The organic food, composed of carbon, oxygen, nitrogen, and hydrogen, must be presented to it in the form of water, carbonic acid, and ammonia. Having thus then considered the constituents of which all other parts are built up, it remains to examine the subject under three heads:—

1st. The products elaborated by the functions of the plant, known as the proximate elements.

2nd. The mode in which, by its vital force, it eliminates them.

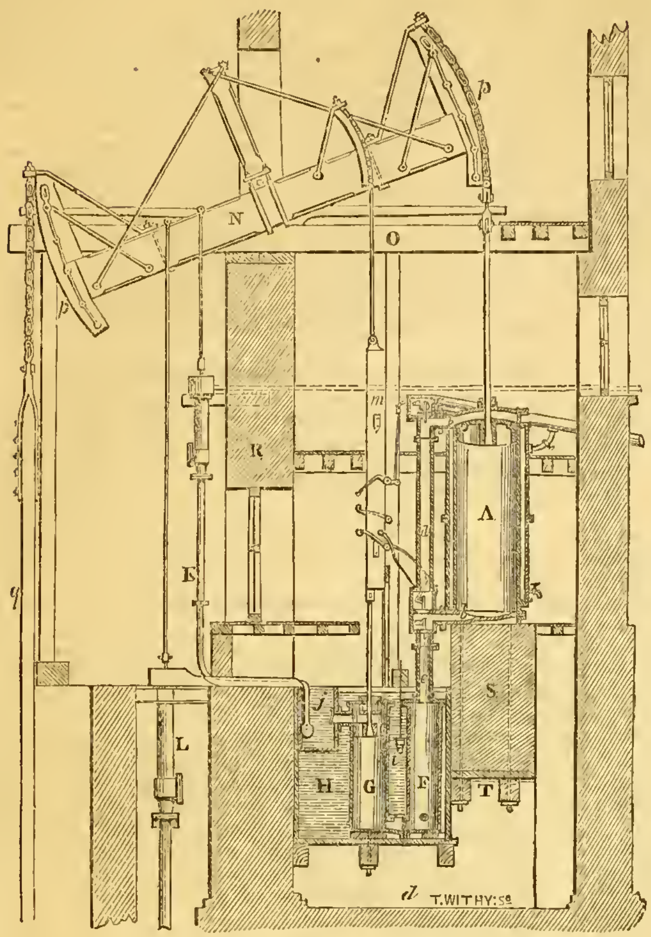
3rd. The mechanical conditions of the soil requisite to enable the plant to carry on these operations in the greatest health and vigour.

Ellis's Improved Turn-Table.—The objection to placing turn-tables of the ordinary construction on the main line of a railway, is, that, by the nature of their construction, they are rapidly destroyed, by the frequent passage of heavy trains over them, besides the injury done to the carriages, and the unpleasant motion and noise. Mr. Ellis has constructed a turn-table, which, when not in use, rests firmly on the curb, and thus allows the train to pass rapidly over it without injury. The iron pintle of the table on which it turns being kept well oiled, works with a loose collar round it in a vertical iron case; which case is supported and kept in its central position by two cross arms of cast iron, at right angles to each other, and attached to the curb. The lower end of the pintle passes through the bottom of the case, below which is a stirrup attached to a cross lever passing at one end through a chase in the circular masonry, or brickwork, supporting the table: attached to the external end of the long lever, is a second lever, working in a vertical direction, and connected with a third, or handle lever, by which the table is put in motion or fixed, as required.

Fountain Extraordinary.—The great fountain now in progress at Chatsworth, is expected to play to a height of upwards of 200 feet. The fountain that plays the highest jet of any fountain in the world at present is in Germany, but the proposed fountain at Chatsworth is expected to surpass it in height about 20 ft.—Derby Mercury.

[1] According to this calculation, the carbon of the daily food, amounting to about 1 lb., is one half returned to the air as carbonic acid.

MESSRS. BOULTON & WATT ON THE STEAM ENGINE.



WATT'S SINGLE ACTING ENGINE FOR PUMPING.

A, Cylinder. *b*, Nozzles and passages. *c*, The cross or steam pipe from boiler. *d*, Perpendicular steam pipe. *e*, Eduction pipe. F, Condenser. G, Condenser or air pump. H, Condensing cistern. *i*, Injection valve. *j*, Hot water cistern. K, Hot water or feed pump. L, Cold water pump for supplying condenser cistern. *m*, The plug tree and working gear. N, The great lever or beam. O. Spring beams. *p*, The great chains and arch head. *q*, Pump rod or spear. R, Main lever wall. S, Masonry or stone platform. T, Wooden platform and bearers to carry masonry.

We now resume this important subject:—

Directions for Putting the Engine together.

SECT. 21. Put the working beam together, and having fastened the gudgeon to it, rest it on the plummer blocks; but do not fasten these to, until the cylinder be fixed.

22. Level the top of the stone platform, and put the outer bottom of the cylinder down in its place; level it truly; and let it correspond with the holding down screw boxes.

23. Apply the inner bottom upon the outer one; and set its upper joint level, by wedging between it and the outer bottom, if required. Then cut out segments of pasteboard, such as is used for boards of books, and not such as is composed of paper pasted together. Let these segments be of such thicknesses as the different parts of the joints may require, accordingly as they be more or less open in different places. Soak the pasteboard segments in warm water, until they become quite soft; then lay them upon boards to dry, and, when quite dry, put them into a flat pan, with a quantity of drying linseed oil. Warm the oil, until the pasteboard ceases to emit bubbles of air; but take care not to heat the oil much hotter than boiling water, otherwise it will harden, or burn, the pasteboard. Anoint the segments on both sides with thin putty, made with fine whiting and some of the linseed oil. Let the whiting be very dry, otherwise it will be very difficult to mix with the oil. N.B. White lead will not answer in place of it. Avoid, as much as you can, using more than one thickness of pasteboard. The segments should be a little broader than the flanch. All the holes should be cut out by a chisel; but not quite so large as the holes in the iron. The segments should also be thinned at the ends, where they overlap each other, that they may form a circle of pasteboard of uniform thickness.

24. Lift up the inner bottom, and lay your segments regularly round upon the flanch of the outer bottom; then place the inner bottom upon them, taking care, at the same time, to put a proper thickness of pasteboard in the joint under the pipe, which proceeds from that inner bottom. In like manner prepare pasteboard for the joints between the inner bottom and the cylinder; and proceed, as has been directed, for the other joints.

25. Having the cylinder ready suspended, lower it down in its place; and in such manner that the square pipe, at its upper end, may be exactly over the pipe of the inner bottom. Thrust a square taper piece of iron, of proper size, into each hole, to enlarge the holes in the pasteboard, and admit the screws. Put in the screws, and screw up the joint, gradually, all round; and do not screw up one side faster than another, or you will be apt to crack the flanch of the cylinder, or bottom, or make a bad joint. No screws must be put through the cylinder flanch over the pipe; therefore that part of the joint must be made with the utmost care, and the pasteboard must be a trifle thicker there. The general thickness of the pasteboard for these joints should be three-sixteenths of an inch.

26. Put in the holding down screws, which should have screws and nuts at both ends; then set the cylinder truly upright, which is done by putting one piece of wood across the bottom, and another across the top, and marking upon both of them the centre of the cylinder at their respective places. Then hang a plummet from the upper centre, and examine if the line be in the centre below; if it be not, you must wedge under the outer bottom, until you bring the line to hang truly in the axis of the cylinder. The holding down screws should be screwed tight, so as to keep the cylinder in its true position after which the screws of the joint must be again screwed up, then taken out one by one and lapped round with a rope yarn and some putty, both under the head of the screw and under the nut, so that each screw may be air tight of itself.

27. Carefully scrape, or rather scour, the rust from the sides and bottom of the cylinder; clean it well out, and grease the sides with tallow. Hang the chains, and put the piston rod cap in their places. Put the piston rod into the cylinder; suspend the piston by two half links, fastened to one of the crosses, and lower it down upon the piston rod. But previous to this, the rod should be tried into the piston; and if the hollow and convex cones do not fit one another, they must be made to do so by chiseling and filing the cone of the rod. A lead ring, an inch square, exactly fitting the inside circumference of the cylinder, must be laid upon the small rim of the inner bottom, to save it in case of dropping the piston; and an iron gland, an inch thick, must be screwed across the base of the cone of the piston rod, by means of two screws passing through the bottom of the piston, and screwed into the gland. The joints of these screws should be cut off, that they may not strike the bottom, when the piston strikes the ring.

28. The piston being lowered down upon the rod, the lid of the cylinder should be laid on without the stuffing box. The end of the working beam must then be lowered down, and the piston rod cap put on the rod, and forelocked fast. The beam must then be raised, and the lid also, and an examination be made, whether the piston has dropped truly down to its place upon the rod. If so, the lid or cover must be let down, and by lowering and raising the beam and the piston, you will perceive whether the rod always moves up and down truly in the axis of the cylinder. It must be made to do so by shifting the plummer blocks out or in; or by shifting the martingales to one side or the other. The utmost care should be taken that the plummer blocks be placed both of one height, and after the beam has been some days in place, it should be examined if the gudgeons be truly horizontal, as otherwise it will cause a most disagreeable motion in the piston-rod.

29. Caulk the joint round the inner bottom, between it and the pipe of the outer bottom, with rope yarn or oakum, as hard drove in as possible. Screw the nozzle to the pipe of the inner bottom; making the joint as has been directed, and with the utmost care, so that the nozzle may hang a quarter or half an inch lower at the point than at the joint, that any water condensed in it may run to the exhaustion pipe. Put a strong wooden prop from the ground to the lower side of the nozzle, right under the perpendicular steam pipe; and care should be taken that the inside of the bottom of the nozzle be even with, or rather lower than, the inside of the bottom of the pipe which comes from the inner bottom of the cylinder, so that no water may lodge.

30. Put on the steam case, screwing the panels together with a few screws. If found to be too short, it may be lengthened by means of a lead flanch put in the middle joint, with a thickness of pasteboard on each side of it; but if found too narrow, and the deficiency, upon being divided equally amongst all the joints, amounts to more than a quarter of an inch, to each joint at the inner side, then a bar of iron must be prepared of such breadth as will make up the whole deficiency, and as thick as it can be received between the screw holes, in the perpendicular flanches of the steam case, and the rings on the cylinder. This bar must be put into a joint of the steam case, on the backside of the cylinder, and be made tight by caulking, or by pasteboard. Re-

member to put the middle of a panel opposite to the perpendicular steam pipe.

31. When you have found that the steam case is of a proper diameter and length, or have adjusted it as has been directed, it must be made tight. Make the joint between the panels, behind the perpendicular pipe and the upper and under rings of the cylinder, by applying a proper thickness of pasteboard and putty, or soft roping, upon the cylinder rings, before you put up these panels; or if you perceive that the joint will admit of it, yoû may wind a soft rope, slackly twisted, once or twice all round the cylinder rings; then screw the perpendicular joints of the panels together (putting in all the screws) until the insides of the joints are quite close, or as close as they will admit; afterwards take oakum, mixed with some putty, made with thick linseed oil; or a soft rope covered with putty, and, with a caulking chisel, drive it forcibly into the joint, and continue caulking in, a little at a time, until you have filled the joint quite to the outside of the flanches. Remember to put oakum, or soft rope yarn, under the head and nut of each of the screws; and do not force the screws too much, lest you break the flanches. Trust, rather, to the caulking. In like manner you must make tight, by caulking the joints between the steam case and the upper and under rings, using a crooked chisel, for more conveniently getting at the under one.

32. Put on the upper part of the lower nozzle, and make its joint. Set on the perpendicular steam pipe, and try the upper nozzle to its place; if the pipe prove too short, lead flanches of a proper thickness must be introduced, equally above and below, to make up the length; but wherever lead flanches be used where hot steam comes, it is necessary to put a thickness of pasteboard, with putty, on each side of them; and the lead should be free from tin. These lead flanches should be a little larger all round than the iron flanches, that their edges may be rivetted up, afterwards, when any leaks are perceived. If the pipe prove a little too long, the upper, or top nozzle, may be raised a little higher than its natural joint, provided that the overlength does not exceed an inch. The round flanch of the perpendicular steam pipe goes uppermost. Four round holes must be drilled into the top of the upper part of the lower nozzle, corresponding to four holes in the flanch of the perpendicular pipe; and they must be screwed together by screws, with heads within the nozzle. Five screws may, in like manner, be put in the flanch above.

33. The cross pipe must next be put on, and its joint made, and the boiler steam pipe must be screwed to one end of it, and the other, be shut by a plate. If any of the joints are not of a proper angle, fill them up with lead.

34. The steam must be made to communicate from some convenient place of the cross pipe to the steam case, by means of a copper pipe, with their copper flanches, which must be fixed to the cross pipe, and the steam case, by small pierced glands, with a square hole in each end, to admit the square necks of two screws, which being screwed at both ends, one end must be screwed into the cast iron, (first tapped for that purpose,) and the other, with a nut, serves to keep on the gland. Another similar, but smaller pipe, must be fixed to the very lowest part of the steam case; but it must be fixed over the flanches, and be inserted into the perpendicular part of the outer bottom, to fill it also with steam. In some convenient part of the outer bottom, as low down as may be, must be fixed a waste pipe, to let out the condensed water. This waste pipe must reach down about five or six feet, and be bent upwards a little at the lower end, and be shut by a valve loaded with a proper weight. This valve will open whenever the elasticity of the steam, and the weight of the column of water, in the pipes, are sufficient to overcome the weight which shuts it.

35. The condenser must now be put into its place, in its cistern. Its joints may be put together, with pasteboard soaked in oil, as directed, and putty; and be firmly screwed up, and caulked afterwards. Or, any where under water, plates of lead may be used, about a quarter of an inch thick, well fitted to the joints, and puttied on both sides. After the joints, made with lead, are well screwed up, and the condenser warmed by fire or steam, the edges of the lead, which had been left projecting a little, must be raised up, both inside and outside. A soft rope about half an inch diameter, coiled round and round, until it covers the flanch, and well puttied, may be used in default of pasteboard, or lead, but either of the two former are preferable, and in every case caulking or raising must be used.

36. If the clack of the hot water pump has two valves, and is not sent ready fitted, the heating, or fixed part, must be chiseled, and filed truly flat. The pivots, or axes of the valves, must be from three-quarters to an inch diameter, according to the size of the engine; the flat part of the iron of the valve, about a quarter of an inch thick, the copper facing, one-sixth of an inch; and the iron plate, under it, also the sixth of an inch. After the two iron plates and the copper facing are firmly rivetted together, they must be heated red hot, laid on their place, a short piece of end wood set above them, and beat down by some blows of a sledge hammer. The pieces of iron, that the pivots move on, must be fixed by means of pins of iron, half an inch or three-quarters square, screwed into the cast iron of the clack, passing through a square hole in the pivot pieces, and forelocked above by spring cutters. Every one of these parts must be made very secure and firm. A guard to prevent these valves from over opening, must be fixed in the hot water pump. This guard may be about an inch thick, and should not touch the edges of the valves, but catch them on the flat part, behind. The cast iron face of the eduction pipe foot must also be made flat, for the valve there to beat against. The pivots of this valve should be one inch diameter. The thickness for the iron, and copper, the same as for the others. The ends of the valves should be one quarter of an inch clear of the sides; and one half inch clear of the bottom of the place it plays in. The pivots should be sunk into the cast iron of the sides until their lower edges be within one quarter of an inch of the opening of the beating part. They should have one inch hold of the iron at each end, and have no play in that direction. In the lid, or clack door for this valve, there should be a groove, for the axis of the valve, that it may not touch it, when the lid is screwed on. The pivots should not be confined against the beating part, but should have a quarter of an inch of play, in that direction, as the air makes its escape partly by the hinge. The valves of the air and hot water pump buckets are to be fitted in the same manner, remembering to make the pivots proportionable to the size of the valves.

37. The condenser being fixed in the cistern, at its proper height below the nozzles, and at a proper distance from the centre of the gudgeon, or of the cylinder, and in such manner, that the middle between the centres of the pumps shall be directly under the middle of the working beam, and the line between these centres, at right angles to the beam, the copper eduction pipe must be fitted to its place. It must be screwed to the flanch of the short pipe, under the nozzle, by means of a loose flanch of hammered or cast iron, applied on the under side of the copper flanch of the pipe. The outside diameter of the loose flanch must be the same as that of the flanch on the nozzle; and its inside diameter must be one inch more than the outside diameter of the bent copper pipe. Its inner angle should be taken off a little, on the side next the copper flanch, lest it should cut that flanch, or crack the soldering. If the loose flanch be made of hammered iron, it should be three quarters of an inch thick, and the holes should be drilled and not punched. In the same way, you must proceed with the joint, at the foot of the eduction pipe.

38. Having carefully tinned the inside of the upper end of the wide, or perpendicular part, of the eduction pipe, and also the outside of the brass ring which goes within it, the ring must be put into its place; and, being heated, the joint must be run with fluid tin solder; after which, four, or more holes may be drilled through both the copper and the brass, and some copper rivets put in them. The spigot and fauset joints must be secured as follows:—An iron ring, three or four inches broad, and half an inch thick, must be put, red hot, on the outside of the fauset part; that, by its contraction in cooling, it may grasp it firmly. The spigot part must then be put in and made tight, by caulking in soft roping and putty. The proper width of a joint for caulking, is three-sixteenths of an inch at the wide, or open end; and drawing quite close at the inner end, but it will do, although a little wider, or narrower. The joints of the bent part of the eduction pipe, and perpendicular pipe, at the brass ring, must also be secured by caulking. If, when the engine shall be set to work, any of the spigot and fauset joints show a disposition to slide, or move, it may be cured, by putting screw hoops round both the spigot and fauset parts, near to the joint; and pulling the joint together, by means of two screws, connected with the screw hoops. In putting the eduction pipe together, care must be taken, to keep the brased joint upwards; that if any defects appear, they may be cured by tin solder. When the eduction pipe is put together, a hole must be cut, in such manner, as to fit the outside of the fauset, accurately. The fauset pipe should point up the eduction pipe, in order that the injection water may strike the upper side of the eduction pipe, within about two feet of the nozzle; but care should be taken, that it do not spout too low; otherwise, it may, by the bent pipe, be reflected against the exhaustion regulator, which will be very hurtful. The fauset pipe, being adjusted to its proper position, and the knee of the eduction pipe tinned round the hole, the fosset must be fixed in its place, either by a strong body of plumber's solder, or by a copper boss, or case, run full of the same solder, heated to a dull red heat. The upper edge of the inner end of the fauset should only go half an inch within the eduction pipe; and the nozzle of the injection, not quite so far. The injection pipe, being set in its true position, the joints soldered with plumber's solder, and its valve soldered on, a hole must be cut into it for the blowing pipe fauset, at, or about, the level of the valve of the injection; not lower; otherwise the engine will blow at the injection, and heat the cistern. The fauset, for the blowing pipe, must be fixed by soldering, or by a boss, as directed for the injection; and its inner end ought not to go more than one or two inches within the eduction pipe, according to the diameter of that pipe. The blowing pipe may then be put together, and its valve soldered on, taking care that the pipe be of such length, that its valve may be six inches under the surface of the water in the cistern. Care must be taken, that the stems of both the blowing, and injection valves, stand nearly perpendicular, when fixed in their places. The injection and blowing pipes must be fixed in

their fausets, by caulking, as directed; and no tin, from any of the solderings, must be left in the pipes.

39. The pump of the condenser must be fixed down by screws passing through the bottom of the cistern and the beam under it; and it must be remembered that its tendency to rise is very powerful, and that if it has any play, it will be sure to spoil the eduction pipe joints; or, perhaps, break it. The hot water pump must have a strong prop under it, and be tied down, as well as the other. A beam of deal, nine or ten inches square, must be put across the cistern, near the air pump rod, to support a pair of shears, or uprights, as a pump break, for that pump, to examine the tightness of the joints by. This break must have an arch, and a chain with a hook, to chain it to the chain of the air pump rod when in use. The buckets of the condenser pumps must be surrounded by a plaited rope, made of rope yarn, of such breadth as will fill easily the interstices between the bucket and the pump barrel. A pudding link chain, four feet long, must be fastened to the top of the sliding rod of the air pump, and to the other parts of that rod which reaches to the working beam. Its use is, to suffer the engine to work without unloosing the hook of the pump break, when trying experiments on the tightness of the engine.

40. The stuffing box of the air pump must be packed with a small soft rope, wrapped round the rod, and forced down into the box pretty tight, but so that the rod may move easily. A flat round piece of wood, about one and a half inch thick, fitted easy to the inside of the box, and to the outside of the rod, must be put above the stuffing, and screwed down by the gland. There need no screws to be put to hold down that side of the air pump lid which is over the connecting box; those on each side of the box are sufficient if proper attention be paid to making the joints. In like manner, the lid or clack door of the lower valve of the eduction pipe foot needs only two screws, one at each end. In the bottom of the air pump must be placed a ring of hammered iron, with three or four feet for the bucket of the pump to rest upon when at its lowest; *i.e.*, when the lower edge of the packing of the bucket is within one inch of the under end of the working barrel. This ring must be so fixed that it may not turn round, and come in the way of the lower valve of the eduction pipe. An upright, six inches square, must be fixed from the bottom of the cistern, near the injection, to screw that pipe to; and its upper end must be fastened to the beam that supports the lever, and the end of the working barrel of the injection. This upright should be fixed firmly; and the injection pipe should be fastened by a stirrup, with screwed ends, grasping the neck of the valve, going through the upright, and having nuts behind it. Any motion in the injection pipe will be apt to loosen or crack the joints of it; therefore it must be firmly fastened.

41. Guards must be fixed over the injection and blowing valves to prevent their opening; for the nob of the spindle, which stops them by the bridge of the valves, is not to be trusted. It may therefore be cut off; which will give the convenience of taking out the fly part of the valve at pleasure. An S hook of iron must be fitted into the eye of the valve, that it may have no motion there; and the rod that pulls it open must have a hole in its lower end, that the upper end of the S may play easily. If allowed to have motion in the eye of the valve it will soon wear it out. Guards must also be fixed over the valves on the air pump lid, to prevent their over opening. These guards may be fixed by means of two of the screws which fasten on the lid.

(To be continued.)

REGISTER OF NEW PATENTS.

(Under this head we propose to give abstracts of the specifications of all the most important patents as they are enrolled. If any additional information be required as to any patent, the same may be obtained by applying to Mr. LAXTON at the Office of this JOURNAL.)

BOILER FURNACES.

Elisha Haydon Collier, of Goldsworthy Terrace, Rotherhithe, Surrey, Civil Engineer, for "*Improvements in the construction of furnaces and flues.*"—Granted September 28, 1843; enrolled March 28, 1844.

This invention relates firstly to a peculiar mode of arranging the flues of furnaces that the smoke and other vapours shall previously to passing up the chimney be made to pass over a clear fire, which fire is in a furnace entirely distinct from the ordinary or original testing fires; secondly, in forming a double flue in the chimney, for the purpose of conducting a current of warm air down the same to the fire.

The drawings which accompany the specification show the improvement as being applied to a marine boiler constructed with five furnaces; the smoke and heated vapours from the two side fires pass through tubes (which the inventor prefers to be made square instead of round) in a direction from front to back of the boiler, and then in an opposite direction (from back to front) through flues, which conduct the smoke to the centre or clear fire; the smoke and vapours after passing over the clear or consuming fire pass along a flue, which at a short distance branches off right and left; at right angles to the furnaces, towards the sides of the boiler, the flues then return and join the chimney, which is at the back and in the centre of the boiler. The chimney is made double, or in other words, is surrounded with a water space, for the purpose of supplying the boiler with a hot feed instead of a cold one; it is also constructed with a double passage, one being for the emission of such smoke as may be unconsumed, and the other for the introduction of air, which air becomes heated in its passage previous to being introduced into the clear fire. The patentee describes two modes of introducing such air into the clear fire; first, by letting the air pass through a perforated plate situate at the front of the fire, and secondly, by way of the ash pit, and through a number of longitudinal openings, at that part of the clear fire or furnace usually occupied by the dead plate: these plates are supported at each end by axis, the arrangement being similar to the Venetian blind, so that by means of a lever the openings can be enlarged or diminished, and the supply of air regulated at pleasure. When applying the improvements, as above, to boilers on land, it will be necessary to place the boilers as near together as practicable; and for coppers, &c., the inventor proposes to construct the flues in such manner, that the smoke from the first fire after passing round the copper, passes over the fire of the next copper, and the smoke of that one over the next fire, &c., and finally over a clear fire of charcoal or coke, other unconsumed smoke and other vapours from the various furnaces then pass off to the chimney.

RAILWAY WHEELS.

Jonathan Saunders, of Soho Hill, Birmingham, Gentleman, for "*Improvements in the manufacture of tyres of railway and other wheels, and in the manufacture of railway and other axles.*"—Granted October 5, 1843; enrolled April 4, 1844.

This invention relates to a mode of so combining iron and steel in the manufacture of tyres for railway and other wheels, that the steel may be at those parts of the surface of the iron most liable to wear, after the steel and iron has been rolled into bars for the purposes above described. In order to carry out this invention the steel and iron is piled together, and then heated to a welding heat, after which they are passed under the hammer and formed into a bloom, and then passed between suitable rollers for forming it into bars adapted for tyres for railway and other wheels; by this means the steel is intimately combined, and is said will possess many advantages over the present mode of applying steel to the face of tyres for railway wheels; the patentee in some cases makes the pile so as to present a surface of iron, with steel underneath, the former being removed when turning up the wheel in the lathe in the construction thereof. The claim is for the mode of manufacturing tyres for railway and other wheels, by rolling them from piles of iron and steel, in such manner that the steel is at the wearing surface.

CANNABIC COMPOSITION.

Benedict Albano, of Piccadilly, Middlesex, Civil Engineer, for "*Improvements in preparing materials and applying them to the manufacture of ornaments, and other useful purposes.*"—Granted October 5, 1843; enrolled April 4, 1844.

The fibrous material to be employed, whether the same be cotton, flax, or hemp, is in the first place to be opened out and then carded, so as to lay the fibres into one even and uniform sheet; a number of these sheets from the carding engine are then laid upon an endless cloth, commonly called a feed cloth, and moves towards a pair of wooden rollers covered with felt, between which the sheets of fibre pass, but previously to entering the rollers, the sheet is copiously sprinkled with boiling water, and then compressed by passing them between the rollers, after which the sheet may be rolled up and laid aside, ready for the next operation, which is as follows:—The dry sheets of fibrous material are to be saturated with a compound consisting of 70 parts by weight of gas tar, and 30 parts of resin, melted together, to which is to be added 15 parts of oxide of manganese. There is also another mixture or compound which consists of 75 parts of linseed oil, 25 parts of resin, and 10 parts of oxide of manganese, which are to be mixed together as before. These two mixtures are then put into a suitable vessel or trough and intimately combined by agitation and gentle heat; the sheets of fibrous material are then placed in the trough (at one end of which there is a pair of rollers), and well saturated with the mixture, they are then passed through the rollers, and as much of the mixture expressed as possible, after which the sheets are conveyed upon an open frame to a hot air stove and dried; they are in the next place subjected to a mixture of linseed oil and yellow ochre, and again passed between the rollers. The sheets are now in a suitable state (after being softened by heat) for being embossed for ornamental moulding, which is effected by means of dies and an hydrostatic or other press. The impressions thus obtained are then to be dried in a stove, and afterwards coated with a composition of resin, dissolved in about one quarter its weight of linseed oil, to which is added a little turpentine and yellow ochre. If the impression is not sufficiently sharp and complete, another coating may be given, and again pressed in the dies. The impressions after being allowed to dry for two or more days, may be coated with a strong animal size and spanish white, when they will be ready for use. The inventor also claims a peculiar method for making the counter die.

CHIMNEY FLUES.

William Denley, of Hans Place, Sloane Street, Middlesex, Bricklayer, for "*Improvements in the construction of fire plnces, flues and chimnies.*"—Granted September 21, 1843; enrolled March 21, 1844.

This invention consists first in an improved method or methods of supplying air to the fire place, to support combustion and draft, and also in the construction of a hollow breast plate for the fire place, which hollow breast plate is placed above or at the upper part of the fire place, and is supplied with cold air, which air becomes warmed therein and is then allowed to issue into the flue, and thereby assist or increase the draft up the chimney, and prevent it from smoking; and secondly, in constructing flues or chimneys, or flues of a series of earthenware tubes or pipes, either round, ovular, or of any other convenient form, and set in brickwork in a peculiar manner; these tubes or pipes the patentee prefers to make of Stourbridge clay or other suitable material, glazed inside to prevent as much as possible the adhesion of soot; and thirdly, in the peculiar construction of downward flues leading from each chimney and fire place tu the basement story of a house, whereby the chimney can be swept, and the dust and ashes from the fire place removed, without the necessity of entering the room.

Fig. 1.

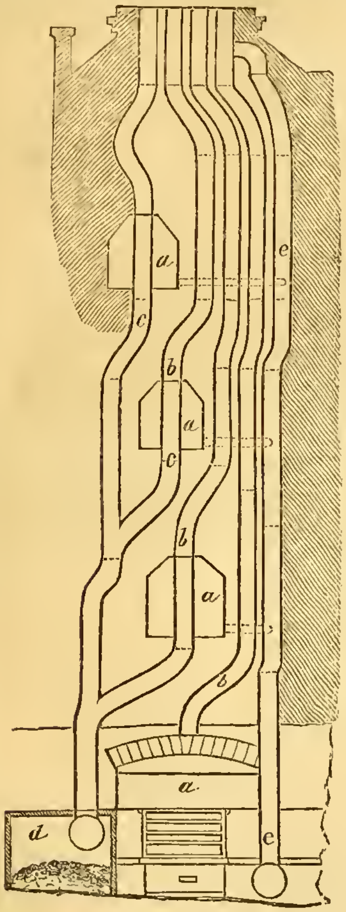


Fig. 2.

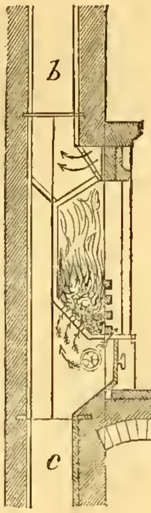

Fig. 1, is a sectional elevation of four fire places constructed according to this invention; *a a a a*, are the four fire places, and *b b b b*, the ascending flues for smoke; *c c c*, the descending flues for soot and ashes, all of which are connected together, and empty themselves of soot, &c. into the box *d*; *e e*, is an air pipe which passes underneath the floor of the basement story, and communicates with the atmosphere; this air pipe is provided with branch pipes, shown in dotted lines, for supplying the fires with air. Fig. 2, shows a transverse section of one of the fire places; *f*, is a perforated plate, which the inventor terms a hollow breast plate, and communicates with the air pipe *e*, the object being to increase the draft, by a current of air passing through the perforated plate, situate just at the entrance of the chimney; *g*, is a branch pipe fixed to the end of the branch pipe leading from the air pipe for regulating the supply of air, which it will be seen is admitted underneath, and at the back of the fire grate, as well as in front in the ordinary manner.

When it is required to sweep the chimney it will be necessary to turn the register plate so as to cover the fire place, when a communication will be formed between the ascending and descending flues, and the operation of sweeping the chimney commenced at the top and swept downwards, driving the soot into the box *d*. The inventor claims first the construction of chimnies or soot flues and downward flues, as above described, of an ovular, cylindrical, or other conveniently shaped earthenware tubes set in brickwork. Secondly, the employment of a hollow breast plate above the fire place, and supplying it with air, as above described; and also the peculiar method of supplying air to the fire for combustion, and to the soot flue or chimney for increasing or assisting the draft.

DRYING OF BRICKS AND TILES.

John Ainslie, of Redheugh, near Dalkeith, North Britain, Farmer, for "*A new or improved mode of drying tiles, bricks, retorts, and such like work made from clay and other plastic substances.*"—Granted September 30, 1843; enrolled March 30, 1844.

The object of this invention is to dry tiles, bricks, &c., made from clay, during the winter and unseasonable parts of the year, by means of artificial heat and a current of air, which removes the vapour from the tiles and bricks as it accumulates, thereby preventing the evaporation being checked. The bricks, &c. to be dried are placed upon carriages provided with shelves; these carriages, which may be placed upon a railroad, are then run into a closed shed or chamber, heated by means of flues passing underneath the floor, or by steam, or the circulation of hot water, or the admission of heated air through small apertures, to about 80° Fahr. The close chamber being heated by any convenient means as above. Cold air may be admitted at certain apertures so as to regulate the temperature of the room, and in order to remove the vapour as it rises from the tiles, &c., an artificial current may be formed by means of a fanner, worked by steam or horse power, or other mechanical means, as will be well understood. The patentee prefers the current of air to be worked about six feet per second; but this, together with the temperature, may be increased, taking care that it be not too high, so as to crack the clay when drying.

IMPROVEMENTS IN FURNACES.

John George Bodmer, of Manchester, Engineer, for "*Improvements in grates, furnaces and boilers, and also in manufacturing or working iron or other metals, and in machinery connected therewith.*"—Granted October 5, 1843; enrolled April 4, 1844.

The first improvements consist in making moveable fire bars, which traverse from front to back of the furnace, carrying the coals along with them, and which are supplied by means of a hopper situated in front of the furnace. At each side and parallel with the ash pit there is a pair of screws, one of which is placed a few inches above the other; these screws are made of cast iron and answer the purpose of bearings for the furnace bars, the ends of the bars resting within the threads of the screws, which threads are cut at the commencement of the screws regular and true, but on approaching the farther or opposite end they are made irregular, commonly called "drunken threaded," so that on giving a rotary motion to the screws, the furnace bars will be simultaneously and steadily carried along, from front towards the back or farther end of the furnace, until they come to that part of the thread in the screws which is made drunken, when they will have an undulatory motion, and which will have the effect of preventing the clinkers accumulating, and free the embers from ashes. At the ends of the screws there is a cam which presses the bars as they arrive at the end of the screws from the upper pair of screws to the lower pair, which latter carry the fire bars in an opposite direction, or from back of the furnace to the front, at which place they are elevated again and placed upon the end of the upper screws. The second improvement is for a metallic packing, consisting of a number of conical rings of brass and tin, or other suitable metal, which packings are calculated to resist a high pressure. The third part of these improvements relates to a screw cutting machine for forming the screws suitable for the purpose above described. The fourth part relates to a furnace similar to that above described for converting iron into steel and smelting metals. The fifth part relates to the application of the description of furnace above described to blast furnaces, and also to puddling hearths. And sixthly, relates to a mode of rolling saw blades, which consists in forming the piece of steel from which the blades are to be made into a hoop, and then passing it between rollers and rolling it to the required thickness without taking it from the rollers.

ARTIFICIAL FUEL.

Ferdinand Charles Warlich, of Eccleston Street, Middlesex, gentleman, for "*Improvements in the manufacture of fuel.*"—Granted October 5, 1843; enrolled April 4, 1844.

The object of this invention is firstly, the submitting fuel composed o small coal, tar, pitch, or other bituminous matter to a high temperature in a retort. Secondly, the peculiar construction of retorts for effecting the same; and lastly, the application of an exhausting apparatus to such retorts, together with the introduction of air into retorts where fuel of the above description is undergoing the process of drying. The patentee commences by stating that it is not necessary to enter into any description of the manufacture, or mode of combining pitch, coal, tar, and other matter into fuel, as the invention does not apply to the compounding of such fuel; at the same time the inventor states that he prefers the compound of coal and bituminous matter to be as follows; 15 per cent. of pitch and coal tar and 90 of small coal, in which may be employed a little "heavy oil" to the extent of from 2 to 5 per cent.; and in order to prevent smoke when such fuel is being consumed, about the same quantity of common salt may be added, or alum dissolved in water. The mixture after being moulded into convenient sizes, is placed in a retort for six or eight hours, and subjected to a heat of from 400° Fahr. and upwards, by which means gases and certain other matters are driven off, which, if permitted to remain, would produce prejudicial effects to which such fuel is said to be subjected.

The retorts, which are of the D form, are built of brick, and are provided with an aperture for the escape of gases, which pass off in the same manner as in the manufacture of gas into an hydraulic main, to which is connected a pipe leading to an exhausting apparatus, which consists of two cylindrical vessels suspended at each end of a beam, and inverted in a tank containing water, so that by raising and depressing the vessels in the water tank, the gases and vapours are exhausted from the retort or retorts, which gases pass off into the atmosphere. At the lower part of the retorts there are a number of apertures which admit a current of warm air, which previous to entering the retort passes through the furnace, so that as the gases are exhausted by the apparatus above described a fresh supply of hot air is continually admitted, which effectually drives off the damp and vapours from the pieces of fuel, which appears to be the object of this invention. The inventor claims the submitting manufactured fuel, containing bituminous matter to a high degree of temperature; also the introduction of highly heated air, together with the exhausting the products from retorts when applying heat to manufactured fuel, which is placed and inclosed in the same.

ORNAMENTAL POTTERY AND MOSAIC WORK.

Richard Boote, of Burslem, Staffordshire, Manufacturer's Clerk, for "*Improvements in pottery and mosaic work.*"—Granted October 5, 1843; enrolled April 4, 1844.

The specification described several methods of impressing devices on pottery, which are as follows. First, in order to produce a coloured design upon a ground of different colours; the device is first made in a mould of the form required, "commonly called figuring:" the devices or impressions thus obtained are then to be put into the mould in which the ware is to be made: the material of the ware when poured into the mould will be found to adhere very closely round the edges of the device, and the same will be imbedded therein. The second method consists in cutting the device in pieces of paper or parchment, which are then to be put in the mould; the two halves of the mould are then fastened together, and the matter which is to form the ground of the ware is poured in; after having stood the necessary time, the parchment or paper forming the device is to be removed, and the colour intended for the device poured in, which will fill up the spaces previously occupied by the paper device. Thirdly, in order to produce raised figures of a different colour from the ground, the figures are first of all engraved or otherwise formed in low relief in a plaster mould: this being done, the colour intended for the raised figures is poured into those parts of the mould which form the figures; the halves of the mould are then put together, and the slop intended for the ground poured in and allowed to stand a sufficient time to form the body of the ware. If the slop is of an expensive nature it will only be necessary to let the slop remain a sufficient time to form a thin coating, after which it may be withdrawn and the substratum filled in with a commoner slop.

Lastly, in producing devices of a mosaic character, the designs are fixed on the halves of the moulds with a composition of the required colour; the halves of the mould are then fastened together, and the slop intended for the body of the ware poured in: after having stood a short time, and the slop adhered the required thickness, the remaining liquor can be withdrawn.

AXLES FOR WHEELS.

John George Briggs, of Leicester, Coach Proprietor, for "*Improvements in axles.*"—Granted October 5, 1843; enrolled April 4, 1844.

This invention consists of forming the axles of two parts or shafts, one solid and the other hollow, whereby greater strength, and less liability to breakage is obtained. In order to carry out this invention the patentee provides a tubular or hollow axle sufficiently long to pass through the bosses of each of the wheels when at the required distance from each other, the calibre or bore of this tube being sufficient to admit the solid axle passing through it, which axle consists of a solid shaft having bearings turned at each end to fit the steps or journals in the frame side of the carriage. The wheels are firmly fixed upon the ends of the hollow axle by means of keys; the solid axle is then passed through the tubular or hollow one, and fixed therein in like manner, by means of keys. When the bearings are within the wheels it will be found necessary in forming the journals to weld two collars upon the hollow axle, so as to obtain greater strength. The claim is for the construction of axles, by combining together solid and hollow shafts one within the other, as described.

SLATE COVERING.

William North, of Stangate, Lambeth, Surrey, Slater, for "*Improvemen in covering roofs and flats of buildings with slate.*"—Granted October 5, 1843; enrolled April 4, 1844.

This invention consists in the application of battens of slate in combination with slates for covering roofs and flats of buildings, which is effected without fixing the slates to the rafters or joists, whereby the joints it is said are not liable to get defective from warping or vibration.

Fig. 1.

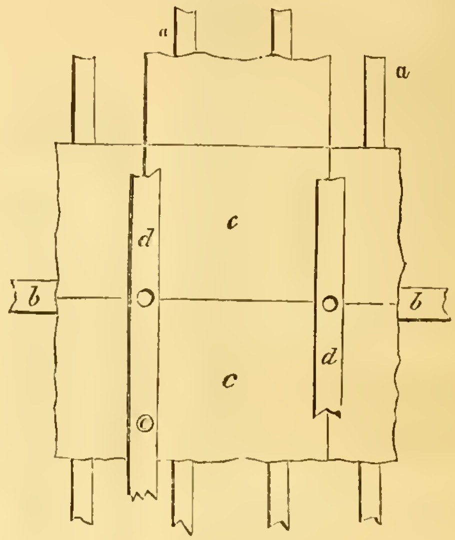

Fig. 2.

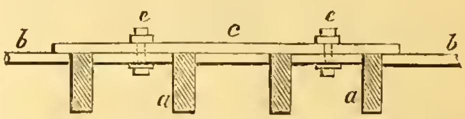

Fig. 1, shows a plan of a roof or flat, and Fig. 2, section; *a a*, are the joists or rafters constructed in the ordinary manner; *b b*, are battens of slate which fit into recesses, formed by cutting a partition of wood from the edge of each rafter; *c*, the slabs of slate, which are supported by the battens and rafters; the ends of the slabs rest upon the battens and are imbedded in putty; *d d*, are fillets of slate; and *e e*, screws, which screws bind the fillets to the slates, and the slates to the battens, the whole being supported by the rafters *a a:* the fillets may if required be placed on the underside instead of the top of the roof or flat.

The pateotee claims the application of slate battens with slate for covering the roof of a building, as described.

SEPARATION OF METALS.

Richard Janion Nevill, of Langennech, Carmarthen, Esq., for "*An improved mode of separating certain metals when in certain states of combination with each other.*"—Granted October 18, 1843; enrolled April 18, 1844.

The inventor takes copper, in which silver is in combination, and melts it in the usual manner; he then pours it in an iron vessel containing lead melted to a red heat or nearly so, and thereby mixes the argentiferous copper with the lead in proportion to the quantity of silver in combination. After the mixture it will be found that the copper with a portion of silver and lead will, as the mixture cools, rise to the surface, which may afterwards be taken off with a pair of tongs, or other mechanical contrivance; for instance, a perforated plate somewhat less in diameter than the size of the iron vessel in which the compounds are, is placed in the vessel, and near the bottom thereof, so that as the metals are melted it will be found that the copper with a portion of silver will rise through the perforations in the plate, and may be lifted out of the vessel together with the plate, which plate is provided with one or more handles for that purpose. The copper with such portion of silver as it may yet contain is then broken into small pieces, and separated by the process of "elequation," which is as follows:—The pieces of copper thus obtained, together with a quantity of charcoal, are then put into a retort or retorts, constructed with an opening at one end, through which the metals ("videlicet" the silver and lead contained in such pieces of copper) flow when in a state of fusion. The retorts, which are fixed in the furnace in a sloping position and closed, so as to exclude all air, are then heated to such a degree as to melt the silver and lead, but not the copper, which former are allowed to pass off through the opening at the lower end of the retort into a suitable vessel, leaving the copper almost free from the silver and lead, which two metals are to be afterwards separated by the ordinary process of cupellation.

IMPROVEMENTS IN BOILERS.

Thomas Morton Jones, of Birmingham, Warwickshire, for "*Improvements in heating liquids and aeriform bodies.*"—Granted October 18, 1843; enrolled April 18, 1844.

Fig. 1.

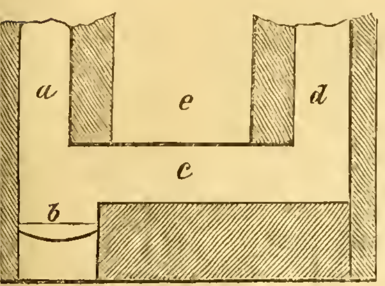

Fig. 2.

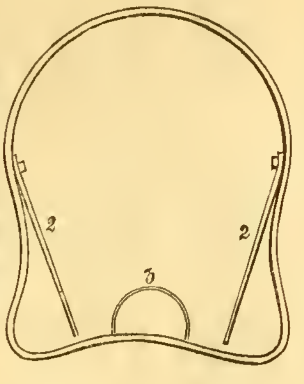

Fig. .

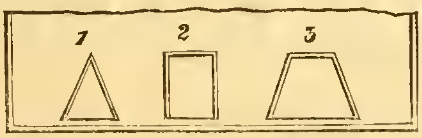


The first part of this specification relates to a mode of constructing a furnace, the arrangement of which will be seen by the accompanying diagram marked Fig. 1, which is a longitudinal section. *a*, is a shaft for feeding the fire with coal or coke; *b*, the fire grate; *c*, the hearth leading to the flue or chimney; *d*, the vessel or matter to be heated, being placed at *e*. The shaft *a*, is covered with a plate, so constructed as to regulate a current of air, which is allowed to descend the shaft *a*, and pass through the upper stratum of coal simultaneously with a current of air which is admitted at the bottom of the shaft and allowed to pass upwards through the fire, which currents meet and pass off with the products of combustion over the hearth to the chimney. The patentee states that it will be desirable to build upon, and over the hearth, a number of arches at convenient distances from each other, under which the flame passes. The second improvement consists in the application of inverted vessels (which the inventor denominates "preservers") fixed at or near the bottom of the boiler or pan, whether the same be open at the top or closed. Fig. 2. shows a transverse section of a wagon boiler with this improvement applied thereto; Q Q, are plates of iron rivetted or otherwise fixed to the sides of the boiler, and extending in the direction shown to within about one-eighth or one-fourth of an inch from the bottom of the boiler. Thus the steam generated within the preserver, that is, between the plate and the side of the boiler, cannot escape above the surface of the water line, but is retained between the boiler and the plate until by its "tension" or elasticity it is forced downwards and underneath the edge of the plate, which will have the effect of sweeping and carrying before it all impurities held in suspension in the liquid, and thereby prevent such impurities from being deposited upon the bottom of the boiler. (Query, how are they to be got rid of?) Number 3, shows an hemispherical preserver; 1, 2, 3, in Fig. 3, show three preservers of the form of a cone cylinder and truncated cone, all of which are supported by any convenient means from the bottom of the boiler, so as to allow the steam, as by its elasticity it is forced downwards and underneath the edge of the preservers, which preservers may be of any required form. The third improvement has reference to the construction of tubular boilers, in which the inventor states, that when tubes containing liquids are exposed to heat, (that is if such are not surrounded by water,) he prefers to make them of copper or brass, or any of the alloys of iron, and insert them firmly through strong iron plates, whereby they may be removed and replaced with much greater facility. When tubes are surrounded by a vapour or liquid, the inventor proceeds to cover them with a suitable meta by means of the electrotype process.

IMPROVEMENTS IN WATCHES.

Edward Mylne, of Albion Terrace, Canonbury Square, Islington, Middlesex, Watchmaker, for "*Improvements in the construction of watches.*"—Sealed October 21, 1843; enrolled April 21, 1844.

This invention consists simply in dishing out or sinking the pillar plates of watches, and inverting the fuzees, thereby obtaining what may be called full framed watches much flatter than heretofore. The pillar plate of the watch is made with recesses, which are turned out to receive the end of the barrel containing the spring, the fuzee, and also the other parts of the watch corresponding. The fuzee is constructed similar to the common fuzee, with this difference, that it is inverted and cut the reverse way, or in other words, left handed, and is provided with a thin circular steel cap. The upper plate of the watch is made about one-third thicker than usual, the pillar plate being about the usual thickness. The patentee claims the mode of constructing watches whereby the fuzees are inverted.

PETER BORRIE'S PATENT REVOLVING STEAM ENGINE.

Sir—I observe in the April number of your *Journal*, that you have been pleased to take notice of my Patent Revolving Engine, and in doing so, you have stated that it differs from one for which a patent was granted to Mr. Woodcock, in 1842, only, in the employment of a double acting air pump in connexion with it. Now I think you have either been misinformed, or have not examined the two engines sufficiently, for on doing so, you will find that Mr. Woodcock's differs very materially in many respects from mine, as you will see by the drawing and description I have sent you; I would have sent it sooner, but have only got the lithographic drawings finished to day.

I have also made an analysis of the economy and power of my engine, which I enclose; this is quite sufficient to show its superiority over any other hitherto constructed.

I am aware that many patents have been taken out for revolving engines, and have successively failed, owing chiefly to defects in their construction; these failures have prejudiced the public mind against all engines on that principle, but from the long experience I have had (both practically and theoretically) with steam engines of every description, I flatter myself that I have entirely remedied the defects common to revolving engines; and from the lightness, compactness, small amount of wear and tear, and greater economy of fuel in my engine, I have no doubt that it will surpass all others hitherto in use.

Requesting the insertion of this letter in your valuable periodical,

I am, Sir,
Yours respectfully,
Peter Borrie.

8, *Princes Square, St. George's East,*
London, 15th April, 1844.

P.S. I may state here that Mr. Mayer Henry has no farther interest in my patent.

Description.

Fig. 1, is a transverse section through the centre of the air pump, and showing an end elevation of the other parts of the engine; and Fig. 2, is a transverse section through the centre of the cylinder.

A, is the foundation plate, to which all the parts of the engine are directly or indirectly attached. B, is the external cylinder fixed to the foundation plate. C, is a smaller cylinder, revolving within the external one, on a shaft D, whose centre is placed so far above that of the external cylinder, that their circumferences may touch one another at the upper point h^1; thus the space between them gradually increases from h^1 to the lower point h^2; (the shaft D, passes through steam tight stuffing boxes in the cylinder ends, and revolves in bearings on the frames Z Z, which are firmly bolted to the foundation plate, and stayed to the cylinder.) E E, are two sliding pistons, consisting each of two arms, connected together by four rods passing over the shaft, their breadth is equal to that of the outer cylinder, and their joint length over their extremeties is necessarily somewhat less than its diameter, owing to the eccentricity of the revolving cylinder; these pistons slide freely at right angles to one another, through passages made in the circumference of the revolving cylinder, their sliding motion being caused by the pressure of one of their extremities on the ascending side of the outer cylinder, (whichever side that may be,) and the eccentricity of the revolving cylinder through which they slide; as their length is always slightly varying during the course of a revolution, the difference is made up by metallic packing placed between the two thicknesses of plates, of which the arms of the pistons are composed, the packing is pressed by springs towards the sides and circumference of the outer cylinder, and will be understood by referring to Figures 1 and 2 on the drawing. There are metallic packings, (in the passages in the inner cylinder, through which the pistons slide,) which are pressed on the flat surfaces of the pistons by springs, and prevent the steam passing to the interior. There are also two steel rollers at the inside of the packings, which are pressed up to the flat sides of the pistons by screws; these are for the purpose of diminishing the friction of their sliding motion. These rollers would not be necessary excepting in large engines. The rim of the inner cylinder is made to project into metallic packing boxes in the cylinder ends, thus the steam is entirely prevented from passing into the interior of the inner cylinder; a packing box is also placed at the point of contact h^1 to prevent the steam passing to either side. It will therefore be understood, that the steam only acts on the projecting part of the sliding pistons, between the inner and outer cylinders.

The steam in coming from the boiler through the steam pipe F, has first to pass the slide G, which is worked by the handle H; it is used for regulating the speed of the engine, and also for stopping it, when required: after passing the above slide it enters the steam tight jacket J, the bottom of which is the slide face having the four cylinder ports K, L, M and N, and the eduction port Q, on it; a slide O, worked by a handle P, passes over these ports for the purpose of reversing the motion of the engine: there are two posts O^1 and O^2, on the slide, one of which, O^2, (in the position the slide is shown on the drawing) is open to the steam port L; the port N, is closed, and the two ports M and K, are open to the eduction port Q, so that when the slide is in this position, the engine will necessarily move in the direction indicated by the arrows, and by moving the slide along until the port O^1 is above the steam port K, then will the port M, be closed, and N and L, open to eduction, so that the steam will act at the opposite side of the cylinder and consequently the motion be reversed.

It will here be observed that the lower cylinder ports M and N, are *never* used for admitting steam, but only for leading off the eduction; the object in placing them so low in the cylinder is to allow the vacuum to act upon the pistons sooner; it will be kept in mind then that, in whatever direction the shaft revolves, the steam is always admitted at one of the upper ports K or L, and the eduction led off at its opposite lower and upper ports. All these ports where they lead into the cylinder, are divided into bridges placed diagonally across them so that the pistons may pass freely over them.

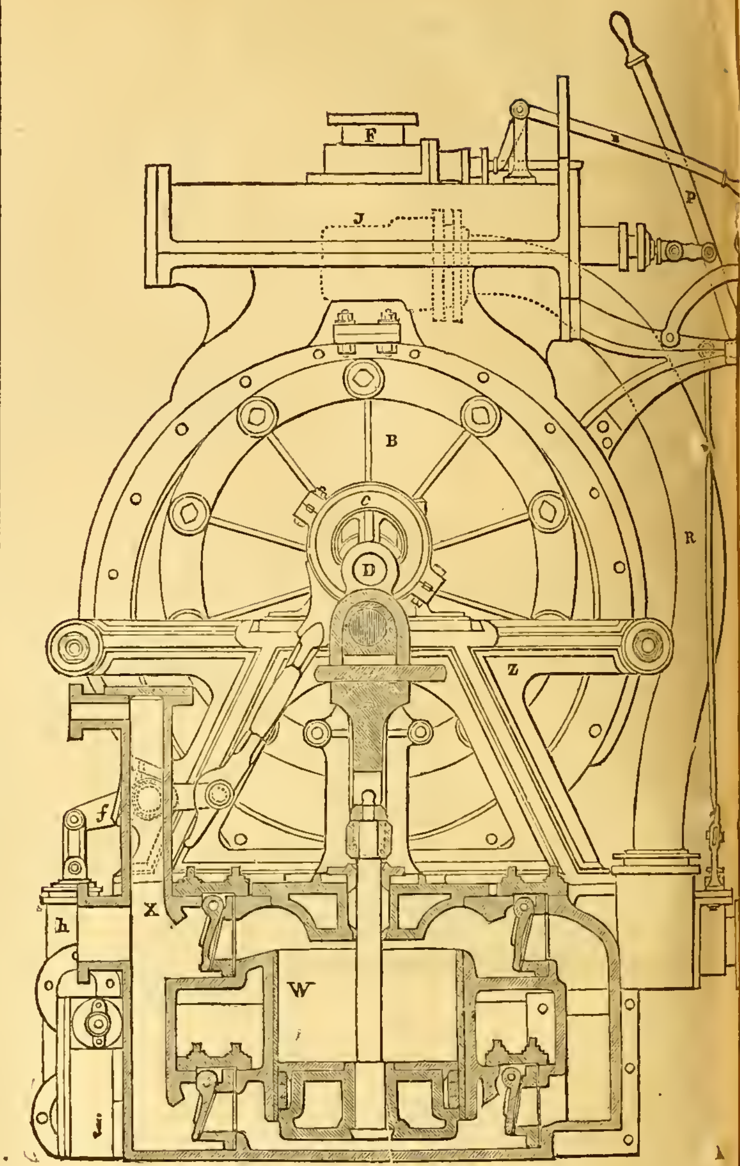
From the relative position of the two cylinders, the distance between their circumferences gradually increasing from contact at the upper point h^1, to the greatest distance at the lower point h^2, (which in this case is one-sixth of the diameter of the external cylinder, but may be varied according to circumstances,) it will be seen that in whatever direction the engine revolves, the area of that part of the pistons which is acted on by steam and vacuum gradually increases, so that the principle of expansion is carried out to its fullest extent, without the aid of expansion valves and gear.

The steam passing through the eduction passage Q, is conducted by the eduction pipe R, to the condenser S; T, is the inspection slide, placed at the lower end of the eduction pipe, and conducting the water up the pipe, so as to act fully on the steam in passing downwards: it is worked by a lever and rod connected to the handle U, which is placed in proximity with the other starting handles H and P. V, is the blow through valve. W, is the air pump, which is a double acting one, the interior arrangement of its valves &c., is shown at Fig. 1; it has a metallic packed piston which is worked from the main shaft by a crank and connecting rod, and the piston rod is, kept parallel by two slide guides bolted on the air pump cover. X, is the hot well, and Y, the discharge passage.

The pumps are worked from the main shaft by an eccentric *c*, connected by rod and lever to a rocking shaft *d*, on which are keyed two levers, *e* and *f*, which are connected by rods to the pumps, *g* and *h*; the pump *g*, is intended for the bilge water (supposing this to be a marine engine), and the pump *h*, for feeding the boilers, the latter has its valve chest *j*, bolted on the hot well.

Among the advantages which render this improved steam engine so peculiarly well adapted for locomotive and marine purposes, may be mentioned the following, viz.;—Small cost of construction, great economy of fuel, the space occupied by it is very little in proportion to its power, and also its comparative lightness, the weight of the engine being only about 2 cwt., per horse power, and that of the boilers only about $2\frac{3}{4}$ cwt. per horse power, so that the whole weight will only be about one half of the lightest engine hitherto constructed.

Fig. 1.*



I herewith annex the following analysis of the power and economy of my "Patent Revolving Steam Engine."

In the above figure, 3, the revolution of one piston is divided into 32 equal parts, and the annexed table shows the quantity of steam consumed; the mean area of the piston, the distance the centre of pressure of the piston travels; the direct, opposite, and effective pressures on the piston; the number of times to which the steam is expanded; and the number of lbs. lifted one foot high in passing through each of these divisions. The external cylinder is 3 ft. 6 in. diameter, and 1 ft. 6 in. long inside, and the greatest distance between it and the internal cylinder, is 7 in. The steam is supposed to be at a pressure of 30 lb. on the square inch, above the atmosphere, and the vacuum to be equal to 12 lb. on the square inch, the shaft making 50 revolutions per minute.

Note.—The direct pressure or force of the steam to turn the engine round in the required direction, is marked on the Table, + pressure, and the opposite or force resisting the motion in that direction, — pressure, of course, their difference, is the effective pressure.

* [We are indebted to our contemporary, the "Mechanics' Magazine," for the use of the wood engravings.]

32	—	9·0	0·285	—	44·5	44·5	400·5	—	114·1

From the Table the following results are obtained.

The quantity of steam required for one revolution of each piston 1944·2 cubic inches. Distance the centre of pressure of the piston travels in one revolution, 10·065 feet. Average effective pressure on the piston, 1080 lb. Greatest expansion 222,5 times.

Number of pounds raised one foot high by the revolution of one piston, 10,980.

Momentum of one piston ..	10,980 lb.	raised one foot high.
Number of pistons	4	
Momentum of one revolution ..	43,920 lb.	raised one foot high.
Number of revolutions per minute	50	
Momentum per minute ..	2,196,000 lb.	raised one foot high.
Deduct for friction say 10 per cent.	219,600	
Effective momentum per minute	1,976,400 lb.	raised one foot high.

$$\frac{1,976,400}{33,000} = 59·9 \text{ horses power.}$$

	Cubic In.
The quantity of steam consumed by a revolution of one piston ..	1944·2
Number of pistons	4
Steam required for one revolution	7776·8
Number of revolutions per minute	50
Steam consumed per minute	388840·0

Steam at 30 lb. pressure on the square inch above the atmosphere, is 609 times the volume of the water of which it was generated, therefore—

$$\frac{388840}{609} = 638·5 \text{ cubic inches, or 37 cubic feet quantity of water evaporated}$$

for steam per minute.

In a common double acting condensing engine of the same power, the effective momentum will be the same on 1976400 lb. raised one foot high per minute, and if we take Tredgold's data that the effective power is ·63 of the power of the steam, it will stand thus:

$$\frac{1976400 \times 100}{63} = 3137113 \text{ lb. raised one foot high.}$$

If the pressure of the steam on the piston be equal to 35 inches of mercury, or 2·4 lb. on the square inch, and the vacuum the same as in the revolving engine, or 12 lb., then the pressure on the piston will be 14·4 lb. on the square inch, and $\frac{3137143}{14 \cdot 4} = 217860$ = the product of the area of the cylinder in inches, multiplied by the velocity in feet, and 217860 × 12 = 2614320

The loss of steam in filling the passages and spaces at top and bottom of cylinder, say 1-12 217860

Cubic inches of steam required per minute, equal 2832180

Steam at a pressure of 2·4 lb. on the square inch, is 1497 times the volume of the water of which it was generated, therefore, $\frac{2832180}{1497} = 1892$ cubic inches, or 1·095 cubic feet, equal the quantity of water required for steam, per minute, $\frac{1892}{638 \cdot 5} = 2 \cdot 96$ times the evaporation required for the common engine, as for the revolving engine, and consequently only about one-third of the fuel would be required for the revolving engine, as would be required for a common reciprocating condensing engine of the same power.

THE THAMES EMBANKMENT.

Rivers of other countries pass through romantic scenery and regions of natural grandeur, the rivers of the new world have a colossal extent, in the presence of which our insular streams shrink into contemptible rills; but, as in other things, so here, moral influences contribute to give a rank. The Thames, rich in historical associations, presents a scene of commercial magnificence, to which even the teeming population of China cannot present an equal. On the banks of the silent highway, the largest and most commercial city in the world, is placed the metropolis of the mighty English empire, and it may truly be said the central seat of civilisation. Regarded by natives and by foreigners with equal admiration, it has often been a subject of regret that no grand and systematic plan has been adopted for regulating the navigability of the river, and preserving a consistent style of architecture on its banks. The ugly, ill devised buildings, which are a blot on its shores, attest the want of a central authority and efficient control.

Remembering that it is by commerce London has attained its present grandeur, and by commerce it is to be maintained, it is self-evident that more regard is to be paid to the useful than the ornamental, at any rate the useful must not be sacrificed. The inhabitants of the Seine and the Liffey can pride themselves on quays, which interfere with no commerce, but we cannot sacrifice for ornament the machinery of wealth which our river affords. A tide river, upon which the largest argosies are borne, and on which many of our war ships have for centuries been launched, cannot be treated like a shallow upland stream, and however interesting the quays of Paris or Dublin may be, certainly, notwithstanding the timber hovels and the misshapen bulks of building, the numerous craft on the Thames are objects not less pleasing. We must not complain, if we do not rival those cities in river promenades, since we surpass them in commercial grandeur.

While we make this declaration it must not be supposed that we deprecate improvement, on the contrary, we esteem it highly necessary that something should be done for the banks of the Thames, but that whatever is done should be done with caution. The testimony of a man like Wren is of the highest value, and indeed the manifest advantages accruing from a proper direction of the stream would alone enlist our sympathies. We may observe, by the bye, it is curious that after Wren's plans for the adornment of the metropolis should have been rejected two centuries ago, in the present age his views are receiving full accomplishment, and as we are widening our streets, and improving our buildings, so we are in the same spirit about to rescue the noble Thames from the neglect with which it has heretofore been treated. The subject of embankment is one which has long engaged attetnion, and been the subject of much discussion of late years, and the government having published a report in relation to it, we have been induced to devote a large portion of our space to a question so important, both in its engineering and architectural bearings, for, if on the one hand, it is a question of magnificence and ornament, on the other it concerns the improvement of an important stream, the regulation of its channel, and the arrangement of its wharfs and quays, and side docks. We may here, by the bye, observe that the engineer and geologist will in the sections of the river introduced in the report, showing the form of the river bed at various times, acquire most important and interesting evidence, as to the power of running streams, and the changes which can be effected by the agency of water in a few years.

The Commissioners have very wisely decided upon proceeding very cautiously, and instead of grasping at once with both sides of the river from Battersea Bridge to London Bridge, they only in the present instance propose to form an embankment or terrace on the Middlesex side of the river between Westminster and Blackfriars Bridges. It will be perceived by the report that there have been several schemes proposed, but there are only three of them which the Commissioners think are at all practicable, they are the plans of Messrs. Walker and Burges, plan A; Mr. Page, plan B; and Mr. Barry, (one of the Commissioners) plan C; and they have selected a modification of Mr. Page's plan, as shown in the accompanying plate. Notwithstanding this selection, we, after mature consideration of the several plans and the evidence given in the report, are inclined to advocate the scheme of Messrs. Walker and Burges with some modifications. We propose to form solid embankments and recesses in the following manner. To commence at Westminster Bridge with a solid embankment, and continue the same as far as Whitehall Place, as shown in the accompanying plan, but without leaving a dock at Whitehall wharf, which we propose to abandon, as this would only involve the purchase of three wharfs; to set against which we shall have saved the cost of forming the dock, and likewise have a valuable piece of land which will produce a large rental for building chambers for parliamentary practitioners and others, on each side of a handsome communication to be formed from the terrace to Parliament Street. This communication, would not require the removal of a single house excepting what belongs to the wharfs. From this embankment a recess to be formed for the wharfs of Scotland Yard, and Hungerford Market, with three openings of 150 feet each to be spanned by suspension bridges; then, again, an embankment extending the terrace of York Gate, between Villiers Street and George Street, thence a recess for the wharfs of the Adelphi and the Savoy, 870 ft. long, partly to be enclosed with a terrace wall, having three openings of 150 ft. each, as before. Thence a terrace to front Somerset House from the Savoy Wharf to Arundel Street, then a recess for the wharfs near Essex Street, followed up by an embankment for an extension of the Temple Gardens, again a recess for the wharfs at Whitefriars, gas works, &c. 930 ft. long, partly enclosed with a terrace wall, having three openings of 150 ft. each as before explained. These large openings will offer facilities for barges getting at the wharfs at all times of the tide as now, and thereby the recesses will not in our opinion be so liable to silt up as Mr. Page's docks will with the contracted entrances he proposes. The narrowing of the stream by the embankment, and the detached terrace walls will create a scour in the bed of the river, and which will cause the shore gradually to deepen and slope towards the centre of the river, and that coupled with the continuous washing of the banks by the swell created by the steamers, will keep the recesses free from silt; on the contrary, Mr. Page's docks will derive no advantage from the steamers passing up and down the river, as the swell will not enter them, and the continuous wall will prevent the mud or silt getting out. The scouring of the sluices will only force channels through the deposit.

We should prefer the terrace being kept down to within 4 or 5 ft. of high water mark so that it may pass under the bridges, a slight rise to be given to the suspension bridges spanning the openings of the recesses to admit barges with sails. By our proposed embankments communications may be made with the present streets; first, to Parliament Street, at Whitehall Wharf: second, at Whitehall Place; third, at Villiers Street; fourth, at the Savoy; fifth, at Norfolk Street; sixth, at Temple Lane; and, seventh, at Chatham Place.

We consider it indispensable that the terrace should be continued under Westminster Bridge to the front of the Houses of Parliament, by which means a fine opportunity would be afforded to the public to view that splendid pile of buildings, particularly the sculpture and enrichments.

According to our proposal, the lengths of the several embankments and recesses or docks, will be as follows:—Whitehall embankment,

	Feet.
Terrace from Westminster Bridge to Scotland Yard	2440
Scotland Yard and Hungerford Market recess, with three openings	560
York Gate terrace embankment	340
Adelphi and Savoy recess, with three openings	870
Somerset House terrace embankment from Savoy Wharf to Arundel Street	1250
Essex Street recess, with two openings	400
Temple Gardens embankment	710
Whitefriars recess, from Temple Gardens to Blackfriars Bridge, with three openings	930
Total length,	7500

We shall now close our remarks by giving some lengthened extracts from the valuable Report of the Commissioners, and heartily wish to see the undertaking brought through the present session of parliament, and that it may not be marred by the narrow prejudices of the city authorities, who, as they did with railways, will attempt to throw obstacles in the way to prevent the Commissioners carrying out the plan, under the plea that it will interfere with the *undoubted* rights and privileges of the citizens of London!

The Commissioners' Report.

Upon a careful review of the many subjects of improvement for which plans had already been before the public, or were subsequently submitted to us, we considered an embankment of the river Thames to have the first claim to our attention.

For a considerable period the condition of a large portion of the river in its passage through the metropolis has been the subject of observation and complaint; and although measures have at different times been submitted to Parliament, having its improvement for their object, yet nothing of a comprehensive nature has been effected.

The causes of the great change which has taken place in the bed of the river Thames, in that portion of its course which lies between London and Westminster Bridges, may be shortly stated. Among the first, if not the very first, of these in recent times, may be considered the removal of Old London Bridge—a measure, no doubt, ultimately beneficial to the interests of the river as a whole, but prejudicial for a time to the navigation immediately above it.

The operation of this change upon the condition of the river, and especially in the portions between the bridges, though great, and, as already observed, no doubt the immediate cause of the present embarrassment experienced in the navigation, has been uniform in its effects, and consistent in its character. It has produced, as was anticipated, a higher rise and lower fall of the tide than heretofore, and is producing, as was also to be expected, a general, though not uniform, lowering of the level of the river bed.

While the first of these consequences, however, has been immediate and manifest, the second, it is obvious, if left to the operation of natural causes, must necessarily be the work of time; and hence, in the interval, the navigation of the river must be difficult at certain states of the tide.

The shoals and irregularities, however, which constitute the greater portion of this difficulty, are, in the evidence before us, attributed to other causes. We are referred to a want of uniformity in the bends and curves of the river, to the disproportion between the breadth and volume of its waters, and probably to the varying nature of the material forming its bed, as natural agents in working out these results, and, as artificial causes, to projections and recesses in the shores, irregular dredging, and other evils alleged to have arisen from imperfect conservancy.

The conservancy of the river Thames is a privilege and a trust vested in the Corporation of London by very ancient charters, confirmed and renewed at various periods. The exact extent of the rights and of the duties thereby assigned to that body have been the subjects of much diversity of opinion, and of dispute and controversy both in and out of Parliament, strongly showing the necessity for some legal decision, or legislative adjustment, upon a matter of so much practical importance. Upon these points, however, it does not appear to us that it is within the province of this Commission to express an opinion; we therefore conceive that we shall sufficiently discharge our duty under this head, by soliciting the attention of your Majesty to the information furnished on this subject (extracts of which are annexed to this Report) by the Commissioners on Municipal Corporations, by the Committee of Parliament on the port of London, and by the City of London Navigation Committee.

Under the authority of the Corporation of London, and, on some occasions, under special authorities obtained from Parliament, the river has been extensively, though not systematically, embanked, and its water-way irregularly contracted, as will be seen by a plan, annexed to this Report, of that portion of the river which flows immediately through the centre of the metropolis.

Other embankments we find are in progress at the present time, under licenses granted by the Corporation, of which embankments plans are also appended.

The effect of these partial and occasional embankment has been from time to time to alter the currents of the river, and to impair its navigable channel.

The embankments constructed under the authority of Parliament are few. The first of these was projected by Sir Christopher Wren immediately after the Fire of London. The object of this embankment was "to make a commodious quay on the whole bank of the river from Blackfriars to the Tower:" and under the authority of the Act of Charles II. for rebuilding the city, and a subsequent Act of the same reign, it was partially carried into effect.

Under the first of these Acts, no house, outhouse, or other building whatsoever, was to be erected from Tower Wharf to Temple Stairs, within 40 feet of the river, cranes and sheds for present use only excepted.

Although few traces of such a way are at present to be found, yet a portion of it from the Tower to Castle Baynard was actually executed. Encroachments, however, were subsequently made upon it from time to time, and in the year 1821, "notwithstanding a very decided opposition to the measure in both Houses of Parliament, on the part of the Corporation of London, and the inhabitants of Upper Thames Street and its vicinity," the Act in question was repealed.

No further plan for regulating or improving the banks of the river was entertained till the year 1767, when a measure was submitted to the Corporation of London for raising £300,000 for the completion of Blackfriars Bridge by embanking the north side of the river between Paul's Wharf and Milford Lane, upon a line extending about half a mile in length. Arrangements were subsequently entered into with the Societies of the Middle and Inner Temple, and other parties, by which this embankment ultimately included the frontage of the Temple Gardens.

The terms in which this proposal was submitted to the Corporation would apply with very little variation to many parts of the river at the present day; and considering that a century at least had then elapsed since any measure has been attempted for the "regulation and improvement" of its shores, and that another century has very nearly arrived at its completion, the statement is not undeserving of attention. "The wharfs," it is observed, "within those limits, by their different and very unequal encroachments, not only form an irregular and disagreeable outline, but afford the owners of some an undue preference and advantage over others; at the same time that the reflected set of the tides, both ebb and flood, throws the force of the stream upon the Surrey shore, opposite to Blackfriars, and, of consequence, slackens the current on the London side; this, together with the large sewers that empty themselves in the neighbourhood, occasions a constant accumulation of sand, mud, and rubbish, which not only destroys great part of the navigation at low water, but renders the wharfs inaccessible by the loaded craft even at high water, unless at spring tides; the mud and filth thus accumulated, notwithstanding the frequent expense the wharfingers are at to clear it away, is, when not covered with water, extremely offensive, and in summer time often dangerous to the health of the neighbouring inhabitants." The Corporation of London, it is presumed, acquiesced in the correctness of these statements, inasmuch as they adopted the plan; and powers were subsequently given by Parliament for carrying it into effect.

The next embankment of importance took place at Durham Yard and the places adjacent, now known as the site of the Adelphi Terrace, and the buildings connected therewith. In the years 1768, 1769, and 1770, Messrs. Adam and other parties applied to the Corporation of London for their consent to this embankment, but without effect. The Court of Common Council not concurring, the parties applied to Parliament for an Act enabling them to effect a large embankment in that vicinity, not in the lines originally proposed, which Act was subsequently obtained, notwithstanding the most decided opposition on the part of the Corporation in every stage of the bill, and notwithstanding that the clauses subjecting the ground to be gained from the river to the acknowledgment originally offerred to the Corporation were not inserted in the Act.

Within a comparatively recent period further embankments, upon a scale of considerable magnitude, have been effected in the same portion of the river. We refer especially to the embankment which forms a part of the present site of Hungerford Market, and which was sanctioned by the Legislature in connexion with that measure; and to the projection devised for the enlargement and rebuilding of the Palace at Westminster for the accommodation of the new Houses of Parliament.

"During the last 50 years," it appears, "numerous grants have been made, under the sanction of the Corporation, for embankments in various parts of the Thames, throughout the jurisdiction of the city of London, by which the general line of the river, to a certain extent," is alleged to have "been regulated and improved. It was not, however, until within the last 15 years, and under an order of the Common Council, that the balance of moneys received on this account, and for other accommodations on the river, after deducting the expenses applicable thereto, were brought in aid of the conservancy.

The insufficiency of the funds strictly applicable to the purposes of the conservancy appears to have long formed a subject of complaint on the part of the Corporation, and we presume that to this, among other causes, is to be attributed the fact, that as far back as there is any evidence of the defective condition of the river, previously to the year 1840, there is no trace of any measure for a general and systematic improvement of the navigation, or regulation of its banks, having originated with that body.

Of the attempts made in Parliament to apply a partial remedy to this state of things, mention will be made hereafter. They failed, as it appears to the Commission, from causes which need not any longer operate:—in the first instance (in 1825), under an apprehension that the removal of Old London Bridge was too recent to admit of any accurate opinion being formed as to its effects; in the second (in 1840), from the indefinite character of the measures proposed, and from the opposition of the wharfingers, and others in trade, to the plan upon which those measures were to have been founded.

The Report then proceeds make some observations on the schemes proposed by Sir Frederic Trench in July, 1841, and by Mr. John Martin, both schemes the Commissioners appear to consider impracticable.

The plans to which the attention of the Commissioners has been directed as appearing to exhibit in their details the best mode of effecting an embankment of the Thames, were three in number, viz.:

A plan prepared by Mr. Walker (A).

A plan prepared by Mr. Page the acting engineer of the Thames Tunnel (B); and

A plan founded upon the suggestions of a member of the Commission (C). These will be occasionally referred to as plans (A) (B) (C) respectively.

The Commission proceeded, in the first place, to examine Mr. Walker and Mr. Page in reference to the objects, advantages, practicability, and expense of their respective plans. The official opinion of Captain Beaufort, and the professional opinions of Mr. Hartley, Mr. Cubitt, Mr. Gordon, Mr. Rendel, Mr. Macneil, Mr. Rennie, and Mr. Giles, were subsequently obtained; first, as to those leading and general points which appeared to apply to all the plans, and secondly as to the relative merits of the three.

Of these opinions, a portion, it is to be observed, was collected by the Commission in the usual form of oral evidence. It occurred to us, however, subsequently that all the essential questions in an enquiry of this nature might be more effectively condensed, and circulated in writing (an arrangement which was subsequently found conducive also to the parties consulted), and the remainder, therefore, were collected in that form.

Copies of these questions were also addressed to Sir Isambard Brunel, and Mr. J. K. Brunel, and Mr. Donkin; but considerations of health in the first case, and professional engagements and want of time in the other two, deprived the Commission of the assistance of these gentlemen.

In addition to the eminent civil engineers above adverted to we had occasion to examine, upon separate and distinct portions of the enquiry, Mr. J. W. Higgins, a surveyor extensively employed in London, and ordinarily referred to by the corporation for valuations, in cases of embankment upon the river; Mr. R. L. Jones, the chairman of the London-bridge Improvements Committee, a gentleman possessing great information on many of the subjects involved in many of these enquiries; and Captain Maughan, the dock-master of the London Docks, whose connexion with a large commercial body interested in the navigation of the pool, added to his practical acquaintance with the wants and habits of the river generally, made his evidence especially desirable. Messrs. Hay, Peache, and Lucey, barge-owners and lightermen, and Messrs. Tayler, Harvey, and Pocock, coal-merchants, or general wharfingers, in the line between Westminster and Blackfriars bridges, were examined principally on points not touched upon by the Select Committee of 1840, and upon the probable influence of any measure of embankment upon their respective interests.

On the feelings and opinions of the trade, as a body, it appeared to us to be more consonant to the convenience of the parties to be consulted, more conducive to a right understanding of the measures contemplated, and more likely to result in a well-considered judgment upon these measures, if our chairman were to address himself to one of its members in behalf of the whole; to enclose for their consideration copies and detailed description of the plans; and to express the desire of the commission to have a deliberate opinion from all parties concerned as to the principle upon which, and the mode in which (consistently with the permanent interests of the river) an embankment might be effected in nearest accordance with their own views and wishes. A letter was accordingly addressed, and plans transmitted to Mr. Tayler, of the firm of Dalgleish and Tayler, extensive coal-merchants and wharfingers in Scotland-yard; and in the appendix a copy of that letter is inserted, as well as of Mr. Tayler's reply.

In addition to these various sources of information on the subject before us, we were favoured with the written opinions of Mr. William Cubitt and Captain Maughan, subsequently to, and in extension of their respective oral examinations; a "Memorandum upon Estuaries and their Tides," contributed by Sir Henry Thomas de la Bèche; and, finally, with three letters, and various tables and statements prepared by Mr. Page, accompanied by sections of the several bridges, and of the river, presenting a large body of valuable matter not bearing exclusively on the local topics and interests more immediately involved in these inquiries, but on the general question of embankment in tidal rivers. With these we have inserted in the appendix, papers, the result of inquiries made under our direction as to the frontages and occupations of the wharfs on the Middlesex side, with the number of barges and other craft in front of each at certain periods of the inquiry; and also as to the heights above Trinity datum of the nearest line of communication parallel with the river between Blackfriars-bridge and Whitehall, showing the great irregularity in the level of that leading thoroughfare.

The Plan of Mr. Walker.—(A.)

The plan of Mr. Walker, referred to in a former part of this report, originally comprised an embankment on both sides of the river, between London and Vauxhall Bridges. In his evidence before the Commission as to the relative expediency of embanking the Surrey and Middlesex sides of the Thames respectively, Mr. Walker stated his attention to have been principally given to the northern side of the river, adding it to he his own opinion (in which, indeed, almost all the authorities subsequently consulted appeared to concur), that "it would be better to establish a principle, and to show its working in a portion of the river in the first instance," and to make the first embankment on the northern shore. The course of inquiry, therefore, pursued in his examination by the Commission, had reference principally to these considerations.

The lines of Mr. Walker's plan are those shown upon plan A in the appendix. It contemplated the formation of quays along the greater portion of the line, at the level of three feet six inches, or four feet above Trinity standard; these quays to become, upon terms to be settled, the property of the respective parties owning the present wharfs, of which the embankment was, in fact, to be considered an extension.

A continuous solid embankment, however, having been deemed impracticable throughout the whole line, Mr. Walker's plan suggested four exceptions, viz.:—one at Northumberland Wharf; a second above Waterloo Bridge, terminating at the bridge stairs; a third above the Temple Gardens; and the fourth commencing at Whitefriars Dock, and terminating at the Bridge Stairs, Blackfriars. At these places he proposed to leave recesses (shown on the plan) varying from 400 to 800 feet in width respectively, and bearing together, a proportion of about one-third to the rest of the embankment.

"As the deepening of the navigable channel might tend to draw down the ground of the respective wharfs into the river, it was proposed where required, to support the same by close piling in the line of the embankment, the top of this piling not to be above the level of the ground where it is driven." The main body of his embankment Mr. Walker proposed to construct of materials to be obtained from the bed of the river; the embankment wall, excepting at Somerset House, where the wall was to be faced with stone, being of brick with stone dressings only.

Of Mr. Walker's plan, a roadway formed no essential feature. In the event of a terrace or a railway being thought desirable, he proposed that it should be at least 50 feet in width; that, commencing in the neighbourhood of Whitehall, it should be carried over both the embankment and recesses, upon flat arches of 100 feet span, at such an elevation generally above the river as would enable the public in the use of it to communicate with Hungerford, Waterloo, and Blackfriars bridges, at the level of their respective roadways. With the last-mentioned of these bridges it would end.

Assuming, therefore, the height of Mr. Walker's embankment, throughout, to be, at high water, four feet above Trinity datum, the elevation of the roadway of this terrace above it would vary at different places; at its commencement at Whitehall it would be from five to six feet, at Hungerford and Blackfriars bridges 27 feet, and at Waterloo Bridge 37 feet above the same standard. To a spectator from the river, it would in each case present, with the addition of its balustrades, an elevation about three feet higher.

As the fall of the tide would throughout the whole line of the embankment, produce, to the eye, a corresponding addition to its base, the river front of the terrace and embankment together would, at times of ordinary low water, have gained an apparent addition to its height of about 16 feet; making its extreme elevation above low water, with the balustrades, about 56 feet.

The estimated expense of Mr. Walker's embankment, as stated to the select committee of 1840, assuming it to be carried to the Horseferry Road, was £300,000. In his evidence before the Commission no proportion of this amount was assigned to the shorter distance since contemplated; but it is probable that, upon the embankment above Westminster Bridge, a small portion only of that amount would have been expended.

The erection of a terrace (if it were desired) as a separate superstructure, with its piers, arches, and roadway together, would, in Mr. Walker's opinion, involve a further expense of about £400,000.; making the estimated cost, therefore, of the terrace and embankment combined, between £600,000. and £700,000.

The plan of Mr. Walker, as we have already stated, excited considerable opposition in Parliament in the session of 1840, from the wharfingers and others interested in the trade of this locality. It was then directed exclusively to the principle of a solid embankment, subject to the exceptions already referred to, as to recesses in certain portions of the line.

The objections urged against it at that period had reference to its alleged interference with the river frontage, of which, though a large portion, in the opinion of the Commission, might undoubtedly, have been improved by the adoption of such a measure; yet a still larger had been appropriated to purposes dependent upon its proximity to the water side, and adapted principally to the habits of the coal trade.

These objections, it should be stated, though the objections of a majority of the parties affected, were not universal. It was alleged by Mr. Walker that many wharfingers were desirous of availing themselves of the privilege to embank, upon the terms then proposed by the city, viz.—the payment of 1d. per annum for every square foot of ground acquired from the river.

It was objected, however, that assuming this to be permitted, a measure so partial in its operation could not fail to be injurious to a large body of the trade, by creating recesses of indefinite width, uncertain as to the time of their existence, and in the mean time favouring the accumulation of mud.

The evidence of Mr. Walker upon all these points, together with the evidence of those who, on these and other grounds, were opposed to the principle of his embankment, has been before the public now for a period exceeding three years, in the report of the select committee already referred to. No doubt, it appears to us, can exist, upon a perusal of that evidence, that it exhibits a manifest preponderance of feeling on the part of the trade adverse to the plan before that committee.

The object of the Commission, therefore, in calling Mr. Walker before them, was not to re-open the discussion of 1840, but, looking to the result of that discussion, his subsequent survey of the river in 1841, and the probability, from these and other causes, of his having communicated with parties interested in the northern shore of the river within the intervening period, to ascertain whether he had seen reason to alter his opinions or to modify his plan, and especially whether he was prepared to bring the question again under the consideration in a shape that might justify them in recommending its adoption.

From our examination of Mr. Walker on these points, his views appeared to have undergone no change; and with reference to the concurrence which his suggestions were now likely to receive on the part of wharfingers and others interested in the line, we found him unprepared to inform us either as to the extent to which such concurrence might be depended upon, or to which the Commission might reasonably consider itself entitled in reviving the consideration of his plan. One of three alternatives appeared to us to be inevitable; either that such concurrence should be obtained in the first instance, and throughout the whole line, or that considerable sums of money must be expended in compensations; or, assuming the impossibility of the first of these alternatives, and the inexpediency of the second, that the embankment must proceed in small and sometimes widely detached portions of the whole line.

The latter of these alternatives would justify a revival of all the objections to the proposed embankment of 1840, and render the execution of a terrace or river road utterly impracticable.

We are not unmindful that Mr. Walker has endeavoured to provide against these contingencies by recesses sufficient in extent and so arranged in regard to locality as to meet the wants of a large body of the trade; but we cannot but remark, at the same time, that these recesses stood in Mr. Walker's plan of 1840; that he would give them no definite assurance as to the time by which they would be completed, or the period for which they might be available; and that, upon being questioned by ourselves as to the grounds upon which he had determined the proportions of his recesses to those of his solid embankments, he admitted that "he had calculated upon the feeling of individual proprietors in the line, of which, however, he knew little."

In stating to the Commission the origin and purposes of his survey of 1841, Mr. Walker observed, "The great object of the City in that survey, as it appears to me, has been to determine a river line, to which parties making applications might, but beyond which they must not, extend their premises; and, to show how the navigable part of the river may be deepened and improved, without injuring the berths for barges where parties do not wish an extension of solid wharf, which is in no instance proposed to be compulsory."

Upon being questioned by the Commission whether that opinion should be understood as applying to the plan under consideration, he replied,

"I have stated that at present there is no intention of anything compulsory, so far as I am aware of. I am not sure that it would not be expedient for a considerable time to leave it to be optional. I think if the measures were now intended to be compulsory, there would be demands from the owners on the banks of the river for compensation; whereas if the thing were left to work its own way for a time, parties would be allowed to carry out and extend their premises; some in the shape of recesses or docks, and some in the shape of embankment the property being then considered theirs in fee. In that way portions being taken in different parts all along the river, if it should be desirable afterwards to be made compulsory upon the minority, the majority of owners and occupiers agreeing in the plan, or if they got to be all unanimous, there would be an excellent standard along the whole course of the river on which to value the land, or to pay for damages if any were done." The Commission upon this observed, "Then the embankment would take place at separate intervals?" To this observation Mr. Walker answered "Yes."

The amount of moneys to be paid as compensation under such circumstances, or of other moneys to be raised in consideration of the land embanked, are subjects, therefore, into which it would be obviously impossible for this Commission to enter with any certainty or profit. According to Mr. Higgins, who was examined before the Committee of 1840, and whose views, like those of Mr. Walker, would appear to have undergone little alteration subsequently, a revenue of about 3,600*l*. per annum might be realised if the embankment were complete; but "he had taken what would be gained by the embankment; in no case what would be otherwise lost." He had made no separate estimate of the amount to be expended in compensations, and his estimate of the revenue was admitted to be irrespective of any outlay of the kind.

The advantages of Mr. Walker's plan for a solid embankment, if it were complete, would undoubtedly consist in its simplicity of outline, its freedom from details, and its entire exemption from restrictions and regulations of any kind for its after-management. In making this observation, we desire to apply it either to a solid embankment throughout, or to the embankment with recesses to which Mr. Walker's proposal is at present limited; for, although the objections, on the score of the accumulation of mud in these recesses, and of the insufficiency of the ordinary traffic of the river for its dispersion, pervade the whole of the evidence taken by the Commission, yet the general tendency of that evidence is to show, that, if they were judiciously constructed in the first instance, a moderate application of artificial means, such in fact as is at present resorted to in the best constructed wharfs on the river, might answer every necessary purpose.

The objections to the plan, however, on other grounds are not so easily disposed of. According to the evidence before the Commission, the abstraction of the tidal water from a navigable river is in principle objectionable, inasmuch as it diminishes the efficacy of the scour. Various opinions were offered as to the degree to which this objection would apply to Mr. Walker's embankment. Mr. Hartley was of opinion that it would be considerable; and, with Mr. Giles, that its effects, if not felt in the Pool itself, would be more or less injurious in the district of the river below the Pool: Mr. Rennie, that it would operate both in the Pool and in the river below the Pool. The general tendency of these opinions, indeed, in reference to the plan immediately before us, was that, assuming the navigable current to be improved by judicious dredging, and an uniform course and increased velocity to be given to its channel, the loss would, in great measure be compensated. But these opinions were given in reference only to a small portion of the river, irrespectively of any system for its general management, and, of course, without contemplating that extension of its present plans, which this Commission may feel it right to recommend hereafter.

It was objected as to the recesses, that in proportion as they were favourable to the trade, they would become injurious to the navigation. Mr. Hartley was of opinion that they would abstract from the full force of the tidal current, and in a limited or proportionate degree affect both the tide and the scour: Mr. Cubitt, that an embankment so formed would not be continuous enough above low water mark to form a good and efficient tide to the river: Mr. Gordon, that by causing eddies they would disturb the current of the main stream, and prevent the establishment of any uniform regimen for the river: Mr. Rennie, that they would have a strong tendency to interrupt the free flow of the tide. Mr. Rendell, speaking in his evidence of these recesses, observes, "I cannot imagine any arrangement which would be more likely to make the bed of the river worse than it is at present. If there were a series of long embankments, and a series of long recesses, they would, instead of giving an uniform velocity to the stream make it more irregular than it is at present." On the other hand, Captain Beaufort was of opinion that, practically, they would have no effect on the scour of the river, and Mr. Macneil and Mr. Giles that "embankments, with occasional recesses," would conduce to its "improvement," and to the "benefit of the navigation."

The mode of levelling these recesses, proposed by Mr. Walker, and of providing them with permanent foundations, is fully explained in his evidence. The objections on this head took a wider range, though intrinsically of less importance, than those above adverted to, inasmuch as they involved the use and the construction of these receptacles for trade. Of the persons in trade examined by the Commission in reference to the dwarf piling proposed by Mr. Walker, Mr. Hay (a lighterman) was of opinion that it would be injurious to the craft. The answers of Messrs. Pocock and Peache (the first a coal, and the second a timber merchant) were not adverse: Mr. Lucey (a lighterman) gave no decided opinion; Mr. Tayler (a coal merchant) and Mr. Harvey (a wharfinger), both of them occupiers of extensive river frontages, were generally in favour of its adoption. The opinions of these witnesses, it is right to observe, were given in evidence, and without any previous reference to plans, sections, or other sources of information. Mr. Tayler and Mr. Harvey appear to have formed the most correct conception of the course proposed to be pursued.

Of the professional witnesses consulted, the attention of the majority appears to have been directed to the effect of this dwarf piling upon the navigation, in connexion with the recesses: of those who expressed their opinions with immediate reference to the use or convenience of it to the trade, Mr. Cubitt thought that dwarf piling would be inconvenient, as forming a step or threshold under water, and Mr. Rendel, that barges would be liable to ground upon, and be endangered by it. These opinions, it should be observed, were given, not in evidence, but upon a deliberate examination of the sections which accompanied Mr. Walker's plan.

The objections of the trade to the general principle of a solid embankment, whether with or or without recesses, have already been adverted to in the history of the proceedings upon Mr. Walker's plan before the select committee of 1840. Of the witnesses in trade examined by the commission, Mr. Harvey objected to a solid embankment, that it would prevent him from getting his barges to the warehouses; that he should have to carry all his goods twice; that his craft, by being exposed to the swell of the steamers, without proper moorings in the stream, would be subject to increased wear and tear; and that any measure which deprived him of his accustomed means of access would be attended with additional expense in the landing and warehousing of his goods. Mr. Pocock attached no great importance to the wear and tear apprehended by Mr. Harvey; but in every other respect concurred in his objections. It was suggested, and assented to by those gentlemen, that piles driven out in the main stream might diminish the difficulty as to moorings, assuming the extent of these to be equivalent to the accommodations of their present frontage (in many cases usurped); but this equivalent would have involved a projection into the navigable waterway of 160 feet in the one case, and from 180 to 190 feet in the other, and, allowing for the depth of solid embankment proposed in this particular locality (viz., in the neighbourhood of Whitefriars), would have carried the piling, on the northern shore alone, very nearly into the present centre of the river.

The opinions of the lightermen consulted on the last-mentioned of these points had reference principally to the exigencies of their own calling. Assuming a solid embankment to be constructed throughout the line, they were agreed that, with the additional velocity to be given to the stream in heavy frosts, and with a channel loaded with ice, the craft would drift at the mercy of the current, and that no system of piling would avail for their security.

The professional opinions consulted by the Commission were very nearly in accordance with each other on both of these points.

On that of the wharfage, Captain Beaufort, Mr. Hartley, Mr. Rendel, Mr. Macneil, and Mr. Giles were of opinion that continuous lines of solid embankment shown upon the plans could not be made consistently with the interests of the trade or the convenience of the public; Mr. Rennie, on the other hand, that the two objects were conjointly practicable; Mr. Gordon—that, "after a serious interference with, and breaking up of, existing arrangements, the trade would be ultimately great gainers by a solid embankment."

On that of the river—Mr. Hartley thought, that "to force all the craft to moor in the navigable stream would be a source of inconvenience to the trade, and of obstruction to the navigation;" Mr. Gordon—that, "as in the present system of traffic on the Thames, the bights or bays are indispensable as places of rest and refuge, the solid embankments of plan A would tend to injure the trade;" Mr. Rendel—that, "if the Thames were embanked with a solid embankment, according to the plan suggested, the wharfingers would find it absolutely necessary for their own protection not to moor out into the stream;" that "as the object of making a solid embankment would be to give the Thames such an uniform velocity as would keep open its channel, that velocity would prevent the use of the then shores by those barges;" that "the strongest run of the tide could not be taken at less than three miles an hour, and that three miles an hour would be quite enough to prevent the mooring of those craft along the shore;" that the utmost extent to which such a course would be practicable would be "a couple of barges in length," and that guard piles carried out to an extent to meet the requisites of the trade "would not continue a week." The opinions of Captain Beaufort, Mr. Cubitt, Mr. Macneil, Mr. Rennie, and Mr. Giles were addressed rather to the question of recesses, and their convenience to the trade as shelter from the open tideway, than to the positive difficulties and disadvantages connected with solid projections.

The foregoing, we think, may be referred to as a faithful summary of the opinions whether for or against the adoption of Mr. Walker's plan, having reference exclusively to its own merits. Its relative advantages and disadvantages, with reference to other plans, will be referred to hereafter.

The Plan of Mr. Page.—(B.)

The principles of Mr. Page's plan are distinct in character from those of Mr. Walker, and, in some respects, opposed to them. It proposes an embankment with side channels, the embankment of itself forming a continuous public terrace. Assuming every abstraction of tidal water from a navigable river to be injurious to the navigation below the locality of the embankment, by depriving a portion of the river of its scour, Mr. Page proposes, first, to avoid encroaching upon the capacity of the river for the reception of its tidal waters, and to make the prevention of encroachments at any future period, as far as practicable, a leading feature. Secondly, to leave to the wharfingers and others interested in the trade of the locality the possession of their present accommodations on the river shore; and, thirdly, to provide increased facilities of communication between the east and west ends of town by a public road constructed in the river.

The details of a plan professing to be founded upon these principles must, it is obvious, be far more extensive and complicated in their character than those of any plan based upon an alternation of solid embankments and recesses only. A river wall interposed between the navigable channel and the shore must have openings to afford facilities of intercourse between the two, the position of these openings would form one subject for inquiry—their width another—the facilities of access at different states of the tide, another. These openings could, of course, be passable only by bridges; and those bridges, in accordance with one of the leading principles of Mr. Page's plan, should be of sufficient width and height to admit of the accustomed traffic of any locality at any state of the tide. On the other hand, Mr. Page's terrace was to pass under the respective bridges which connect the Middlesex and Surrey shores of the river; and hence it would appear impossible entirely to satisfy one of these conditions without conflicting, in some measure, with the other.

Another point, the importance of which was not to be overlooked, was the convertibility of these side channels into docks or floating basins. The treatment of this question involved the discussion of locks, their position, their capabilities, their size, and their probable cost. The relative advantages of tidal docks and floating basins, in reference to the trade and the navigable interests of the river; the supervision necessary to the regulation of either; their respective tendencies to silt, and the facilities for cleansing and keeping them free from mud, furnished further subject for inquiry, and, the Commissioners are compelled to add, for much conflicting opinion.

Of the plan before the Commission a copy will be found inserted in the Appendix, together with a statement of its objects and alleged advantages, drawn up by Mr. Page at our suggestions. As its features were comparatively new, and as we had not before us, as in the consideration of Mr. Walker's plan, a body of existing evidence to refer to, we were induced by these and the causes previously mentioned to examine Mr. Page at great length, and to enter minutely into detail on matters some of them exclusively technical in their character, and to which therefore it is scarcely necessary to refer in this Report, except as to their relative importance to, and bearing upon the main subject of inquiry.

Looking to the principles which Mr. Page assumes as forming the basis of his plan, its consideration may be divided, as stated by himself, under three heads; viz.—

1. As any embankment constructed upon these principles may affect the Thames as a navigable river.
2. As it may affect the wharfingers and other proprietors on its banks; and
3. As it may improve the means of communication in the metropolis by opening new facilities for traffic, and for promoting generally the health and convenience of the public.

The first of these considerations opened of itself an extensive field of inquiry, and involved a class of interests not so much connected with the locality immediately concerned as with the Pool and lower portions of the river. We trust that the magnitude and importance of these interests have not been forgotten.

The abstraction of the tidal water from a river, wherever an embankment is projected upon its shores, and the prejudicial consequences necessarily arising from that abstraction, are topics upon which, of course, this Commission can be competent to express an opinion only upon the evidence before it. The expediency of maintaining if not increasing the volume of tidal water in the higher portions of the Thames, is stated by Mr. Page to have suggested a leading feature of his plan, and many of the letters and papers already referred to as inserted in the Appendix to this Report, are addressed to this interesting but necessarily difficult branch of the inquiry. Of the soundness of the principle which it is the object of these papers to enforce, and looking to the embankment of the locality under consideration as part only of a larger system of improvement, which is at this moment professed to be in operation in various parts of the river, of its great practical value we can entertain no doubt whatever; and, if the evidence before us is not altogether so concurrent as might have been desired as to its application to that particular locality, irrespective of other portions of the river, yet the very conflict of opinions has had its use in impressing upon us the necessity of caution.

The plan under consideration was, of course, open to little positive objection on this head. Captain Maughan, indeed, considered even Mr. Page's embankment as involving prima facie a violation of his own principle, inasmuch as it would displace by its own bulk a portion of that water, and, pro tanto, abstract it from the scour of the river below. In the letter, however, addressed by Captain Maughan to the Chairman of the Commission, he observes, that, assuming the water in the side channels "to pass in and out with the tide, Mr. Page's plan, compared with the other plans, would curtail in a lessened degree the tidal water; while one of his propositions being to remove the mud banks and other inequalities of the river above low water mark, it is probable that the cubic spaces so gained would equal those lost by the terraces, and that thus the river below would sustain no injury."

Its merits, therefore, are to be tested, in the first instance, with reference to the trade of the river shore. The principal objection to which it is obnoxious may perhaps be best stated in the words of Mr. Harvey, a general wharfinger, in considerable trade, occupying the Grand Junction Wharf, Whitefriars:—"I consider that any obstruction, whether by wall or otherwise, which would prevent me from getting my barge into the stream, at any time while she was afloat, would be a disadvantage. The embankment itself would be an obstruction; wherever a barge lies now, whether we want to go up or down, we have only to put her astern and get into the stream. If there is a flood-gate, and we have to go out at one particular spot, we must accommodate the other craft, so as to come out at that particular place. At present it requires a good deal of contrivance to place a large barge alongside of our wharf; and, if the room were much lessened, it would be almost impracticable." To a question whether his objections were confined to the inconvenience of access, he replied, "The inconvenience of access is one point. Then it shortens my water-way. If the embankment take place outside what we consider our present water-way, I could not of course complain, except as to the impediment of access." Mr. Pocock, the owner of an extensive coal-wharf in the same neighbourhood, concurred in these objections of Mr. Harvey. The outer pile of Mr. Harvey's wharf was stated to be 160 feet—that of Mr. Pocock's wharf to be from 180 to 190 feet from the shore, the space assigned to these wharfs, upon Mr. Page's plan, was about 140 feet; the space usually granted by the city, according to Mr. Richard Lambert Jones, from 70 to 100 feet.

A further reference, however, to the evidence of Mr. Jones on this point may help to clear up much of this difficulty. In reference to Mr. Page's plan, he observes, "I dare say the coal merchants would say, at first starting, that there is not sufficient room for them; for I know enough of the applications by the various coal merchants to the corporation of London to put piles in, and to have what they call floating craft; but we never can confine them to that; though they may ask for one pile, they will carry it further out, We confine them that they shall not come out more than five or six craft into the river; and they will take the liberty of having seven or eight; that is, they make the warehouses for coals on the river, instead of having them on the land, as they are at Liverpool and other outports; it is the cheapest warehouse they can get."

Mr. Tayler, on the other hand, of the firm of Dalgleish and Tayler, coal merchants and general wharfingers in Scotland Yard, to a question as to the bearing of this plan of embankment on their interests as wharfingers, replied, "I should rather have the river (speaking of it as merely connected with our business) as it is. It would give us a great deal more trouble getting out and in of this dock; it would impede our business a little, but I think not to a material degree." These gentlemen are the occupiers of two wharfs adjoining to each other, at which the average number of barges is about 30, the mooring room at one of them alone being sufficient for 53.

Of the professional opinions obtained by the commission upon this part of the question, there were none addressed directly to the reasonable sufficiency of Mr. Page's inner water way. No doubt, however, as to its sufficiency is expressed by these gentlemen in the discussion of any portions of Mr. Page's plan, or of the modifications of which it was represented to be susceptible; and the commission think it will be clear, from the general tenor of their evidence, that no such doubt was entertained.

The evidence of these gentlemen as to the merits of the plan under consideration, as it would affect the wharfingers and other proprietors on the bank of the river, involved questions of detail upon which it was necessarily difficult for the commission to obtain, or indeed for them to give, direct and unqualified answers. Having no personal interest to serve, the tendency of their evidence was rather to suggest alterations, than to take objections, upon all the really practical parts of the inquiry. The reply of Captain Maughan to one of the questions of the Commission affords an illustration of this statement:—"Mr. Page's plan," he observes, "admits of two modes of application—either with open entrances (or entrances open only during particular periods of the tide), or locks, which would make his side channels floating basins; but the object of it, I understand, is to leave the wharfs as they are at present, and otherwise to meet the exigencies of the trade, whichever mode of entrance may be more convenient;" and the bulk of the evidence on this point is accordingly associated with one or other of the modes of application above adverted to.

To the inquiries of the Commission as to the best mode of improving the navigation of the river, with reference to the trade of the locality, and assuming approximate uniformity of width to be desirable for such improvement, Mr. Hartley observes, "I am of opinion, that approximate uniformity of width is desirable for the purpose mentioned, and I conceive this may be obtained without injury to the trade of the locality, by leaving open the spaces between the embankment and the shore for the use of those now occupying the margin of the river." Mr. Gordon—that "as in order to regulate the river, it should be brought to approximate uniformity of width, the best mode of accomplishing this, with reference to the convenience of trade, would be the principle of the plan B, whereby the present river fronts remain intact, and, all things considered, the craft would have better and safer accommodation than at present." Mr. Rendel—"that the local trade would be best consulted by leaving the space between the wharf and the embankment open to the tidal flow and ebb." And Mr. Macneil—that "the best mode of accomplishing the object, having reference to the trade of the same localities, will be to construct a wharf wall sufficiently wide to form a thoroughfare upon it, and at such a distance from the shore as to allow barges and other craft to ply to the different wharfs, as at present, upon the principle of plan B." In Mr. Cubitt's judgment, on the other hand, "the better mode would be to construct the shores of the river with strong walls, and to form floating docks between such walls and the present shores, and wharfs for the accommodation of the trade." The opinions of Captain Beaufort, Mr. Rennie, and Mr. Giles are not directly expressed on the point, and are consequently not available.

To a subsequent question, whether the principle of plan B would be better carried out by the substitution of locks and floating basins for tidal docks or side channels, as originally proposed, the replies of Mr. Cubitt, Mr. Rendel, Mr. Rennie, and Mr. Giles were in the affirmative; of Mr. Hartley, Mr. Gordon, and Mr. Macneil, in the negative. In the series of questions submitted to the Hydrographer to the Admiralty, this question was inadvertently admitted.

We think it right, in reference to this point of our inquiries, to advert to the distinct and practical testimony of Captain Maughan. "Side channels," he observes, "admitting the rise and the fall of the tide would, in my opinion, be preferable to docks." The former appear to possess advantages over the latter plan, viz., access for the barges at all times of the tide (at least as long as there is water inside the terraces), the saving of a very considerable expense in constructing locks, double lock gates, &c., as also the usual cost of maintenance, and of the establishments for working them. Locks would also very much encroach upon the side channels, and, if many of them should be required for the admission of barges, the annual cost would be very heavy indeed."

He adds, "If the side channels were converted into floating basins, the abstraction of tidal water would of course be equal to the cubic contents of these docks; and so far as the navigation is concerned, this modification of Mr. Page's plan would be as injurious as a solid embankment."

The next in the series of considerations connected with Mr. Page's plan are the alleged difficulties of entrance to these side channels from the river. The number, position, and dimensions of these, it is obvious, might be modified at almost any period previously to the commencement of the works, and we confined ourselves, therefore, to points less susceptible of modification. Mr. Hay, a lighterman, observes, "I think Mr. Page's plan is the best I have seen, and if a project of that kind is to be executed, I have never seen any plan equal to it; but if the river is narrowed, the tide will go up with greater velocity. We have great difficulty, now, in bringing up with our craft. Now, we can bring up to the wharfs, and bring up in a recess, and get out of the way; but I doubt whether we can ever bring up at all when the tide is running so hard as it would. Still Mr. Page's plan is a very excellent one; I have seen nothing equal to it, if these difficulties of getting in at the openings can be done away with." On being further questioned whether his objections would equally to open entrances, he replied, "If there is a plan intended to be carried into effect on the river, there cannot be a better; but I fear when we come to the openings the tide will carry us by." Mr. Lucey, also a lighterman, apprehended no difficulty whatever; referring to the entrances of London and St. Katherine Docks, he depended upon the eddy to assist him, and gave his reasons for that dependence. Mr. Tayler thought there would be no difficulty, "unless the speed of the tide were very much increased. In the flow of the tide it would then require some very experienced bargeman to bring up, and ring-bolts or piles must be resorted to for the purpose." Assuming an increase of 15 per cent. upon a velocity of three miles an hour, he anticipated no difficulty whatever. Mr. Harvey had conversed with intelligent lightermen, and inferred, from the same causes, that admission would be more difficult. Mr. Pocock adverted to the increase of existing difficulties since the removal of Old London Bridge, and was also of that opinion, attaching little importance to the drift or eddy anticipated by Mr. Lucey; and Mr. Peache, referring to the fact that a great portion of the craft was worked by only one man, considered that there would be difficulty, in such cases, in getting in without further assistance.

On this point it is observed by Captain Beaufort, "the entrance to the docks in plan B would be often difficult when the tide might be strong; and, if these entrances were converted into locks, great inconvenience would probably arise from several barges arriving at the same time. At the docks which are used by large vessels, specific times of the tide are selected for letting vessels in, and they are then attended by a sufficient number of men to overcome all difficulties; whereas a barge is moved about the river by a single man, who would be quite incapable of conducting her into a narrow gate or lock."

Looking to this question as one having rather a practical than a scientific bearing, the opinions of the engineers consulted were, perhaps, not unexpectedly, discordant. Mr. Hartley and Mr. Cubitt disapproving of the particular entrances shown in plan B, were nevertheless of opinion that there would be no difficulty in designing entrances such as should afford entire protection against strong currents and high winds; the first, however, saw no necessity for locks, the second admitted locks in deep recesses. Mr. Gordon also was of opinion that there would be no difficulty, thought the gates in the plan "judiciously placed," and recommended the addition of others. Mr. Rennie, observing that all the entrances to the various docks at present on the river are occasionally affected by currents and high winds," assumed that "a careful observation of the prevailing winds would determine their position;" Mr. Giles, that "they would be affected by the same causes, but that these would not impose greater difficulties than exist at the entrances of the various docks on the river, and which might, by the means resorted to in these cases, be overcome." On the other hand, Mr. Macneil was of opinion, that "these entrances would impose difficulties and obstructions such as do not now exist at the entrances to the various docks or wharfs on the river;" and Mr. Rendel, that "they would be difficult, if not dangerous, except for an hour and a half, at most, before and after high and low water."

The experience of Captain Maughan may here be again of service in elucidating a practical question. To questions whether the entrances should be at right angles with the stream, he replies, "As regards facility of entrance, I think that is of very little importance. The craft will have to stop outside first of all, and, if there is no tide, which I apprehend there will not be, close to the embankment wall, they will go in as they like; I do not think the stream will run rapidly close to the terrace, so as to prevent the easy ingress of barges." He apprehended no difficulty in getting in, no pressure of the tide upon the vessels at the entrances. In his letter he observes, "The difficulties which have been raised about entrances at right angles I confess I cannot understand; they appear to me very much exaggerated. With a floating platform or dumb-lighter, and piles driven down at proper distances to check the barges, any lighterman could pass in his craft, even should the stream run up rapidly outside, but which I very much doubt its doing, as stated in my evidence."

The discussion of these entrances, without reference to the principle involved in the one or other of the modes of appropriation already suggested, involved a further consideration of some difficulty. The sufficiency of their width was generally admitted, but their height above high water mark, assuming moveable bridges to be dispensed with, afforded subject for much difference of opinion. Mr. Tayler and Mr. Pocock considered, as coal-merchants, that from six to eight feet headway would be sufficient for their purposes; but for straw barges, and other description of craft engaged in similar traffic, and, in short, for general uses, Mr. Hay regarded, 10; Mr. Lucey, 11; Mr. Peache, 12; Mr. Tayler, 14 or 15; and Mr. Harvey, 30 feet, as the smallest allowable reservation. The diversity of opinion upon such a point, between parties whose interests and daily habits should make them conversant with these details, is sufficient, we think, to justify a doubt as to the reasonableness of some of these requisitions.

As the object of any measure for the improvement of the river should be obviously to get rid of the mud at present accumulated upon its shores, the attention both of Mr. Walker and Mr. Page had, of course, been directed to these points: Mr. Walker trusted chiefly to the inclination of his recesses towards the river, and to the tide in cleansing them; Mr. Page, to an inclination to be artificially given in the first instance, and to the subsequent operation of culverts and sluices.

The relative advantages of, and objections to, Mr. Walker's recesses in regard to this question have been already stated in referring to his plan. The tendency to such an accumulation in the side channels of Mr. Page, and the efficacy of the means devised for its prevention or removal, gave occasion to much diversity of opinion, and incidentally involved the discussion of a point already adverted to, viz. the relative merits of open docks and floating basins. Upon the former of these points, it is observed by Mr. Cubitt, "I think the docks proposed by plan B, with single pairs of gates only at their entrances, and subject to be filled up and emptied at every tide, for the purposes either of navigation or scouring, would be very subject to silt up with mud."—Mr. Gordon's opinion was to the same effect, though qualified; Mr. Macneil's, that they would have a greater tendency to silt than the recesses of plan A; Captain Beaufort's, that the tendency would be at least as great; Mr. Hartley's and Mr. Rendel's, that it would be less. Captain Beaufort and Mr. Cubitt were of opinion that, by the conversion of these docks into floating basins, the evil would be diminished; and all concurred in stating that either by the means immediately recommended, or other artificial resources, they might be rendered practically unobjectionable.

The necessity of resorting to these means, however, even upon the simplified basis of side channels, as originally proposed, implied at the same time a necessity for supervision, and this supervision an expense, to which any modification of the plan in the shape of floating basins with lock entrances, would of course involve some addition. Assuming, therefore, the plan B to give to the wharfingers in common the use of large reservoirs of water, and to require the supervision of officers, whose duty it would be to regulate the scour, and the ingress and egress of craft at particular states of the tide, we submitted to the professional gentlemen consulted, whether this supervision, if restricted within proper limits, would entail any serious expense, or offer any obstruction to the trade, or injuriously affect the interests, or trench upon the convenience of the owners or occupiers of the adjoining property. We submitted, at the same time, a second question; viz., whether it would give them any advantages which they do not possess at present?

In reply to the first of these inquiries, Mr. Rennie answered simply, and generally, in the affirmative; Mr. Giles, "that it would become an objectionable restriction upon the freedom of the navigation of the river;" and Mr. Rendel, "that the interests and views of the numerous owners and occupiers of wharfs would make the supervision and police of such docks difficult and expensive; that supposing the entrances to be made sufficiently commodious and numerous, and the docks kept clear of mud, the owners of the wharfs would have no reasonable ground of complaint." Captain Beaufort, Mr. Hartley, Mr. Cubitt, Mr. Giles, and Mr. Macneil, were of opinion that the supervision need entail upon the parties affected no injury, serious trouble, or expense, or none, at least, for which its advantages would not afford ample compensation; and concurred with Mr. Rendel, that the conversion of the side channels into floating basins, notwithstanding its attendant increase of expense, would give them a positive accession of advantages.

The remaining considerations connected with the plans before the Commission involve a discussion of their relative claims to adoption. With the plans of Mr. Walker and Mr. Page, a terrace and public thoroughfare are undoubtedly consistent. In both plans the sewage is treated upon the same principle—viz. by extending the sewers to the outer line of the embankment, and connecting it with the river under low water mark.

After an attentive examination of the plans of which we have thus explained the principal features and details, and also of the evidence adduced in support of each of them, the first question upon which we felt called upon to exercise a judgment was, whether an embankment of the Thames between London and Vauxhall Bridges be indispensable to the improvement of the navigation of that part of the river; or whether, referring to the means by which an embankment might be made available for other objects of public utility, it should be treated as a question of expediency, having reference to other interests combined with those of the navigation.

Upon the urgent necessity which exists for some measure having the improvement of this portion of the river for its object, we think there can be no doubt whatever. It is a fact open to daily observation and complaint, that in this part its bed presents an alteration of deeps and shoals, prejudicial to the navigation; and that its shores, on the Middlesex side especially, exhibit for the greater portion of every 24 hours, accumulations of mud which cannot fail at certain seasons to generate disease, and at all times to become a powerful auxiliary to it when arising from other causes.

An inquiry into the the cause of mischief, at the present period, offers no practical advantage, except as leading to the suggestion of a remedy. Whether natural or artificial, it falls under the supervision of that body in which the conservancy of the river is vested, and whose especial duty it is to investigate and to cure these evils.

Of the causes to which the present state of the river between London and Vauxhall Bridges is to be attributed, the number of its projections and recesses, especially on the Middlesex side of the river, is undoubtedly the most prominent. The discreditable state of the shore in the neighbourhood of Hungerford Market and the Adelphi was first occasioned by large embankments in the river in the neighbourhood of Whitehall and Privy Gardens, and these parts have, in their turn, been subsequently embedded in mud by the still greater projection of the site of the new Houses of Parliament higher up the river. We think it evident, with such irregularities still existing, and with their prejudicial effects before us, that no system of dredging can alone be looked to as ensuring a permanent uniformity in the bed of the river in this neighbourhood;—that, dredging itself, unless very carefully and systematically performed, becomes a source of evil;—that the necessity for such operations should be as much as possible avoided;—and that the obvious, if not the indispensable course under such circumstances would be, after giving the bed of the river the best possible form, so to regulate the natural agencies that they should maintain its condition.

On reference to the "Questions" already referred to in this Report, it will be seen that our earliest inquiries were addressed to this portion of the subject. Adverting to the shoals and irregularities at present existing in the navigable channel of the Thames, we submitted to the Hydrographer of the Admiralty and the civil engineers consulted, the following question: "Do you think it desirable to remove them, and, if you do, are you prepared to suggest any plan less expensive than that of a general embankment for accomplishing this object, consistently with the prevention of future shoals and irregular deposits, and the maintenance of the river at a proper and uniform depth?" We have stated the precise terms of the question, in order to show that our inquiry had reference to the navigation, and the navigation alone. The answers, it is true, in some instances, glanced at objects to which, on other grounds, an embankment might be rendered of undoubted public utility; but the result of these opinions generally, in reference to the navigation alone, may, we think, nevertheless, be fairly collected. In Mr. Gordon's opinion, "a system of embankments is the only certain means of establishing an uniform régime." Mr. Rendel is "not prepared to suggest a complete plan for effecting the desired object short of an embankment." Mr. Macneil recommends "walls and embankments, with dredging, so as to ensure such a sectional area, and such a regular velocity of current, as will neither make a scour nor allow a deposit." Mr. Giles "considers the plan of a general embankment, coupled with dredging the channel to a proper and uniform depth, to be the least expensive and most effectual means of accomplishing the object." Capt. Beaufort,—"if there were a sufficient fall from London to the sea,"—and Mr. Cubitt,—probably assuming such a fall already to exist, consider "the sinking of a new bed and the raising of new shores" would be sufficient for all the necessary purposes;—Captain Beaufort, however, concludes "the only resource to be embankment." Mr. Hartley and Mr Rennie incline to "a judicious and well organised system of dredging."

With the exception of Mr. Hartley and Mr. Rennie, therefore, the whole of these authorities make the improvement of the river dependant upon an altered condition of its outline; Captain Beaufort, Mr. Gordon, Mr. Rendel, Mr. Macneil, and Mr. Giles, by the erection of embankments; Mr. Cubitt, "by forming new shores in a less expensive manner than by continuous walls of masonry." "Taking into consideration the other subjects of navigation, trade, and communications along either side of the river," Mr. Cubitt, "indeed is not aware of any plan short of a general embankment that could, at a moderate expense, effect all these objects;" Mr. Hartley observes, "I do not assume that an embankment must be constructed for the proper navigation of the Thames; but in a general point of view, I consider that embankments would be very desirable;" and Mr. Rennie does "not think embankments necessary, but only in the light of auxiliaries, and not of equal importance to the river with dredging."

A second question suggested itself to us in connexion with the foregoing, which was as follows: viz.—If an embankment be deemed expedient between London and Vauxhall Bridges, is it necessary that the river should be embanked on both sides at the same time, and as a part of the same plan of operations; or, looking to the necessarily experimental character of any proceeding for regulating the current of the river, and maintaining a proper uniformity in its bed, should it begin on the Middlesex side, as that which, according to the evidence before the Commission, would afford the best means of working out this result?

The opinions of Mr. Walker upon these points have been already stated. With reference to the navigation of the river, the expence to be incurred, and the engineering difficulties to be encountered, "his feeling upon the whole was in favour of the Middlesex side," and his conclusion, that "it would be better to establish the principle, and to show its working on a portion of the river before embracing too much." To the questions addressed to the several civil engineers consulted, the answers were, in their general tenor, consistent and uniform. Mr. Rennie assigned the priority of importance, if embankments were to be executed, to the northern shore. Mr. Hartley, Mr. Cubitt, Mr. Gordon, Mr. Rendel, and Mr. Macneil, were also of opinion that preference should be given to the Middlesex side of the river. Mr. Gordon, however, qualified his opinion of this alternative by describing it as one "excluding every consideration save the mere regulation of the river." He thought it "highly expedient," and Mr. Giles "deemed it equally necessary," that embankments should be constructed on both sides of the Thames, and that they should be carried out as part of the same plan, and at the same time, Mr. Cubitt, Mr. Gordon, and Mr. Rendel were further of opinion that, of the northern or Middlesex side of the river, the portion between Westminster and Blackfriars Bridges demanded the earliest attention.

A third question which it became necessary for us then to consider was, whether looking to the frontage of that portion at present occupied for the purposes of river trade, the requirements of that trade were incompatible with an improvement of the navigation? Upon this point we found no diversity of opinion whatever. The whole of the professional authorities consulted concurred with us in believing the two objects to be perfectly compatible. The interests of the navigation were first to be considered; secondly, those of the trade; and the mode of embankment was to be determined as far as practicable on the principle of combining a due provision for the former, with the utmost possible accommodation to the latter.

A fourth, and, with reference to the objects of this commission, an important question to be considered was, whether the interests of the trade and the exigencies of the navigation between Westminster and Blackfriars Bridges were incompatible with an extension of the present means of land traffic in the same locality; or whether, looking to the demand for new and improved thoroughfares in the line of the river, especially on the Middlesex shore, an embankment could be so constructed as to combine these objects by the appropriation of the superstructure as a public terrace or highway? On this point, also, there was great concurrence of opinion amongst the professional authorities consulted by the commission, as well as in assigning the greatest necessity for such a communication to the northern side of the river.

It then remained for us to consider whether, assuming the objects to be attained by an embankment, in whatever part constructed, to be—

1. To improve the navigable course of the river;
2. To insure to the river side trade its present accommodation to the greatest possible extent; and,
3. To extend the facilities of intercourse between the two extremities of the town;

the several plans before the commission were both in principle and in their respective details, equally adapted to satisfy these requirements: or whether the weight of evidence before the commission gave a preference to any one of them, as being better adapted than the others for effecting all these objects by reason of its principle or its details, or on the ground of the greater economy with which it might be carried into execution.

With reference to the lines of embankment laid down on the respective plans, and their probable effect in improving the navigation of the river, Mr. Hartley, Mr. Rennie, Mr. Giles, and Mr. Macneil, considered those of Plan A to be the best: Mr. Gordon, on the contrary, observes, "Of the three plans before me, A has the least reference to the principles which ought to guide the choice of lines." On the other hand, it is observed by Captain Beaufort, "There is but little choice between the lines presented by these plans, all being sufficiently continuous;" by Mr. Cubitt,—"There is great similarity in the lines of all the three plans, and, as regards the question of navigation, only, the adoption of either, as permanent lines of bank, would be a great improvement;" by Mr. Macneil,—"I have no doubt that any one of the lines would be found, with some partial modification, to answer the purpose intended;" by Mr. Hartley, in answer to the fifth question,—"There can be no doubt that any of these plans would tend much to benefit the channel of the river and improve its navigation." The relative value, therefore, of the embankments proposed, as agents in working out such a result, is undecided by these observations.

There seems little reason to doubt, from the evidence, that a terrace or roadway could be usefully and consistently made upon the embankments projected in all these plans; of course with the same qualification as to the relative facilities and advantages of either.

But there is not the same concurrence of opinion in reference to the accommodations of the trade, combined with the furtherance of these objects; and in this respect there appears to us to be a material difference in the relative merits of the three plans.

The inquiries of the Commission on this part of the subject were not limited, as we have already stated, to the opinions of professional men. They involved points, it is obvious, upon some of which science could throw no light whatever, and upon which, if a choice of opinions were indispensable, the practice and experience of those in trade would undoubtedly, in the first instance, be referred to. On the other hand, however, the evidence of parties interested, either directly or by the habits of their various callings, in the probable issue of improvements of this nature, is seldom altogether free from prejudice; and upon the whole, probably, the professional acquaintance of civil engineers with questions involving the requirements of trade, in connexion with those of navigation, may be considered as supplying the best general evidence on such a subject.

We have been induced to present the foregoing minute and detailed review of the very voluminous evidence, and the great mass of professional opinion, which we have collected with reference to an Embankment of the Thames, by the conviction that we could not by any more summary exposition of it, have done justice to the importance of the subject itself,—to the various and extensive interests connected with it,—to the high character and station of the eminent professional gentlemen from whom we have derived so much valuable information (most readily and unreservedly afforded), and also to the authors of the several plans which we have considered in comparison with each other.

We have observed with great satisfaction the almost unanimous concurrence in opinion, upon all the main topics to which our inquiries were directed, among the scientific and practical gentlemen thus consulted; and it was with a corresponding confidence that we finally came to the following Resolutions:—

1. That it appears to the Commission that the present state of the river Thames above London Bridge is such as to render highly expedient the adoption of some proceedings for remedying the existing defects, and for preventing the further deterioration of the navigation.

2. That for securing these important objects, an embankment of the river would be the most effective measure.

3. That though a general embankment between Vauxhall and London Bridges appears to be highly expedient, yet that it is most urgently required on that portion of the Middlesex, or left bank of the river, which lies between Westminster and Blackfriars Bridges.

4. That such an embankment might be advantageously combined with the formation of a carriage and foot line of communication between Scotland Yard and Blackfriars Bridge, whereby the great objects of public recreation and health would be promoted, and considerable relief be given to the existing insufficient thoroughfares between the eastern and western districts of the metropolis.

5. That by the adoption of the general principles of embankment presented in the plan of Mr. Page, or plan B (with certain modifications which have been suggested, and others which may be suggested hereafter), there is reason to expect that the great public benefit of the improvement of the river, and the obtaining a new line of communication, may be acquired without detriment to the trade now conducted on the Middlesex shore.

6. That the Commission being disposed on these grounds to recommend the adoption of this great metropolitan improvement, will proceed forthwith to ascertain as nearly as it can be done, the probable expense of carrying it into execution; and also to inquire in what manner the funds required for the purpose may best be provided, so as to press with the least possible weight and inconvenience on the inhabitants of the metropolis and its environs.

In pursuance of these resolutions it became necessary for us to place ourselves in immediate communication with Mr. Page, and to direct his attention to such modifications of his plan as had occurred to us in the course of this inquiry. These modifications, however, necessarily involved many deviations from the estimate already before us, and we directed, therefore, that further and detailed estimates might be prepared and submitted for our consideration. The nature of these modifications will be best explained by reference to the appendix. They involve, as will be seen, in principle, no departure from Mr. Page's original plan.

The estimate based upon the plan originally proposed comprised an embankment and roadway between Blackfriars and Westminster Bridges, on the northern shore of the river, 40 feet in width, and varying from three feet six inches to 10 feet above Trinity high water mark, with carriage road, foot path, balustrades, &c. from Middle Scotland Yard to Blackfriars Bridge. The whole outlay upon this portion of Mr. Page's plan would have amounted to £192,728

Add for gas fittings, lamp posts, irons, &c.	2.450
	£195,178
Add for contingencies, 10 per cent.	19,517
	£214,695

The further estimate which Mr. Page was directed to prepare and lay before us, was to comprise an embankment and terrace 20 feet in width from Westminster Bridge to Whitehall Place, and 50 feet in width for the remainder of the distance, varying in height from 3 feet 6 inches to 10 feet above Trinity datum; and to show the relative expense of constructing these—1st. With brick walls faced with granite; and 2nd. With brick walls and granite dressings only. The following was the result:

For an embankment and terrace 50 ft. in width and varying from 3 ft. 6 in. to 10 ft. in height, having brick walls and a facing of granite .. £366,409

For a like embankment and terrace, having brick walls with granite dressings only £301,391

As the mode of connecting the general line of the proposed embankment with the frontage of the premises now occupied by the residents in Privy Gardens, and also with that of the Temple Gardens, may be subject to modifications of various kinds, with a view to meet the convenience of the respective parties, the foregoing estimate may be affected by the ultimate determination respecting these portions of the work, probably so as to diminish the cost of it to the public.

A decision upon these, and upon many of the less important details of this plan may, we think, be profitably reserved for the present until your Majesty's Government shall have determined, after a perusal of our Report and its accompanying evidence, and estimates, upon the expediency of adopting and bringing under the notice of Parliament, the measure to which these relate. To that evidence we think we may confidently refer in proof of our desire to enter into all the bearings of this difficult, and, as far as regards the general character of metropolitan improvements, somewhat novel inquiry; to test the accuracy of the estimates laid before us, and ultimately to obtain for the inhabitants of the metropolis, as large a measure of improvement, of its kind, as could be effected, consistently with the extensive and important class of interests involved in its accomplishment.

We have adverted to the manner in which the funds required for the improvements in the City of London, connected more or less, with the approaches to London Bridge, and also the great alterations more recently sanctioned by Parliament, and now in progress, have been provided; and although it may not appear strictly a part of our duty to accompany our recommendations of such further improvements as may appear to us to be the most desirable by suggestions of pecuniary resources for defraying the cost of them, we trust that we shall not be considered as transgressing the limits of our Commission if we submit to your Majesty our views of the means which appear to us the most readily available, and with the smallest degree of pressure and inconvenience to the inhabitants of the metropolis and its vicinity, for the immediate object of our present Report, and also for some of those further improvements which it will be our duty hereafter to submit for the approval of your Majesty and of Parliament.

We have stated that the coal duties of 8d. per ton in the Port of London are now charged until the year 1862, with the improvements already made or in progress. The whole rate of duty upon this article, as now collected, is 13d. per ton; viz. 8d. charged as before-mentioned,—4d. received by the Corporation, in lieu of certain rights and interests,—and 1d. also collected by them for compensation to be paid to individuals, and other expenses incidental to the coal market, on the occasion of the new regulation of the coal trade under the Act of 1831.

It is estimated that the charges upon the last-mentioned duty of 1d. per ton will be extinguished in about three years from the present time.

Such being the existing state of these duties, it is our opinion that it may be advisable to augment the total rate of the tax collected from 13d. to 18d. per ton; making the duration of the whole contemporaneous with that of the duty of 8d. per ton, as above-mentioned—excepting of course the duty of 4d. per ton belonging to the City of London, which is permanent. By these means there would be at the disposal of Parliament, for Metropolitan improvements, and more immediately for that which is the subject of our present consideration, the produce of a duty of 5d. per ton until the duty of 1d. per ton, appropriated to the coal market, is set free, and of 6d. per ton for the remainder of the term. It is estimated that the annual amount would be, in the former case, £54,875, and in the latter, £65,851.

We are anxious that your Majesty should be assured that we should not lightly recommend even this comparatively inconsiderable augmentation of local taxation, nor without a careful consideration of the interests of that great community on which this additional temporary burthen would be imposed. We should not, indeed, venture to offer this suggestion except under the strongest conviction that benefits much more than equivalent to the sacrifices thus proposed would result from the adoption of the plans now submitted for your Majesty's approval. The labours of successive committees of the House of Commons who have pursued elaborate inquiries, and have expressed decided opinions on the subject, have spared us the necessity of setting forth in detail the grounds upon which we consider that an addition to the coal duties is (within certain limits) the most equitable and the least burthensome mode of providing for improvements of this description; and we therefore cannot hesitate to recommend it as the best resource for the accomplishment of a measure having for its object to secure to the metropolis the advantages of an improved and better regulated navigation of a great portion of the noble river which flows through it; and calculated at the same time to contribute largely to the convenience, the recreation, and the health of its inhabitants.

Appendix—Description of Mr. Walker's Plan (A.)

This plan (A) proposes, as a final measure,—

First, to bring the river Thames to a more uniform width than it is at present, by means of embankments, in the lines shown on the accompanying plan. Secondly, to improve the present river lines where the ground is not built upon, by easing the present quick curves. Thirdly, to remove the shoals by dredging, and to form the bottom of the navigable channel to a regular line, (Plate VI. Figure 1,) the excavated material being applicable to filling in behind the embankments, and thus to form quays at the level of 3 feet 6 inches or 4 feet above high water, Trinity standard. These quays to be, upon terms to be settled, the private property of the parties owning the present wharfs, of which they may be considered as an extension. Fourthly, to continue the covered sewers out to the front of the proposed embankment, where they may discharge below the level of low water. Fifthly, to avoid the heavy claims that might be made for interference with the coal and timber merchants, if a solid embankment were at present formed in front of their premises, it is proposed not to interfere with such at present, if the parties object to an embankment, but to leave them, forming open docks or recesses. (Plate VI. Fig. 2.) It is supposed that four of these docks may at present be required between Westminster and Blackfriars Bridges, viz., one at Northumberland Wharf, one above Waterloo Bridge, terminating with the Bridge Stairs; one above the Temple Gardens, and one commencing at Whitefriars Dock and terminating with the stairs at Blackfriars Bridge. There may be modifications in the situation of these, at the request of parties. As the deepening of the navigable channel may tend to draw down the ground of those wharfs into the river, it is proposed, where required, to support the same by close piling in the line of the embankment, the top of this piling not to be above the level of the ground where it is driven; the loose mud to be taken out from these recesses or docks, and small chalk and gravel, laid in a regular slope, to be substituted; this, and the wash by the winds and steamers, will, it is supposed, keep the bottoms clear of mud without much trouble.

The dotted lines upon the plan show the proposed future margin of the river on both sides; but as it is proposed first to embank the north or Middlesex side, between Westminster and London Bridges, the number and position of the docks or recesses on the Surrey side have not been considered. Nor is it intended entirely to preclude barges from lying *outside* the embankment; but the stations there will be less convenient than the recesses for such trades as coal and timber.

Should a terrace, or even a railway, be thought desirable, the marks upon the plan (coloured yellow) show the position of piers to support flat arches, 100 feet span. The roadway, which is shown by dotted lines, might enter on the embankment at Whitehall and terminate at Blackfriars Bridge, crossing Hungerford and Waterloo Bridges at the level of their roadways, and thus communicating with these thoroughfares.

(Signed) James Walker.

[We have not been able to give an engraving of Mr. Walker's plan, but it will be sufficiently understood, with the following explanation, by a reference to the annexed engraving. Mr. Walker's plan has a solid embankment from Westminster Bridge to Scotland Yard, then a recess; then embankment in front of Hungerford Market to Salisbury Street, then a recess to Waterloo Bridge; then embankment in front of Somerset House to a little below Arundel Street, then a recess for the wharfs at Essex Street; then embankment fronting the Temple Gardens to Whitefriars Dock; and, lastly, a recess to Blackfriars Bridge. The dotted line on the Surrey side of the river is Mr. Walker's boundary for an embankment.—Editor.]

Appendix.—Description of Mr. Page's Plan (B.)

Mr. Page's plan pre-supposes terraces and side channels, and may be referred to under three heads:—

First, as any embankment constructed upon this principle may affect the Thames as a navigable river.

Secondly, as it may affect the wharfingers and other proprietors on its banks.

And, Thirdly, as it may improve the means of communication in the metropolis by opening new facilities for its traffic, and for promoting generally the health and convenience of the public.

In the first case, the arrangement is based on the principle that any abstraction of the tidal water from a navigable river by embanking or otherwise, must injure that river to a certain extent below the locality of the embankment; and although the injurious effect of embankments may be greater in estuaries which depend for their depth of water on the tide alone, it is a known fact that the reservoir of water in a river at any particular spot now available for the scour, operates to that effect as far as it runs out with the ebb tide. Taking as an instance the locality of Hungerford, the water in the broad expanse of the river in that part operates in scouring the bed of the river as low down as Woolwich, according to the duration and velocity of the ebb; and it is assumed, therefore, that any abstraction of this water must, to a certain extent, deprive that portion of the river of its present scour.

It is further assumed that it is desirable in all navigable rivers to attain great depth and moderate velocity; that the permanent and efficient scour is produced by depth of water and moderate velocity combined, as is instanced in the beds of all rivers as they approach the sea; and that, therefore, the greater capacity of a river at high water at any particular spot, the more important is that water for scour, because it then acts with the greatest effect, namely, when the greatest body of water is passing down, say from high water to half ebb. It is therefore also assumed, that the loss of water at the sides and bays of a river cannot be compensated for by deepening its mid-channel,[1] inasmuch as the water so gained, if any shoal or shelf occurred below it, would not flow away in the ebb, remaining in fact in the reservoir dredged for it; or, if being higher than the surface of the water below, it did flow down, would be available only towards low water, when, though the current is stronger, yet, for want of body of water, it would be inefficient in producing scour.

It would appear to be admitted, from the observations of engineers of experience, that the river Thames has been injured by solid embankments; that in the case under notice the effect of such embankments from Hungerford to Milbank is shown by the accumulation of mud banks below them; that not only the tendency, but the practice in every alteration by the river side, has been to encroach upon the river, even by projections beyond a straight or a continuous line; and in the few cases where engineering authorities have been consulted, it would appear that the principle of non-abstraction of the tidal water, though fully acknowledged, has been perverted to suit particular cases. It is also assumed, therefore, that in any alteration of a public nature, the condition of preventing further encroachment should, if practicable, be a leading feature.

Secondly, With regard to the wharfingers, the object of the proposed plan is to leave their wharfs, warehouses, means of unloading, &c., in their present state; in fact, not to interfere with their property, and to allow all the accommodation for their barges, &c., in the very places they now occupy, as may be consistent with the width required for the main stream of the river; and,

Thirdly, With these provisions for the river, and for the wharfingers, the plan provides for increased facilities of communication between several points of the metropolis, and extensive promenades by the river side.

For obtaining a more uniform boundary for the main stream of the river, it is proposed to construct lines of terraces from Milbank, where the river is 600 ft. in width, to Queenhithe, where it is 650 ft.; the width between the terraces varying from 650 to 750 ft., and leaving side channels between the terraces and the wharfs varying from 303 to 150 ft. in width. The width of the terraces is 40 ft.; 10 ft. of which on the river side is appropriated for foot passengers, and the remainder for carriages.

The areas of these side channels are, on the Middlesex side, 37 acres, and the Surrey side 40½ acres; together 77½ acres, or more than double the area of the London and St. Katharine's Docks, exclusive of the basin.

The lengths and widths of the side chanoels are shown by the following table:—

---

[1] This may be illustrated by supposing that in the part to be deepened there are five feet water at the lowest run of the tide, and the bed of the river be then dredged four feet deeper; there would then be nine feet water at the lowest run of the tide; but no portion of this water would run out and scour the river below. It is assumed, therefore, that all the water which does scour the river below any locality, is contained between low water mark and high water mark; and that the greater cubic quantity of water between those two points, the more efficient will be the scour.

Middlesex Side.	Length. Feet.	Av. Width. Feet.	
From Westminster Bridge to Blackfriars Bridge	520	250	
	1,150	245	
	500	325	
	200	230	
	323	360	
	900	280	Opposite Waterloo Bridge & Somerset House.
	830	140

Surrey Side.			
From Lambeth to Westminster Bridge	1,000	140	
	600	160	
	800	170	
	300	230	
	350	180	
From Westminster Bridge to Blackfriars Bridge	1,250	210	
	1,910	220	
	1,900	230	
From Blackfriars to Bankside	1,000	170	
	600	120	

The entrance to the side channels would be by openings as conveniently situated for the admission of barges on the flood tide as circumstances will admit. They may be increased in number for greater facility of entrance, but, from observation at other entrances, are concluded to be fully equal to the wants of the wharfingers. The openings are 40ft. in width, capable of admitting two barges abreast, and are provided with gates for the purpose of enabling the wharfingers, of course under proper regulations, and subject to the supervision and control of properly appointed persons, to retain the water after high water if requisite; secondly, for preventing the overflow of the river at high runs of tide; and, thirdly, for providing for the cleansing of the side channels by means of sluices in the cross walls of communication with the streets.

These communications are proposed to be solid and provided with sluices for the sole object of retaining the water in any one division of the side channels, and cleansing the adjoining division by an easy flow of water through them, say once a week, probably at wider intervals, but the period would necessarily be very much subject for after regulation.

As the object is to enable the wharfingers to carry on their business in the same manner as they do now, these side channels are not provided with locks, it being assumed that with these, although additional facilities for sending away barges at all times of tide might be gained, there would be an increase of trouble and expense; and they are to be regarded, therefore, merely as side channels, and the gates are not to be closed except for the purposes above mentioned. The retention of the water for two hours after high water, for the purpose of expediting the unloading of the barges and giving this additional quantity of water for the scour of the river is only provided for, but is not an essential part of the plan.

The height of the terrace generally, although first proposed to be four feet above Trinity high mark, is, for the more easy entrance of craft, and for preserving uniformity of transit on the terrace, proposed to be 10ft. above that line, except in front of Whitehall Gardens and the Temple Gardens. The height of 10ft., however, is not to be considered as any essential portion of this plan, but as having been suggested since the plan was first brought before the Commission, and to meet a difficulty applying only to a particular description of craft, not very numerous, it is believed, on the river.

The width of the side channels is considered amply sufficient for the accommodation of the barges in front of the respective wharfs. From Blackfriars to the Grand Junction Wharf, a distance of 600ft., some of the wharfingers state that they require 200ft. in front of their wharfs, and the distance from the wharfs to the terrace allowed by the plan at this particular spot is not more than 180ft.; this is considered to be as large a waterway as could be strictly insisted upon, and more than would probably be asked for if the plan proposed were properly carried out.

It is not an object of the design that width for the general passage of barges should be provided in the side channels, the main stream of the river being the proper and more desirable channel for their transit; but sufficient space is attainable for ingress and egress without inconvenience to the barges unloading, and two barges abreast might be moored outside the terrace to the mooring-rings and piles provided for their accommodation.

This provision, and the space in other parts of the side channels forming receptacles for barges, would, it is believed, amply accommodate the various craft, on the spot they now occupy.

For the efficient action of the water from the sluices on the shores at the wharfs which may require cleansing, it is proposed to bring the shore of the side channels to a regular inclination as per diagram, disposing it in three planes: the first, with a slight inclination of say three inches in sixty feet towards the wharfs; the second, an inclined plane sloping towards the terrace; the third, horizontal. When the shores are to be cleansed, the barges would be removed to the sloping bed A C, and the upper sluices being opened, the mud on the first bed, the accumulation whatever it might be, would be washed away by the flow of water, the excess of water above the point A flowing down the sloping bed to the lower level, the sluice of which being afterwards open would clear away all the remainder into the main steam.

At present the sewers discharge at the line of the wharfs, leaving a deposit of filthy mud, and discharging noxious effluvia at every outlet. In the plan it is proposed to continue the sewers under the bed of the side channels and under the terrace into the main stream, so that the sewage would be discharged below low water mark. As the wharf property would be relieved from any deposit of sewage, the mud which might collect would consist of the general sediment of the river water, and although provision is made for clearing away any deposit, it is anticipated that very little would take place, as there would be a stream in the side channels at both flood and ebb tide.

By this arrangement the wharfs and warehouses are left undisturbed; the same facilities the wharfingers now possess for carrying on their business they would retain; their craft would be better protected from damage and depredation, and from the losses occurring during drifts of ice; and these advantages it is considered would far outweigh any difficulty in passing the openings to the side channels. As there are several slips and docks on the wharf property, these, it is assumed, might be increased in number and area as occasion might require. The general tendency to encroach on the river would give way to a general tendency to set back, and every alteration on this principle would be beneficial to the port of London by increasing the reservoir of tidal water for its scour.

By the proposed plan, it is intended that communications for the public should be opened from Blackfriars Bridge to Whitehall on the Middlesex side, without purchase of any property, except a small garden and one house; and that the crowded thoroughfare of Fleet Street and the Strand should be cleared of much of the lighter class of traffic which at present obstructs it.

On the Surrey side the same communication from Blackfriars to Nine Elms would be attained without the purchase of any property, and below Blackfriars a foot communication, as shown on the plan.

Embankments for pleasure ground, with capacious culverts running through them, are proposed in front of Whitehall Gardens (Crown property), and in front of the Temple Gardens, leaving to the former a private river front, and opening to the latter a desirable communication to the western part of London; but inasmuch as these embankments would form expensive portions of the plan, and to a certain, though not important extent, abridge the space for water between the terrace and the shore, the tide might, in the first instance, be allowed to continue its present course past both of these localities, and the conversion of them into pleasure grounds might, if necessary, be effected hereafter.

Note.—Although these observations are intended to apply principally to the terrace as an embankment, including a carriage way and promenade, it is not out of place to state, that instead of filling up its contents with solid matter, it is proposed to construct a continued reservoir within it, equal to a circle of 28ft. in diameter (Fig. 3), into which the pure waters of the river Wandle may be conducted, for the supply of those four water companies which now provide their respective districts with water from the Thames (mixed with the sewage), and for the general use of such establishments as may wish to avail themselves of it. But into the particulars of this proposition it is not considered necessary to enter at the present time, as the plans are quite independent of each other.

(Signed) Thomas Page.

[We have not given Mr. Page's plan (B), but we have given the modified plan of the Commissioners, founded upon plan B, which will sufficiently illustrate Mr. Page's description.—Editor.]

Reference to Engraving, Plate VI.

The plan exhibits the river wall or terrace on the Middlesex side of the river between Westminster Bridge and Blackfriars Bridge. The dotted line, L. W., is low water mark, and the dotted line nearly parallel with the bank on the Surrey side is the extent of Mr. Walker's proposed embankment and Mr. Page's proposed docks.

Fig. 1, one of Mr. Page's transverse terraces of communication with the streets, with culverts for sluicing and openings for the passage of barges. A, terrace with proposed reservoir for pure water; B, gates with sluices, the gates to be closed and sluices worked when the side channels require cleansing; C, culvert for sluices; D, section of present wall: E, continuation of sewer; F, present sewer; H. W., Trinity high water mark, and L. W., low water mark.

Fig. 2, a transverse section of the river with Mr. Walker's embankment wall A, to be filled in behind, B present wharf, *h. w.* high water, *l. w.* low water; the irregular line *c*, the present bed of river, *d* bottom of river of the proposed deepening. Fig. 3 shows a transverse section of the river with one of the recesses, *e*; bed for barges as at present; *f*, guard piles; *g*, dwarf piling the top to be driven down to the level of the bed of the river; *c. l.*, central line of river.

REVIEWS.

FARADAY AND THE ELECTRICAL SCIENCES.

Lectures on Electricity, comprising Galvanism, Magnetism, Electro-Magnetism, Magneto and Thermo-Electricity. By HENRY M. NOAD, Author of Lectures on Chemistry, &c. London: George Knight & Sons, Foster Lane.

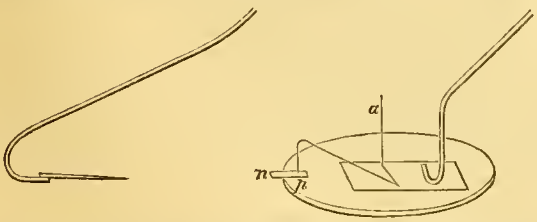
Mr. Noad has published a new edition of his Lectures on Electricity, which give succinctly an account of each department of electrical science, with the forms of illustrative experiments and the history of the most recent discoveries and improvements. In perusing this work we have seen with gratification how much Dr. Faraday has contributed to every branch of these sciences, and we thought we could not give a much better example of the value of Mr. Noad's book, nor a more interesting selection for our readers, than to extract some account of Dr. Faraday's valuable labours.

It will not be forgotten that it was by means of an apparatus, in some degree resembling the Electrophorus in principle that Faraday succeeded in demonstrating that induction is essentially a physical action, occurring between contiguous particles, and never taking place at a distance without polarizing the molecules of the intervening dielectrics. The conclusion seems to be that induction is not through the metal of the apparatus, but through the air in curved lines. In fact, as Mr. Noad puts it, it is an action of the contiguous particles of the insulating body thrown into a state of polarity and tension, and capable of communicating their forces in all directions. With regard to the theory of electro-chemical decomposition, in his second ecture, page 77, Mr. Noad remarks—

"The following beautiful experiments, made by Faraday (See Exp. Research. series v. 462 et seq.), prove that, so far from electro-chemical decomposition depending upon the simultaneous action ot *two metallic poles*, *air* itself may act as a pole, decomposition proceeding therewith as regularly and truly as with metal.

"A piece of turmeric paper, not more than 0·4 of an inch in length, and 0·3 of an inch in width, was moistened with sulphate of soda, and placed upon the edge of a glass plate opposite to and about two inches from a point connected with a discharging train arranged by connecting metallically a sufficiently thick wire with the metallic gas pipes of the house, with those of the public gas works of London, and with the metallic water pipes of London. A piece of tin-foil resting upon the same glass plate was connected with the machine and also with the turmeric paper by the decomposing wire *a* (Fig. 1.)

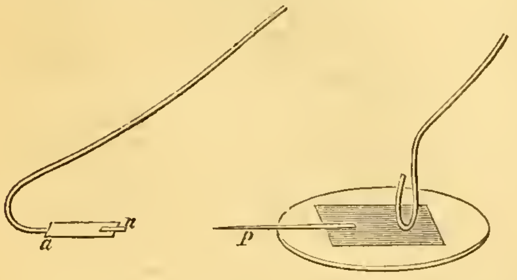
Fig. 1.



The machine was then worked, the positive electricity passing into the turmeric paper at the point *p*, and out at the extremity *n*. After forty or fifty turns of the machine (a plate fifty inches in diameter), the extremity *n* was examined, and the two points or angles found deeply coloured by the presence of free alkali.

"A similar piece of litmus paper dipped in a solution of sulphate of soda (Fig. 2) was now supported upon the end of the discharging train *a*, and its

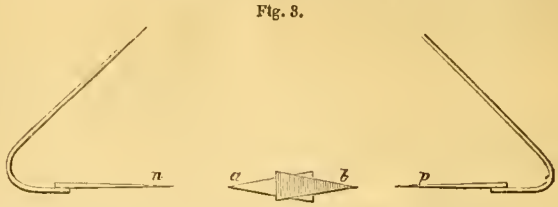
Fig. 2.



extremity brought opposite to a point *p*, connected with the conductor of the machine. After working the machine for a short time, acid was developed at both corners towards the point, that is, at both corners receiving the electricity from the air. Then a long piece of turmeric paper, large at one end and pointed at the other, was moistened in the saline solution and immediately connected with the conductor of the machine, so that its pointed extremity was opposite a point upon the discharging train. When the machine was worked, alkali was evolved at that point; and even when the discharging train was removed, and the electricity left to be diffused and carried off altogether by the air, still alkali was evolved where the electricity left the turmeric paper.

"Arrangements were then made in which no metallic communication with the decomposing matter was allowed, but *both poles* formed of air only. Pieces of turmeric and litmus paper, *a* and *b*, (Fig. 3,) moistened with solution of sulphate of soda, were supported on wax between the points, con-

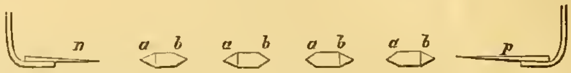
Fig. 3.



nected with the conductor of the machine and the discharging train, as shown in the figure; the interval between the respective points was about half-an-inch. On working the machine, evidence of decomposition soon appeared, the points *b* and *a* being reddened from the evolution of acid and alkali.

"Lastly, four compound conductors of litmus and turmeric paper were arranged as shown in Fig. 4, being supported on glass rods; and on working

Fig. 4.

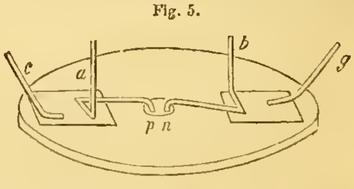


the machine carefully, so as to avoid sparks and brushes, evidence of decomposition was obtained in each.

"Notwithstanding, then, the absence of metallic poles, we have here cases of electro-chemical decomposition precisely similar to those effected under the influence of voltaic battery; and we appear to have direct proof also that the power which causes the separation of the elements is exerted not at the poles, but at the parts of the body which is suffering decomposition.

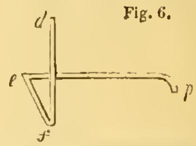
"The arrangement shown in Fig. 5 was employed by Faraday for effecting electro-chemical decomposition by common electricity. On a glass plate, raised above a piece of white paper, two small slips of tin-foil, *a*, *b*, were placed: one was connected by the insulated wire c with an electrical machine, and the other by the wire *g* with a discharging train, or with the negative conductor. Two pieces of fine platinum wire, bent as in Fig. 6, were provided, and so arranged that the part *d*, *f*, was nearly upright, while the whole rested on the three bearing points, *p*, *e*, *f*.

Fig. 5.



The points *p*, *n*, thus became the decomposing poles. They were placed on a piece of filtering paper wetted with the solution to be experimented upon. When litmus paper, moistened in solution of common salt or sulphate of soda, was employed, it was quickly reddened at *p*; a similar piece, moistened in muriatic acid, was very soon bleached at the same point, but no effects of a similar kind took place at *n*. A piece of turmeric paper, moistened in solution of sulphate of soda, was reddened at *n* by two or three turns of the machine; and in twenty or thirty turns, plenty of *alkali* was there evolved. On turning the paper round, so that the spot came under *p*, and then working the machine, the alkali soon disappeared, the place became yellow, and a brown alkaline spot appeared in the new part under *n*. When pieces of litmus paper and turmeric paper, both wetted with solution of sulphate of soda, were combined, and put upon the glass, so that *p* was on the litmus, and *n* on the turmeric, a very few turns of the machine sufficed to show the evolution of acid at the former and alkali at the latter, exactly in the manner effected by a volta-electric current. (See Exp. Researches, third series, 309 et seq.)

Fig. 6.



"In these experiments the direct passage of sparks must be carefully avoided. If sparks be passed over moistened litmus paper, it is reddened; and if over paper moistened with solution of iodide of potassium, iodine is evolved. But these effects must carefully be distinguished from those due to electro-chemical powers, or true *electrolytic* action, and must be carefully avoided when the latter are sought for. The effect just mentioned is occasioned by the formation of nitric acid by the chemical union of the oxygen and the nitrogen of the air: the acid so formed, though very small in quantity, is in a high state of concentration, and therefore reddens the litmus paper, and decomposes the iodide.

"It does not appear that Faraday was more successful than Wollaston in effecting a true electro-polar decomposition of water. He says, 'there is reason to believe that when electro-chemical decomposition takes place, the quantity of matter decomposed is not proportionate to the intensity, but to the quantity of electricity passed; but in Wollaston's experiment this is not the case. If with a constant pair of points the electricity be passed from the machine in sparks, a certain proportion of gas is evolved; but if the sparks be rendered shorter, less gas is evolved; and if no sparks be passed, there is scarcely a sensible portion of gases set free. On substituting solution of sulphate of soda for water, scarcely a sensible quantity of gas could be procured, even with powerful sparks, and almost none with the mere current; yet the quantity of electricity in a given time was the same in all these cases."

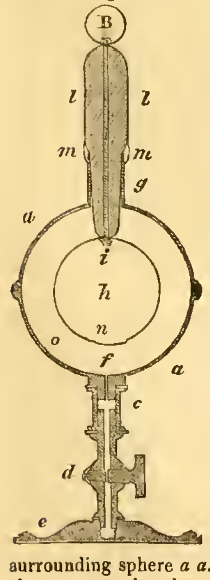
"I believe at present that common electricity can decompose water in a manner analogous to that of the voltaic pile. But when I consider the *true effect* only was obtained, the quantity of gas given off was so small, that I could not ascertain whether it was, as it ought to be, oxygen at one wire and hydrogen at the other. On substituting solution of sulphate of soda for pure water, these minute streams were still observed; but the quantities were so small, that on working the machine for half an hour, I could not obtain at either pole a bubble of gas larger than a small grain of sand; and if the chemical power be in direct proportion to the absolute quantity of electricity which passes, this ought to be the case.' In paragraph 359 he says, 'It is doubtful whether any common electrical machine has yet been able to supply electricity sufficient in a reasonable time to cause true electro-chemical decomposition of water.'

"Mr. Goodman, of Salford, near Manchester, who has published a very ingenious essay on the 'Modifications of the Electric Fluid," has, however, succeeded in decomposing water *by current alone*, and with *unguarded poles*."

We think it will be interesting here to give Faraday's views of induction and conduction. "According to this philosopher, both *induction* and *conduction* ought to be considered the same in principle and action—every body appearing to discharge in a greater or less degree, which makes them better or worse conductors—worse or better insulators. He considers the first effect of an excited body upon neighbouring matters, to be the production of a polarized state of their particles, which constitute induction; and this arises from its action on the particles immediately in contact with it, which again act upon those contiguous to them; and thus the forces are transferred to a distance. If the particles can maintain this polarised state, then *insulation* is the consequence; and the higher the polarised condition, the better the insulation; but if the particles cannot maintain their polarized state, if they possess the power to communicate their forces, then conduction occurs; and the tension is lowered, conduction being a distinct act of discharge between neighbouring particles. Thus, as the higher the polarized condition which the particles of the body can assume, the better insulator is that body; so is a body a better conductor in proportion to the inappetency of its particles to retain a state of polarity. The discharge which takes place between two conducting surfaces is termed *disruptive*; it is the limit of the influence which the intervening air or dielectric exerts in resisting discharge; all the effects prior to it are inductive, and it consequently measures the conservative power of the dielectric. It occurs not when all the particles have attained to a certain degree of tension; but when that particle which is most affected has been exalted to the subverting or turning point, all must then give way, since they are linked together, as it were, by the influence of the constraining force, and the breaking down of one particle must, of necessity, cause the whole barrier to be overturned. In every case, the particles amongst and across which the discharge suddenly breaks, are displaced—the path of the spark depending upon the degree of tension acquired by the particles in the line of discharge. The spark may be considered then, as a discharge, or lowering of the polarized inductive state of many dielectric particles by a particular action of a few of the particles occupying a very small and limited space: all the previously polarized particles returning to their first or normal condition in the inverse order in which they left it, and uniting their powers, meanwhile to produce, or rather to continue the discharge effect in the place where the subversion of force first occurred."

Mr. Noad also says:—

Fig. 7.



"It was with an apparatus constructed on the principles of the Leyden phial, that Faraday succeeded in proving by the most decisive experiment that *induction has a particular relation to the different kinds of matter through which it is exerted*. A section of this ingenious contrivance is shown in Fig. 7. *a, a*, are the two halves of a brass sphere, with an air-tight joint at *b*, like that of the Magdeburgh hemispheres, made perfectly flush and smooth inside, so as to present no irregularity; *c* is a connecting piece, by which the apparatus is joined to a good stop-cock *d*, which is itself attached either to the metallic foot *e*, or to an air pump. The aperture within the hemisphere *f* is very small: *g* is a brass collar fitted to the upper hemisphere, through which the shell-lac support of the inner ball and its stem passes; *h* is the inner ball, also of brass: it screws on to the brass stem *i*, terminating above by a brass ball B; *l, l*, is a mass of shell-lac, moulded carefully on to *i*, and serving both to support and insulate it and its balls *h*, B. The shell lac stem *l* is fitted into the socket *g* by a little ordinary resinous cement more fusible than shell-lac applied at *m, m*, in such a way as to give sufficient strength and render the apparatus air-tight there, yet leave as much as possible of the lower part of the shell-lac stem untouched as an insulation between the ball *h*, and the surrounding sphere *a a*. The ball *h* has a small aperture at *n*, so that when the apparatus is exhausted of one gas and filled with another, the ball *h* may also itself be exhausted and filled, that no variation of the gas in the interval o may occur during the course of an experiment.

"The first substance submitted to examination was shell-lac, as compared with air.

"On making the experiment with all the care and attention that could be bestowed, an extraordinary and unexpected difference appeared, and the conclusion was drawn that the specific inductive capacity of shell-lac as compared with air is as 2 to 1. With glass a result came out, showing its capacity compared with air to be as 1·76 to 1; and with sulphur a result showing its capacity to be as 2·24 to 1. With this latter substance the result was considered by Faraday as unexceptionable, it being, when fused, perfectly clear, pellucid, and free from particles of dirt, and being moreover an excellent insulator.

"During the experiments with shell lac, Faraday first observed the singular phenomenon of the *return charge*. He found, that, if, after the apparatus had been charged for some time, it was suddenly and perfectly discharged, even the stem having all electricity removed from it, it gradually recovered a charge which in nine or ten minutes would rise up to 50° or 60°. He charged the apparatus with the hemispherical cap of shell lac in it, for about forty-five minutes, to above 600° with positive electricity at the balls *h* and B, Fig. 7, above and within. It was then discharged, opened, the shell lac taken out, and its state examined by bringing the carrier ball of Coulomb's electrometer near it, uninsulating the ball, insulating it, and then observing what change it had acquired. At first the lac appeared quite free from any charge, but gradually its two surfaces assumed opposite states of electricity, the concave surface, which had been next the inner and positive ball, assuming a positive state, and the convex surface, which had been in contact with the negative coating, acquiring a negative state; these states gradually increasing in intensity for some time.

"Faraday was at first inclined to refer these effects to a peculiar masked condition of a certain portion of the forces, but he afterwards traced them to the known principles of electrical action. He took two plates of spermaceti and put them together, so as to form a compound plate, the opposite sides of which were coated with metal. The system was charged, then discharged, insulated, and examined, and found to give no indication to the carrier ball: the plates were then separated, when the metallic linings were found in opposite electrical states. Hence, it is clear that an actual penetration of the charge to some distance within the dielectric, at each of its two surfaces, took place by conduction: so that to use the ordinary phrase, the electric forces sustaining the induction, are not upon the metallic surfaces only, but upon and within the dielectric; also extending to a greater or smaller depth from the metal linings."

Mr. Noad in discussing the subject of chemical phenomena, page 196, says, "*Chemical Phenomena.*—Before entering upon this interesting branch of our subject, it will be necessary that we describe the new terms introduced by Faraday, and state his reasons for adopting them. According to the views of this celebrated philosopher, electro-chemical decomposition is occasioned by an *internal corpuscular action*, exerted according to the direction of the electric current, and is due to a force either *superadded to, or giving a direction to the ordinary chemical affinity* of the bodies present. He conceives the effects to arise from *forces* which are *internal*, relative to the matter under decomposition, and not *external* as they might be considered if directly dependent upon the poles. He supposes that the effects are due to a modification, by the electric current, of the chemical affinity of the particles through or by which that current is passing, giving them the power of acting more forcibly in one direction than in another, and consequently making them travel by a series of successive decompositions and recompositions in opposite directions, and finally causing their expulsion or exclusion at the boundaries of the body under decomposition, in the direction of the current, *and that* in larger or smaller quantities according as the current is more or less powerful.

"What are called the *poles* of the voltaic battery are merely the surfaces or doors by which the electricity enters into, or passes out of, the substance suffering decomposition; Faraday hence proposes for them the term *electrodes* from ηλεκτρον and οδος a way, meaning thereby, the substance, or surface, whether of air, water, metal, or any other substance which serves to convey an electric current into, and from the decomposing matter, and which bounds its extent in that direction.

"The surfaces at which the electric current enters, and leaves a decomposing body, he calls the *anode*, and the *cathode*; from ανα upwards, and οδος a way,—*the way which the sun rises*; and κατα downwards, and οδος a way,—*the way which the sun sets.*

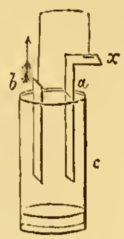
"Compounds directly decomposable by the electric current are called *electrolytes*, from ηλεκτρον and λυω to set free,—to *electrolyze* a body is to decompose it electro-chemically; the elements of an electrolyte are termed *iöns*, from ιων, participle of the verb ειμι to go; *anions* are the iöns which make their appearance at the anode, and were formerly termed the electro-negative elements of the compound, and *cations* are the iöns which make their appearanc at the cathode, and were termed the electro-positive elements. Thus chloride of lead is an *electrolyte*, and when *electrolyzed* evolves two *iöns*, chlorine and lead, the former being an *anion*, and the latter a *cation*: water is an electrolyte, evolving likewise two iöns, of which oxygen is the anion, and hydrogen the cation: muriatic acid is likewise electrolytical, boracic acid on the other hand is not."

Another of Faraday's grand discoveries is that of definite electro-chemical action. In the experiments on this subject he proved that water, when subjected to the influence of the electric current is decomposed in a quantity exactly proportionate to the quantity of electricity which passes through it, whatever may be the variations in the conditions and circumstances under which it may be placed, and this is generally true of all electrolytic bodies. We regret that while on this subject we cannot give the interesting summary of results at page 209 of Mr. Noad's work.

On the subject of the voltaic pile it is well known that Faraday has given his support to the chemical theory, and the evidence adduced by him has greatly contributed to its reception in this country.

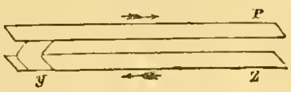
"The source of the electricity of the voltaic pile was made by Dr. Faraday the subject of the 8th, 16th, and 17th series of his Experimental Researches. Having succeeded in producing electricity *quite independent of contact*, a plate of zinc (Fig. 8) was cleaned and bent in the middle to a right angle; a piece of platinum, about three inches long and half an inch wide, *b*, was fastened to a platinum wire, and the latter bent as in the figure. These two pieces of metal were arranged as shown in the sketch; at *x* a piece of folded bibulous paper, moistened in a solution of iodide of potassium, was placed on the zinc, and was pressed upon by the end of the platinum wire; when, under these circumstances, the plates were dipped in the diluted nitric and sulphuric acids, or even in solution of caustic potash, contained in the vessel c, there was an immediate effect at *x*, the iodide being decomposed, and iodide appearing at the anode, that is, against the end of the platinum wire. As long as the lower ends of the plates remained in the acid, the electric current proceeded, and the decomposition proceeded at *x*. On removing the end of the wire from place to place on the paper, the effect was evidently very powerful; and on placing a piece of turmeric paper between the white paper and the zinc, both papers being moistened with a solution of iodide of potassium, alkali was evolved at the *cathode* against the zinc, in proportion to the evolution of iodine at the *anode;* the galvanometer also showed the passage of an electrical current; and we have thus a simple circle of the same construction and action as those described in the last lecture, except in the absence of metallic contact.

Fig. 8.



"The mutual dependence and state of the chemical affinities of two distant portions of acting fluids, is well shown in the following experiments. Let *P* (Fig. 9) be a plate of platinum, *Z* a plate of amalgamated zinc, and *y* a drop of dilute sulphuric acid; no sensible chemical action takes place till the points *P Z* are connected by some body capable of conducting electricity: then a current passes; and as it circulates through the fluid at *y*, decomposition ensues.

Fig. 9.



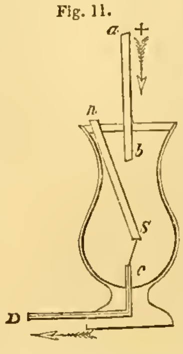
"In Fig. 10, a drop of solution of iodide of potassium is substituted, at *x*, for the acid: the same set of effects occur; but the electric current is in the opposite direction, as shown by the arrows."

Fig. 10.

He has also shown that electrolytes can conduct a current of electricity of an intensity too low to decompose them, and has given his support to the chemical theory of galvanism. We wish much we could enter at length into Faraday's views with regard to the magnetism of metals. He considers all metals as magnetic, in the same manner as iron, though not at ordinary temperatures or under ordinary circumstances. His opinion is that there is a certain temperature for each metal (as in the case of iron where it is well known) beneath which it is magnetic, and above which temperature it is devoid of magnetic power. He thinks too that there is a relation between such point of temperature and the magnetic intensity, which the body can acquire when reduced beneath that point.

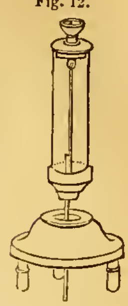
Upon the subject of magnetism, Dr. Faraday, reasoning on the relative motions of the needle and electrified wire, "Conceived that the pole of a magnet ought to revolve about the conductor, and the conductor about the pole of a magnet, and by the following ingenious apparatus he succeded in proving this to be the case:—Into the centre of the bottom of a cup, as in the vertical section, Fig. 11, a copper wire *e*, D, was inserted, a cylindrical magnet *n*, *s*, was attached by a thread to the copper wire *c*, and the cup was nearly filled with mercury, so that only the north pole of the magnet projected. A conductor, *a*, *b*, was then fixed in the mercury, perpendicularly over c. On connecting the conducting wires with the opposite ends of the battery, a current was transmitted from one wire, through the mercury to the other. If the positive current descended, the north pole of this magnet immediately began to rotate round the wire, *a*, *b*, passing from east through the south to west, i. e., in the direction of the hands of a watch; but if the current ascended, the line of rotation was reversed. Conversely, a magnet was fixed in a vessel of mercury, and the conducting wire hung from a hook above it, the end just dipping into the fluid; the electric current being then transmitted through the moveabl conductor, Faraday found

Fig. 11.



that the free extremity instantly began to revolve round the pole of the magnet, in a direction similar to the last. A good contrivance for exhibiting this is shown in Fig. 12."

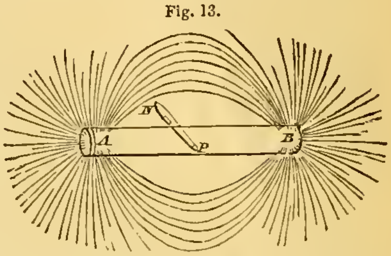
Fig. 12.



To conclude—

"The direction of the current of electricity which is excited in a metal when moving in the neighbourhood of a magnet is shown to depend upon its relation to the magnetic curves. Faraday, with his usual happy method of illustration, has given us this popular expression of it. Let A B, Fig. 13, represent a cylinder magnet, A being the marked, and B the unmarked pole; let P N, be a silver knife-blade, resting across the magnet with its edge upwards, and with its marked or notched side towards the pole A; then in whatever direction or position this knife be moved, edge foremost, either about the marked or unmarked pole, the current of electricity produced will be from P to N, provided the intersecting curves proceeding from A, abut upon the notched surface on the knife, and those from B upon the un-notched side; or if the knife be moved with its back foremost, the current will be from N to P, in every possible position and direction, provided the intersected curves abut on the same surfaces as before. A little model is easily constructed, by using a cylinder of wood for a magnet, a flat piece for the blade, and a piece of thread connecting one end of the cylinder with the other, and passing through a hole in the blade for the magnetic curves; this readily gives the result of any possible direction."

Fig. 13.



We must observe that Dr. Faraday has given to the world a laborious work, entitled Experimental Researches on Electricity, embodying the results of the papers he published from 1831 to 1840, and he is a constant contributor to the Philosophical Transactions of the Royal Society, and to the scientific periodicals.

DESIGNS.

Original Geometrical Diaper Designs. By D. R. HAY, Decorative Painter to the Queen. London: Bogue. Part I.

Those who take up this work must closely attend to its title, for it purports to give no more than what it does give, geometrical diaper designs. Those therefore who may fancy that they are to have examples of general decoration will be disappointed, and have only themselves to blame. The restriction of the work to diaper designs shows the importance which is beginning to be attached to decoration in this country, a movement which has been in a great degree forwarded by Mr. Hay himself, and before which movement it would have been quite hopeless to have expected a work on a single branch of decoration, and still more hopeless to have brought it out. As it is there are many who will look at Mr. Hay's lines and circles, and marvel what there can be in them, or why people should ever buy such worthless trifles. Design however in no department can be safely neglected in a commercial country, and still less in this country, where we have suffered and are yet suffering in a high degree the consequences of our disregard for art. The mechanical genius of our countrymen, their unequalled manual skill avail us nothing, the moment any degree of taste is required in the production of a marketable article, and we have as it were abandoned many of the most lucrative branches of manufacture to foreigners who labour with our own machinery. The foreign trade of France in manufactured goods entirely consists of articles of taste, fine silks, fine cottons, jewellery, ornaments, stained paper and decorated articles of every description, of which they have the monopoly in foreign markets. So it is with the Swiss, the Prussians, the Belgians, and other competitors, they exist mainly by our ignorance and our neglect, at the same time that they absolutely import largely into this country. The consequent loss is not to be reckoned by thousands or hundreds of thousands, but by millions, which, had we the requisite instruction, might be spent in the employment of our own operatives of every description. Here too we see that this is no matter, dependent for its importance on the whims of connoisseurs, or the fancies of dilettanti, but one which affects all classes of art. In truth the Nasmyths, the Bramahs, the Rennies, have a much deeper interest in it than Sir Martin Archer Shee or Sir Richard Westmacott; the latter indeed have rather a jealousy as to the field of art being still more overcrowded, but it is evident that if we increase our production of textile or other fabrics in the same ratio must a demand be created for steam engines, for power looms, and for the various machinery by which manufactures are in this country carried on. With the same feeling, we say, it is a matter of interest even to the machine makers that sound instruction in art should be given in the schools of design. They form their pursuits, and with the idea, as they imagine, of benefiting their own workmen, have a prepossession for mechanical drawing, drawing from objects à la Butler Williams, and all the various artificial cork-swimming contrivances which convert designs into a matter of rules and compasses. On the other hand we maintain that they have the strongest interest in supporting instruction in design on the basis of art, and we hope that in Manchester, Glasgow, Liverpool, Edinburgh, Newcastle, Birmingham, and other places, the machinists will not only be forward in subscribing to the schools of design, but that they will be foremost in promoting the due cultivation of taste in design, which, although it is to be aided by geometrical study, can never be attained on such a basis. The independent instruction of the eye is the grand thing, and lines and compasses so far from effecting that absolutely detract from it most seriously. Nay so strongly do we feel this that we say it is better for the mechanical draftsman himself to begin with the delineation of the human figure, and that he will profit more by such studies in his own branch than he would under the ordinary curriculum. Here however the change is hopeless, for if you could convince the employer, you can never convince the self-satisfied mechanic, whose preconceived ideas are an invincible obstacle.

It is with such impressions of the importance to all classes of our readers of the study of design, that we are pleased to see Mr. Hay's work as one useful in itself and gratifying as an evidence of the progress which has been made. These designs are intended for the use of decorative painters, weavers of carpets, damasks and shawls, printers of calico, paper stainers, stained glass manufacturers and others, and will, we have little doubt, prove of value, for Mr. Hay has paid particular attention to this branch of design, which is of extensive application, and as to which few accessible examples exist. For the classes to whom it is addressed it is essential that such a work should be in a cheap form, and in this respect Mr. Hay has not been neglectful, while it will from its intrinsic interest prove an attractive work for the study and the drawing room. Each plate is of a large foolscap size, and each design in duplicate, one plate being an outline and the other with tinted compartments. The outline plates will of course be found useful for filling up as coloured patterns in different branches of decoration, and we should recommend Mr. Hay to publish the outline plates in a separate form for this purpose. The filling up of these plates in colour may be made to serve as a very useful study both for private students and in schools of design. A very good exercise and an appropriate means of competition would be to require the emblazoning of a plate in a particular key colour, say blue, or orange, or purple, from which competitions great advantages would accrue, for according to the relative taste and instruction of the pupils, many diversities of treatment would result, which would become the subject of comment and the means of improvement.

Prefixed to the present part is the commencement of an essay on ornamental design, which has many points of interest, and which subsequently is to be directed to the discussion of the practical points of decorative study. In the following extract from this essay, we fully concur, and we think many will agree that its applicability to architecture is not its least merit.

"There has been much said and written upon purity of style, and it may startle some to see it asserted, that this has had only one tendency, and that has been to retard the progress of the art of ornamental design in this country. But many of the kinds of ornament called styles being themselves impure, in so far as they are destitute of the first principles of beauty, a servile adherence to them is not only a very questionable kind of purity, but calculated to corrupt the taste, while it retards originality of conception.

"If an ornamental designer were asked to imitate another in the same profession, he must either be conscious of his own inferiority, or feel his reputation compromised by the request. And the same may be said of any other profession where conception or originality of design is required, to constitute excellence. If a poet imitates the works of another poet, he thereby acknowledges his own inferiority; and so does the artist who copies the work (either ancient or modern) of another artist. But in neither case can the works copied constitute or supersede the laws or first principles of art. The greatest merit of all works of art, either in poetry, music, painting, or sculpture, consists in their being unlike the style of any that have preceded them; for there are no limits to the inventive powers of genius; and indeed it is only invention and originality that prove the possession of that divine gift. But the mode of proceeding in regard to tuition in the ornamental arts has, in this country, been of a very opposite character. What has hitherto been understood by purity of style, is nothing more than servility of copying, and if we were to inquire very closely into the origin of what are termed styles of ornament, we should find their claims to this distinction to rest on a foundation of a very slight and unsatisfactory kind."

Before we leave this subject, we may remark that we are glad to hail the formation of a Society for the Promotion of Decorative Art, for much good must accrue from such an institution. It will tend to make decorative art a respectable pursuit, and respectability, as a matter of political economy goes a good way towards cheapness, and it will be the means of strengthening good impressions and diffusing new ideas. It will also, we hope, serve to brush up other departments of art. The architect, the painter, and the sculptor, want the exercise of a wholesome influence upon them, until they duly feel which they will never put forth the energies which, as Englishmen, it behoves them to exhibit, nor leave the fleshpots of Egypt, the servile imitations of the works of antiquity. What dwarfs do even our mighty appear when we come to compare them in any respect with the great men of old. Our people have no love of wisdom for her own sake, a love of her as a holy thing, but all they care about is just the smallest amount of knowledge in their own particular pursuits that will give them a money-mongering proficiency. Where are we to look for a Michael Angelo—architect, sculptor, poet, engineer, anatomist, mathematician, great in every pursuit; and who has acquired fame in each where a Leonardo da Vinci, whose engineering discoveries were not less admirable than his pictorial triumphs, where a Titian, a Raffaelle, a Rubens, an Alonzo del Cano, a Holbein, men who considered art a Catholic pursuit, who not merely acquired manual proficiency in every branch of it, but thought it could not adequately be studied, if literature and science were neglected, men who commanded esteem by the extent of their acquirements, were entrusted with the most varied employments, and looked up to with respect as the rightful ministers of the public, wherever the highest degree of instruction, and the most extraordinary talent were to be displayed. To such a mean pass, have, we come that painters are regarded as next to musicians and actors, that class which has the least sympathy with learning, and architects, defeated in every competition, are threatened, with invasion by the engineers. To seek a painter who could read a page of Homer would be a hopeless task; to find one decently acquainted with our own literature, or our own history, would be scarcely more easy. We need hardly say that art has suffered much from these facts, art and learning have become dissociated, and art has become a poor relation, so neglectful of appearances as not to command respect. Undoubtedly one main reason why you have not lecturers in art at London, Oxford, or Cambridge, is because you have not got painters, sculptors, or architects, who have the decent rudiments of letters to qualify them for the task they would have to perform. What an expositor of Homer, of Sophocles, or Herodotus, would he be who could not read him, and how could one, fathoms in acquirements below the dullest freshman, command respect. Lectures from such men would be farces, in which students would be more occupied in criticizing the ignorance of the exhibitors than in acquiring any other degree of instruction from them. We have heard attempts within a metropolitan college, and we must say they were sickening. It is very true, the lectures were not attended by the body of the college, or there would have been much to disgust. Now, it is under these circumstances, we conceive any kind of brushing up will do good, and even the humble students of decorative art, having healthier sympathies, and a greater love for knowledge, will be able to read a useful lesson to their sophisticated superiors. We sincerely hope this will be done, for we wish well to art, and should not have laboured so many years for its advancement, if we had not felt that there are the elements of improvement, and that art is not at the present moment duly pursued, nor its possessors in that elevated position which, from the right exercise of their acquirements, they would derive.

RAILWAY ADMINISTRATION.

A Letter to the Right Hon. W. E. Gladstone, M.P., President of the Board of Trade, on Railway Legislation. "Nitor in Adversum." London: Nickisson, 1844.

We have seldom seen a more masterly exposition on the subject of railways than is to be found in this brief pamphlet; if, therefore, we dissent from its reasonings and the remedies it proposes, it is because we draw different conclusions from the same premises, and regard premises upon which our author has not argued. At a time when rant and cant are so prevalent with regard to railways, and a pretext is earnestly sought to hunt them down, it is matter of great consolation to find an advocate so staunch come forward to defend them, one earnest to do them due justice, at the same time too impartial to defend their errors. Those, however, who have deeply studied the subject, and been intimately connected with them as our author has been, know that railway bodies have been much more sinned against than sinning, and will feel cautious in what way they interfere with an institution which has shown and possesses such elements of good. The railway system of England is both a moral and physical phenomenon of the age. A connected chain of public ways extending over 1800 miles, and in the construction of which 60 millions sterling have been embarked, the largest sum ever yet applied in any country in bulk to any other purpose than that of war, naturally excites attention to the colossal magnitude of the enterprise, but the moral features are still more deeply interesting. Not only has this vast sum been raised by private means, and expended under private direction, but difficulties of the most serious character have had to be contended with. At every step experience had to be acquired, invention exerted to overcome difficulties and establish new precedents, the immense amount of money required and expended, enhanced the cost of procuring it, and the price of every kind of labour and material. No colony, no new political institution, was ever formed with such difficulties and such success as the railway system; financiers, engineers, contractors, had to be created, while, as we have said, the very vastness of the works have enhanced the cost of their execution. It is well, at the present time, and with our present experience, to turn round and say the railways could have been executed for less. It is true if, as our author says, there had been no parliamentary contests, no law, no extravagant landed compensation, that much might have been saved, but we are not quite so sure as he is that the future lines to be executed will cost only the present moderate rate, and we deny, therefore, the propriety of measuring things by the present standard. At this time money is abundant and interest low, so is the price of labour and materials, and as many contractors have been ruined, and none have too much work, a line can be let at a very low price. Prices are however rising, and will rise; labour will cost more, timber will get up, iron double in price, to say nothing of a crisis by and bye, and the serious consequences of depression in the money market, which it is in the nature of events to bring about from time to time. We would not have contractors or engineers blind to these facts, for it was to such facts that many difficulties were owing at a previous period. The much vilified estimates of Stephenson, Brunel, Rastrick, Braithwaite, &c., were founded upon works actually executed, but, in the interval, a most serious difference in prices was created by the number of contracts in the field. While, however, we expect prices to rise as a matter of course, we do not anticipate the serious excesses of the old system, because many of the difficulties have been overcome. In the infancy of the railway system, as the development of traffic was not foreseen, so neither was the cost of stations duly provided for, then it must be remembered that in those days contractors were not used to works so gigantic, and were not so competent to undertake them. Now, the weight of locomotives is ascertained, and the rails will not have to be increased in weight 50 per cent. above the estimate, as was the case previously in consequence of the experience gained in the course of the working. Now, many and economical arrangements are well known, people are not afraid to lay down timber bridges, as to which formerly much prejudice and misconception prevailed.

We say that this experience, now so advantageous, had then to be gained and to be bought at every step, and that the old system instead of being chargeable with blame, is deserving of the highest degree of praise and admiration. Few know the burthen which weighed on the minds of railway managers in those days, and rarely have exertions so great been made, and received so little appreciation. Our author graphically describes the difficulties of the panic.

"Still worse was the condition of some other lines two years later. The commercial embarrassments that weighed so heavily upon the country bent them to the ground. The proprietors were totally unable to answer the calls upon them. No credit could be given—no money could be obtained. Contractors failed—works were stopped—loans were raised at usurious interest—capital was provided at a sacrifice of one-third of its amount. Whatever censure boards of directors deserved in other matters, at this time they stood forward manfully to face the storm. Many of them supplied large sums from their individual resources, and pledged their credit to a frightful extent. They risked ruin for the benefit of their fellow-proprietors, which they never would have hazarded for their own. Few know the perilous state of some of these now flourishing concerns, or of the anxious days and sleepless nights of those who had to provide the sinews of war, to uphold a sinking credit, and ward off impending bankruptcy and ruin."

We disagree with him, however, as to railway directors pushing on the works at any cost, *because* they were deeply imbued with the gambling spirit of the day. They pushed on the works as a matter of financial necessity, to which they were in the strongest degree urged by their proprietors. To the bulk of the then holders on the realization of a traffic and a dividend depended the tenure of their property, often whether they were to be rich men or beggars. When the panic came the resources of many became inadequate to meet the heavy calls; they had to borrow or to hold on by any means. To go into the market and sell was ruin, to hold was their only chance, until the opening of some portions of the line made their shares a better security, or until the subscription of two-thirds of the capital enabled the companies to postpone the calls, and to raise money on debentures. Any sacrifice of capital to gain time was preferable to throwing shares on the market, where scarcely any description of property was at par, while the perils of forfeiting everything by non-compliance with the act of parliament made shares without a traffic totally unavailable as a security for raising money. When all these circumstances are taken into consideration, railway managers will not be censured for excesses of estimates, which circumstances alone produced.

The evils produced by the legislature the pamphlet before us well shows, it particularly dwells on the legalized extortions of landowners, and the prohibitions of level crossings of common roads, which, of course, it proposes to remedy.

We have now, therefore, to consider the present state of the railway interest. We have so many hundred miles of railway, costing so many millions, and as a new institution has arisen, new public wants have been created, first and foremost of which is cheap travelling. In a national point of view there can be no question upon this subject; cheap travelling is in the highest degree desirable: how is it to be obtained? Every one has his remedy; and the legislature is called upon by many well-meaning individuals to cut the Gordian knot, and to buy up the whole of the railways: others, among whom our author is one, propose modifications of this principle. For our own parts we are most free to admit, that on the leading lines of traffic the charges for travelling are absurdly high, and the accommodation for the labouring classes totally inadequate; still we are inclined to say that it is better to let the matter alone than to legislate upon it. The mischief hitherto has been in legislating for questions of public enterprise, imposing restrictions and giving privileges, which are the fertile sources of mischief, and we anticipate little good therefore from any legislative remedy, the most efficient in such cases being in our opinion to legislate as little as possible, but to proceed upon the broad economical principle of leaving industry to regulate itself. Not that we doubt the right of the legislature to interfere in this specific case or in any similar case. Apart from the question of rails and locomotives, shares and shareholders, the railway system is an institution having the same public relations as a bank, a college, an hospital, or a public house, and in which any rights of private property exist subordinate to the public objects. On the equity of the case, it must be remembered, that if railways have been allowed a maximum fare, it was on the express condition that any body should be allowed to compete with them on their own lines. This, however, is found to be injurious to the public, and the legislature have, therefore, the equity of requiring some other equivalent security for a reasonable rate of fare. Our ground for letting the railways alone on the subject of fares is, that it is more remunerative for railway companies to charge low fares than it is to charge high fares, and that this principle is making satisfactory progress, and must and will be adopted by all companies.—The following observations from a very able article in the *Railway Record*, will be read with interest. "A very large amount of manufacturing business has been created by the railway system, for the supply of railway stock, and this will be ever on the increase, not merely for England alone, but for her colonies, and for foreign lands. We are prepared to see railways rise in value, in the same proportion that canals have risen. For although it be true, that the price of making railways has been reduced very low of late, it is quite certain that, with increasing traffic, those prices will rise. When railways shall commence in the East and West Indies, in Australia and China, English capital will find so many vents, that the intense existing competition will be lessened, and assuredly the value of land will rise as our population thickens. The greater the numbers of the community the more valuable will the roads become. England will be virtually the metropolis of the continent, by means of free communication throughout all lands.

"Nothing can defeat railway prosperity, but, at the same time, nothing can check it so much as injudicious high fares. We cannot too strongly insist on this point. The increase of expenses in railways is great in proportion to the diminution of traffic, and the increase of traffic is followed by a very slight increase of expenses on the annual amount, while the proportionate decrease is very great. People are gradually getting used to travel, the circle continually widening, and as they get used to it, it becomes a necessary of life. They can no more do without it, than they can forego their provisions. But they must be inoculated to it, and this inoculation will not take place while they are frightened by high fares. We are of opinion that it would be a wise thing for Railway Companies to establish some rule in lowering their fares in proportion to the increase of their passengers. It is the largest number that will pay best, in all cases, and we apprehend that the lowest fares will also pay best, unless where the number of passengers is limited." The author before us certainly does not go far enough for us in his proposed legislation, for he is content to have open third class carriages at ¾d. per mile attached to all trains. Now we think as a matter of public health it is desirable that all trains should be covered as in Belgium, and that sufficient distinction in comfort will always exist between the several classes of carriages. Third class carriages should be provided with seats, covered with tarpaulin, and have curtains; and second class carriages be first class carriages without the cushions. In practice this arrangement has worked well, and will work well. On short omnibus lines, however, open stand-up carriages do no harm. On all lines a step remains to be taken, which may be pursued with advantage, we mean the running of slow, cheap trains, going at the rate of some ten miles an hour. Such trains can be worked much cheaper than high speed trains, and there are large classes of the public to whom time is of less importance than money, females in particular. All these things, however, may be safely left to experience, and experience is beginning to show that a high fare is the wrong system for extracting the greatest revenue from a railway. The cheap fare system is satisfactorily progressing, and will establish itself without legislative aid. A great many experiments are also being made as to excursions, return tickets, weekly, monthly, season and yearly subscriptions, the results of which are promulgated by the railway press to the general information. Here, too, we may observe, that it is not one of the least remarkable features of the railway system, that it has created a press, by the competition and energy of the members of which a degree of information is diffused which has been productive of the greatest benefits, and which under no central administration could exist. By the means of this agency upwards of a hundred reports of directors and engineers are yearly brought under the scrutiny of the great body of railway capitalists, while the comments of the shareholders at the meetings are recorded at a length, and with a degree of accuracy only surpassed by the reports of the Houses of Parliament. This is totally independent of the weekly communication of every kind of intelligence, and the keen investigation of a number of editors experienced on the subject, and solely engaged in such discussions. Indeed it is not one of the smallest marvels of the railway system to see one of these papers with more than thirty of our pages of close type recording the minutest details of railway management, and the most trivial observations of the humblest shareholder or official, for the perusal of many hundred railway directors, secretaries, engineers and functionaries. The loss of such auxiliaries consequent on the centralization of the railways by government, would deprive us of an engine of improvement which no other machinery could supply, even supposing the government to be willing at its own risk to keep up for the benefit of its functionaries a *Railway Journal*, *Railway Record*, for even if it found the money it could not find the materials. Seeing the influence which this press has in the diffusion of intelligence and the propagation of truth, we are quite satisfied that the directors still holding out against low fares will not be for long.

The grand remedy, however, we think lies in improving the arrangements for obtaining Acts of Parliament. This our author has also turned his attention to, but we think he has not struck at the root of the evil. In common with many other individuals he has the customary horror of projectors and share jobbers, and for the sake of remedying any evil connected with share jobbing, he is willing to sacrifice the interests of the community. We say give every facility for obtaining acts of parliament for railways, harbours, docks, bridges, and all useful works, take no trouble about whether the work will pay, or whether the parties have money to carry it on, leave them to look after that themselves, and do not for the fear of encouraging share jobbing prevent people from carrying out useful works. Let such parties also have the power of raising as much money as they can upon the works, and let the parties lending the money look to their own investigations for the security and not to the legislature. We know these are views diametrically opposed to the prevailing practice, but let them be canvassed and they will be found to be right. Depend upon it, the more trade is left to regulate itself, and the more it is carried on by private enterprise, the better. The public is very well able to protect itself, and to form its own judgment as to the advisability of an investment without any legislative aid on the score, which after all is totally erroneous—for have not many of the lines guaranteed by parliament to pay five per cent., been for years without a dividend, and others on the contrary surpassed all parliamentary calculations. As to the bubble companies, we have no fear on that head; West Middlesex swindlers may exist as they have existed, but a whole community is not to be fettered to prevent the perpetration of crime. Give every facility for obtaining railway bills, relax the standing orders, do away with all deposits, and you need entertain no fears about existing lines charging high fares. Here, too, we may observe that nothing could be more absurd than the doctrine lately held in the legislature that no new line should be authorised to compete with an existing railway, for the more railways the better for the public at large. The idea, too, of the vested interest of a railway in the traffic between particular towns is supremely ridiculous, for it is evident that it did not regard the vested interest of the turnpike road it superseded. No one can have a vested interest in abuse, and it is an abuse to subject the public to a high rate for travelling, when they can be carried more cheaply.

The suggestions of the author, that the 5 per cent. government tax on railways might be appropriated as a tax for buying them up, is an exceedingly good one, and we think such a fund might be advantageously applied in the gradual purchase of shares at the market value without involving any great interference with the grand principle of private enterprise, for after all, what we have to look to is not what we shall do with the present railways, but how we shall keep up the national energy, by which such great works have been prosecuted and by which still greater things can be effected in our own country, and in our vast colonial empire.

Ricerche sull' Architettura piu propria dei Tempi Cristiani, e Applicazione della medesima ad una idea di Sostituzione della Chiesa Cattedrale di S. Giovanni in Torino. Del Cavaliere Luigi Canina. Roma, 1843, gr. folio, con 58 Tavola.

'Luigi' seems to be a baptismal name of good omen for architects, it being that of three of the most eminent modern Italian ones, Cagnola, Canonica, (very recently deceased), and Canina. The last has contributed largely to the literature and history of architecture, first by his "Architettura Antica," (1832, &c.,) and now by this second splendid folio work, whose full title we have given above. While the work itself deserves the epithet magnificent, there is something even princely—not at all likely te be imitated in this country—in the mode in which it is given to the world; the term "given" being to be understood literally, since all the copies are for private donations and presents. That there should be none at all for sale, is, however, to be regretted; still the bringing out so costly a work—all the more costly in proportion as the impression is a limited one, contrasts more strikingly than flatteringly with the niggardly trading-like doings in this country on the part of opulent professors and patrons of art. Instead of presenting his medals and coins either to the British Museum or to one of the Universities, to be there deposited as the Devonshire Collection, one of the wealthiest of our English Dukes, sends them to an auctioneer's sale-room,—perhaps because he has found a royal visit to be a very expensive sort of honour.—This, however, is an *apart*, which the reader is not obliged to notice.

In regard to this new work of Canina's, we are sorry to be obliged to confess that we cannot speak of it from perusal or autopsy, but can report of it only according to what is said by a foreign journalist, who has had an opportunity of inspecting a copy deposited in the University Library at Leipzig. Had we ourselves been able to obtain a sight of it, we should most assuredly have made a somewhat different use of the opportunity, for we should have paid especial attention to the Canina's own designs for a new Cathedral, which, it seems, it is in contemplation to erect at Turin, in the immediate vicinity of the Royal Palace, in lieu of the present old one of San Giovanni; which is all the information the journalist affords us on the subject, since he does not even so much as say if these designs are a mere volunteer *projét* on the part of the architect, or were prepared in consequence of an intimation that his ideas would be acceptable. As to what they really are, we are left entirely in the dark, not a single particular of any kind, relative to them, being stated in the journal we speak after; —nothing even to convey so much as some general idea; not even a syllable expressive of either approbation of, or dissatisfaction at, this attempt to revive the Basilica style, or that of the early Ecclesiastical Architecture of Italy, in a modified form, so as to adapt it for churches at the present day, in preference to the style which has been in vogue in that country during the last three or four centuries.

This silence on the part of the reviewer does not augur very favourably for the merit of Canina's designs: at any rate, it would seem that those plates are the least striking of all in the volume; yet it certainly would have been interesting to learn how far the original character, as shown in the historical examples of that class of buildings, which forms the subjects of the other plates, had been retained and kept.

Whether the chapters on the subject of the Basilicas which are brought forward as examples, contain anything new in the way of historical information, or aught instructive in the shape of original comment, is also one of the reviewer's secrets. Still we do not suppose there can be much in regard to fresh information—unless Canina has entered unusually fully into the subject; because it has been treated at considerable length by Bunsen, in his text to Gutensohn and Knapp's "Basiliken des Christlichen Roms;" and by Mr. Gally Knight in the introduction to his splendid pictorial and antiquarian work, entitled "The Ecclesiastical Architecture of Italy." Founded upon this last mentioned publication, is a paper in the current number of the "Westminster Review," headed the "Basilica style of Architecture," which enters into a consideration of that style—its elements, qualities, and capabilities; and recommends the application of it among ourselves. We confess that it does seem to us far better suited for adoption at the present day, than the first Early English or Lancet style, which is now so greatly affected, although its comparative cheapness seems to be its chief, if not its sole recommendation. Most assuredly this last cannot be received as the perfection of the pointed style, more especially when—as is generally the case—the degree of finish it admits of is not kept up, but its details are so slurred over that all qualities disappear save those of meagreness, tameness, and insipidity. Much more, we conceive, might be made of the Basilica style, particularly for interiors; we say "*made of*" it, because it requires some mind to be brought to it, and not merely taken and copied just as it is found.

Canina, we are told, is disposed to classify early Ecclesiastical Architecture, into three leading divisions or families: viz., 1. The *Eastern*, or Byzantine, strictly so called; 2. *Western*, or Romanic Byzantine, otherwise termed—and not without great propriety—Lombardic; 3. The *Northern*, the Pointed or Gothic style: further, however, our deponent sayeth not.

The Architectural Nomenclature of the Middle Ages. By R. Willis, M.A., F.R.S., &c.

In this essay, which forms the ninth number of the publications of the "Cambridge Antiquarian Society," Professor Willis has treated, in a manner entirely new, a subject of great interest to the architect. In connexion with the study of the architecture of the middle ages, it is impossible to appreciate too highly the numerous existing documents relative to the original construction of the buildings of that period, and considering how long such documents, and the works of our old writers, have been in request as a means of illustrating the antiquities of English architecture, it is extraordinary how little has hitherto been done in good earnest toward the indispensable measure of collecting and explaining the technical terms with which they abound, and which are indeed their very pith as regards this purpose. The fact is, the course of study requisite to conquer the difficulties of reading and construing the jargon of ancient MS. rolls, is seldom to be found in union with the practical knowledge necessary to digest and apply them, and when documents of this nature have, from time to time, found their way to the public, it has too often been in forms so crude and imperfect, as to have rendered "*black-letter man*" almost a term of reproach. The labours of Professor Willis in the essay before us, differ from those of either the collector, the glossarist, or the etymologist. "My object, in the following pages," says the author in his preface, "has been to draw up an account of the mediæval nomenclature of architecture, as far as it can be deduced from the remaining documents, and from the comparison of them with existing buildings. The words are principally to be found in indentures and accounts relating to the expenses of buildings and monuments, which are necessarily expressed in the language of workmen. Other terms, but not so strictly technical, may be picked out of the monastic chronicles and biographies. Several well-known collections of these terms have been already made, of which the first strictly architectural one was that of Mr. Willson, appended to Pugin's "Examples of Gothic Architecture," in 1823, and which is a most admirable performance, to which I am under great obligations. But many documents have come to light since the appearance of this Glossary, and the subject has been more closely investigated. Also, the alphabetical form of these collections is not the best adapted for the illustration and comparison of terms like these, which are commonly of a strange and capricious kind, defying the usual processes of etymology, and some of whose meanings can only be deduced by collating every passage that contains the term, and comparing it with the entire nomenclature of the architectural member in question." And he adds in conclusion, "that he proposes not to construct a complete nomenclature, but to elucidate those words that either remained in obscurity, whose meanings were doubtful, or which had been misapplied."

The first chapter, and not the least interesting, is on the nomenclature of mouldings, and is principally directed to an examination of the terms to be found in the "Itinerarium of William of Worcester," the most complete specimen of the nomenclature of the mediæval mouldings which has been preserved to us. This work, the MS. of which is preserved in the Library of Corpus Christi College, at Cambridge, contains, among other interesting matter, a detailed description, illustrated by diagrams, of the doorways of the Churches of St. Mary Redcliff, and St. Stephen, at Bristol; but although this work has been in print ever since 1778, and has been abundantly used as an authority by glossarists, no one has hitherto thought of comparing these descriptions with the existing buildings. Much new light has resulted from the employment of this process by Professor Willis, the accuracy of whose deductions from this source are confirmed in a very remarkable manner. Among other particulars relating to Redcliff Church, noted by William of Worcester, we are told that the tower pier contains 103 members, a statement which appears to be in perfect conformity with the fact.

From the explanation of the mediæval names of mouldings, Professor Willis passes to those in use at the present day. It might be supposed that at the "renaissance" of the classical style of architecture, either that the old words would have been appropriated, or that they would have been exchanged for classical terms, but this is by no means the case. The history of the present nomenclature is so curious that Professor Willis traces it at some length, and shows it to be a medley derived from the different languages through which we obtained our first knowledge of Vitruvius and the modern Italian masters, during the 16th and 17th centuries. *Apropos* to Vitruvius, we have the following excellent comment:—

"Vitruvius has not written expressly upon mouldings; he merely names them when they occur in the course of his description of other architectural members. But a name may in this way be given to a moulding, either in the general sense, from the form of its section, as when he terms the hollow or casement a *scotia*, from the shadow which it holds; or the name may be assigned to the moulding only from the peculiar function which it performs, or from some form which it derives from that function: as for example, the same scotia, when it occurs in the base of a column, is also termed in conjunction with its fillets *Trochilus*, the pully; for it exactly resembles a pully in this use of it, but not when it is straight. Now when we attempt to pick out a nomenclature from this author, we are often in a doubt whether a given term be a *sectional* name or a *functional* name; and this distinction has not been sufficiently attended to. It will presently appear that the same functional name may be given to two different mouldings, if they are each capable of performing the office to which the name alludes."

The following chapters treat on masonry, walls, and *tablements*—pillars, arches, and vaults—windows—pinnacles, and tabernacle work. We cannot pretend to follow Professor Willis through the mass of curious information developed in the investigation of the nomenclature of these elements of our Gothic buildings, amounting to upwards of three hundred and forty technical terms, not including the Vitruvian words or mouldings of the *renaissance*. And here we may notice two words which have an appearance so classical that their etymology may not be generally suspected. Entablature, which is derived from the mediæval word tablement, the term for horizontal mouldings in general, and pediment, upon which Professor Willis observes—

"As I am upon the subject of these additions to the classical terms, I may as well mention another word, which although English, and confined for a long while to the workmen, has now assumed the place and resemblance of a good classical term—I mean *Pediment*, which we now universally apply to the triangular gable of classical architecture, the 'Fastigium' of Vitruvius and of the Italians, who also, together with the French and English writers, employ Frontispicio—Frontispice—Fronton—Frontispiece, respectively. Evelyn says, 'those roofs which exalted themselves above the cornices had usually in face a triangular plain or gabel within the mouldings (that when our workmen make not so acute and pointed they call a *Pediment*) which the ancients named Tympanum.' Evelyn's 'Account of Architects and Architecture,' 50. The earliest example of the word that I have been able to discover, is in the English translation of the Hypnerotomachi, 'the Strife of Love in a Dreame,' 1592. The original passage, describing the façade of a temple, 'Al frontispicio overo fastigio,' &c. is translated (and with the marginal note) as follows:

"'And to return to the view of the whole frame, in the disposing thereof as aforesaide, the Coronices by a perpendycular lyne were corrospondent and agreeing with the faling out of the whol worke, the Stilliced or Perimeter, or vtter part of the vppermost Coronice, onely except,' (p. 22,) ('il' stillicidio della suprema cornice.') The 'stillicidio' is generally 'gocciolatoio' in Italian. The insertion of the word *Perimeter* seems to show that this writer derived *Periment* from it, as a space surrounded or bounded by a perimeter of mouldings. *Pedamento* in Italian is used by Scamozzi for the Stereobate.'"

The marginal note referred to is, "A periment in corrupt English."

In pursuing our notice of this valuable contribution to the literature of architecture, we must confine ourselves to a few examples illustrative of Professor Willis's mode of investigation, in which it has either produced new results or corrected existing errors. The term *orb*, which has puzzled Mr. Willson, and another equally obscure, which he has confounded with it, viz., *cross quarters*, are both explained thus—

"It is well known that in the later periods of Gothic architecture the use of stone panelled tracery increased gradually to so great an extent, that in the more elaborate buildings the walls and vaults, and every space unoccupied by actual windows, were covered by them. I shall proceed to show that these panels were termed 'orbs.' This I shall do by comparing three independent passages, in which the word occurs, with the existing buildings to which they refer.

"The Indenture for the tomb of King Richard II. and his Queen, in Westminster Abbey, covenants that there shall be niches for statues on each side having *orbs* between them to match. 'Et les ditz masons ferront measons (maisons) pur xii images, c'est assavoir vi a lune coste et vi a lautre coste du dite toumbe, et le remenaunt du dite toumbe sera fait ove (avec) *orbes* accordauntz et semblables as dites measons."

"Accordingly the tomb has tabernables *(maisons)* at the sides between which are placed blank panels *(orbs)* corresponding to them, as may be seen from the drawing of the tomb of Edward the Third, which is exactly similar, in Blore's 'Monumental Remains.'

"William of Worcestre describes the tower of St. Stephen's at Bristol in the following words;

'Habet 4 storyes et ibi in quarta stori sunt campanæ.
In superiori historia tres orbæ in qualibet panella.
In secunda et tercia historia sunt duæ orbæ in qualibet panella 4 panellarum.
In inferiori *historia* sunt in duobus panellis in qualibet panella south and west fenestræ, in aliis duobus panellis ex parte boriali et *orientali* sunt duæ archæ.'"

"If orba be translated 'a blank window,' the above becomes a correct description of the existing tower. For its decoration consists not so much in stone panelling as in literal blank windows, which are formed in each story. The lower windows are open as usual, but in the upper story, where the bells are, the blank tracery is not pierced, but a window-opening is formed between part of the mullions only of the central blank windows of each side. The description, if translated thus, will agree perfectly with the tower as it stands:—

The tower has four stories, and the bells are in the fourth or upper story.
In the upper story there are three *blank windows* on each side.
In the second and third stories are two *blank windows* on each side of the four.
In the lower story there are *windows* on the south and west sides, but on the north and east there are *arches*, (for on these sides the tower joins the church.)

"There exists an indenture for the furnishing of one tower at some one of the corners of King's College Chapel (probably as an experiment); for in the same document it is covenanted that all the fynyalls (pinnacles) of the same Chapel shall be made according to one that had been set up. It is agreed that the said tower is to have 'fynyalls, rysant gabbletts, batlements, *orbys*, and crosse quarters, and every otherthynge belongyng to the same—accordyng to a plat thereof made.' This description corresponds very well with the existing tower."

"I shall return to this in the next section, and shall now merely point out the *orb*, or blank panel, with its cinquefoil head, observing that this is not opened with tracery for glass as usual, but that the tracery, or string of *cross quarters*, is so introduced, as to be a mere piercing of part of the stone panel, without destroying its character as a blank panel.

"As in all these examples the word so plainly applies itself to a blank or blind window, I imagine it must be derived from the Norman French *orbe*, 'qui est caché, secret, priveé de quelque chose, aveugle. *Orbus*. Lat.'

"The fact that stone panelling was first called by a name that implies a blank window, would explain the history of its introduction into mediæval architecture, even if the existing examples did not show it."

The familiar terms *mullion* and *tracery* seem to be traced no higher than to Sir Christopher Wren. The original form of the former word (sometimes written munnion) seems to be *monial*, derived from the French "*moyen*, qui est au milieu," the old form of which is *meian* or *menel*. They are called "menaux or croisillons des fenêtres," in that language. "These words (mullion and tracery) were adopted by Bentham and Milner, both evidently deriving them from Wren, from whom they quote largely with admiration. Dr. Plot, his cotemporary, also uses the word; and from these authorities the words derive their present universal employment. Other early antiquarians make use of awkward circumlocutions for tracery. Thus Warton, one of the first admirers of Gothic architecture, can yet find no better terms for this beautiful and characteristic principle of decoration than 'Ramified windows divided into several lights, and branched out at the top into a multiplicity of whimsical shapes and compartments.' But soon after he introduces a description of 'fret-work thrown like a web of embroidery over the old Saxon vaulting of Gloucester.' Instead of tracery every mediæval account relating to windows contains an abundance of stones called *form pieces*, and allusions to *forms*, which, as I shall proceed to show, was their proper word for the tracery.

"In France the stone frames of Gothic windows are to this day termed *formes de vitres*, forms or seats for glass; for, as is well known, the word form (pronounced with the long *o*) bears, amongst others, the sense of a seat or receptacle, as a long bench or the seat of a hare. Bailey defines *form* (in mechanics) to be a kind of mould whereon a thing is fastened or wrought; and we have examples of this in the printer's forme of types. In French and in the mediæval Latin the stalls of a choir are so termed, and the French use it for a stone dry dock."

Professor Willis approves of Sir James Hall's term of *cusps* for the points in tracery, which Rickman has misapplied to the curve, and not to the point, the mathematical cusp being the point formed by two parts of curves meeting. On the authority of William of Worcester, *genlese* appears to be the mediæval term for these points. The application of this term was first made by Mr. Willson, but he writes the word *gentese*, being misled by the printed edition of the "Itinirarium." Finial is proved to apply to the entire pyramidal portion of a pinnacle, and not to the extreme termination. The proper mediæval name for the latter seems to be the *croppe*, which means also the top of a tree, and *corse* or body, is the square shaft.

We must not, however, extend the limits of this review. The paper concludes with some very curious particulars respecting the *herses* or canopies placed over the coffins at royal obsequies. A complete account of four herses erected at the funeral of Anne, Queen of Richard II, is extant, from which they appear to have been elaborate architectural compositions modelled in wax. Every part of the work is minutely described, and the terms evidently apply to a profusion of tabernacle work, to which the immense quantity of four tons and a half of wax was applied, independently of that consumed in tapers and links, amounting to above two tons more. The herse set up on that occasion at Westminster is described as containing "280" buttresses of different sizes, 72 "botants," or arch buttresses, and 96 bodies, besides housyngs, &c., and 428 tapers.

We must conclude by thanking the author for this valuable addition to the many obligations under which he has already laid the friends and professors of architecture, by his researches and publications.

ROYAL EXCHANGE CLOCK.

Sir—A copy of a letter in reference to the clock and chimes making for the New Royal Exchange, dated Brighton, 21st July, and signed E. J. Dent, of 82, Strand, and 33, Cockspur-street, addressed to Mr. Whitehurst, of Derby, having been very generally circulated among the members of the corporation of London, in which it is stated that I was a competitor to be employed to make the clock and chimes for that building, I beg to say that statement is wholly incorrect, the direct contrary being the case. In a letter I had occasion to write to R. Lambert Jones, Esq., the chairman of the building committee, so long since as the 8th of February, 1843, I stated my determination not to be a candidate, and repeated the same to Mr. Tite, the architect to the building, in a letter dated the 27th ofu Jly, in answer to an application from that gentleman to furnish a tender and estimate; and in a letter dated two days subsequent, he expressed his regret at my determination. Your insertion of this communication will much oblige,

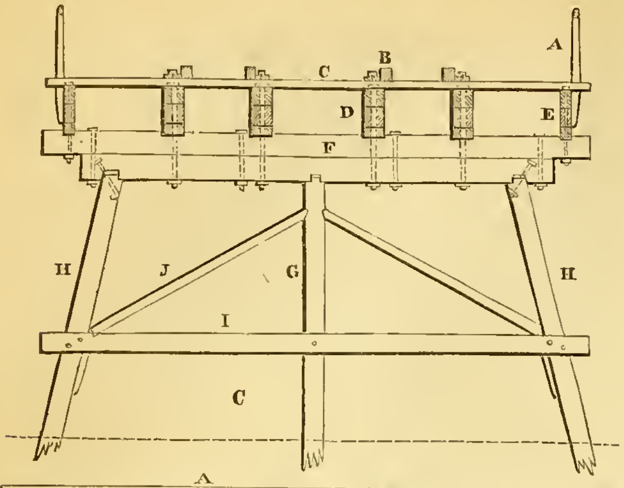
Sir, your most obedient servant,

B. L. Vulliamy.

Pall Mall, April 16, 1844.

TIMBER VIADUCTS ON THE SOUTH EASTERN RAILWAY.

Fig. 1.—Transverse Section.



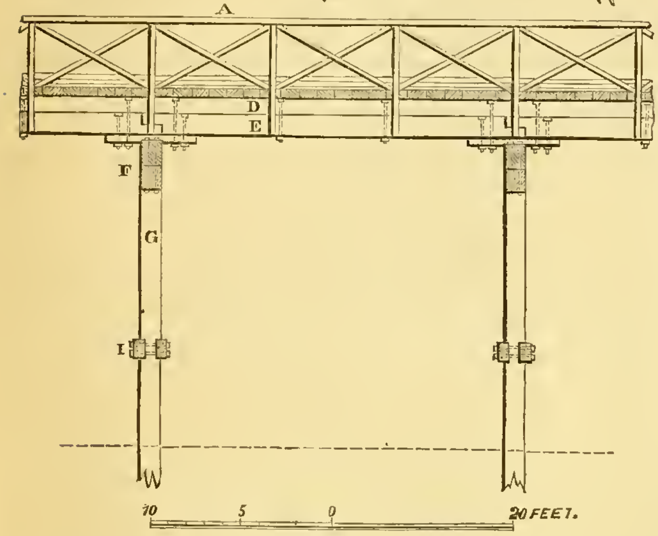


Fig. 2.—Elevation.

The annexed engravings show a transverse section and elevation of the timber viaducts adopted at the South Eastern Railway on the branch from New Cross to the Bricklayers' Arms, and also at the Shakespere Viaduct, between Folkestone and Dover, under the direction of Mr. William Cubitt the engineer in chief.

The parapet or railway A stands 4 ft. above the platform, the top rail is 4 in. by 3 in. rounded on the top, the upright posts 4 in. by 4 in. with intervening cross-rails; the guards or timbers B, lying alongside the iron rails, are 6 in. square. The platform *c* on the top is 30 ft. wide out to out, and consists of timber laid close together 4 in. thick. The 4 longitudinal bearers in the centre D consist of 2 pieces of whole timber 13 in. square, and 1 piece of half timber 5 ft. long, 13 by $6\frac{1}{2}$ in.. lying on the top of the transverse beams; the two outer bearers E are half the scantling horizontally and the same vertically. The transverse bearer F consists of 2 pieces of timber 30 ft. and 26 ft. long, and 13 in. square. The posts or piles G, H, are 13 in. square, the two outer piles H are placed 23 ft. apart from out to out on the top, and are driven in with a batter of 3 in. in a foot. The piles are prevented from spreading by two horizontal ties I, 30 ft. long 12 by 6 in., and are bolted on each side of the piles; there are also 2 diagonal struts J, above 9 in. square abutting at the feet on cleets nailed on the inner side of the outer piles.

It will be perceived that the whole of the timbers are well secured with iron bolts.

The distance in the middle on the top of the platform, between the centre of the rails is 6 ft. $2\frac{1}{2}$ in., and between the centre of the railings 4 ft. 11 in.

The horizontal dotted line at the bottom is Trinity Datum.

DECORATIONS OF THE PALACE AT WESTMINSTER.

WOOD CARVING, STAINED GLASS, &c.

The present exhibition, under the authority of the Royal Commissioners of the Fine Arts, is held in the St. James's Bazaar, King Street, St. James's, a very convenient room. Notices, it will be recollected, were issued last year calling for specimens of designs in relation to the decoration of the new Houses of Parliament, under the several heads of wood carving, stained glass, arabesque, and heraldic decoration, ornamental paving, metal casting, &c. The call seems to have been well responded to, so far as number is concerned, and proves the existence, in this country, of an adequate number of artists engaged in such pursuits; but although the works sent in are respectable, they do not impress us by their originality of conception, or by their superior merits in execution. Much evidently remains to be done, though a great good has been effected by calling public attention to departments of art little known, much neglected, and not adequately appreciated. If we look to the designs, we find a want of historic appreciation, an inattention to political and historic propriety, and the most common-place sources of illustrative detail. One artist brings Lycurgus into the English Houses of Parliament, another Moses, a third King David of Scotland, and the Princes of Tara, while more than one artist has made the Queen's husband, Prince Albert, a prominent personage, introducing his statue or his arms.

We may observe of the wood carving that it shows great respectability of attainments in the exhibitors, and the extent to which the art is now cultivated, owing to the increased encouragement of ecclesiastical decoration. Exhibitors have sent in from many parts of the country, and particularly from the cathedral towns, the wood-carvers being about 25 in number (the designs and specimens 57), the glass painters 20, and the decorative painters pretty numerous. Most of the leading artists in each branch are contributors. To resume the subject of wood carving, the subject of which is a door for the House of Lords, the general defect we observe, beyond the want of originality in the designs, is the appearance most designs convey of being copied from tombs, altar screens, and west windows, having an air too ecclesiastical, neither have the appliances of Gothic art been well directed. The resources of varied tracery, have, except in rare instances, been neglected, while many works exhibit a poverty of ornament; few artists seem to be aware what a door ought to be, and some have covered their doors with panels in high and low relief, representing various events; none seem to have studied the numerous and interesting specimens which are to be found in Holland, Belgium, and Germany. Those of Italy do not, we think, afford such good studies.

We shall not speak of the carved specimens generally, as they are for the most part respectable, and no more.

No. 1 is a poor affair of peer's coronets, and mitres, a wretched idea, which several artists have adopted as their sole emblems and illustrations:

No. 3, by William Ollett, of Norwich, has four compartments with decorated headings, surrounded by a bordure of the shields of English sovereigns. Mr. Ollett, as well as some others, has, without discrimination, introduced the arms of the Saxon kings, which are an invention of the mediæval monks, and armorial bearings also were of much later introduction. If they must represent the early princes, as indeed they ought to be represented, let the white horse of the Saxons and the raven of the Danes be employed.

No. 5, by John Steel, is in a modern style, quite out of character.

William Freeman, jun., has the Barons demanding the Charter of Liberties from King John, a constitutional subject, but one of a violent character, and calculated to meet with little favour from the Royal Commissioners, who have it is said refused to place among the statues of chief magistrates. that of Oliver Cromwell, the acquirer of Jamaica.

No. 9. by Samuel Pratt, jun., is a very original design, and one of the most gratifying. He has shown that something may be done with tracery. The coronets are, however, a poor idea.

S. A. Nash's, No. 11, is a very good subject. On the panels of the doors are on one Henry III. (from his tomb in Westminster Abbey) under whom the first traces of a Parliament in the present form exhibited themselves, on the other panel her present Majesty, appropriately uniting the present and the past. In a panel over the door is represented the sitting of 3rd May, 1253, in Westminster Hall, when the peers obtained from Henry III. a solemn confirmation of the Great Charter of Liberties.—No. 13, by John Thomas is a good work, the details rich.—John Wolstenhome, of York has contributed No. 15, which is modelled from York and Beverley Minsters, and is too much like an altar screen or tomb.—No. 17, by F. W. Brown, is in a florid style, bad and inappropriate. His carving is however good.—Wm. Thomas, in No. 19, has some strange work, twelve panels in which figure the Death of Ananias, the Inquisition, and similar un-English imaginations. This artist has been led astray by works of the time of the revival. His bas relief of Trial by Ordeal, we must say is well executed.—Henry Ringham, of Ipswich, has a thing like the mullions of a parish church window, and paltry.—The carve to the Cambridge Camden Society, Joseph Rattee has an affair with modern details, and Prince Albert's arms. His carving is better.

William Allan, of Edinburgh, has a design very ill chosen, comprising

Cranmer and his Bible, David I. King of Scotland administering justice, and St. Patrick before the Kings and Princes of Tara. His wish to illustrate the union of the several countries is a laudable one, but he should have selected events in which each has a common interest, not the transactions of local chiefs of no constitutional import. Mr. Allan's commemoration of Robert Fitzwalter is a very proper idea, and we are surprised that no one on this occasion has thought of Simon de Montfort, Earl of Leicester, to whom, and not to Henry III., we owe the institution of the representative system — The design of No. 29 is bad.—Some of the carving in Messrs. Colling and Vincent's, No. 80, is good, but it is ineffective as a whole. No. 33, by the same artists is a superior work, with good applications of tracery.—No. 34, by R. B. Boyle, of Dublin, is in a mixed modern style.

No. 36, by Samuel Nixon, is too much in the painted window style of Sir Joshua Reynolds. The subjects of his No. 37, show a proper appreciation of history, but we do not approve the effect of a dozen panels of sculpture. The life of Alfred the Great, to whom many of our institutions are attributed, is a proper subject, as the first flotilla defeating a Danish squadron, trial by jury, the assembly of the Witan. His carved work we like.

No. 39, by William Steel, is poor. He is more successful with his chisel than his pencil.—Thomas Drew has sent in the most wretched work in the room, No. 43.—The effect of the niches and statues in No. 44, by Henry Ringham, is not in our opinion favourable.—Mr. Samuel Pratt certainly makes the most favourable figure among the contributors. We have approved of his No. 9, and we must express approbation of his No. 45, though we could wish for something still better.

The carving, No. 46, by W. S. Williams, is bad. Stephen Prebble is the ingenious individual who introduces Lycurgus as a representative of English legislators, whether as a satire we know not. It is a pity he had not room for Draco. No. 49, by Benjamin Baker, is out of style. The effect of No. 51, by John Lees, is poor; so is that of No. 52, by W. S. Williams.

John Black has chancemedleyed the Hanoverian Sovereigns, Church and State, St. George and the Dragon, Fame, Britannia and Peace. This would have done for St. Paul's 30 years ago, but we hope such absurdities are now exploded.—James T. White has an idea still more exquisite, No. 54. His ornaments are portraits of members of the late and present ministry—we should suggest in addition those of the future ministry.—Peter Cummins has an ill-conceived collection of Swords of state, Stars and Garters, Coronets, Britannia, and Magna Charta.—No. 57, is also in the allegorical style, having Wisdom, Prince Albert, Virtue, Power, Magna Charta, and Moderation. Why is *Punch* left out?

The stained glass affords the next series of designs and specimens. We are sorry that we cannot speak most favourably of the specimens of painted glass exhibited, too many of them are smudgy. We should recommend Hay on colour to these gentlemen, as a useful study.—No. 58, by John Summers, is very bad.—No. 59, by Ward and Nixon, is in a purple key, and is well carried out.—C. E. Gwilt owns No. 60, which is in a crimson key. It is a good piece of colouring. No. 61, by Spence and Co., of Liverpool, is too confused, though the idea is good. No. 62, by Charles Clutterbuck, is a good work of its class. Daniel Higgins owns No. 63. The figures are bad, and the shields relating to Henry VIII. show want of research and poverty of idea.—No. 64, is seemingly unfinished.—Ballantine and Allan, of Edinburgh, have sent in No. 66, which shows much instruction and a laudable desire to produce a good work, but the colouring is patchy and the tone wants ensemble —No. 67, is a superior work, by Cobbett and Son, well carried out.—No. 68, is also a work of high class. It is by W. Warrington, and the general tone is well attended to.—The design by James Warrington, No. 69, is fair.—The design by Henry Pether, No. 70, shows a want of conception.—No. 71, by Edward Corbould and George Hoadley, has a good effect, but it opens the question whether pictures should be attempted on glass. The subject, though one of historical interest, conveys a national reflection, and should be avoided. It represents Edward I. entering Westminster after having vanquished the Welsh in 1282.—No. 72, by Edward Baillie, is good, though we doubt the effect of the medallions.—We are afraid No. 73, by Cobbett and Son, is too picturelike, while we certainly deprecate the compartment with Prince Albert in the robes of the Order of the Garter, introduced upon an equality with the sovereign. The battle of Bosworth and the triumph of the usurper Henry VII., is not quite complimentary to the legislative body.—No. 74, by J. A. Gibbs, is glittering, but no more.—The design, No. 75, by Messrs. Chance, Brothers, and Co., wants tone; and the introduction of bishops, warriors, judges, statesmen, Piety, Valour, Justice, &c., is in bad taste, as is the introduction of Prince Albert's arms, unless he is brought in as a member of the Commission of the Fine Arts.—No. 76, by Thomas Wilmshurst, has good drapery, but there is a want of ensemble in the composition.—No. 77, by John G. Crace, is not in colours, and is devoted to a religious subject offensive to the majority of the inhabitants of the English empire. A piece of stained glass we must notice is the introduction of Duke Ernest the Pious of Brunswick, ancestor of the Queen and Prince Albert, but having nothing to do, we presume, with the Houses of Lords and Commons.

Having gone through the stained glass, we come to numerous and varied specimens of decoration, the whole of which we cannot enumerate.

No. 78, is a very fine design, by Richard Popplewell Pullan, which we regret we cannot notice in detail. It shows much study, much labour, and a firm hand.—The frieze, by the same artist, No. 79, is very gorgeous.—No 81, by R. A. Harrison, in the style of the ninth century, is in a good tone.—Richard Prosser, C.E., of Birmingham, has realized the idea suggested by us just now; and in a design for ornamental pavement, No. 82, has represented the arms of the Commissioners of Fine Arts. We now beg to suggest those of Messrs. Grissell and Peto, the contractors, and Mr. Bellamy, housekeeper to the Commons. Another design for a pavement, No. 83, by J. Bowron, is poor and complicated.

In No. 85, designs for inlaid flooring, by Austin and Rammell; the material is good, but the design poor. The series of drawings, marked No. 89, by Owen Jones, are most laborious. One of them, a tremendous cartoon, exhibits a plan for all the pavements of the Palace. We do not, however, like the designs so well as many we have seen by Mr. Jones.

The materials proposed for the several pavements we regret we have not time now to notice.

Specimens of metal casting, by Messrs. Bramah and Co., are very fine.—Henry Pether has a design for a pavement, No. 92, very poor.—A similar design, by Thomas Jago, No. 93, is not well conceived.—The design for a cast iron gate, by Messrs. Paterson and Son, No. 94, is poor and out of style.—The specimens of iron and brass castings, by Messenger and Sons, exhibit a high degree of skill. We do not, however, think any castings here come up to the Berlin work.—Messrs. Elkington have shown some favonrable examples of electro-bronzing, gilding, &c.

The castings exhibited are too numerous for us to specify, but we may repeat we do not think they are so good as they might be.

The inlaid, tesselated and encaustic tiles of various kinds seem good as materials.

A number of specimens of fresco, encaustic, tempera, and various decorative paintings come next, by Crace, Simpson, Moxon, Sang, Collman, Bohn, &c. These are mostly in modern styles, and can only be regarded as specimens of manipulation and material if and not as designs appropriate to the Houses of Parliament. On the staircase are some good cartoons.

Next month we shall enter more fully into an examination of some of the articles, at which we have only just had time to take a rapid glance.

Several railways are to be opened in May. On the 1st, the Bricklayer's Arms branch to the Croydon and Dover Railway will be opened, also the extension of the Bristol and Exeter Railway, which will be completed the whole distance, forming a direct communication of 200 miles from London to Exeter; the Norwich and Yarmouth Railway, and the Liverpool and Derby junction line.

The disaster which lately occurred at the Bricklayer's Arms station of the Croydon and Dover railway, by the falling of the roof, was occasioned by too great exertions being made by the contractors in proceeding with the works, and laying the boarding and slating, before the framing was completely fixed. Although the iron work appears to be very light, the roof has been proved in the presence of General Pasley and others, to bear a breaking weight of 62lb. per foot super. double the pressure a roof is ever likely to be submitted to. Notwithstanding the extent of damage, the whole of the works of the station have been completed, and will be ready for the opening on the first of May; we hope in the next *Journal* to be able to give a drawing of the roof.

Newcastle-on-Tyne.—The church of the Hospital of St. Mary, Newcastle-on-Tyne, lately used as a grammar school, has been pulled down by order of the corporation. It was founded in the reign of Henry II., by Aselack of Killinghowe, or Killingworth. Brand, the historian, 1788, says, "The grand eastern window, now entirely built up, contained in its painted or stained glass an image of the Virgin Mary with her child on her knees, and that the present floor covered a pavement of Dutch tiles of different colours laid lozenge-wise. Mr. John Dobson, architect, prepared a fine plan for its complete restoration; the whole of the antiquity lovers are sore at the unaccountable and unwarrantable proceedings of the Council in pulling it down as it is not contemplated to erect any building upon the site.

Mr. Bain has had an opportunity of practically testing the capabilities of his electric printing telegraph, described by us in the *Journal* Vol. VI. pp 284 and 300. It has been fixed at the terminus of the South Western Railway at Nine Elms, and the station at Wimbledon, a distance of six miles, at each of these places is a similar apparatus, as shown at p. 300, and a communication formed between them by a single wire through which the electric fluid is conveyed. By the aid of the apparatus a printed correspondence may be kept up between the two stations.

The whole of the works of Trafalgar Square, excepting the steps round the Nelson column, are completed, and will be opened in course of a few days.

SEVERN STEAM BOILERS.

Sir,—I have had my attention only just called to your review in a recent number, of Mr. Macqueen's pamphlet on the subject of the Royal Mail Steam Packet Company, and from it I perceive that you have inadvertently been led to adopt that gentleman's unsupported and oft refuted statements, and in consequence to pursue a course of argument, in reference to the directors which, when acquainted with the facts, your sense of justice to all parties will induce you to withdraw. I allude particularly to the imputation of their having allowed boilers to be put into their ship *Severn*, the malconstruction of which caused that vessel to take fire. I have frequently denied and disproved not only her having caught fire from any fault of the boiler furnaces, *but her having caught fire at all*, that I am surprised at Mr. Macqueen's blind and pertinacious repetition of a purely malicious an invention. I have, however, no wish to make your columns the field of contention upon a subject, that in the opinion of all unbiassed readers of our correspondence, has long been set at rest, and therefore content myself with referring you to my letter upon this subject to Mr. Macqueen, in *Herapath's Railway Journal* of the 16th instant.

Relying on your impartiality, I am, Sir,

Your obedient Servant,
John Croome.

Bristol Iron Works,
March 29, 1844.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTE OF CIVIL ENGINEERS.

April 2.—The President in the chair.

The discussion on the subject of slips in cuttings and embankments of railways was renewed, and extended to such a length as to prevent any papers from being read. Some observations were made by Sir H. T. De la Beche, the Rev. Mr. Clutterbuck, and several members, on the geological features of the slips, whether occurring naturally in cliffs, as at the back of the Isle of Wight, or in the artificial cuttings of railways. It was contended, that, in both cases, the reduction of the lower and softer beds to the state of mud, by percolated water, rendered them incapable of bearing the weight of the superincumbent strata, and that the mass, when saturated, slid down by its own gravity; but that slips in railway work, were accelerated by the vibration caused by the passage of the trains. The vibration of the air from the discharge of a gun, had been known to cause an avalanche; and the cases were almost analogous. More attention both to surface and bottom drainage of the slopes was much insisted upon; and it was urged, that the back drains, so close to the top of the cuttings, were prejudicial; that in the dry season the bottoms cracked, the rain found its way through, and it had been frequently noticed that the slips commenced at a few feet below the level of these drains. The dry shafts which had been sunk in the slopes of the Eastern Counties Railway, by Mr. Braithwaite, with the concurrence of Sir H. T. De la Beche, were instanced as successful in rendering wet and treacherous strata comparatively dry and secure. A section was exhibited of the embankment at Hanwell, on the Great Western Railway; this embankment, which was of gravel, was 54 feet high; it was laid in a marshy valley traversed by the river Brent; the London clay, upon which it was laid, inclined towards the river, and at one of the numerous fissures with which that stratum abounds, a subsidence occurred squeezing up at the same time on the lower side to as great an extent as the embankment sunk, which was stated to be nearly as much in one year as the entire mass of the embankment. This subsidence was stopped by loading the foot of the slope, and thus restoring equilibrium, and it was stated to be at present quite secure. It was urged that, in the earthwork of canals, where there was no vibration, the slips generally occurred in the first few months after the formation of the embankments; but that, on railways, they occurred quite as frequently after the lapse of several years. It appeared, therefore, that much was due to vibration.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

April 15.—W. Tite, V.P., in the Chair.

A paper was read by [illegible]ley, the Honorary Secretary, giving "*An analysis of a Work o[illegible] Pr[illegible]*' [illegible]esented to the Institute by M. G. Abel Blouet, of Paris. The con[illegible]deration of the subject of Penitentiaries having of late occupied the public mind in France, the Government, in 1836, commissioned M. de Beaumont and M. de Tocqueville to proceed to America, for the purpose of inquiring into the general working of the Penitentiary system in that country, who on their return made a report which met with a favourable reception by the public. Subsequently, the Minister of the Interior commissioned M. Demetz to visit America, to make himself acquainted with the moral results, obtained in the United States, from the system, since the visit of M. de Beaumont and M. de Tocqueville, and M. Blouet accompanied him, charged to study the architectural part of the question, that is to say, the advantages or inconvenicnces of the arrangement of the Principal American Penitentiaries; their condition with respect to discipline, and more especially with reference to the expense incurred in their construction; with a view to the ultimate adoption of a modified general system throughout France for such structures. M. Blouet subsequently visited England, Switzerland, Rome, and most of the departmental prisons in France. It is well known that in America there are two different systems in operation, known respectively as that of Auburn and that of Philadelphia. M. Blouet gave at considerable length his reasons for preferring the last-mentioned system, and combatted the objections that have been made to it. The design particularly described, and illustrated with drawings, was the result of M. Blouet's studies for a prison with solitary confinement, by means of spacious cells, for 585 prisoners, (in his opinion the maximum number of the population of a prison,) with the requisite offices and appurtenances, houses for the governor, inspector, chaplains, and other inferior officers, together with yards for exercise, &c., wherein the prisoners are constantly under the supervision of the governor and turnkeys, and so arranged as to afford the means of walking one hour in the day to each prisoner. From a central inspection station, the governor has a view of all the doors of the cells, the galleries, the turnkeys' rooms, yards, and indeed all the points where he may wish to exercise a supervision.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM MARCH 30, TO APRIL 24, 1844.

Six Months allowed for Enrolment, unless otherwise expressed.

John Robert Dicksee, of Old Compton Street, Soho Square, artist, for "Improvements in the manufacture of mosaics."—March 30.

William Crosskill, of the Iron Works, Beverley, for "Improvements in machinery for making wheels for carriages."—March 30.

Henry Clayton, of Upper Park Place, Dorset Square, Regent's Park, plumber and machinist, for "Improvements in the manufacture of tiles, drain pipes, or tubes and bricks."—March 30.

John Biggs, of the borough of Leicester, manufacturer, and Richard Harris, the younger, of Leicester, aforesaid, manufacturer, for "Improvements in the manufacture of looped, woven, and elastic fabrics."—March 30.

Leonard Bostwick, of Fen Court, Fenchurch Street, London, merchant, for "Certain improvements in machinery or apparatus for sewing all kinds of cloth or other materials."—April 2.

William Stace, of Berwick, Sussex, farmer, and Philip Vallance, of the same place, farmer, for "Improvements in applying power for drawing or working ploughs and other implements and carriages used for agricultural purposes."—April 2.

John Parsons, of Selwood Terrace, Brompton, gentleman, for "Certain improvements in machinery or apparatus for cleansing or sweeping chimneys and flues."—April 2.

James Murdoch, of Staple's Inn, London, mechanical draughtsman, for "Certain improved apparatus and processes for preparing the Phormium tenax, or New Zealand flax, so as to render it applicable to various useful purposes." (Being a communication.)—April 2.

Frederick Brown, of Luton, Bedford, ironmonger, for "Improvements in stoves."—April 10.

James Murray, of Garnkirk Coal Company, Scotland, for "A new method of using and applying artificial gas made from coal, oil, or other substances, for lighting and ventilating caverns, pits, or mines, or other pits where minerals or metals are worked or extracted."—April 10; four months.

Richard Barber, of Hotel Street, Leicester, confectioner, for "Improvements in apparatus for giving quick rotary motion to mops and such like instruments."—April 10.

John Aitken, of Surrey Square, for "Improvements in water machines, or engines and steam-engines, and the mode of traction on, or in canals or other waters or ways."—April 10.

George William Lenox, and John Jones, of Billiter Square, London, merchants for "Improvements in the manufacture of sheaves and shells for blocks, and of bolt rings or washers, for the purposes of shipwrights and engineers."—April 10.

James Kennedy, of the firm of Bury, Curtis, and Kennedy, of Liverpool, engineer, and Thomas Vernon, of the same place, iron ship-builder, for "Certain improvements in the building or construction of iron and other vessels for navigation on water"—April 15.

John Lawson, of Leeds, engineer, and Thomas Robinson, of the same place, flax-dresser, for "Certain improvements in machinery for heckling, dressing, combing, and cleaning flax, wool, silk, and other fibrous substances."—April 16.

Edgar Heale, of Brixton, gentleman, for "Certain improvements in the construction of carriages for the conveyance of passengers on roads and railways."—April 18.

Donald Grant, of Greenwich, esq., for "Improvements applicable to the ventilation of apartments in which gas and other combustible matters are consumed by ignition."—April 18.

John Bailey Denton, of Gray's Inn Square, land-agent, for "Improvements in machinery for moulding or shaping clay and other plastic substances, for draining and other purposes."—April 18.

James Murdoch, of Staple's Inn, mechanical draughtsman and civil engineer, for "Certain improvements in the construction of vessels for holding aërated liquids, and in the means for introducing such liquids into the said vessels, and retaining them therein." (Being a communication.)—April 18.

John Smith, of Bradford, York, worsted spinner, for "Improvements in machinery for tentering and stretching cloths or fabrics."—April 18.

Richard Roberts, of the Globe Works, Manchester, engineer, for "Certain improvements in machinery or apparatus, for the preparation of cotton and wool, and also for spinning and doubling cotton, silk, wool, and other fibrous substances."—April 18.

Joseph Woods, of Barge Yard Chambers, Bucklersbury, gentleman, for "Improvements in regulating the power and velocity of machines for communicating power." (Being a communication.)—April 18.

William Hodson, of New King Street, Kingston-upon-Hull, estate agent, for a machine for "Making and compressing bricks, tiles, square pavers, and ornamental bricks."—April 18.

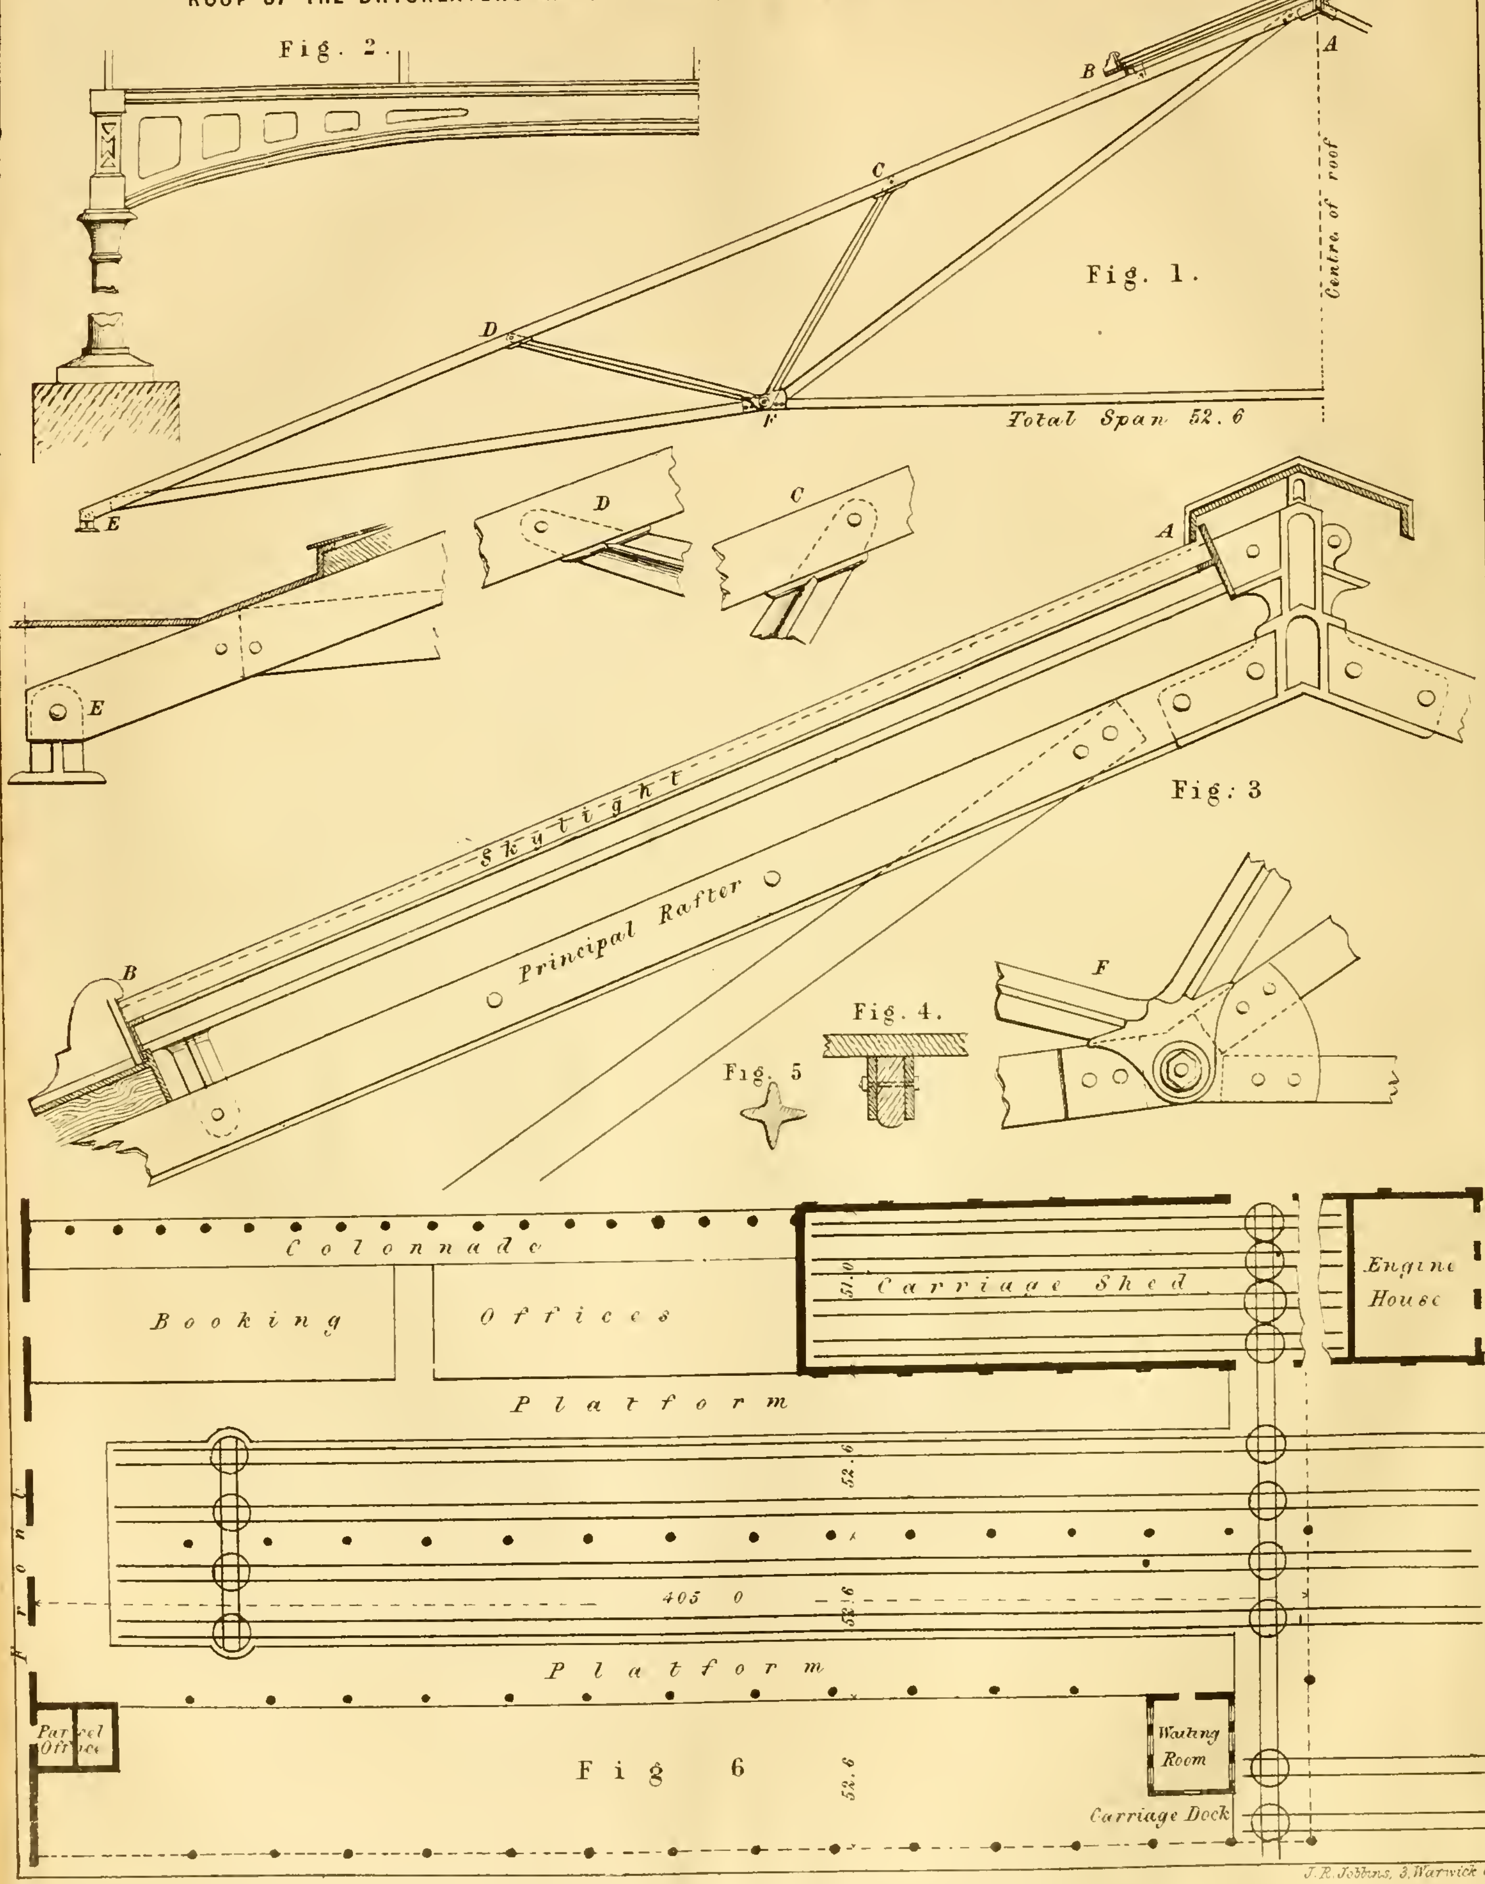
Henry Frearson, of Arno Vale, Nottingham, lace manufacturer, for "Improvements in the manufacture of warp fabrics."—April 23.

Peter Lear, of Boston, Suffolk, of the State of Massachusetts, America, gentleman, for "Certain new and useful improvements in machinery for propelling vessels through the water."—April 23.

William Taylor, of Birmingham, door spring manufacturer, for "Improvements in the manufacture of axle pulleys, and in pegs or pins for hanging hats or other garments."—April 24.

René Allaire, of Charlotte Street, Fitzroy Square, dyer and cleaner, for "Improvements in cleansing gentlemen's garments."—April 24.

ROOF OF THE BRICKLAYERS ARMS STATION, DOVOR & CROYDON RAILWAY.



J. R. Jobbins, 3, Warwick Ct.

THE IRON ROOF

AT THE BRICKLAYERS ARMS' STATION OF THE DOVER AND CROYDON RAILWAYS.

(With an Engraving, Plate VII.)

REFERENCE TO THE ENGRAVING.

Fig. 1. Section of roof; and Fig. 2. Girders or bearers, both figures drawn to a scale of ¼ in. to 1 ft. Fig. 3. Parts at large, drawn to a scale of 1½ in. to the foot. A, King head, with ridge piece over. A B, Skylight. B, Flashing piece foot of skylights. C and D, Abutments of stays at the principal. E, Foot of principals, with half of a gutter, and a shoe. F, Abutment plate of stays, showing the connexion of the feet of the two stays and the tie rods. Fig. 4. Section of principal rafter. Fig. 5, Section of stays, D F, and C F. Fig. 6. Plan of station.

In our last month's number we mentioned that, notwithstanding the accident, which had destroyed a considerable portion of the roofs of the sheds, that the station would be opened on the 1st of May, the day appointed; this was realized, by the spirited exertions of the subcontractors for the roofs, Messrs. Fox, Henderson and Co., of the London works, Birmingham, and the indefatigable energy of Messrs. Grissell and Peto, the contractors for the whole of the works of the station.

In the annexed plate fig. 6 is a plan of the station which sufficiently explains the general arrangement. The arrival shed is paved with wood and the platforms laid with the Seyssel Asphalte in a very superior manner; the Colonnade columns are of the Tuscan order, and support a heavy entablature, the roof over the booking offices is covered with large Italian tiles, and the front of the building is in the Italian style with massive iron gates in each of the openings opposite the ends of the rails. The roofs which cover the arrival and departure platforms, rails, and carriage shed, extend in length 405 ft. by 157 ft. 6 in. wide. The space is formed into 3 divisions with iron roofs spanning each which it is our present object to explain.

The roofs are of a remarkably light construction, but by a judicious distribution of the material; they have been found, upon actual experiment hereafter reported, to be of ample strength. Fig. 1 shows the framing of the roof, one half of one span is only shown as the other half is but a repetition, the total span is 52 ft. 6 in., and the rise above the springing at E, is 11 ft. and above the centre horizontal tie bar 9 ft., the framing of the principals or trusses shown in fig. 1 are placed 6 ft. 4 in. apart from centre to centre without any intervening rafters, the covering as will be presently explained is laid upon this framing. There are 195 pair of principals; each may be divided into five distinct members. (1) The two rafters A E; (2) the two outer tie bars, E F; (3) the central tie bar, F F; (4) the two suspension bars, F A; and (5) the four struts, F D and F C. The rafters are composed of two wrought-iron bars A E, each the whole length of one side of the roof, and are 2¾ inches deep by $\frac{5}{16}$ thick; between these two bars, a flitch of deal 3 in. deep by 1⅝ thick (four pieces are got out of a 2½ inch batten) which projects below the iron work and forms a bead as shown in fig. 4, these iron bars and deal are bolted together with iron bolts 15 inches apart; the deal not only stiffens the rafters, but affords a nail hold for securing the boarding, the rafters abut at the top on to a cast iron king head as shown at large at A, fig. 3, and at the foot they abut on iron shoes to which they are bolted as shown at E., these shoes are merely bedded on the wall or girders and are not in any way bolted down, this allows for the free expansion of the metal. The suspension bars A F, and central tie bar F F, are of wrought iron 2 inches deep by ⅜ thick, and the outer tie bar is 3 in. deep by ⅜ thick; the struts C F and D F, are of cast iron 5 ft. 6½ long of a section as shown in fig. 5, three inches diameter in the centre, and two inches diameter at the ends, the ends of the bars it will be seen by reference to fig. 3, A, C, D, and E., pass in between the two iron bars of the rafters, and are there rivetted together by ⅝ rivets; the ends of the two tie bars at F, and the suspension bar are first secured by means of wrought iron cheeks with two ⅝ and ½ inch rivets to each end as shown at F, and over these is a cast iron abutment piece which clips the wrought iron cheeks, and allows the ends of the two cast iron struts to pass between; a ¾ inch nut and screw bolt is then passed through the eyes and secures the whole together; it should be here observed that these struts together with the abutment pieces, are all made alike so that it makes no difference whether the diagonal struts be for either the right or left hand abutments—at the top and under the skylights, there are ⅝ wrought iron stay bolts between each pair of rafters which cross each other, and give great stiffness to that part of the roof.

Between each pair of principals is a skylight, 6 ft. 3 in. wide and 4 ft. 2 in. long, of cast iron, A B, Fig. 3, the bars are 2 in. deep and 1 in. wide, across two rabbets, and between each skylight is a cast iron gutter 2½ in. wide and 2½ in. high; the top of this gutter is secured by a bolt to the king heads, and at the foot by an iron stud bolted to the principal: on each side of the skylights there is a rabbet cast which turns down into the gutter just described, and at the foot are cast iron flashing pieces, which are overlapped at the top edge by the skylight. Over the top of the skylights is a ridge piece, of cast iron, as shown at A, in length of about 5 ft.; each end has a fillet cast on the top, these ridge pieces leave a space between the ends, over which is fitted a cast iron ridge capping with a fillet on the underside of the ends so as to clip over the fillets cast on the ends of the ridge pieces, and in the centre is a boss with an eye which passes over the end of a bolt eye cast on the top of the iron king heads, and there secured by means of a key passing through the eyes as shown at A fig. 3.

By a little attention to the description of the construction, it will be seen that although the parts are put together with great simplicity, considerable judgment has been bestowed upon them to allow for the free expansion and contraction of the metals, and at the same time to give stiffness to the several parts.

The covering of the roof consists of 1⅛ inch boarding, (out of one-cut battens,) planed, grooved, and tongued with hoop iron, and nailed down to the principal rafters; they are laid longitudinally, and are stiffened by plates of fender iron 4 in. wide by $\frac{3}{16}$ths. nailed on the top of the boarding in a diagonal direction: the external covering is of queen's slating; the gutters between the roofs at the eaves are of cast iron, as shown at E, the joints of which are secured with iron cement. The feet of the principals, as we before stated, are secured to iron shoes, which are of various forms, either for bedding on the walls or the iron girders. The roof is supported on cast iron girders, as shown in Fig. 2, of an elliptical form; the centre is 12½ in. deep, and the ends 2 ft. 8 in.; they are let into grooves in the standards over the iron columns, and there secured longitudinally by iron bolts. The distance between the columns is 25 ft. 4 in. from centre to centre; the standards above the columns are 6¾ in. square in the middle and 8 in. square at the base and top, and are 2 ft. 8 in. high; they are let into a socket cast on the top of the column. The columns are 13 ft. high and 6½ in. diameter at top, and 8 in. at bottom: they stand on iron bases 2 ft. square and 4 in. thick, bedded on brick piers 3 ft. square, taken in all cases down to the gravel; 12 columns are cast hollow and form pipes to convey the water from the gutter to the drain.

The carriage shed and engine house have a similar roof, as just described, excepting that they are not covered with boarding, consequently there is no flitch of deal between the wrought iron bars of the principals, but they are kept apart by small pieces of cast iron, and a rivet passes through it and both bars; the slates are laid on iron laths 1 in. deep by ½ in., placed edgeways. Instead of the skylights over the engine house being laid on the principals they are elevated 2 ft. to allow for the free escape of the smoke and steam from the engines.

The experiment.—In order to prove that the accident occasioned by the falling of the roof was not in the slightest degree caused by defective construction, the contractors ordered two principals to be framed and boarded, and so placed that railway bars could be turned from an overhanging scaffolding placed on the other side of the wall near which the experimental rafters were placed; the bars were then gradually lowered so as to evenly load one of the two principals until the load was equal to 40 lb. upon the square foot, that being double the load intended to be carried by the roof in question; the principals were then left for 24 hours for the inspection of the Inspector General of Railways (General Pasley) and other gentlemen interested, when their ultimate strength was to be tested; which was done on the 16th of April, in the presence of General Pasley, Messrs. J. and L. Cubitt, Messrs. Grissell and Peto, Mr. Ranger, Mr. Fox and other gentlemen connected with the railway; the same plan of lowering the bars was adopted, and they were loaded until the weight of 65 lb. per square foot broke the cast iron king head, the wrought iron rafter then buckled, but did not sustain the slightest fracture. Every one present expressed the greatest satisfaction at the result of the experiment which fully carried out the statements of the contractors, respecting the sufficiency of the roof.

Engineering Honours.—It is with great satisfaction we have to announce another engineer, Dr. MacNeil, has been honoured by a knighthood, there is not a member in the profession who is more respected than Sir John MacNeil, and we feel assured it will be a great gratification to the profession generally. We have long since advocated for honours being granted to the Engineering Profession, and it now affords us much pleasure to see that our desires are being gradually fulfilled.

TO FIND THE MAGNITUDE AND FIGURE OF THE EARTH, WITH THE ASSISTANCE OF RAILWAYS;

Without presupposing it to be any particular form.[1]

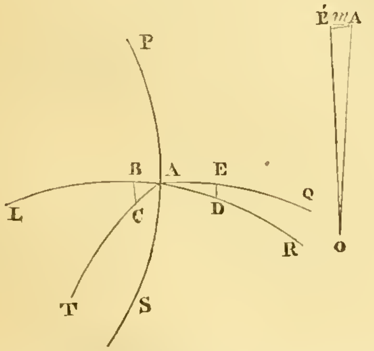
By OLIVER BYRNE, Mathematician, &c.

To find the length of a degree in any position on the surface of the earth, with the assistance of railroads, presents no obstacle whatever to the mathematician.

In England, America, and on the Continent, there are at present a considerable number of railroads long enough for the purpose, so that we can have a sufficient number of examples. The lengths, bearings, elevations, and depressions, &c., of the several planes which compose each railroad, may be had from different companies or their respective engineers, and if the dimensions thus obtained, are not considered accurate enough, they can be easily taken over again. When this information is acquired, the length of the arc on the surface of the earth between any two given points in the line of road may be very readily determined, on account of the approximant of the general line of most railroads to levelness. By astronomical observations the latitudes of both ends of the road, or any point in it may be determined, and also the length of a degree upon any arc passing through either extremity, and a point in the line of road; as the bearings and length of such arc can always be found.

Then supposing a railroad selected of such a length, that from a point in it the length of a degree is known on the arc passing through that point and the beginning of the road, and also that of a degree on the arc passing through the said point and the termination of the road, and the arcs to be oblique; or it will answer the purpose as well to have two roads in the same latitude or nearly so, such that the length of a degree on the arc passing through the extremities of each is ascertained; from which it is required to find the length of a degree on the meridian, and also that of a degree on an arc perpendicular to it, at the same point.

This may be done as follows:—



Let L A R be an arc of the meridian, S A P an arc of the curve at right angles to it, A T one of the arcs upon which the length of a degree is known $=$ L; and A Q the other upon which the length of a degree $= l$; also, let the bearings of these arcs, or the angles L A T and Q A R, which are known $= a$ and b respectively; again, let $g = 57°{\cdot}295779,5$ the arc equal in length to the radius, therefore the radius of curvature at A in the arc A T $=$ Lg; and that at A in A Q $= lg$. To find the radius of curvature of the arcs R A L and S A P, let the radius of curvature of the meridian at A $= x$, and that of its perpendicular or of the arch S A P at the point A $= y$. Take A C, an indefinitely small portion of A T $= s$, and A E, an indefinitely small portion of A Q $= s'$.

Then A B $= s$ cos. a, and B C $= s$ sin. a, as A C is supposed to be indefinitely small.

Now from the nature of the osculating circle at A, in the arc R A L, the distance of the point B from the horizontal plane passing through A,

$$\text{is } \frac{s^2 \cos.^2 a}{x}:$$

for A′ B′, fig. 2, stands in the same position as A B, fig. 1, and may be considered as a perpendicular from the right angle at A or A′, falling between radius of curvature O B, and the depression m B′ of the point B′ below A′, or that of B below the horizontal plane passing through A; and the depression of C below B is $= \dfrac{s^2 \sin.^2 a}{y}$, for the radius of curvature of the arc B C is ultimately the same with that of S A P at the point A, the total depression of C below A is equal,

$$\frac{s^2 \cos.^2 a}{x} + \frac{s^2 \sin.^2 a}{y} = s^2 \left(\frac{\cos.^2 a}{x} + \frac{\sin.^2 a}{y} \right).$$

Again, by the property of the circle above quoted,

$\dfrac{s^2}{s^2 \left(\dfrac{\cos.^2 a}{x} + \dfrac{\sin.^2 a}{y} \right)} =$ the radius of curvature of the arc A T, at the point A $=$ Lg;

$$\therefore \text{L}g = \frac{1}{\left(\dfrac{\cos.^2 a}{x} + \dfrac{\sin.^2 a}{y} \right)} = \frac{x y}{y \cos.^2 a + x \cos.^2 a} \ldots \quad (1.)$$

By the same process of reasoning, we find,

$$\frac{x y}{y \cos.^2 h + x \sin.^2 h} = l g \quad (2.)$$

In (1) and (2) for the sine and cosine of a, substitute s, and c respectively; and s' and c' for the sine and cosine of h; let L$g = r'$, and $l g = r'$. Then equations (1) and (2) become

$$\frac{x y}{y c^2 + x s^2} = r \quad (3.)$$

$$\text{and} \quad \frac{x y}{y' c^2 + x' s^2} = r' \quad (4.)$$

$$y = \frac{r s^2 x}{x - r c^2} \text{ from (3)} \qquad y = \frac{r' s'^2 x}{x - r' c'^2} \text{ from (4)}$$

$$\therefore \quad \frac{r s^2 x}{x - r c^2} = \frac{r' s'^2 x}{x - r' c'^2}, \text{ hence we find}$$

$$x = \frac{s^2 c'^2 - c^2 s'^2}{r s^2 - r' s'^2} \times r r' \text{ and } y = \frac{s'^2 c^3 - c'^2 s^2}{r c^2 - r' c'^2} \times r r.$$

By restoring the values of r and r', we have

$x = \dfrac{s^2 c'^2 - c^2 s'^2}{\text{L} s^2 - l s'^2} \times \text{L} l g$, and $y = \dfrac{'s^2 c^2 - c'^2 s^2}{\text{L} c^2 - l c'^2} \times \text{L} l g$, the radius of curvature of the meridian, and that of the arc perpendicular to it at the point A.

$\dfrac{x}{g} =$ length of a degree on the meridian $= \dfrac{s' c'^2 - s'^2 c^2}{\text{L} s^2 - l s'^2} \times \text{L} l.$

$\dfrac{y}{g} =$ length of degree on arc perpendicular $= \dfrac{s'^2 c^2 - c'^2 s^2}{\text{L} c^2 - l c'^2} \times \text{L} l.$

By restoring the values of s, s', c, c', we have

$\dfrac{\sin.^2 a \cos.^2 h - \sin.^2 h \cos.^2 a}{\text{L} \sin.^2 a - l \sin.^2 h} \times \text{L} l, =$ the length of a degree on the meridian: and, $\dfrac{\text{in}.^2 h \cos.^2 a - \cos.^2 h \sin.^2 a}{\text{L} \cos.^2 a - l \cos.^2 h} \times \text{L} l =$ the length of a degree on an arc perpendicular to the meridian at the point A.

By the help of this problem the true figure of the earth, with very little trouble, might be ascertained, as we are not obliged to imagine the earth to be any known form, because be it of whatever form it may, the planes which compose a line of railroad must be in its surface or very nearly so: nor is it very hard to find a degree or more of road in the same direction.

[1] This articles is extracted from Mr. Byrne's extensive unpublished work, entitled, 'A New Theory of the Heavens and Earth."

AN EXPLOSION OF SUBTERRANEOUS WATER took place lately in the district of Vizeu, in Portugal, by which the soil was torn up, and earth and atones flung to a great height into the air, for the distance of more than a league, between the small river Oleirns and the Douro. All the cultivated land over which the water flowed waa destroyed, and in many places it created ravines forty feet in depth, and thirty fathoms wide. It carried away and shattered to fragments in its course, which was of extreme rapidity, no fewer than fifty wind and water mills, choked the Douro with rubbish, and caused the death of nine persons, including one entire family. On the same day a similar explosion took place in the mountain of Marcelim, in the same district, arising from the same source, but branching off in the direction of the river Bastanza. It carried away a farm-house, four cows, and some sheep and goats. A similar occurrence took place here last year and the year before, and 18 months since in Madeira.—Times.

ALTAR-SCREENS.

(From the Ecclesiologist.)

There are two ways of ornamenting the Eastern wall of a Chancel, which we had not space enough to mention when arguing in our last number against the admission of stone or wooden Altar-screens in a parish church.

First, there is ample authority for hangings of costly materials and suitable colour.

There can be little doubt that this was a very common way of relieving the plainness and ugliness of plaistered walls: the use of tapestry and embroidered work is mentioned repeatedly both before and after [1] the Reformation. Many of our readers will remember, that a hanging of crimson is at this day to be seen behind the Altar in Jesus College Chapel: would that the present state of that beautiful structure could be quoted, for any other particular, with approbation by the *Ecclesiologist.* Hangings are in use also in Merton College chapel, Oxford. It is obvious how simple and inoffensive this plan would be; a rich effect of colour will be obtained without any solecism; shall we add as an additional advantage, at a trifling cost? The chief excellence, however, of such a plan is, that it is but temporary; it inflicts no permanent blemish or absurdity on the church. The hangings, easily varied or renewed, will be always rich and in keeping; and can at any moment give place to a more correct (if it may be) or a more substantial method of decoration.

We have before had occasion to observe, that at present our wish to restore has gone beyond our knowledge: as was remarked in a paper read before the Society at its last meeting, the restorations of the nineteenth century may be classed with the sacrilege and indifference of the preceding, as scarcely less dangerous to the consistency and original beauty of our ancient churches. To connect this with our present subject. We doubt if there is anything so hard to design as a screen. Assuming the usual axioms of reality and the like, we believe that many *ancient* and universally admired screens will be found faulty when tried by such canons. And this is the place for another caution; staunch as we are for adhering to precedent, bigoted as we are called in our admiration of ancient works, we protest strongly against being supposed to admire irrationally and indiscriminately all that is clearly original or even of the pure period. We believe, indeed, that in perhaps all exceptions and anomalies of the old church-builders, some great genius, some counteracting and preponderating principle, something even to be admired will be found. But in the attempt to revive ancient architecture, we have no safe course but to find out by induction some (at least) general rules, and to lay down some general principles: by which we must try our own attempts at imitation; by which, should they be confirmed by use and experience, we may test the truthfulness and excellence even of the ancient remains themselves. It will therefore be of small use to bring forward a solitary example of a detail or arrangement as authority for its imitation. Is it right according to canons which have been carefully drawn up, and are as yet undisputed? Is it defensible upon the principles which we believe to be the life of ancient art? If not, it is no more to be followed than any exception in the Æneid, however striking or beautiful, is allowed to be parodied in a school-boy's copy of verses. But if even ancient screens, in particular, may be thus criticized, it is easy to infer the great difficulty of designing modern specimens; a difficulty much increased by our unwillingness to introduce, or our ignorance in executing, the fair imagery which is necessary to the proper effect of a stone reredos. Can anything be more absurd than to make deep niches, with canopies complete, to hold a brass plate engraved with the Commandments? It were even more sensible to enniche the officiating clergy, as we mentioned in our last paper. We would refer to the expensive stucco reredos lately placed in Holy Trinity church, Brompton, as peculiarly open to such objections of principle. For a failure in stone parclose screens, take that of the choir at Canterbury. Until then we know more about designing in this branch, what is more reasonable than to adopt the temporary arrangement of tapestry and hangings?

We next come to the consideration of pictures, as "Altar-pieces." We premise by expressing our own great preference of fresco or distemper-work for the decoration of churches to the use of paintings on canvass. The latter are almost always incongruous, and often become, by their unwieldy size and frames, rather eyesores than ornaments. What, for instance, can be worse than the setting of the Altar-piece in St. John's College chapel; or the huge picture of St. Michael, with its cumbersome pagan frame-work in the Trinity College chapel? But where there is no other reredos, and where the church has an oil-painting, we wish strongly to recommend the re-introduction of triptychs. A triptych will always give a fitting dignity to an Altar, and besides keeping the size of the picture within bounds, provides it with a suitable frame. An ancient example is preserved at St. Cross's hospital, though now removed to the Hall.

Triptychs are still to be seen in two churches in Worcestershire. One advantage consequent on the revival of triptychs, would be the cultivation af a severe school of painting. Far less money than is expended on many showy screens, would procure a good devout picture, the leaves of the triptych, in ordinary cases, being simply diapered. A demand for ecclesiastical painting would soon command a supply. And if such encouragement did not find out some English disciples of Overbeck, (though there is little doubt of this in the present improved state of feeling,) what should hinder that foreign artists of the new Catholick school should supply us with what we want? How simply by means of a triptych and hangings, could the barest East end be made not decent merely, but rich and dignified. The triptych will stand behind the Altar, forming alone a sufficient background; on each side, hangings, plain or embroidered, from a moderate height, will hide the rough wall, with no disguise, and add beauty and colour to the whole.

Connected with this is the consideration of fresco or distemper painting as applied to internal walls. We are persuaded that decorative colour will ultimately win its way even with the most obstinate. It is sincerely to be hoped that the example may be soon and well set. Take the worst East end, which the removal of a revived-Pagan framework has left bare and rough: why not make this good and richly paint it? Thus you avoid solecisms, you make a really substantial restoration, you gain a beautiful coloured enrichment, you encourage one of the noblest of arts. What might not be hoped for, if the Church would once again make Painting her handmaid? Instead of the "portraits" of the "Exhibition," we should have a national school of art working for the holiest of services; and perhaps (it may be) rivalling those English painters, who in 1350, under Hugh of St. Alban's, made St. Stephen's chapel in Westminster, the glory not only of England but of Christendom itself.

There is another point upon which we wish to offer a few remarks. Much difficulty has been felt by church-builders and restorers respecting that part of the 82nd canon, which enjoins "that the Ten Commandments be set up on the East end of every church and chapel where the people may best see and read the same." Let us confess at once that we believe this injunction to have lost its meaning and force; yet at the same time let us boldly declare that we have no wish to evade, on our own responsibility, what may be shewn to be its real obligation. The difficulty is to know what is really enjoined. There are indeed many at this time, who, despising the one hundred and forty other canons, are forward in putting forth the claims of part of this one. For ourselves, we merely intend to suggest some considerations, which may help to explain this ordinance, and hasten on perhaps the adjustment of what is certainly a difficult question. What we chiefly, however, wish to shew is, the impropriety of niches, or any permanent construction, *behind the Altar*, to receive the tablets.

Firstly. This is the *only* place where the arrangement is ordered. It is an incidental detail, rather than part of a system. It is not reconcilable with what we know was the usual treatment of the East end at that time. It is not ordered (we believe) either in the Irish or Scotch canons.

Secondly. It is doubtful what part of the church is meant—whether the East end of the Chancel or the Nave. 'Church' has often been interpreted to mean the Nave, as distinguished from the Chancel; which latter is a technical name recognized in the rubrick. Now, if the Chancel were meant, the object of the injunction is defeated; for how can "the people best see and read the same" when they are excluded—as there is ample evidence our Church intended them to be—from the Chancel, and are kept off by the Rood-screen some thirty or forty feet from the Tables? If the Nave be meant, then there is not the shadow of an excuse for placing them behind the Altar, or for spoiling reredoses in order to admit them. Again, if the Nave be meant, where is its East end? It can only be above the Chancel-arch; so high, in most cases, as to be out of people's sight.

Thirdly. Is it not reasonable to suppose that this order was meant only to be temporary; like others of the canons, such as those relating to preachers, to canonical dress, &c.? For *now* almost every poor man that can read—and if he cannot read what is the use of painting up the Commandments for him?—has his Prayer-book: so that, to re-enact the Canon, with the practical reason there assigned, would be absurd; as if now, when Bibles are so common, we should still chain a large Bible in the church for publick reading.

Fourthly. If we set them up in obedience to the canon, it is clearly

---

[1] We may refer to the "Hierurgia Anglicana" for a copious and interesting collection of extracts in proof of this assertion.

necessary to write them in plain Roman type, "that the people may best see and read them." To use the extraordinary alphabets in which we now so often see them, illegible black letter rendered ingeniously still more illegible by rubrications and flourishes innumerable, is a mockery. We may observe also that it is not easy to see how people should be able to read Roman type, when set up over the Altar; since the Altar itself, and in most cases the rails, must hinder a sufficiently near approach; in cases even where the Chancel itself is accessible.

Fifthly. There is no rule *how* they are to be set up; so that there can be no excuse for making niches to receive them a part of the *construction*. But Archbishop Grindal and Bishop Cox recommend them to be "written on fair sheets of paper, and pinned up against the *hangings* of the East end." If the canon may be thus complied with, the stone tablet system becomes still less excusable.

Sixthly. Our own belief on the subject is that the Commandments were intended to supply the blank left by the demolition of the Great Rood. In all probability the head of the arch above the Rood-loft was often, however bad this arrangement certainly would have been, blocked up. The ancient painting of the Doom still preserved in St. Michael's, St. Alban's, was *originally* in this position. So in Bettws Newydd, where the Cross remains, and in Llangwm Ucha, Monmouthshire, the head of the arch is panelled up. Now something was wanted to supply the place of the defaced Rood or Doom; and thus we believe the Commandments came to be set up. This, be it remembered, would be at the East end of the church (Nave), and would be within sight of the people both from position and height. But we should scarcely defend the boarding up of the head of the Chancel arch, either as a point of taste or expediency. This plan really would seem to shut the Chancel off from the Nave, which is never the effect of the Rood-screen, however high. In short, the boarding remaining, the Communion-service must still be read from the reading-pue; as was almost universally the case a short time since. At any rate, if we block the heads of our Chancel-arches for the Commandments, we must have the service intoned again: or the people may read the Commandments, but will not hear them from the Altar.

Seventhly. Confirmatory of the last theory is the fact, that the oldest tables of Commandments are found blocking the head of the Chancel-arch and not at the Altar. For instance, a very early example is so found at St. Margaret's at Cliffe, near Dover. Indeed it is little known how few examples of any antiquity are to be found at the Altar. In looking through twenty-five church-schemes from different counties, in which the article "Commandments" is filled up, the writer finds twenty in other positions, of which nine cases are over the Chancel-arch. In one, St. Mary's, Lambeth, an old copy exists in this situation, and a more modern copy at the Altar—a significant fact. Two of these churches have *none*: in five they are north and south of the Nave; in one, north and south of Chancel; in one, north and south of Chancel-aisle: in one, north of north Transept; in the last, *west* of Nave. So much for uniformity in the interpretation of the canon. It is well known indeed that many churches, and particularly cathedrals and college chapels, never had them; also that in many they have disappeared without question; and that many new churches have been consecrated without them.

Eighthly. It is remarkable that in any early pictures, known to the writer, *e.g.* the curious engraving given by Mr. Markland of the desecration of a church by the Puritans, the Commandments are not represented as over the Altar: in the case referred to, indeed, there is a triptych. On the other hand, Mede (folio, 1677, note, p. 396) interprets the canon to mean "over the Communion-table," but seems to wonder at the Injunction. Finally, for the setting up of the Creed and Lord's Prayer there is no authority whatever.

In conclusion, were we called upon to suggest a course to church-builders to whom this subject presented a difficulty, we should recommend that the case be submitted to the Ordinary. We can scarcely believe that the canon would be enforced, or at least be ruled to mean the East end of the *Chancel*. In either case the Ordinary would probably sanction the distempering the Commandments in scrolls upon the wall: thus making no construction necessary for them, and allowing them to bear a part in the decorative colouring of the building.

ATMOSPHERIC RAILWAY SYSTEM.—Herr Sichrowsky, Secretary of the Emperor Ferdinand Railway, who was last year in Ireland studying the atmospheric system, has just obtained a grant for the execution of a railway on that system, uniting Vienna with the beautiful palace and gardens of Schoenbrunn, the Windsor of that locality. It will follow the banks of the river Wien, on which are a number of large commercial establishments, and which route during the summer is much frequented by the holiday folks. The distance is five miles, and the estimate, including seven stationary engines, is 2,000,000 florins (£200,000), in 200 shares of 10,000 florins (£1000) each, and which were subscribed in 36 hours.

FOREIGN QUACKERY AND BRITISH CREDULITY.

It appears that in so far as decorative Art is concerned, the people of England are destined in all ages to be the dupes of Foreign quacks and quackery. Fifty years ago an Italian, who assumed the high sounding name of Michael Angelo Pergolizi, was extensively employed in decorating the palaces and mansions of the English nobility and gentry. And in this present year a German adventurer, ycleped Mister or "Herr Sang," to naturalize whom a bill has been hurried through Parliament, has been employed to decorate the new Royal Exchange—and rumour whispers that it is not unlikely he may also be employed to Germanize the pure English Architecture of Barry in the New Houses of Parliament.

The resemblance between Pergolizi and Sang is remarkable, and it may help us to form an idea of what effect the productions of the latter is likely to have in the present day, if we revert to the debasing influence which the works of the former had at the time when he exercised unbounded sway over his patrons and admirers.

A glance at Pergolizi's book of ornamental design, which by the way was dedicated to a number of his noble patrons, will show what a wretched imposter he must have been. He compounded and distorted ill-drawn patches from Raphael, Watteau, and others, and produced an admixture of bastardized abominations which he had tact enough to palm upon his employers as original and novel designs, and through the extensive influence and patronage which he commanded he was enabled to poison the stream of English Decorative Art, and sweep away every portion that then remained of pure national taste, in connection with decorative house painting. Instead of the massive and graceful geometric and foliated ornament, with which in ancient times cathedrals and palaces had been decorated, there were now to be seen incongruous assemblages of trumpets, drums, vases, and monsters interwoven with meagre and unnatural foliage. Every ornament introduced, whether on ceiling, walls, or wood, was of the smallest, the leanest, and the most unsatisfactory kind, and architects, plasterers, wood carvers, and iron masters, imitated the style and aped the manner of the *great Italian master, Signor Angelo Pergolizi.*

Thus by the introduction into England of this trifling and meretricious style of ornament was the national taste depraved; and it was not until within these few years that there were any symptoms exhibited of a desire to return to the first principles of design, or any prospect of us being able to invent ornamental decorations in keeping with the characteristic features of our own country. Just, however, when we had begun to move onward in the right direction, Mister Sang was imported from Germany, with a spick and span new set of German patterns, or tracings; and he and his pupils have commenced to adorn the interiors of some of our principal buildings with a superabundance of German leaves, plants and flowers, together with German conceits and monstrosities, as far removed from the indigenous plants and flowers of Britain, and as alien to the feeling of Englishmen as were the productions of Michael Angelo Pergolizi. Is this to be tolerated with impunity? What are our native Artists and Decorators about? Are they so lost to every sense of shame as to sit tamely down under such an insult? What have our Schools of Design been doing? Was the late magnificent display of Cartoons not a proof of the rising character of British Art? Does not the present exhibition in St. James' Bazaar, wherein the celebrated Herr Sang cuts so poor a figure, triumphantly prove the superiority of our home bred House Decorators? In that exhibition, those London houses who have employed French artists to execute their designs must see the poverty of their Anglo-French productions, when compared with the specimens of British Art by which they are surrounded. In the Club Rooms and other places of fashionable resort, the decorative house painting is equal to what can be found in any country; while to a house painter in a provincial town (Mr. Hay of Edinburgh,) we are indebted for the most complete and satisfactory digest which has yet been given of the primary laws that govern form and colour. Notwithstanding all this, however, native talent is thrust aside to make way for German humbug and quackery. Shame on't! shame on't! Let all interested in the cultivation of the national intellect protest against such a practice. Let a demand be made for genuine British decorations, ornaments composed of forms or subjects peculiar to the country, and we will soon not only equal but surpass other nations in Art, as we have already done in Science and Literature.

OBSERVATIONS ON ARCHITECTS AND ARCHITECTURE.

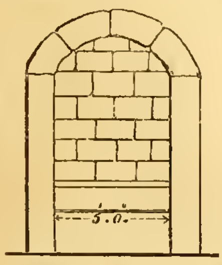
By Henry Fulton, M.D.

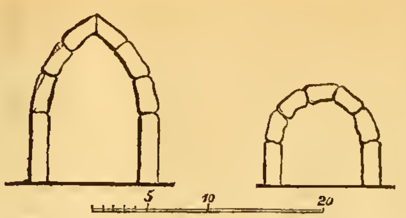
No. 9.

In Observations No. 3, Vol. VI., page 403, I had the honour to call attention to the circumstance of the British Institute of Architects being engaged in forming a collection of the different editions of the works of Vitruvius; and to express a hope that as soon as the collection was complete, it might, with the addition of Palladio and Sir William Chambers' works, be committed to the flames. We could mention other works published since "the end of the reign of George III.," did we not fear that by so doing we might, as Mr. Gwilt says, "come into contact with our contemporaries and their connexions, and that our office if not dangerous and fearful, might be unpleasant." The Institute and our readers generally can be at no loss in making a numerically respectable list of culprits for this literary *auto da fé.* As to the propriety of the measure there can be no doubt. Has not Professor Hosking unanswered, stated that geography and history might be as well learned from Gulliver and the Seven Champions of Christendom, as architecture from Vitruvius? But in order to satisfy the most sceptical, we beg now seriously to propose that a subscription be made for the purpose of giving a medal for the best essay on the subject, and if the Institute will have the kindness to receive the subscriptions and act as judges, we shall gladly contribute our mite. Institutions as well as individuals often involve themselves in dilemmas, and if the Institute should take in Vitruvius, they must turn out Professor Hosking himself, which, "if not dangerous and fearful, might be unpleasant," as there are those who esteem Mr. Hosking's works, and yet are so purblind, as not to be able to recognise any merit in those of Vitruvius or his admirers; besides, the Professor has already engaged the services of Captain Gulliver and the Seven Champions, who no doubt will prove themselves to be valuable auxiliaries in the event of hostilities.

Of course especial care must be had not to include in the *index expurgatorius,* those orthodox works which attempt to write down "mere amateurs" and "literary idlers," if it must be, let them have a milder sentence, on their covers let "flames be represented *points downwards,*" and the rather as it is desirable not to add too much fuel to the flame, let them then be consigned to the trunk makers according to the suggestion of Horace, not Horace Walpole, but the other one, (Quintus H. Flaccus:) Walpole's panegyricks on Lord Burlington's architecture have already performed the grand tour in trunks. If authors themselves do not find it convenient to go on their travels, by these means they can send their works as proxies. There is one author, however, to whom I would beg to recommend a trip to Germany, either in person or by proxy, if only to see the edifices erected by Schinkel and Klenze, some mention of which he may find in the article at page 445 of the 6th vol. of this *Journal.* But if the Institute be averse to discarding their collection of the works of Vitruvius, fortunately they have still an alternative, namely, to collect the travels of Gulliver and the exploits of the Champions, for the purpose of brushing up their knowledge of geography and history.

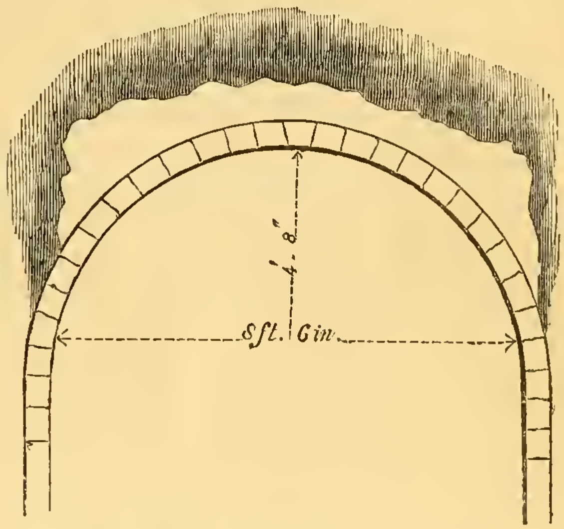
II. Mr. Frederick East, at page 354 of the third volume of this *Journal,* on the authority of Strabo states that, the earliest record of the existence of the arch relates to those supposed to have supported the hanging gardens at Babylon, which were constructed about twelve hundred years before our era. Mr. East is followed by another writer in the fifth volume, page 251, under the signature of O. T., who takes the same view. I have not found any writer who seems to be aware of the discoveries of Mr. Hoskins in Ethiopia and Egypt, which throw much light on this long disputed question. At Meroe, the ancient capital of Ethiopia, and the ruins of which he fairly supposes to be of much greater antiquity than any of those existing in Egypt, he found in one of the pyramidal tombs, the stone arch, of which we give a diagram, it is taken from the vault or porch of the entrance, and this vault consists of alternate courses of four and five blocks; of course, where, as in the annexed cut, there is only four, there is no keystone: the arch at the spring measures five feet, and the joints are truly given.





The next are a circular and a pointed arch, from the interior of pyramids at Gebel el Birkel; the date of which Mr. Hoskins does not suggest, although he considers them of great antiquity; they are situate near the fourth cataract. The pointed arch consists of six stones slightly hollowed out to the shape of the arch, and are supported by lateral pressure; they are not joined by cement, but above the roof are a quantity of small stones, which are kept together by a soft cement. The scale of both these is an inch and a quarter to twenty feet.

We give, in the annexed cut from the same author, a view of the



brick arch from the tomb of Amunolph I. at Thebes, who reigned 1550 years before our era. There is a vacant space between this elliptical arch and the rock, as may be seen in the cut. The span is eight feet six inches; its height is four feet eight inches.

As the Ethiopians taught architecture to the Egyptians, who instructed the Greeks, from whom the Romans derived their knowledge of the art, by the discoveries of Mr. Hoskins, the question of the claims of the Greeks and Romans is in a great measure set at rest. It remained in abeyance almost with the Egyptians, and with the Greeks also, except as a mere shadow in the corbelled roof of the tomb of Agamemnon at Mycenæ; still the Romans may be entitled to be called inventors just as Europeans were the inventors of gunpowder, printing, and the mariner's compass, although all these were previously long known to the Chinese.

In the second series of Sir William Gell's Pompeiana, Vol. II., Plate LXV., House of the Dioscuri, a doorway is given in the background, which has a close resemblance to the lancet arch. I do not recollect any thing of the kind at Pompeii: perhaps some person whose eye this may meet can throw some light on it, or may have the means of making enquiry on the subject.

A very general feeling exists against the introduction of arches and columns in the same composition; certainly, as far as the columnar arcades of the Palladian School go, nothing can be worse: but this arises more from the wide, straggling, and unequal intercolumniations than any thing else, and also from the practice of imposing arches instead of architraves, and also placing them on other and lesser columns; when these anomalies can be avoided the objection would loose most if not all its force. Arches behind insulated columns would have a better effect than either pilasters or square headed windows.

I agree with Mr. R. C. Long, of Baltimore, Maryland, (see fifth volume, *Journal,* page 370,) in his very judicious remarks relative to the capabilities of the Roman arch, which he considers has not yet been fully developed as a beautiful feature in architectural composition. What in the architectural world can exceed in sublimity and grandeur the long unbroken line of arches in the Roman wilderness? But there must be no higgling, sniggling, paring, frosting, tinkering, and the rest of the little *ings* and things with which our modern arches are ornamented. I verily believe that the man who spoils an arch with a dropping keystone could be guilty of inserting a ring in the nose of the Venus de Medici, and although it might be merely his own bright idea, he might think all the while, persuading himself that others thought so too, that it had been selected by the fair hand of science to set off the Queen of Beauty to advantage. I have seen, or perhaps only think I have seen, sculptured keystones which had a good effect, the sculpture alone being in relief. By the bye, sculpture is too seldom called in aid by architects to embellish their works, I do not mean the Paul Pry intruding or protruding keystone with mere glyphs, but something like what is to be found in nature relieved on a smooth ground, appearing like a single star in the firmament, or to speak of things terrestrial, a single and well selected ornament on the arched and unwrinkled brow of beauty.

For the history of the arch one naturally looks for information to the Encyclopædia of Architecture, but the information there given is scanty enough. Who indeed would suspect Mr. Gwilt of taking a leaf out of the travels of any "mere amateur" or "literary idler?" No, no, such small fry must not be encouraged to travel, or at least to write, with the object of throwing light on the history or practice of the art; besides, Mr. Gwilt seems to have been seized with a Rip Van Winkle sleep commencing at the end of the reign of George III., (which he says was also the end of the 18th century,) and to have remained from that epoch in a state of imperfect *clair voyance*, from which he has aroused at the end of nearly half a century, for the purpose of compiling his Encyclopædia: but although he seems to have slept profoundly, he did not sleep soundly, for he appears to have been disturbed by dreams of mere amateurs and literary idlers thoughout: it is to be hoped that he is now wide awake and has thrown off the night mare from his breast. If not, the sooner he does so the better.

III. In a very sensible letter written by Censor, page 147 of this volume, it is stated that very few of the profession purchase foreign architectural works; it might have been added, or domestic ones, or even read one or the other. I did not wish to be the first to call attention to this subject, but I firmly believe that there are many architects who never read professional works. Vitruvius gives a goodly list of accomplishments which he considered necessary for an architect, but he carries it to one extreme by requiring too much—modern practice to the other by requiring too little. Although it be unnecessary that an architect should know everything, which the professors of other branches of science and art should respectively be acquainted with, yet it is absolutely necessary that he should read every thing which bears on his profession; and if he do not, he might as well, like Mr. Rip Van Winkle or Mr. Joseph Gwilt, be asleep, whilst all the rest of the world are wide awake; and after sleeping orty years, rouse up and think he could compile another Encyclopædia without filling up the hiatus. One man or one profession cannot stand still whilst other men and professions are progressing, without being left behind in the race of knowledge. I know that in some professions those who in the estimation of their brethren are placed at its head, are amongst those who consider themselves only students. Nature gave to Hogarth a genius which was calculated to make him the finest painter the world every saw; but the gift was marred by education, (or rather the want of it,) and vanity, fostered by ignorance, prevented him from profitting by the knowledge and labours of others, whilst, by availing himself of these advantages, he might have eclipsed them all.

"Knowledge is power," said a person called Bacon, or some such name. Buy books of merit, gentlemen, and read them; let it not be said of architects—

> "But knowledge to their eyes its ample page,
> Rich with the spoils of time, did ne'er unroll;
> Chill penury repressed their noble rage,
> And froze the genial current of the soul."

Depend on it a good use of a good library is essential to make a good architect. "The more extensive your acquaintance is with the works of those who have excelled, the more extensive will be your powers of invention; and what may appear still more like a paradox, the more original will be your conceptions," (*Sir Joshua.*) From what I have myself seen of the nakedness of the land, I greatly fear that if some "Devil on Two Sticks," were to escape out of his bottle, he would give a sad account of the empty shelves in the studios of modern architects. I have heard that in a city which I could name, there is only one architect who possesses a respectable professional library. As Sir Joshua says, "It is indisputably evident that a great part of every man's life must be employed in collecting materials for the exercise of genius. Invention, strictly speaking, is little more than a new combination of those images which have been previously gathered and deposited in the memory; nothing can come of nothing: he who has laid up no materials, can produce no combinations." Every man is not born a genius; but no man who has not talent and desire to profit by the works of others, has any right to consider himself an architect. No doubt it is owing to a want of the right perception of this, that architecture does not *now* occupy in the scale of art the commanding position which it should. A knowledge of the disease is a step to the remedy; on the profession depends its successful application.

Clonmore, Dublin,
May, 1844.

CAMDENISM AND PAGANISM.

Such is the ultra intolerance and bigotry of the Cambridge Camden Society, that it professes almost a mortal hatred for every thing partaking of classical architecture, and would not only henceforth exterminate all such styles in practice, but even interdict all inquiry and discussion relative to them. That the Ecclesiologist should be sadly wrath with the article "On the present condition and prospects of Architecture in England," in Part III. of Weale's Quarterly Papers, is natural enough—is no more than was to be expected, because the writer has been not a little bitter in his remarks upon the Camden and similar societies. Yet wherefore it should protest against as "mischievous" another paper entitled "Outlines and characteristics of Styles," is not so apparent; or it is apparently for no other reason than because it treats of the Characteristics of those styles which the Camdenists regard as profane. For having accomplished well, as much as he undertook to perform, and for having explained more lucidly than is generally done, a great many seemingly insignificant but really important matters in classical architecture, the writer obtains no credit from the Ecclesiologist; which not only severely condemns all practical application of classical architecture, but would even suppress the study of it, and no doubt, would commit to the flames all publications and writings connected with such study.

If therefore Mr. Weale is at all solicitous to propitiate the Camdenists, he will in future exclude all similar heretical essays and topics from his "Papers," and confine them exclusively to subjects of Ecclesiastical architecture and decoration. That being done, the next step on the part of the Camdenists may be to take the Royal Academy to task for rewarding architectural *paganism* with "gold medals," and for admitting designs in any other than the ecclesiastical style, into its exhibitions. Luckily the Ecclesiologist does not pretend to interfere in matters of Painting, or it might exclaim against the enormity of exhibiting subjects from heathen mythology,—perhaps might object to the somewhat too liberal display of female loveliness in Etty's pictures. Neither would the pictures in the National Gallery escape reproach for their naughtiness,—for instance, Rembrandt's lady paddling in the water, which was formerly in the collection of a *clergyman!*

If the Camdenists are quite right, then the nation has been exceedingly wrong, and has acted very foolishly in purchasing the Elgin marbles, and in now endeavouring to obtain a fresh stock of paganism of the kind from Lycia.

But to come to the main point,—it is pleasant to hear Pugin inveigh against the scandalousness of an architect's daring to paganize at the Universities, and University men thundering against pagan architecture, since of all persons in the world, such reproaches do not come with the very best grace possible from them. It is not to be denied that Paganism does infect modern literature and art to a very great extent, and sometimes very fantastically. The odour of it mingles even with the strains of Milton; the taint of it is imbibed with almost the very first elements of education, at least of *gentlemanly* education. And whom have we to thank for this? truly, no other than our venerable ecclesiastical institutions—our so greatly extolled seats of piety and learning—our Universities, Colleges, and endowed Schools, which have made Heathen Literature not only a part, but one of the most essential parts, the absolute *sine qua non* in liberal education!

Now, to our dull apprehension, this sort of actual Paganism, which mixes itself with our very thoughts and feelings, is infinitely more dangerous and mischievous than that which Camdenists and Puganists so lustily complain of. If we can tolerate Paganism in poetry, in painting, in sculpture, all of which bring more or less vividly and actually before us the gods, and the idols, and the extravagant, often shockingly impure, fancies of Greek and Roman mythology, it becomes over-acted, farcical prudery to be scandalized at our admitting anything partaking of, or reminding us of Paganism into our architecture. In this last all the moral uncleanness and pestilential virus of heathenism either evaporate or are neutralized. It may be very bad taste to prefer Grecian—which we ourselves do not do, otherwise than as we prefer a good Grecian design to a bad Gothic one; but that is chiefly matter of taste—certainly does not amount to a very flagrant moral delinquency.

However, we are quite ready to join the Camdenists, and that too most cordially, in a crusade against Paganism; but then we do not agree to their half measures, but insist upon 'going the whole hog!' If Paganism is really to be rooted out from the land, let us lay the axe to the stem of the tree, and that right vigorously. Let not pagan poets be any longer made the studies, and the corruptors of Christian youth; let us have no aspirants to episcopacy employing themselves in editing Greek tragedies; let us not hear Homer spoken of with as much reverence as if the Iliad were a book of Holy Writ and Christian doctrine. Let us purge not only our libraries, but also our galleries, both public and private, of the rank paganism there hoarded up as precious works of art. If art sanctifies what is heathen and profane, when it comes in such shape, it may also render us tolerant of such comparatively innocent paganism as that of Greek and Roman columns and entablatures;—and now, to make use of a not very polite expression, we have flung the *Ecclesiologist* "a bone to pick;" but dare say that it will consider it altogether beneath its notice; the most convenient and prudent course which Tartufferie and pharasaical hypocrisy can take. After all, too, the *Ecclesiologist* is not even tolerably consistent as far as it goes, for if its anger be stirred up against mere literary articles, which according to its own account, are too dull to do any mischief, it ought to empty the vials of its fiercest indignation upon those *monuments* of architecture which, by their *Paganism*, (a mighty pretty bug-bear word,) must so shock the pious feelings and the orthodoxy of Camdenists:—for instance, that flagrant example in Cambridge itself, the Fitzwilliam Museum. With what sort of sincerity the Camdenists, and their organ the *Ecclesiologist*, take the interests of architecture to heart is sufficiently apparent from the studious suppression of all mention of or reference to the beautiful little cemetery chapel lately erected at Cambridge by Mr. Lamb. No doubt, they would if they could abuse it, as they have done Mr. Blore's church at Hoxton; for it may, in their eyes, have a far greater defect than even that of Paganism, namely, of heterodoxy, the building belonging to Dissenters; and the Camdenists are wonderfully orthodox, and no less wonderfully liberal,—quite *pattern* people, and amazingly consistent to boot. Their orthodoxy extends even to their orthography, in which they display a singular affection for, a silly affectation of the now exploded *k*, in such words as Catholic, Gothic, &c., spelt by them Catholic*k*, Gothic*k*, which may be very proper, yet seems to us very finic*k*al and very comic*k*al.

Z Z

ARCHITECTURAL DRAWINGS, ROYAL ACADEMY.

Almost might we stereotype the remarks with which we have hitherto opened our notices of the architectural department of the Academy's Annual Exhibitions. But it would seem that the *corrigenda* are also *incorrigibilia*: in regard to them, there are not the slightest symptoms of amendment;—not even of there being any desire to effect improvement, notwithstanding that it is so obviously needed. We must therefore, per force, conclude that the architects belonging to the Academy are mere cyphers in it, without authority, influence, or interest of any kind; and that their zealous endeavours to abate the grievances and inconveniences complained of, and to obtain for architecture more liberal treatment at the hands of the Academy—so long at least as it continues to form any part of their exhibitions,—have been quite unavailing. If we do not account for matters this way, we are driven to a very ugly alternative—that of supposing that those gentlemen who represent the interests of Architecture—their own profession—at the Academy, leave it entirely to shift for itself, well knowing that their own drawings are certain of being hung to advantage.—To give them their due, however, they are tolerably considerate, and do not monopolize a very great deal of space. Only three drawings constitute the entire quota of those sent in this year by the Academician Architects—namely Barry and Hardwick. As to the Architectural President, Professor Cockerell, instead of doing the honours of his own department, he again keeps away altogether, which may be very dignified, but is not particularly gracious or encouraging on his part.—Like Sir John, he is ashamed to march with the ragged rogues through Coventry; so puts himself to Coventry.

Besides the Professor, there are many others whose names we this year miss from the Catalogue, although hitherto they have generally exhibited something each season. No wonder therefore if the average merit of the present Exhibition is below, rather than at all above that of some preceding ones; especially as we do not find old acquaintances supplied by new ones of any note or promise.

We will break off from our general remarks—crusty ones?—and turn at once to Barry's splendid pair of drawings Nos. 1186 and 1196, the first a "View of the New Palace at Westminster, as it *will* appear from Lambeth;" the other a view of it "as it *would* appear from the Surrey side of the river, near the foot of the new Hungerford Bridge, in connexion with a suggested new Bridge at Westminster." As to the "*will appear*" promised for the first subject, that we somewhat doubt, unless Mr. Barry be a second Joshua, and can prevail upon the sun to tarry in the East and light up the river front of his edifice in the same manner as is here shown. Neither will the building ever display itself from Lambeth in the same manner as is represented in the drawing, the station selected by the artist—and extremely well selected it is in itself—being very much nearer. There must also, we apprehend, be some mistake or miscalculation in regard to the point from which the other view is taken, it being immediately close to the "suggested" Bridge, showing the latter as it would be seen from upon the river, therefore not near to Hungerford Bridge. This will probably be thought hypercriticism; and such indeed it is in regard to the drawings, for there artistical licenses of the kind in order to show the subject to the greatest advantage, are allowable enough; but the case becomes somewhat different when, as in this instance, it is above all things important to calculate beforehand the precise effect of the structure when completed, without any exaggeration or flattery. That Mr. Barry himself professes to be very exact, is evident enough, else he would hardly by particularizing the precise stations from which they are taken, have led us to question the veracity of the drawings in that respect. Be the mistake however either on his part or ours, there can be no mistake as to the magnificence of the architectural ensemble which Mr. Barry here displays to us. He has not at all reined in his imagination, but it is not so certain that John Bull will not apply the curb to it, for we now perceive to what prodigious extent the architect proposes to carry out his plans. According to what is here shown, we find that all the houses on both sides of Bridge Street are to be swept away; and that the South side of that street will be formed by another extensive range of buildings, similar in character to the other elevations of the "Palace," and entirely enclosing behind it Westminster Hall and New Palace Yard. Then are we to have terraces and shrubberies on the other side of the street, at least along the river; also other terraces, and a splendid pavilion or Water-gate, extending from the south end of the River Front. Neither does Mr. Barry stop short here, for there are now additional towers, and the original Clock-Tower, is now prodigiously enlarged and converted into a lofty upright mass, whose ensemble has more of the character of Foreign than of English Gothic, and which is withal somewhat heavy in outline in its upper part, where there is a most enormous clock-dial—not unlikely to obtain the name of the "Prince of Wales' pocket watch." In comparison with what is now contemplated—at least by the architect himself, the edifice will be expanded to about double the extent of the original plan; therefore what with the prodigious increase that way; with fresco-painting and other closely decorations in the interior; with a vast deal of additional external decoration also; and lastly with the suggested Bridge,—the sum total will be truly startling.

Without wishing any ill to the Palace of Westminster, we should not like to see it entirely swallow up all disposable resources, when some are much needed for other purposes. Mr. Barry's ideas are so *elastic*,—he has such a superabundance of imagination and invention that we wish he would out of charity's sake, bestow a little of it—some of the mere crumbs and sweepings—upon Sir Robert Smirke, they would surely be acceptable to an architectural Lazarus. It seems, however, that Sir Robert will accept nothing, not even advice: although he takes very coolly a pretty large stock of reproaches, and it must be confessed that he does not take them without having fairly earned them. After so much has been said about the Façade of the British Museum, many persons may have supposed that there would certainly be either some drawing or the model of it in the present exhibition. So far from looking for any thing of the kind, we should have been as much startled by it as if we had found the Museum itself in Trafalgar Square. Were all others in the profession to take pattern by Sir Robert Smirke, and we may almost add the "Professor" himself, there would be a *finis* to architectural exhibitions altogether.

As to Professors, they are rather shy of exhibiting; we get however this year a subject from one of them, whose name is almost a stranger in the Catalogue, and what is more, a subject which challenges direct comparison with Barry; viz., Professor Hosking's design for "Remodelling the superstructure of Westminster Bridge upon the present piers," as shown by plans, constructional drawings, &c., in Nos. 1143 and 1148. "The main object of the design," the Catalogue tells us, "is the illustration, in a familiar manner, of Mr. Hosking's suggestions, in his 'Treatise on Bridges,' for reducing the weight and cost, and increasing the rigidity of the superstructure of an arched bridge, by the introduction of an inner transverse arch, groined to the usual longitudinal arches." The idea is ingenious, and would be attended with a pleasing effect; but we cannot say much in favour of the taste shown in the design itself, which is not likely to find many admirers, seen as it is almost in juxta-position with Mr. Barry's. In adopting Gothic, Mr. Hosking had evidently no intention of attempting to vie with the Palace of Westminster, or even to conform at all with the style of that edifice; the Bridge "suggested" by him, being quite contrary to the principles of decoration observed in any one of the various styles of Pointed Architecture. What should be panels and other ornamental details, are upon a monstrous scale in comparison with the structure itself. In fact, as far as appearance is concerned, the bridge might just as well remain as it is, without any attempt being made to assimilate or accommodate it to Mr. Barry's edifice. Mr. Hosking seems to have designed his Bridge without taking into consideration at all the excessively ornate character of the adjoining "Palace;" whereas had he wished to convince us how well his Gothic would harmonize, or how agreeably it would contrast with that of Mr. Barry, he ought to have exhibited a perspective view, showing not only the bridge, but some portion at least of the other edifice. If we have been rather prolix in our remarks on Westminster "Palace" and Bridge, it is partly because there are very few other designs for public buildings and improvements—churches excepted—that claim notice. One *projét*, however, there is for what would form a very desirable and no less feasible improvement at Whitehall, viz., Messrs. Wyatt and Brandon's design (No. 1219) for erecting on the site of Gwydir House, a building (either for government offices or a Club establishment), corresponding with the "Banqueting House," and uniting the whole into one general façade by means of a central compartment flanked with pavilion towers and cupola turrets. It is somewhat curious that, notwithstanding the excessive admiration—almost might we say veneration that has ever been professed for the only part of Inigo Jones's project for Whitehall Palace, that was executed, it has never been thought worth while to finish up the exterior consistently as far as it goes, continuing the design at the ends—which now present only bare brick walls,—and keeping the building quite clear from any others. In its actual state, that piece of Jones' architecture has always struck us as looking somewhat lumpish and monotonous, and evidently intended only as a portion or feature belonging to some larger edifice. Whether the project emanates entirely from themselves, or whether aught of the kind is contemplated in other quarters, we know not, but Messrs. Wyatt and Brandon now propose to make such addition to Jones' building as would form a well arranged architectural composition of considerable extent. It is true the centre would be the narrowest division of the façade, and would also recede back a little, but this is almost inevitable, for as it cannot be allowed to project forward unto the pavement, it must either be set back a little, or there could be no break at all in the line of front, consequently no motive for introducing the towers,—which are well imagined characteristic traits adopted from Jones' ideas for Whitehall.

After this design there is scarcely another in the room, which shows any thing either proposed to be done or lately erected in the metropolis, if we except No. 1101, Mr. Turner's "Façade buildings of the Joint Railway Terminus at London Bridge," which design has appeared in our journal. We meet indeed with a design *for* the new Conservative Club-house (No. 1218, T. Hopper), but it is not the one adopted, nor does it rival it by many degrees; but of course Mr. Hopper thinks differently, or he would not have challenged comparison. There are a good many other designs in the same predicament, having been put *hors de combat*, but how far they have been superseded by any thing better we are unable to judge, there being no drawings or models of the approved ones. For the "Leicester Memorial" alone there are four or five designs,—all of them columns—made according to *order*, we suppose—and all so exceedingly poor and insipid that they seem to have been sent to the Academy for no better eason than that they were ready to be sent. By way of producing something less hackneyed than the eternal Doric or Tuscan column, one of them substitutes the capital from the Tower of the Winds at Athens! Of Mr. Donthorn's column, which is the one to be executed, the capital is described as being altogether a novel composition, consisting of the heads and fore-parts of animals, but whether placed all round, or only under the angles of the abacus, we cannot tell, for he has not thought proper to exhibit the design, or any drawing or model of the capital only.

Of Prize Designs we have *quantum suff.*, things that may deserve the Academy's gold medals, but do not say much for the judgment which proposes such wildly extravagant subjects as are those upon which architectural students are invited to exercise their invention. The one this year is a "Metropolitan Music Hall and Royal Academy of Music," upon such a scale that it seems intended to contain the whole Musical "Million," and to require full a million to erect it. It is quite preposterous to encourage students, to encourage mere beginners to attempt such monstrously out-of-the-way things before they can display any taste and invention in designing a moderate-sized house, or even a single room. Subjects of the last-mentioned kinds are always, we are sorry to say, exceedingly rare: there is not a single design for the front of a street house or a town mansion. Architects seem to be able to make nothing of such subjects: they accordingly favour us only with cottages, villas, country mansions and castles. Of interiors they are equally shy—except they be merely those of churches—notwithstanding that so much has of late been said on the subject of interior decoration and the study of it; that in itself it affords such a wide and varied scope; and that it may be adopted with comparative facility and economy. Promise, however, is now made of what has long been a desideratum among architectural publications, by No. 1134, "The Morning Room, one of a series of designs for Interior Decoration," E. B. Lamb; yet while so many insignificant and paltry things are allowed to stare us full in the face, this drawing is put nearly quite of sight, notwithstanding that it is of a kind to require close inspection. Placed where it is, all the detail—all that constitutes decoration is entirely lost; hardly therefore would it have been a whit more preposterous to have hung it upside down at once. Nothing can be made out except the general forms and masses. Its author's name is however a pledge of its merits, since no one understands better than Mr. Lamb, the application and adaptation of former styles to actual purposes, in such manner as to retain their characteristics, and that, not merely in bits and patches, but consistently and throughout. Accordingly, we trust that ere very long we shall behold his "Series of Designs" in a published form; for it certainly would prove a most excellent companion work to those by Joseph Nash, and would be far more generally useful, inasmuch as the subjects would be designed with express reference to what is required for or capable of being introduced into modern rooms, and in spaces of less extravagant amplitude than ancient baronial halls.

The only other interior of a room—properly so called, is No. 1160, the "Library of the Parthenon Clubhouse," in Regent Street, one of the two mansions built by Nash for his own residence and that of his brother-in-law Mr. Edwards. Never has Mr. Beazley satisfied us so well as in this interior, which although of no great size as a room—in fact a narrow and not very long gallery, is unusually scenic in its architectural character. It consists of three divisions or compartments covered by as many domes and their pendentives, which constitute the chief architectural decoration, the walls being nearly covered by book cases, on which are placed busts. Each of the end compartments is lighted by a *lunette* or semicircular window over the book-cases on the left hand side; but the centre one is enlarged by a bay window on that side, which gives greater space to the room, and variety to the design. We speak doubtingly, but we suppose that this Library is not an entirely new addition to the house, but a remodelling of the small gallery shown in the plan of it in the "Illustrations of the Public Buildings of London."—This design is not only more than ordinarily interesting as a subject, but also as being suggestive of further ideas, and as affording an agreeable "episode of plan."

(To be continued.)

MR. J. TOWNSEND'S LECTURE ON THE FINE ARTS.

SEVERAL of the Greenwich and Kent papers have spoken in terms of very high admiration of this Lecture, which was delivered at the Greenwich Literary Institution, on the evening of May 1st.; and in so doing some of them have indulged in sharply satirical remarks—not it would seem without reason—on the want of taste and also of good feeling shown by the people of Greenwich, who instead of encouraging talent in a fellow townsman, left him to address almost empty benches. This is all the more extraordinary, because the room would have been very decently filled, had there been but a tolerably fair attendance on the part of the members belonging to the Institution. But after what fashion it is that they bestir themselves in promoting intellectual taste either in regard to literature or to Art, is now pretty manifest. It will be lucky for them should not the very pointed and caustic remarks of some of the newspaper editors obtain for the people of Greenwich, the title of the Kentish '*Bœotians*.'

By the few who were present the lecture was exceedingly well received, for it abounded in original and striking observations, and in highly eloquent passages, which drew forth frequent applause. This will hardly be questioned after perusing the following extracts from it, which appeared in the "Kentish Mercury" of May 4th, and we think that our own readers will thank us for affording them the opportunity of judging for themselves of the Lecturer's style, and mode of handling his subject.

"*Influence of Forms of Government on the Fine Arts.*

"It is the same with regard to that other knotty question—how far the Fine Arts are influenced by forms of government;—whether they thrive better in republics or in monarchies,—whether the spirit of liberty, or that of despotism invigorates them most,—whether they themselves tend to encourage and keep alive the spirit of either the one or the other; or whether forms of government have nothing to do with the matter.

"Those who take the side of republics, and also lay stress upon the influence of climate, will of course, triumphantly refer us to Athens as affording most incontestible evidence in confirmation of their doctrine. But then the instance of another Grecian republic upsets it all again; for wherefore did not the Lacedemonians distinguish themselves in literature and art just as much as the Athenians? They were republicans, they were Greeks, and as far as climate is concerned, were placed in a more southern latitude. Their temperament and disposition, their manners and institutions, indeed, were different, therefore we may well account for the other difference, but this last also shows that republican form of government—for such was virtually that of the Spartans and Lacedemonians—has very little to do with the matter.

"Louis XIV has shown the world how much may be achieved by royal despotic will, and how very *little* that much is. He affected the fame of a second Pericles—or rather that of being Pericles, Augustus, Leo, all in one; and as the world is not over vigorous in examining into similar pretensions, he for a time, obtained it. Pericles and Louis Quatorze!—certainly they resemble each other just as much as do the Parthenon and Versailles.

"Taken under the auspices of Louis, art was compelled to attire itself in a court-dress, and the muses to wear hoop petticoats. It was also expected from art that it should pay in kind for the patronage so bountifully and graciously bestowed upon it. It was hospitably received as a guest, on condition of its playing the part of a parasite also, and celebrating *a l'outrance*, the bountiful *mu*nificence and the boundless *mag*nificence of the Grand Monarque.

"*The Church and the Fine Arts.*

"As the Church of Rome increased in wealth and power, she added pomp to pomp, and splendour to splendour, superstition to superstition, till it seemed as if she wished to absorb within herself all the pomps and all the vanities, and all the allurements, and all the illusions of mundane power. Art was honoured,—religion sensualized; the one was enrobed as a priest,—the other decked like a harlot.

"No wonder therefore that on separating and withdrawing their allegiance from the Church of Rome, and rejecting its traditions and superstitions, the first Reformers—at least their followers, rejected its ceremonies and its pageantries, as mummeries worse than unmeaning; or that the work of destruction began afresh. The grievous havoc then committed either by spoliation or wanton defacement, has been a theme of bitter complaint with antiquaries and artists; but if it displayed it too indiscrimately, popular indignation was not altogether unjustifiable.

"From that period, art has been greatly circumscribed in Protestant countries, and expelled from that ministry in the temple, which it held both in Pagan and Christian times, consequently put upon quite a different footing. Having no occasion for the services of art,—except it be that of architecture, the Protestant church has no employment for, consequently no patronage to bestow on it. This has been deplored—even bewailed; and not without reason—that is, supposing the interests of art are to be held paramount to all other considerations. But with the example of what sort of services it has rendered to religion, in the case of the Roman Catholic Church, before our eyes, there is some reason for being suspicious of it. Were it admitted into the Protestant Church, it would, no doubt, be sufficiently discreet and unassuming at first; but then, for how long? probably no longer than it had established itself upon such a firm footing that it might bid defiance to those who should endeavour to turn it out again. In such case you have to deal with a servant that will not take warning to leave; you may discharge him, but there is no other way of getting rid of him than by fairly kicking him out of doors, and thereby causing a hubbub.

"In fact, so far from being rendered more solemn and impressive as religious edifices, and devotional in character, many churches in Italy and other Catholic countries, look more like picture galleries and museums of art, and are visited merely as such by strangers. Instead of asking why we do not admit painting into our own churches, the more proper question, perhaps, would be, why do we not exclude sculpture also? Since of the greater part of it as there found, the most that can be said in its favour, is, that there is no danger of its encouraging superstition.

"Many and strong are the remarks which have of late been made upon the public monuments in Westminster Abbey, and St. Paul's, and it must be admitted that while they are but little creditable to us as productions of art, considered as which they are many of them both puerile and bombastic, little better than mere stone-carver's jobs, they are the reverse of Christian in their ideas. They are for the most part, *Paganism* without its poetry,—are made up of frigid and school-boy conceits, where *link-boy genii* figure with their inverted torches among Britannias and lions, which last are sufficiently numerous to stock a menagerie.

"Should it be asked—'what then is to be done? how is sculpture of that kind to be so christianized as to be completely purified from all taint of Paganism?' I must confess that I am not prepared with an answer; neither I believe is any one else. Therefore another question arises, namely, are we justified in persisting to make use of what we acknowledge to be both improper and unsatisfactory, merely because we know not how to render it otherwise? Sculpture is all too corporeal for Christian art and for the expression of Christian ideas; beauty of form is its element; of mental emotion, of spiritual feeling, it scarcely admits any strong expression, without falling into caricature, and theatrical gesticulation.

"Even were such monuments perfectly satisfactory in themselves, both as works of art, and as intelligent and expressive memorials of those to whom they are erected, they would still be objectionable on the score of propriety.

"Great would be the outcry, were it now for the first proposed to place within the walls of a sacred edifice—within the house of prayer and Christian devotion, triumphal effigies—as they may well be called—of our fellow mortals, not of martyrs for the faith,—not of men who have been a guide to others, in the holiness of their lives, and their earnestness in the cause of truth and religion; but of men who have signalized themselves far differently, who have, indeed, proved their claims to earthly laurels and earthly renown, but to no more. Were this, I repeat, now first proposed to be done, great would be the indignation excited: we should be told of the shocking desecration—even profaneness. Although Rome deified its emperors, even heathens did not place statues of their distinguished men within the fanes consecrated to their deities. Custom, however, reconciles us, hardens us to what we should else consider glaring and indefensible improprieties; so much so that the refusal to permit the statue of Byron, by Thorwaldsen, to be put up in Westminster Abbey, has been stigmatized by some as an act of ungenerous bigotry. Yet there to have placed the author of 'Don Juan,' would have been viewed by others as a gross indecency.

"Even the statue of Watt, the *author* of the steam-engine, is not particularly edifying, although characteristic enough of the steam-engine, Mammon-worshipping times in which we live, and in which *steam* obtains far more of our cordial *esteem* than falls to the share of art. No! let us testify our grateful veneration for valour, for heroism, for genius, for intellect; for noble achievements in arms or acts—in the senate or in the field! but while we honour them, let us not dishonour the temples of our faith; let us not, within their sacred walls, be reminded and surrounded by trophies of worldly ambitions—of mundane triumphs and mundane glories, which thereby look only all the more abject and pitiful. No, as there is a time, so, also, is there a place for all things; and a Protestant church is assuredly not the most suitable place to be made an exhibition room for works of art, or even a pantheon of 'British worthies.'

"It becomes a question then, whether it be not more advisable rather to expel sculpture, than to admit painting. It is surely no reproach to Protestantism, that its service needs no such material aids to devotion; that it scorns to entice by amusing the fancy, and addressing itself to the imagination. For a religion of external forms, ceremonies and pageants, of devotiona etiquette and representation, art indeed does much, if only because it is in keeping with, and contributes towards enhancing that sort of spectacle and pomp which is affected in all besides.

"But what need of art, or what can art do for a church constituted like our own, whose solemnities are not intended to impress the outward senses? Otherwise than for monuments—and how objectionable and incongruous they for the most part are, has just been pointed out. Sculpture is almost entirely out of the question; more especially if it aims at being classical, for in proportion as it is antique in gusto, so it is likely to be found Pagan in character and in spirit.

"How, again, is painting to employ itself in our churches, if debarred from all those subjects and representations which Protestantism rejects as superstitious or profane? It does not tolerate portraits—of course imaginary ones—of patriarchs and saints, apostles and martyrs; much less would it tolerate the embodying of the Trinity as indulged in by Catholic artists—even at the present day; and the many other representations which are at once shocking and absurd—under human forms.

"Protestant artists are interdicted—and justly so—from venturing upon purely celestial subjects and scenes; they may not attempt to scale and scan the heaven of heavens—obtruding upon us their own puny phantasies, as distinct revelations, of what eye hath never beheld, and which it passeth mortal intelligence to adumbrate ever so faintly in idea alone.

'But fools rush in, where angels fear to tread.'

"'Last judgments'—'assumptions'—celestial visions—saints sprawling upon clouds, or hovering overhead like balloons—are all interdicted us. Scenes of martyrdom would be objected to as by far too disgusting to be suitable subjects for the pencil at all;—nor have we that almost inexhaustible stock of legendary traditions which Catholic painters have availed themselves of, so largely. Consequently nothing remains for Protestant artists to work up but subjects from scriptural history, and no nobler—no higher walk of art, it will be said, can possibly be desired: with the dignity of history it unites the sublime of religious sentiment. Very true, such is—or rather ought to be the case; but let us for a moment look at the matter as it really stands: now, so far from being what its name implies, historical painting is entirely fiction, without the slightest pretence to literal truth, being worked out by imagination upon no substratum than a bare recorded fact. Be they conceived ever so powerfully,—treated ever so ably, still the images on the canvass are only those of the artist's own imagination. The representation is only a poetic guess—a probability;—therefore, although as a work of art it may be admirable—even ot surpassing worth, its artistic excellence and the vigour of imagination, it may happen to display, do not entitle a work of the kind to be received into the service of the church. At least, if the inspirations of genius, and poetic imaginings are to be admitted in one shape, why not also in another—and that a less material—more spiritualized one? Or would it be too daring—too profane an intrusion were the muse of Milton permitted to enter also? most certainly it would be so considered; yet Milton brought quite as much of pure religious inspiration to his solemn subject as ever did the greatest genius in painting.

"In general, the world looks for some degree of consistency between the character of a man and his productions: it has no great esteem for those who can skip not only 'from grave to gay,' but from the religious to profane, and back again from the profane and sensual to the devout, just as the immediate occasion may demand:

> "'Now deep in Taylor, and the book of Martyrs,
> Now drinking citron with his Grace and Chartres.'

Nevertheless, the utmost latitude in this respect seems to be granted to artists: they are permitted to be alternately Christian and Pagan; to take their subjects from the Bible, and from Ovid the next;—Magdalens or Ledas, Crucifixions or Carnivals,—Bacchanal revels, or the Sacraments of Church,—all are pretty much alike to them, for many of the great masters have displaying equal ability in the two extremes of their art, and perhaps have been quite as sincere in the one as in the other. Hence the operations of art are generally considered to be those of the hand rather than of the mind, at any rate to be influenced by the head, rather than the heart; nor can it be denied that such is to a great extent the case. And this is one tolerably sufficient reason wherefore painting and sculpture should not be allowed to assume in any degree the office of teachers, instructors, and interpreters, in matters religious and spiritual,—intruding themselves into the sanctuary, under such character. If the library—not the church, be the more suitable place for sacred poetry, so also is the picture gallery, for paintings from scriptural subjects. The case might be materially different, were there artists who devoted themselves entirely and exclusively to the service of the church, from motives of piety, and out of sincere religious feeling, conscious that they had a high mission and most responsible office to discharge. During the middle ages of Christian art—before the so-called revival of the arts, such was partly the case. In the productions of that earlier period there was, indeed, of real art too little, of superstition too much, but there was also the spirit of Religious Sentiment. After the Revival, there was far less of this last, art became more perfect, more tasteful, more refined, but also more sensual, more worldly. Protestantism, therefore, acts discreetly in excluding painting from its religious edifices.

"There is, however, one particular species of painting which it still tolerates, and which is just now receiving great encouragement, notwithstanding that it seems to be in some respects quite opposed to Protestant sentiments, inasmuch as it partakes somewhat largely of the *Iconology*, or Image-worship of the Romish church. Having said this, I hardly need explain, perhaps, that I allude to glass-painting and its stained windows; presenting a gorgeous display of Saints and Martyrs, many of them blazing in the most vivid colours. The inconsistency of thus admitting in one shape what we altogether refuse in another, is if not quite removed, at all events much diminished, when we take into consideration the great difference of character between that and other modes of painting, and the widely different manner in which it is employed. Glass painting makes very little pretensions to being an imitative art; rather is it a mere emblematic one and altogether conventional and decorative, for painted windows are to be looked at not as pictures, but as a portion of the general architectonic ornamentation of the edifice. The subject contained in them may have little or no meaning, or if any, it may utterly escape attention, such painting being almost entirely hieroglyphical. The details—the individual figures are unregarded: it is the general effect—the 'glorious confusion' of colours, which sheds an atmosphere of transfigurated light through the whole building, completely filling it, as it were, with an incense of all hues mingling together into solemn radiance—that captivates and charms, and certainly tends to heighten devotional feeling. Such at least is the poetical view of the matter; but it has also another, and, it must be confessed, a very prosaic aspect; because although when looked at through 'antiquarian barnacles,' the figures in ancient stained glass may be admired as so many specimens of art native and undefiled, ordinary optics are apt to discern in the majority of them, more of the grotesque and the ludicrous than is altogether seemly;—to fancy that they bear in regard to drawing a singular resemblance to those in China tea-cups and saucers; besides at the same time a most unlucky likeness to the personages depicted on Court cards—their Majesties of Clubs and Hearts, Diamonds and Spades!

"That Protestantism is decidedly unfavourable to art—that is, in immediate alliance with religion—is not to be denied; but then it must on the other hand, be admitted that art has seldom shown itself worthy of being admitted to such alliance. If superstition be religion, if childish fancies—often most shockingly profane were intended to be most pious, are to be received as worthily expressing the mysteries of our faith, then indeed, the services of art have been both great and many in the cause of the church, but even so not of our church; at least quite unintentionally as regards the latter—only as it helped to build up that accumulated mass of superstitions which eventually led to the Reformation."

We know not whether Mr. Townsend intends to make another trial in some less *Bœotian* place than Greenwich; but whether he do so or not, we hope that he will eventually give this Lecture to the world, in a permanent form, by publishing it as a literary composition.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTE OF CIVIL ENGINEERS.

SCREW PROPELLERS.

"*Account of some experiments on a vessel called the 'Liverpool Screw, fitted with Grantham's engines and Woodcroft's screw propeller.*" *From the Minutes of Proceedings of Institution of Civil Engineers, Feb.* 13, 20, *and* 27, 1844. *With Eagravings, Figs.* 1 *to* 10, *Plate VII.*

The *Liverpool Screw*, upon which the experiments, described in this paper, were tried, is a small iron vessel 65 ft. long by 12 ft. 6 in. beam, and 3 ft. 9 in. draught of water. She is propelled by two high pressure oscillating engines, with cylinders of 13 in. diameter and 18 in. length of stroke. The steam, which varies from 56 lb. to 60 lb. pressure in the boiler, is admitted to the piston for one-fourth the length of the stroke, the remainder working by expansion. The nominal power was 20 horses, but the effective power rarely exceeded $18\frac{1}{2}$ horses. The cylinders are placed diagonally, at right angles to each other, and work to one crank upon the main driving shaft, which runs direct to the propeller without gearing or bands. The propeller, which makes 95 revolutions per minute, is on Woodcroft's plan, with a pitch expanding from 10 to 11 ft.; after being enlarged at three several times, from 3 ft 10 in. diameter, it is now 5 ft. 4 in. diameter by 20 in. long; it is of wrought iron, and consists of four short arms, whose united area is equal to 16 square feet; of this, only about 13 ft. are immersed, a portion of the upper side being constantly above the water: the angle of the centre of the floats is 45°, and about 40° at the periphery. The author then gives the details of a number of experiments, and he states that, although the proportions of the vessel were not favourable for speed, her length being only five times the beam, and the sectional displacement 28 ft., the speed was greater than that of all the steamers on the Mersey, except the large sea going steam vessels. That the "slip" of the propeller, when tried by Massey's log, was less than five per cent. That the action of the screw across the way of the vessel, did not appear to affect the steering, or have the slightest tendency to turn the head of the vessel.

The author is of opinion, that engineers in general, fearing a loss might take place from lateral action, with a long pitch, and that the steering would be affected if the propeller was not immersed, have made the propellers too small, and that the short pitch, which had rendered a high velocity necessary, was detrimental. Several satisfactory experiments, in towing vessels, are also mentioned, and it is stated that in a heavy sea, the superiority of the screw propeller was very visible. The dimensions are then given for vessels of war and of commerce, working with screw propellers, driven direct by oscillating engines, which the author anticipates would prove much more serviceable and sea worthy, than any of the paddle wheel steamers now in use.

The paper is illustrated by a diagram of the propeller of the *Liverpool Screw*, and by plans of the machinery and general arrangements of the proposed frigate and large steamers.

Remarks.—Mr. Rennie observed, that the Institution was much indebted to Mr. Grantham, for bringing forward the subject of screw-propellers; the more particularly as it had now become of national importance, and that every attempt at perfecting the sub-marine propeller merited encouragement. It was difficult, correctly to assign the merit of the first invention of this species

of propeller, as it had been tried at various periods, and with as varied results, on the Continent, in the United States of America, and in this country;[1] but it appeared certain that Mr. Samuel Brown, the inventor of the gas vacuum engine, was among the first who applied the sub-marine propeller with any practical effect. The propeller used by him was on the principle of a regular screw, and consisted of two blades, which were affixed at an angle of 45° to a horizontal shaft, which was placed in the bow of the vessel, and he believed that it had also been used in the stern. This propeller was driven by a gas vacuum engine, of the nominal power of 12 horses, and actually caused a vessel of 60 feet in length, to move at the rate of six or seven miles per hour. M. Sauvage of Boulogne-sur-Mer, had also made several attempts at propelling vessels by the same means, and it was very gratifying to find that his services had recently been acknowledged and rewarded by the King of the French. It was, however, Mr. F. P. Smith who first rendered the screw propeller practically useful; for his perseverance, being aided by spirited capitalists, induced the building of the *Archimedes* steamer, the machinery of which was constructed by Messrs. G. and J. Rennie, in the year 1839. The results obtained from that vessel were well known, and caused the subsequent construction of the *Princess Royal*, the *Great Northern*, H. M. S. V. the *Bee*, the *Rattler*, and the *Dwarf*, formerly the *Mermaid*, a model of which was exhibited, with the various forms of screws used in the different experiments. The *Great Britain* not having yet been to sea could only be mentioned as a projected experiment. Figs. 1 and 2, Plate VII. are drawings of Mr. Smith's Double Threaded Screw adopted in the "Archimedes."

The *Dwarf* was 130 feet in length, 16 feet 6 inches in breadth, 9 feet deep, and was 164 tons burthen. The power of the engines was 90 horses, making from 30 to 32 strokes per minute. Friction wheels without teeth were first tried for giving motion to the propeller; but on account of their slipping and being very noisy, they were abandoned, and two spur mortice-wheels with wooden teeth, working into iron pinions, were substituted; the speed thus attained was from 150 to 160 revolutions per minute. The propeller was of cast iron, and was moulded in loam without a model, by means of iron templates cut to the required curve, which was formed from a solid cone revolving on its axis, during the perpendicular descent of a tracer. The advantage of this form over the cylindrical screw, was an increasing pitch, so formed, that while the propeller was rotating on its axis, the vessel was advancing and thus producing the least possible amount of "slip." This was exemplified by the form of the various models on the table. The principle point to be obtained in a screw propeller, was a form which should offer but little obstruction to the water, and yet act upon it so as to exert full power in propulsion; a large portion of a complete screw having no useful effect had induced the introduction of propellers with several blades; thus doing away with the useless part of the surface. A great portion of the centre part of the screw of the *Archimedes* had been cut away, but the effect had not been so good, on account of the arms of the screw obstructing the free passage of the water; the propellers with three arms were, he believed, preferred to those with a larger number. The *Dwarf's* propeller consisted of three curved blades, fromed on the conoidal principle, by variable curves approximating to angles of from 27° to 30°, and advancing at the rate of 7 feet 6 inches per revolution. It was 5 feet 10 inches in diameter, by 2 feet deep in the direction of its axis, and the area was about 15 square feet, which was nearly one-fourth of the area of the midship section of the vessel at light draught; but since the *Dwarf* had been transferred to H. M. service, the mean draught had been increased one foot, and the area of the midship section in proportion; her speed had in consequence been reduced from 12 to 11 statute miles per hour. Figs. 3 and 4, Plate VII. are drawings of Mr. Rennie's Conoidal Screw Propeller.

The following were the results of the trials made by Captain Sir Edward Parry, Mr. Lloyd, and Mr. Murray, at the measured mile in Long Reach on the 15th May, 1843:—

				Stat. Miles.	Mean.
1st	Experiment	against tide	..	9·890	12·145
2nd	ditto	with tide	..	14·400	
3rd	ditto	against tide	..	9·756	12·078
4th	ditto	with tide	..	14·400	
5th	ditto	against tide	..	9·890	12·203
6th	ditto	with tide	..	14·516	
	General Average		.. ..		12·142 Stat. Miles per hour.

The draught of water was 5 feet 8 inches.

The *Dwarf*, under the command of Lieutenant Nicholls, left Greenhithe in company with the *Hecate*, Captain Bower, on the 14th January, 1844, and reached Portsmouth on the following day; on the 20th she left Portsmouth accompanied by the *Hecate*, and although it was necessary to reduce the speed of the engines to 26 revolutions, in order to keep with her consort during the night, they reached Falmouth on the 21st, after an additional run towards the Scilly Islands, making a distance of 200 miles in 23 hours, having burned 10 tons of coals in 27 hours, from the time of getting the steam up. The two steamers left Falmouth on the 23rd, and reached Bear Haven on the following day, having run 135½ knots, or 156 miles by the log, in rough weather in 12 hours, and with bad coal; the engines making from 28 to 29½ revolutions per minute. She anchored during the night at Bear Haven, and on the following day, (the 26th,) reached Tarbert, the total distance from Falmouth being upwards of 400 miles.

Mr. Galloway said, that it was extremely difficult, if not impracticable, to arrive at the true amount of the "slip" of the propeller, because from its position abaft, or in what is termed the deadwood of the vessel, it acted in a current which was continually flowing to fill up the cavity, which would otherwise be formed by her progress through the water. The relative motion of a stream through the arches of a bridge, and in the wake of its piers, was an apt illustration of what unquestionably took place, (and from the same law,) in the case of a moving vessel. The screw, therefore, when acting in this current, might be compared to what would occur, if a paddle-wheel steamer was supposed to be moving in still water, while the floats acted in side canals, which flowed in the same direction as the vessel. Whether the benefits derived from this following current giving resistance to the screw, were not counteracted, by the deduction of so much of what is termed minus pressure from the ship itself, was not at present under consideration. His object was to show, that an accurate estimate of the amount of "slip" of a screw, could not be arrived at, until the rate of the following current, was first ascertained. That the "slip" must be much greater than Mr. Grantham assumed, would, he thought, be admitted, both from the circumstance he had stated, and from the fact that screw propellers, when worked with the vessels at their moorings, invariably moved at a ratio at least equal to one-half the speed obtained when running. It was clear, therefore, that the "slip," which was dependent on the proportion of the resistance of the screw, compared to that of the vessel, must always exist in a degree; but that, it might in the screw, be reduced below that of the paddle-wheel, was evident, because in the best modifications of wheels, or where the immersed segment was small, the paddle must turn in the water, in effecting a change of position from its angle of entrance to that of its emersion, and this unavoidable angular action, even when the upper edge of the float coincided with the rolling circle, was still so much "slip" inevitably encountered; this "slip" too became very considerable when the vessel was in a sea-way; but the "slip" of the screw decreased with its magnitude, and in the like proportion, its action approached that of a screw moving in a solid. It appeared, therefore, to him, that if the "slip" was small, the spiral or increasing pitch, would be a disadvantage, because a true screw would under those circumstances create little or no disturbance; while the spiral in that case, would have the contrary effect, for the same reason that a helix would pass with facility through a solid, in which a spiral or untrue thread would become fixed, or would move with difficulty. In the absence of all "slip," or in so small a slip as Mr. Grantham assumed to have taken place in his experiments, the effect of a propeller with an expanding pitch, would be like that of a curved plate, moving through the water in a right line; while the true helix would have acted like a flat plate moving in the direction of its own plane; that is to say, the opposing forces would merely consist of edge resistance and surface friction, which were common to every kind of propeller. The advantage too, which was assumed to arise from this spiral propeller, merely affected the question of magnitude, for it was clear that, whether the screw acted upon a large body of water at once, or gave a second impulse to a lesser quantity, the result would be similar, as to the sum of the effect upon the vessel. It was true that in certain kinds of fish (he would instance the electrical eel), the impulse produced by the ventral fin, was by an increasing spiral, the length of the curves becoming greater towards the tail; yet it appeared probable, as we could only see this eel in confinement, that the peculiarity he alluded to, was only developed in producing a change from rest to motion, for which it was well adapted (because the "slip" was great and the progress small,) and that when in rapid motion, it was probable, that the fin acted in a true spiral.

Mr. Rennie stated that the "slip" of the screw of the *Dwarf* was from $\frac{1}{8}$th to $\frac{1}{9}$th. That with respect to the general question of ths "slip," he conceived that it depended upon the comparative resistance between the vessel and the propeller. The case was similar to the immersed plane surfaces of the paddle-wheels of a steamer and of the vessel itself; the resistance of the midship section was reduced by the forms given to the fore and after bodies, which gave the vessel what might be termed more "mobility." According to the experiments of Mr. Peter W. Barlow, read before the Royal Society, May 29th, 1834,[3] the "mobility" of several of Her Majesty's steamers was found to vary from $\frac{1}{15}$th or $\frac{1}{24}$th of a plane surface, equivalent to the area of the midship sections; or in other words a plane float

[1] The dates of the experimenta on screw propellers are nearly in the following order:—

Baron Seguier	1792	Cummerow	1828
Fulton	1796[2]	Sauvage	1832
Shorter	1802	Woodcroft	1832
Trevithick	1815	Ericson	1836
Milliogton	1816	Smith	1836
Lowe	1817	Lowe	1838
Whytock	1819	Huot	1839
Perkins	1824	Rennie	1839
Brown	1825	Blaxland	1840
Woodcroft	1826	Carpenter	1841

[2] In a letter to Dr. Cartwright, dated Parls, February 16, 1798, Fulton says, "I have just proved an experiment on moving boats, with a fly of four parta, similar to that of a amoke-jack, and I find this apply the power to great advantage, and it is extremely aimple."

[3] "An Investigation of the Laws which govern the motion of Steam Vessels, deduced from Experiments, by Peter W. Barlow, C.E." Phil. Trans., 1834, p. 309.

of 1 foot square was equivalent to the midship section of the vessel, of which the mobilities were from $\frac{1}{15}$th to $\frac{1}{24}$th. There could be no doubt, that the improvements in the forms of the modern vessels, would have produced even less resistance, and he believed that it might now be taken at from $\frac{1}{30}$th to $\frac{1}{40}$th, so that consequently a less area of float or propeller, would suffice to overcome the equilibrium and produce less "slip."

Mr. Smith, of Deanston, observed, that the screw with three blades, which had been used in the *Dwarf*, seemed calculated to produce the best effect. The opening towards the centre of motion, by reducing the arms of the screw blades, as far as the requisite strength would allow, was judicious, as from the comparative slowness of the rotative motion towards the centre, little propulsive effect was produced; whereas the resistance to onward motion, by the arms, if they had not been reduced, might have been considerable; besides, if the arms were in the part broad, there would have been greater tendency to produce centrifugal action on the water. The gradual alteration of the angle of the blade, to the axis of the screw or onward path of the vessel, was also judicious, as it afforded a greater onward action of the blade at the entrance, whilst it gradually curved round to nearly a right angle with the path, so as to leave the water without causing any revulsion; it had thus an action in some respects similar to that of the tail of a fish. The salmon, when it "made a run," put down all its side fins, and solely by the oblique action of the tail, was propelled forward with great force and speed, to which the flexibility and form of the tail, and more especially its curving form to accommodate its leaving the water without causing revulsion, principally contributed. Some years ago, Mr. Smith had made experiments with fans for blowing air, and so far as he could recollect, the form of greatest effect, much resembled in principle, that of the propeller under consideration.

Mr. Farey said, that in order to continue the series given by Mr. Rennie, of steam vessels, which had been recently constructed with screw (or rather oblique-acting) propellers revolving under water, it would be desirable that the meeting should have the particulars of a vessel called the *Napoléon*, which had been built at Havre by M. Norman, and fitted with engines and machinery constructed in this country by Mr. Barnes. Whilst at Havre last summer, Mr. Farey had very minutely examined that vessel, and he considered it equal to anything that had yet been executed of the kind, and a fair specimen of the perfection to which that mode of propelling, had (up to the present time) been brought for sea-going vessels. Mr. Barnes and M. Norman were well known in their respective departments, aud they had been accustomed to co-operate during some years past. The engines which had been made and sent by Mr. Barnes to France, and fitted in vessels constructed by M. Norman had, in most cases, paddle-wheels, with moveable or mechanical paddles, on the plan introduced by M. Cavé, which possessed a decided advantage over ordinary paddle-wheels: the loss of power occasioned by the paddles entering and leaving the water too obliquely, being much diminished. In comparing the performance of the *Napoléon*, with vessels fitted with those mechanical paddles, there was less effect produced by the oblique acting submersed propeller, when considered merely as a mode of employing a given amount of power, to propel a given vessel through the water in a calm; but if the same power, as the engines of the *Napoléon*, had been applied with mechanical paddle wheels at the sides of the vessel, (such as Mr. Barnes had been accustomed to construct,) the vessel would have had more speed in calm weather and smooth water, than had been attained by one revolving propeller, with oblique acting blades, applied under water at the stern; and it was possible that a greater amount of speed might have been attained, even with well-proportioned common paddle wheels. Nevertheless, the submersed propeller at the stern, admitted of the use of sails, in concert with steam power, or in lieu of it (when the wind was strong, and in a tolerably favourable direction) with much greater advantage than could be done in steam vessels, with the ordinary or even mechanical paddle wheels, although the latter were well adapted for acting in concert with sails, because they would perform well, when the paddles were either deeply, or slightly immersed. The proper and most advantageous action of ordinary paddle-wheels was very greatly impaired, by variations of immersion; the mechanical paddles (when properly proportioned) were less influenced, and the submersed propeller still less; in fact, being wholly under water, at all times, its action did not appear to be sensibly affected by any such alterations of the depth of its immersion, as were likely to take place in the roughest waves, or the greatest variations of draught. When all circumstances were considered, it might be safely concluded, that vessels fitted with revolving submersed propellers, would answer well for making regular sea voyages, either in winter or summer; and on an average, he thought, that their passage would be performed at least as well (if not better) than those of any steam vessels now in use, and with an economy of fuel, arising from such vessels making a more advantageous use of their sails, and less use of their engine power.

M. Norman, in reply to questions from Mr. Rennie, regretted that his slight knowledge of the English language, not only precluded him from fully comprehending the narrative of the paper, and the statements of the several speakers, but also rendered it obligatory that he should communicate to the meeting in French, the few remarks which he could not withhold, after the pressing notice of the chairman. Many experiments had been made in France, with screw propellers by numerous inventors, as far back as the latter part of the 18th century, and by M. Cavé and others at recent periods, but the most extensive experiment was that of the *Napoléon*, for which Mr. Barnes had constructed the steam engines and machinery in England, and which he might be allowed to say had given complete satisfaction. The *Napoléon* was built at Havre, and launched at the latter end of 1842, for the service of the French Government Post Office in the Mediterranean. The vessel was built of oak timber, copper fastened and coppered. Its dimensions were as under:—

	Metres.		English. feet.	in.
Length of vessel from stem to stern . .	47·5	=	155	8
Ditto at the surface of the water . .	45·2	=	148	6
Extreme breadth	8·5	=	27	8
Ditto ditto at the surface of the water .	8·32	=	27	4
Draught of water when light loaded, abaft .	3·6	=	11	10
Ditto ditto forward .	2·26	=	7	5
	Sq. metres.		Sq. ft.	
Area of the midship section, at the above draught of water	13·4	=	144	
Ditto of the surface in contact with the water, occasioning friction	401	=	4320	

The revolving propeller, was fixed in a space or opening abaft the usual stern-post, (to which, in an ordinary vessel, the rudder would be hung,) and withinside another stern-post, which was erected on a prolongation of the keel, farther aft, for sustaining the rudder, so as to leave a space between the two posts, for the reception of the propeller. The centre of the propeller was (1·82 metre=) 6 feet beneath the surface of the water; its diameter was (2·28 metres=) 7 feet 6 inches, and the highest point of its periphery was 2 feet 3 inches below the water line, when the mean draught of water aft was about 11·82 feet. Four propellers of the same diameter, but of different forms, were made, in cast iron, under the direction of Mr. Barnes, and were tried with various success during the past year. The propellers had been altered several times, and it was found that within certain limits, by cutting away the ends so as to shorten the length of the screw, (which had also the effect of diminishing the surfaces of the blades,) the speed of the vessel was increased, and the vibration was reduced; a portion of this effect had however been attributed to using four arms. A propeller with three blades, occupying the whole of the circle, was first tried; others which presented less central surface answered better, and the best, which was still in use, had four blades, which occupied $\frac{6}{10}$ths. of the area of the circle, when viewed in the direction of the axis, leaving $\frac{4}{10}$ths. of that area vacant, for the free escape of the water between the blades, whose obliquity was such as to produce an advance of (3·12 metres=) 10 feet 3 inches in a revolution. The steam engines were nominally of the power of 65 horses each,=130 horses together: their cylinders were 45 inches in diameter, their pistons making usually from 27 to 28 double strokes of 3 feet 6 inches in length per minute. The motion was communicated to the propeller by a spur wheel of 126 teeth, working into a pinion of 29 teeth, which gave nearly $4\frac{1}{3}$ revolutions for each stroke of the engine, or about 120 revolutions of the propeller per minute. The ordinary speed of the vessel, without any sails being used, was 10 knots or $11\frac{1}{2}$ statute miles per hour. She had three masts of considerable height, the rigging being that of a brig forward and that of a schooner at the main and mizen masts, with as great an extent of canvass as would be used in any sailing yacht. When the wind was favourable and the sails could be used, the speed increased to 11 or 12 knots per hour. After a series of experimental voyages, the vessel had gone to her station in the Mediterranean, where she was now in constant service, and had gone through some rough weather with great success; her motion was described as being remakably easy, she rolled very little, steered better than ordinary vessels, for the propeller appeared to give increased effect to the rudder, and the propeller had never been observed to show itself above the water even in the heaviest seas, when the pitching was at its maximum. Plate VII. Figs. 5 and 6, are drawings of the *Napoléon* Screw Propeller.

Mr. Galloway remarked, that the properties of a screw with an increasing pitch, had been slightly investigated by Tredgold, in his work on the Steam Engine, p. 310, so early as 1827. The author had briefly referred to the subject of screw propellers, and had given some logarithmic calculations of their properties, from which he drew the conclusion, that the true screw could not be carried beyond a single convolution, with any good effect; whereas by a progressive increase of the pitch, the propelling effort would be continued, until the spiral became expanded into a straight blade parallel to the axis. It was Mr. Galloway's opinion, that more was to be expected from ascertaining the best position for placing the screw, with reference to convenience and effect, than from any slight change in the form or the number of the blades of propellers.

Mr. Samuda said it appeared to him, that the action of the propeller tended to drive the water from it at a right angle with its surface, and as it formed a diagonal line with the keel of the vessel, some portion of the force was not efficiently used for propulsion; he conceived therefore that by a judicious arrangement of shrouding, round the extreme circumference of the propeller, the diagonal currents of the water, might be diverted into a direction parallel with the way of the vessel, and thus cause the whole of the reaction to become available for propelling. Such an arrangement would enable propellers of a much coarser pitch to be employed, and their speed being reduced in proportion, they could be more readily driven directly by the engine, without the intervention of bands or gearing.

M. Norman said, that M. Cavé had tried a series of experiments on screws of various forms working in cylinders; and also, he believed, with shrouding on their extremities, and he understood that no advantage had been found to result from such modifications.

Mr. Cowper presented an instrument, which he had exhibited when the aerial machine was incidentally mentioned; it consisted of a fan composed of three or more blades, set at a regular curve upon an axis. When this axis was placed vertically in a socket, and a rapid rotary action communicated to it, the fan rose in the air to the height of between 100 and 150 feet. On reversing this fan and using the same propelling force, it would not rise at all. This fact evidently showed that the action of the curved fan upon the air, or of the propeller upon the water, was like that of a screw in a solid, every part of the surface of the blade of a well-formed propeller producing its portion of effect. Mr. Cowper directed attention to the contrary effect produced by two fans of similar areas, whose arms were, in the one case, mere planes set at an angle with the axis, and in the other, blades forming part of, and being placed at a given curve around the axis. If it were supposed, that the surface of each blade was divided into a given number of equal parts, when the fan, of the former or angular shape, was set in motion, the first part impinging on the air, communicated a movement to it, and the second and succeeding parts finding no resistance from the disturbed fluid, the body had no tendency to rise; but in the latter, or curved shape, the second and succeeding parts, tended to overtake and act upon an undisturbed fluid, and thus had a tendency to rise upon an irregular inclined plane, described by its gyration through the air. By the law that the resistance increased as the square of the velocity, he conceived, that in adapting propellers to vessels, their dimensions should be proportioned, not only to the area of the midship section, but also to the speed of the engine. At the same time, the consideration of the form of the blades was very important. In experiments with the revolving fan instrument, he found, that although on all occasions, the same rotative force was applied, a fan with three arms, whose united areas were 3·721 inches, when set at a given angle, did not rise freely; the same form and area, when set to a proper curve, rose to a very considerable height; but when a fan of twelve arms, formed from a circle or disc of 28·274 inches area, divided into twelve arms was set in motion, it would not rise at all. With other fans, of intermediate forms, areas, and curves, various results were obtained, which were curious problems for engineers interested in the construction of propellers.

Mr. Grantham expressed his pleasure at finding his paper had so much excited the attention of the meeting, and he hoped it would be followed by communications from members who had devoted more time to the subject; for instance, the numerous experiments made by Mr. Brunel and Mr. Guppy, before deciding on the use of the screw-propeller for the *Great Britain*, and those made in the presence of the Government Engineers, Mr. Lloyd and Mr. Murray, on board the *Bee*, the *Rattler*, &c., would be very interesting. Mr. Grantham exhibited a diagram of the propeller used on board the *Liverpool Screw*, figs. 7 and 8; composed of four blades with broad shovel ends, fixed at a mean angle of 45°. This form, although very successful in this case, could not, he thought, be recommended for large diameters. The results of his observations induced him to think, that the blades of a propeller should not be more than four feet apart; he would, therefore, advise the adoption of Ericson's form, and mode of construction, which he considered the best that had hitherto been introduced; the ring within the arms permitted any number of blades to be affixed, and a large area of acting surface, judiciously disposed, could thus be obtained. He objected to propellers with three arms, chiefly on account of the small amount of surface obtained. As to the "slip," which Mr. Galloway had so ably commented upon, he was aware that it did exist in all cases, but he was of opinion that the amount was exaggerated; he had not only made accurate experiments with Massey's log, but being repeatedly in a small boat, which was towed close astern of the *Liverpool Screw*, he found that there was very slight disturbance of the water, and that there was not any depression behind the blade of the propeller on entering the water; this could be easily observed, as a portion of the upper blade was always above the surface. It had been anticipated that this arrangement would, with so short a vessel as the *Liverpool Screw*, have caused a constant tendency to bear over in one direction, but not the slightest disturbance of the steering was perceived, and the vessel's course seemed to be quite as straight as it would have been with paddle wheels. Mr. Grantham wished it to be understood, that his object in bringing forward the account of the *Liverpool Screw*, was not so much to cite that vessel's powers, as to point out the feasibility of working propellers at a slower speed, and that condensing engines could be applied with advantage, avoiding the bands and gearing, which had hitherto been found so objectionable.

Mr. Braithwaite was of opinion that where deep immersion was not practicable, two propellers would be preferable, in order to prevent any disturbance in the steering. Captain Ericson had adopted that plan in boats of light draught. Mr. Braithwaite then presented a drawing of the midship section of the *Princeton* American frigate, showing the elevation of Ericson's engine on board. The vessel was 164 feet long, with a breadth of beam of 30 feet; the depth of the hold was 22 feet 6 inches, the draught of water was 17 feet 6 inches, and the burthen about 700 tons; the propeller was 14 feet in diameter, with six blades, and made from 32 to 36 revolutions per minute, at which rate the vessel's speed was stated to be nearly 14 miles per hour. The engines were about 400 horses power; they were of peculiar construction, having two steam cylinders or chests, containing vibrating pistons or flaps, with cranks upon the ends of the suspending pivots; both these were coupled by connecting rods to a main crank on the driving shaft; the length of these cranks being so proportioned, that their alternate vibrations should give a rotary motion to the main crank, and thus act directly upon the propeller, without the intervention of bands or gearing.[5] This principle was tried successfully in the year 1839, by Ericson, on the Thames, in a tug-boat named the *Robert Stockton*,[6] after the projector, who had succeeded in introducing the system to the American navy, and now commanded the *Princeton*. The boilers of the *Princeton* were constructed for burning Anthracite; the whole of the machinery was so placed as to be out of the reach of shot, and the vessel was ship-rigged, so that by unshipping the screw, she could be rendered as effective as any sailing vessel, with a fair wind, or in case of accident to her machinery. Mr. Braithwaite hoped in a short time to bring before the Institution, an account from Captain Ericson, not only of the *Princeton*, but of several of the other vessels he had fitted with his engines and propellers, since his residence in the United States. Figs. 9 and 10, Plate VII. are drawings of Ericson's Screw Propeller.

Mr. Galloway said, that during the experiments with the *Archimedes*, a proof had been elicited that the "following current" had a very considerable effect on the action of the propeller. During one of the trials the vessel was backed astern, when it was found, that the speed of the engine increased three or four revolutions per minute, while the speed of the vessel appeared to have diminished. This experiment was, he contended, conclusive as to the fact that the "slip" was greater than would appear by looking merely at the rate of the vessel compared to that of the screw. He did not, however, think that the "slip" ought to be considerable, with a well-constructed propeller. Increased magnitude in a screw, would have the same effect in creating resistance, as increased magnitude in any other submerged body. The utility of the increasing pitch, however, was involved in, and solely dependent on, the amount of "slip" which would be found to be attended with the least disadvantageous results in other respects; and here Mr. Galloway would observe that Mr. Cowper's experiments with the revolving fan instrument confirmed his view; for it must be recollected, that there the "slip" was much greater than the rate of ascent; the only condition being thus developed in which the utility of an increasing pitch could be contended for. The advantage of turning the propeller by the direct action of the engines, was generally acknowledged. The method of driving it was nearly the only problem remaining for solution, and that difficulty being once overcome, screw-propellers must necessarily, from their vast advantage over paddle wheels, in every respect but that, be universally adopted.

Mr. Hawkins said, that about the year 1825, Mr. Jacob Perkins adapted to the stern of a canal boat, a propeller of about 25 feet in circumference, which might be described as resembling two sets of windmill vanes, the solid axle of one set revolving within the hollow axle of the other, the two axles being turned in contrary directions, and the dip of the blades being about half their radius. The propulsive force was stated to have been very effective; the experiments, which were put an end to by the breaking of part of the engine, were never renewed, in consequence of disputes among the patentees; but he considered that propeller as the best that had hitherto come under his notice, and he had endeavoured to draw attention to it by reading an account of it, at the meeting of the British Association at Cork, in 1843.

Mr. Grantham stated, that in order to test the comparative effect of the expanding pitch, Mr. Woodcroft had adapted to the stern of a vessel, two screws of equal area, one being of a regular, and the other of an expanding pitch; they were connected by a cross shaft, and were worked by manual power, and it was found that the vessel always yielded to the impulse of the expanding pitch propeller, and was turned by it from the direct course. With respect to the advantage of a large amount of surface, he had found that the action of the propeller of the *Liverpool Screw*, which had been enlarged three times, was decidedly improved by the alterations; the speed of the engines always remaining the same.

Mr. Galloway said, that the surface of the propeller of the *Liverpool Screw*, might probably have been too small at first, and therefore each increase would naturally improve its effective power. The area of the propeller should be in proportion to the body to be moved; this law was common to screw-propellers and to paddle-wheels.

The President expressed the gratification he felt at the useful discussion, which had been raised on so interesting and novel a subject as the screw-propeller, which had become one of such importance in steam navigation, that the Government had directed the serious attention of their officers to it; and he trusted that the examination of this question, like that of the action of Cornish engines, at the meetings of the Institution, would materially tend to its elucidation. As soon as any new and really useful invention was matured, and brought sufficiently into use, to enable its merits to be calmly discussed, it was one of the main objects of the meetings, to examine it, and he hoped that in a short time a detailed account of the Atmospheric Railway, would be submitted by Mr. Samuda, for the consideration of the Institution.

Oxydation of Iron.

Mr. Perkins stated, that on a recent examination of the *Napoléon* at Mar-

5 Vide Mech. Mag., vol. xxxii., January, 1840, p. 290. 6 Ibid., vol. xxx., January 1839, p. 281.

seilles, the cast iron of which the propeller was composed, was found to have undergone considerable change, and to have become so soft, that it could be cut with a knife.

Mr. Grantham believed, that circumstance was owing to the cast iron propeller, working too near the copper sheathing of the vessel. Iron vessels would not be liable to that objection. The amount of oxydation was apparently increased, by the cast iron remaining in a state of rest; now as screw propellers were usually in rapid rotation, and were also generally so constructed that they could be unshipped, they could be painted and preserved from any injurious amount of external corrosion, although a chemical change might still be induced, when the cast iron was in contact with copper.

General Pasley had observed, in the metal raised from the wrecks of the *Edgar* and the *Royal George*,[7] that the cast iron was generally soft, and in many instances resembled plumbago; that when small pieces were cut from any of the iron guns, or that these pieces were pounded in a mortar, heat was evolved, but after two or three days the metal cooled again! some of the shot which had been found had burst into several pieces, under this heating action.[8] The wrought iron was not so much injured, except when it was in contact with copper, or gun-metal; some of it appeared to have undergone an unequal action, and presented a reticulated surface, as if the softer portions had been destroyed, leaving the harder fibres uninjured.[9] Those portions of the wrought iron, which were used by the smiths in the Dockyards, were declared to be of a better quality than any modern iron. Neither the copper, nor the gun-metal, were much acted upon, unless they were in contact with iron.

Mr. Cottam had observed, with great attention, the iron guns which were brought from the *Royal George* to the Tower; when they arrived, they were soft, and could be easily cut with a knife;[10] but when he examined them some time afterwards, the metal had resumed its original hardness. This was frequently the case with pump-trees, which had become soft, from immersion in mineral water, but on being taken out and laid aside for a time, they became hard again.

Mr. Galloway stated, that this spontaneous development of heat by cast iron, which had been long immersed in salt water, had been frequently observed. A striking instance of this kind occurred at Woolwich, when an attempt was made, to preserve the copper sheathing of vessels from corrosion. Sir Humphrey Davy suggested to the Admiralty, that the decomposition of the copper sheathing could be neutralized, by the application of tin, zinc, or any other easily oxydable metal; the plan was tried on several vessels, by attaching to them zinc plates, and the protection was so perfect, that the ships' bottom became covered with barnacles and weeds. Cast iron was then substituted, on the supposition that the partial oxydation, which would be permitted by the iron, would prevent the fouling of the copper, but that the ordinary rapid destruction would be modified.[11] The *Magicienne* frigate, having been at sea for some time, with cast iron protectors, was docked at Woolwich for examination; when it was found, that the protection instead of being partial, had been local, for while the greater portion of the surface of the copper was oxydized as usual, the parts contiguous to the iron had been perfectly protected and were covered with barnacles. Mr. Marsh (of the Ordnance department) broke off some small pieces of the iron, which presented the appearance of plumbago, was easily cut, was greasy to the touch, and left black marks upon paper;[12] in a few minutes the heat became so great, as to ignite the paper in which the pieces were enveloped. The development of heat, was generally supposed to proceed from the rapid absorption of oxygen by the mass, on being brought into the air, from the water, where it had already received a certain amount of oxygen. The production of heat, being in this case, governed by the same law, as that under which animal heat, and the heat of combustion, were developed.

Mr. Homersham said, that the water of the Thames, up as high as Richmond, had the same effect as sea-water, in rendering cast iron soft.

Mr. Simpson believed, that if hard grey cast iron with a good surface, was used for castings, which were subjected to the action of sea-water, but little injurious effect was to be dreaded; he was so convinced of the fact, that he was about to use cast iron extensively for piles. He hed recently examined some cast iron piles, which had been in sea-water for 16 years, without any detrimental effect being produced.

Mr. Jordan thought that it was very desirable, to mark the difference between the composition of brass, and the alloy of copper and tin, used in casting guns. With brass, in which zinc formed a part of the composition, it was probable, that the iron would have been acted upon with less energy, because it was more electro-negative than zinc; but the gun-metal acted positively upon the iron, and apparently, altered the substance.

Mr. Braithwaite said, that the proportions of the mixture, used for the bearings of machinery, were usually 92 per cent. of copper and 8 per cent. of tin.

The President said, that although the discussion had taken a direction which had not been anticipated, and was foreign to the original subject, he had not attempted to lead it back again, because the question of the causes of the chemical change in cast iron, in certain positions, and the means of preventing it, was of the utmost importance to engineers, particularly as in all modern works so much cast iron was used.

PUMP VALVES.

(From the Minutes of Proceedings of the Institution of Civil Engineers, with Engravings, figs. 11 *to* 13, *Plate VII.)*

Mr. J. B. Jordan exhibited and described a model, showing the principal pump valves, used by mining engineers. Mr. Jordan stated, that the model before the meeting, was intended to illustrate mining machinery, and was one of a series, now in progress of construction for the Museum of Economic Geology. There were eight differently constructed valves in it, each surmounted by a glass valve-chamber and pipe; the large central pump, served to circulate the water through all the valves simultaneously, so as to show their comparative action; the water was then discharged from the collar launders over each valve, into that at the head of the pump, so that by repetitions of the pump-stroke, the circulation through the valves might be kept up at pleasure.

The valves shown in the model might be divided into four classes:—1st. Those in which no attempt was made to counteract, or avoid the violence of the beat, or concussion, on closing the valve. 2nd. Those in which that evil was reduced, by dividing the horizontal area of the valve, into several parts. 3rd. Those in which the same object was attained, by reducing the horizontal area of the moving parts of the valve. 3th. That in which the concussion was reduced to any desired amount, by making one side or portion of the column, to a certain degree, balance the other.

Valves of the first class were so well known, that they required little description; they were the common pump clack, moving on a leather joint, and having generally a very small water way—the improved metal joint clack, in which the water way was much increased—and the 'button clack,' or as it was called in Cornwall 'hcantlebury's clack,' which was a disc of metal with a central spill or stalk, which rose and fell in a guide. Of these valves, the second was considered the best, inasmuch as it had the largest waterway (some portion of which was direct), and it was free from some minor objections, to which the leather-jointed clack was liable. This valve was therefore in very common use in mine pumps, where the area of the pump and the height of the column, were not such as to produce any serious inconvenience from concussion, in closing the valve.

In the second class of valves, the injurious effect of a violent beat was somewhat avoided, by the ingenious expedient, of dividing the valve into several rings, or segments. The simplest of this class, was the well known 'butterfly valve,' in which two semicircular parts opened on a central hinge of leather, and the beat was divided into two parts; but as those closed at the same time, the concussion was principally reduced by the fall not being so great. The next valve was composed of several triangular pieces, opening on leather joints, from the circumference of the valve seating; it had been much used by Capt. Reed, of the Mold Mines, Flintshire, and was reported of favourably, by several other mining engineers. It closed with very slight concussion, on account of the are of each part being small, the base of each triangle forming the joint, while the water way was large, and nearly all direct, admitting the mass of water to pass forward, in line parallel to the side of the pump. In the other valves of this class, no leather was used, a circumstance which rendered them more applicable to large pumps, where continuous working was of the utmost importance, particularly in the case of deep mines.

The two annular valves shown, were invented by Mr. Hosking of the Perran Foundry, and Mr. Jenkyn of the Copper-house Foundry, (Cornwall). The first of these, was composed of a series of rings working on a vertical spill, each ring having its seat on the one beneath it; (see figs. 11 and 12); there rings have different areas, and fell in succession through a small space, compared with that which would be requisite, if the valve were in one piece,

---

7 The "Edgar" was sunk in 1711, and the "Royal George" in 1782.

8 A similar action was observed, in the cast-iron shot raised from the "Mary Rose," which was wrecked in the reign of Henry VIII.

9 This appearance was also noticed by Mr. Mallet, and is mentioned in his paper, "On the Corrosion of Iron, &c."—See "Journal," Vol. VI., p. 386.

10 Vide Trans. Inst. C.E., Vol. I., p. 204.

11 Vide Mr. Wilkinson's paper "On the Sheathing of Ships," "Journal," Vol. V., p. 169.

12 In Dr. Thomson's "Annals of Philosophy," are the following remarks:—"Dr. Henry states, that 'cast iron having been in contact with muriate of lime, or muriate of magnesia, most of the iron was removed. The specific gravity was reduced to 2·155, and what remained was chiefly plumbago, and the usual impurities.'

"Dr. Brande found that 'a cast iron gun had undergone a like change, from being long immersed in sea-water. To the depth of an inch it was converted into a substance, having all the external character of plumbago. The component parts were—

Oxyde of iron	81
Plumbago	16
	97

"Mr. Mushet, in his work on 'Iron and Steel,' states, that wrought iron sometimes, though very rarely, undergoes the same change.

"Professor Daniel, in the 'Quarterly Journal of Science,' Vol. II., p. 290, says 'I am inclined, under all the circumstances, to believe that the triple carburet, as it is at first obtained, consists of iron and silicum in the metalline state, united to carbon. When brought into contact with oxygen gas, the metals become converted to protoxydes, giving out heat, without separating from the carbon.'

"By analysis, he found the substance to consist of—

Red oxyde of iron 7·0 = 6·2 black oxyde
4·9 silex
11.2 carbon

"The same author states an important fact, bearing on the present question, namely, 'that it took three times as long to saturate an acid, when it acted on white cast iron, as when it acted on the grey kind.'"

so that the concussion was much reduced, while the water way was increased; but the latter being all lateral, it was requisite to have a large valve chamber. The beats of this valve were formed of tin. Mr. Jenkyn's valve, differed in construction from the one just described, in having the rings connected with each other by shackle-joints, instead of their working on a vertical spill; the mode of forming the beat was also peculiar; it was composed of two thicknesses of leather, between which, wedges of wood were driven, into a groove, cast for their reception in the rings; these materials were so placed, that the edges of the leather, and the end grain of the wood, might form the striking surface of the beat, after being turned off in the lathe.

In the third class of valves, which avoided concussion by reducing the horizontal area of the moving parts, were Messrs. Harvey and West's, and Mr. Hosking's double-beat, (See *Journal*, 1840, vol. iii. page 41 and plate 1,) and Mr. Darlington's cylindrical single-beat valves. The first of these was a modification of the double-beat steam valve, so long used in the Cornish engines; the second named was similar in principle, and was only slightly different in construction. They were both good valves, each giving large lateral water ways, and therefore they required valve chambers of corresponding size, to ensure their perfect action. Mr. Darlington's cylindrical single-beat valve, was contrived for a large set of pumps under his management, at the Alport Mines (Derbyshire.) The rising column of this pump, was 38 inches diameter and 22 fathoms in height; it was therefore desirable in such a pump, to reduce the concussion, as much as was consistent with the power of closing the valve in proper time; this was accomplished, by causing a cylinder to rise over a metal-ring packing in the seating of the valve, so much, as to give a large lateral water way under the beat, formed by the bottom of the cylinder. This valve was found to act well, but it required a very large chamber for the water to enter; the reason for adopting one, instead of two beats, was to avoid or lessen the leakage, caused by chips getting between either of the beats.

The only valve belonging to the fourth class, was that of Messrs. Palmer and Perkins, (See *Journal*, 1841, vol. iv. p. 335); it consisted of an elliptical disc, moving on an axis placed parallel with, and near to, the minor axis of the ellipse, and closing at a considerable angle, against the interior surface of a cylinder. In a valve so constructed, it would be readily perceived, that the concussion might be reduced to any extent, by bringing the working axis nearer to the geometric axis of the ellipse; because the force with which it closed, must depend on the difference of area, between the upper and lower portions of the disc. It possessed an advantage in the extent and character of its water way, over all the other valves described, nearly the whole of the water-passage being parallel to the side of the pump. On the other hand it was objected, that the axis would be liable to rapid abrasion, and consequently the valve would become leaky; but Mr. Jordan did not concur in the opinion, of that being an insurmountable difficulty, and he hoped that the valve would be tried, under circumstances which would put its merits to a severe test.

Remarks.—Mr. Taylor said, that the subject of valves for pumps had been so ably treated, by Mr. Homersham, in his paper, (which was read before the Institution last session, (See *Journal*, 1843, vol. ii. p. 42J,)) and in the discussion upon it, that there remained but little for him to say. He could not, however, allow the model, which had been exhibited by the permission of Sir Henry De la Bèche, to pass without a few remarks.

In Cornwall, after the improvements in steam-engines had made considerable progress, attention was directed to the more perfect construction of the pumps. The plunger was introduced about that period, and the merit of it has been claimed by different parties;[13] its use was attended with many advantages, and had now become almost universal. Some of the benefits derived from its substitution, for the common piston or bucket, had no reference to the subject of valves, and therefore need not be mentioned. In one point it was of great importance; for as the size of the water-way of the valves in the bucket, was necessarily limited by the diameter of the working barrel, an arrangement like that of the plunger pump, which permitted both valves to be fixed in seatings, of which the areas might be increased to any convenient extent, became the more desirable; it was therefore extraordinary that such tardiness had been exhibited, in taking advantage of such an obvious improvement, when the principle had been long known, and the loss of power, consequent on the former system was admitted. The model which had been explained by Mr. Jordan, showed how much the attention of engineers, had now been directed to the subject. In the discussion of Mr. Homersham's paper, Mr. Taylor had mentioned the advantage which had resulted, from the extension of the water-way of some large pump-work, by having two suction-pipes, or wind-bores, and thus doubling the passage through the valves. It appeared important, for all the valves that discharged the water laterally, that more space should be provided, round the seatings in which they were placed, and for want of that precaution, some excellent valves had not answered so well as they would otherwise have done. That which was invented by Mr. Darlington, to avoid some inconveniences in the use of the double-beat valves, would have been improved by an enlarged space around it. As mines increased in depth, and the volume of water became larger; as steam-engines came into use, having a rapid and sudden motion, as compared with that of water-wheels, which were formerly universally employed for pumping, a great inconvenience was felt, from the concussion in the columns of the pumps; this was occasioned by the beating of the valves upon their seats, and in pumps, of the diameter needful for draining some of the mines, this evil became very serious. Almost all the improvements in valves were made with that view; the division of the old butterfly valve into segments was an obvious first step; it had succeeded extremely well, and was still not much excelled. The annular valves of Hosking, Jenkyn, Simpson[14] and others, were based on the admitted principle, of dividing the falling clacks into several parts, that they should not rise so high, and that they might collapse in succession, and thus avoid concussion. Harvey and West's double-beat valve partook of that principle, but was stated to have the advantage, of presenting a small area, to be acted upon by the pressure of the column of water upon it. Darlington's valve, which was contrived to avoid the inconvenience, arising from the leakage, from both the beats of Harvey and West's valve, when any substance obstructed its perfect closing, presented also a small area for the pressure to act upon; but as it discharged the water laterally, it required an increased space around the seating.

The model exhibited a valve, introduced by Messrs. Palmer and Perkins, upon a principle, by which concussion might be considerably reduced, by bringing into action, a part of the superincumbent pressure, to check the descent in closing the orifice. This valve had not yet been tried in large pumps; but the opinions of practical men appeared to be in its favour.[15] In the construction of all valves, it was of importance, not only to attend to the points which had been mentioned, but also to their durability, and their facility of removal and repair. The actual cost of the valves was of little importance, when compared with the labour and hindrance in removing, or changing them, where the influx of water was great. Serious expense, and loss of time, were frequently occasioned by such stoppages, and the deeper parts of the mines, were exposed to obstructions, which were overcome with great difficulty, notwithstanding many ingenious and well-arranged contrivances, to render the process of repair easy and expeditious. Very powerful capstans and other means were provided for these emergencies, and as the labour of fifty or sixty men was sometimes required to work these machines, it would be easily conceived, how important it was, that such operations should occur as seldom as possible, and that the most perfect and durable construction should be aimed at.

Mr. Perkins observed, that although at the first view, a certain degree of resemblance might appear to exist, between Belidor's valve and the disc valve of Palmer and Perkins, there existed in reality, but little similarity between them. The former was placed horizontally, whether used as a clack or as a bucket; in all cases it required to be adjusted to a seating formed of reversed cones, like the ring of a steam throttle valve; and it was always attached to a packed bucket or piston. Whereas the latter worked at an inclination of about ¼ of the diameter of the pump; it was adjusted within the bored pipe without any seating; and it formed a piston without any packing. Its form being that of an oblique section of a solid cylinder, whose diameter was equal to the interior of the working barrel, and the line of its suspension being beyond the diameter, the areas of the two portions of its surface were unequal; consequently, there was more pressure on one side of the line of suspension, than on the other. By this extra amount of pressure, the disc was turned on its axis, allowing a free passage for the water, parallel with the sides of the pump. The closing of the lower valve on the return stroke was, for this reason, without noise or concussion. It was evident also, that as packing was not necessary for the disc piston, and as the rubbing surface of its periphery was very small, the friction must be greatly diminished. Messrs. Bramah and Robinson, made an experiment for comparing a pump, with a packed bucket and butterfly valves, with one having a disc piston; the diameter of both pumps was 10 inches, with a stroke of 8 inches, a lever of six to one, and a lift of water of 5 feet; it was found that the former required a force equal to 460 lbs., and the latter 196 lbs to complete a stroke. As regarded their duration; a disc pump 7 inches diameter, with a stroke of 8 inches, and a lift of 40 feet, drawing its water through 600 feet of suction pipe, rising in that length 28 feet vertically, and worked by a steam engine 26 strokes per minute, had been found, after working nearly night and day, at the Equitable Gas Works, during fifteen months, without repair, to exhibit but little appearance of wear in the piston, and both it, and the clack valve, were perfectly tight. As the subject appeared to interest the Institution, he promised to present, on a future occasion, a more detailed account of some similar pumps, with the actual results obtained.

Mr. Lowe corroborated the statement, of the efficiency and duration of the valve, used at the Equitable Gas Works; its friction was necessarily very

---

13 The plunger was used by Sir S. Morland in 1683, for the force-pumps at the Machine de Marly.

14 The annexed engraving of a treble ring valve, fig. 13, is a section of Mr. Simpson's valve described by Mr. Homersham, in his paper of last session before referred to. It is a conical valve formed of rings, shutting down upon separate seatings, allowing a passage for the water both inside and outside the rings. Valves of this construction have been introduced at the Lambeth and Chelsea water works. The valve at the Lambeth works is 30 inches diameter, the perpendicular rise or lift when fully open does not exceed 1¾ inches. The clear uninterrupted area through which the water passes is more than two thirds of the whole area of the valve, the internal diameter of the seating being 27 inches. The valve at the Chelsea works is 43½ inches diameter, and the greatest height to which the rings of the valve rise, does exceed 2¼ inches.

15 A valve of a very similar construction is described in Belidor's "Architecture Hydralique," vol. iii., p. 221, as having been introduced by him in 1737, for the improvement of the water-works at the Pont Notre Dâme, Paris. The situation of the pivot of the valve, is described to be, at one-twelfth part beyond the line of the geometrical diameter of the pump-barrel.

small, for as it formed at the same time both piston and valve, and in the return stroke, from its nearly vertical position in the working barrel, the parts in contact, were reduced to the area of the points of the minor axis of the disc, the friction was in proportion to that area. As a seat valve, he thought it less liable to become defective, than any other, as it was scarcely possible for any sand, or other foreign matter to lodge upon it, and the valves which he had seen at work did not show any symptoms of being so affected.

Mr. Farey said, that it was an axiom relative to steam engines, that their action became more perfect as their size increased, but that this could not apply correctly to pump valves; for as their size had augmented, the difficulties in their construction had been more fully developed. With small valves it had been considered, that the vertical height of the lift of a clack, should be one-fourth of the diameter of the barrel, but it was evident that rule could not be adhered to with large valves. Other forms, allowing a free passage for the water, had therefore been resorted to, and with great success, but there was still room for improvement. He had a high opinion of the valve, which had been used originally by Messrs. Boulton and Watt, and which was called, from its form, the 'Bishop's cap,' It consisted of four triangular flaps of leather, hinged on the periphery of the valve and meeting in the centre; the number of these flaps had been, he believed, increased to six and eight for very large sizes, and they afforded a very free passage for the water. Much yet remained to be done, in improving the valves of the air pumps of steam engines, especially in adapting them to the speed of the engine, so as to avoid the loss of power, consequent on drawing, or forcing the water through contracted passages.

Mr. Jordan was happy to find his opinion of the disc valve corroborated. He had viewed it almost entirely as a clack valve, on which the whole weight of the column of water would rest, and for that purpose he thought it particularly suited. He could not agree in the opinion that chips of wood or other substances, would be liable to accumulate near the axis, and render it leaky. He thought, on the contrary, that it would clear itself very easily, and as the faces or seats were vertical, it was not possible for anything to rest upon them. It had been urged that these valves were difficult of construction, and would scarcely be found tight, under a very heavy column. He conceived however, that with modern machinery, there could not be any trouble in making them perfectly accurate, and that the simple addition of a beard of leather, fixed on the upper side of the longer portion of the valve, and to the seating at the shorter part, would render the valves quite tight.

Mr. Homersham observed, that any particular form and proportion of a valve, which enabled it to answer well, in one situation, was no criterion of its doing the same, under other circumstances; for instance, the suction and delivery valves, of the pump of a Cornish mine engine, required to be differently proportioned; as in order to follow the speed of the plunger, the water was obliged to move through the former, more rapidly than through the latter; for the velocity of the down stroke of the steam piston of a Cornish engine, was chiefly regulated by the portion of the stroke at which the steam was cut off, whereas its velocity in going out, was most usually adjusted by varying the period of the pause at the end of the stroke; although it was also somewhat governed by the number of strokes per minute, which were required to be made. Therefore, as the plunger always moved quicker in the former, than in the latter case, the velocity of the passage of the water through the suction valve (unless its area was increased), was greater than through the delivery valve, and the moving part of the valve, against which the water impinged, required to be heavier in the former than in the latter, to insure its closing, before the return stroke of the engine commenced. This had been pointed out in his paper on valves, which was read in the last session, and a rule was given[16] for their relative weights, which should always be in proportion to the velocity of the water passing through them; if this were not attended to, and they were both made of the same weight, the delivery valve would not open freely, and thus more weight would be required to carry the engine 'outside,' and the duty would be diminished. He was therefore of opinion, that every valve required to be adjusted expressly for the situation in which it was placed, and the duty it was required to perform.

Mr. Galloway drew the attention of the meeting, to a pump which was introduced by Mr. Jacob Perkins in 1820,[17] and was rewarded by the Society of Arts. The barrel consisted of four boards, nailed together, so that its horizontal section formed a square. The bucket-rod was enlarged to a broad end, intersecting the square diagonally; to this, two valves were affixed by leathern hinges. Their form was that of an isosceles triangle, the base of each being united to the rod, and the other sides resting, in an inclined position, against the inner sides of the barrel, filling the entire area. In the down stroke of the bucket, this form offered little opposition to the water, and was sufficiently tight for common purposes, with but little friction. Mr. Galloway subsequently constructed a pump with a wooden barrel, in which the valve was in one piece; the preponderating action, like that of the oval disc pump, was effected, by giving the barrel the form of a trapezium, the valve being suspended by an axis, which crossed it at the bases of the two unequal parts. Neither the trapezium valve, nor that of Jacob Perkins, were, he conceived, generally applicable; their utility would not extend beyond domestic purposes, or those countries, where the means of boring cylindrical barrels were not attainable. Mr. Galloway was of opinion, that the principal objections to the elliptical disc valve were, first, that as the axis of the valve, did not coincide with the minor axis of the ellipse, the spindle would either benp, on the valve being raised to a vertical position, or it would not fit the cylinder when it was shut; secondly, that there was no compensation for abrasion, across the minor axis, so that when the valve was worn, either by the friction of sand or from other causes, it would become leaky. Mr. Galloway then exhibited a form of valve, by which he submitted these objections would be obviated. If an ellipse was intersected diagonally, at an angle of 45° with the major and minor axes, and one portion was turned over, so as to produce a heart-shaped figure, when joined to the other portion by a hinge; it was obvious that these two leaves, when placed in a cylinder, would fill the cavity as the original ellipse had done; both the minor and major axes being at different angles. These leaves being supported from beneath by rods with ball and socket joints, the wear in any direction, would be compensated by the extension of the leaves, as their constant tendency was to become horizontal. The rocking rods, acting at points on the leaves, where the preponderance of surface was in one direction, enabled the water to open and close them, with that easy motion which was so much desired in heavy lifts.

Mr. Jordan wished it particularly to be understood, that he had directed attention to the disc valve, hoping that from its simplicity of action, it might be tried and found serviceable, for the clacks of deep mine pumps, of large diameter, and working under a column of from 10 to 50 fathoms in height. There was little doubt of the valve being tight under ordinary circumstances, and with short lifts, but when a heavy column of water, was allowed to rest upon a valve, the slightest inaccuracy was detected.

Mr. Homersham differed in opinion with Mr. Jordan, as to the applicability of the disc valves to deep mine-pumps. He conceived there would be a certain amount of difficulty, in constructing them so as to be perfectly tight, under a heavy column of water, and the spindle or pivot of the valve, would require to be of large diameter, to insure its being strong enough to bear the pressure. It was also necessary, for the perfect action of the valve of a pumping engine, that it should be closed, by the time the piston of the pump arrived at the top, or the bottom of its stroke; this could only be accomplished, by the weight of the valve, balancing the maximum velocity of the water put in motion through it, so that it should begin to close, as the flow of water diminished, and be quite closed, when the motion of the piston ceased; this, he conceived, would be difficult to accomplish, with the valve then under consideration.

Mr. Palmer remarked, with reference to these objections, that the opinions given, were clearly in opposition to facts, deduced from fifteen months operation of this pump, raising water under a vertical column of 40 feet, during which period, the slip or loss of water, approached nearer to the calculated result, than any pump duty that had come under his observation. In reference to the second objection, it was quite clear the valve-spindle must be of adequate strength, to support the column of water the pump had to lift: he believed that no greater evil (considered in an abstract sense) could result from the use of a large spindle, than an increased friction at its bearings, and a corresponding loss of velocity in the fall of the valve. These evils were, however, neutralized by increasing the excentricity of the spindle, and thereby enlarging the valve's area above the spindle, which increased area would always be considered, in reference to the altitude of the column of water above the valve, in order to insure the least loss of water, and at the same time to avoid the percussive action, so detrimental in other pumps. As regarded the third objection, namely, that there would be great difficulty in keeping the disc-valve perfectly tight; he would remark, that in the pump referred to, the minor axis of the piston was not sensibly worn, while the major axis was shortened $\frac{3}{20}$ths of an inch, but still preserving the true elliptic form, and fitting the pump as accurately as when first put into action, although the piston had made upwards of 16,800,000 double strokes, and had travelled over a rubbing surface exceeding 2,100 miles, during the upward or effective stroke. The wear of the clack-valve at the major axis was less than $\frac{1}{30}$th part of an inch, while at the minor axis it had undergone no change, although the number of beats it had made equalled the number of strokes of the pump. The modifications of the elliptic disc piston and valve into the trapezium form, as proposed by Mr. Galloway, appeared to him to be attended, not only with a considerable increase of cost in the manufacture and the fitting of the trapezium valve, and the working-barrel, but also increasing the amount of rubbing surface, with a corresponding amount of wear and tear, as compared with a pump having the elliptic valve performing the like amount of duty. The two semi-elliptic valves proposed by Mr. Galloway, were ingenious, but they were contrived with the view of remedying an evil that did not really exist in the disc-elliptic piston valve, namely, wear and tear of the minor axis, and leakage at the parts supposed to be worn; nor would the action of the two elliptic leaves, he conceived, be as efficient as the simple elliptic disc piston valve.

---

16 The following is the rule refered to by Mr. Homersham. "The mean velocity of the water in feet per second through the valve being ascertained, one half more is added, and considered as the maximum velocity of the water through the valve, and the height of the head of water being found that would produce the velocity, every $1\frac{3}{4}$ inches of such height is then considered as equal to an ounce weight avoirdupoise acting upon every square inch contained in the area of the valve, against which the water impinged in its passage to the pump barrel, allowance being made for the difference of the weight of the ring when immersed in water, compared with its weight in the air."

AGRICULTURAL CHEMISTRY.

By Professor Brande, F.R.S., &c.

Lecture VIII.—*Delivered at the Royal Institution, March* 10, 1844.

(Specially reported for this Journal.)

Quitting now the consideration of the ultimate elements of plants, attention will be directed to the substances elaborated from them by the plant, into which, by its vital functions, it converts the carbon, hydrogen, oxygen and nitrogen, by grouping them together in various proportions. This operation, which is the peculiar province of the plant, and which the animal is completely unable to perform, is an operation almost as yet beyond the skill of the chemist, who can in some cases, change one of these elaborated substances into another, but cannot, except in some small isolated cases, construct them from their elements. It has been shown that plants do not feed on carbon, hydrogen, oxygen, or nitrogen in their crude state, nor until they have combined into forms which may be considered as intermediate between organic and inorganic matter, viz., water, ammonia, and carbonic acid, and decomposing and recombining their ultimate elements, produce these secondary products, which are termed the proximate elements of plants, and are known by the names of gum, starch, sugar, gluten, fibrin, albumen, lignin, resin, oil, &c. These are of the greatest importance to the agriculturist, because it is on these that animals live, and therefore on their relative proportion depends the value of a crop. The proportion in which two of these proximate elements are present in some of the commonest crops, is shown by the following list:

	Starch.	Gluten.
Wheat flour, from	39 to 77	8 to 35 per cent.
Rye . .	50 ,, 61	9 ,, 13 ,,
Barley . .	67 ,, 70	3 ,, 6 ,,
Oat . .	70 ,, 80	2 ,, 5 ,,
Rice . .	84 ,, 85	
Buck wheat .	50 ,, 60	
Peas and Beans .	40 ,, 50	
Potatoe . .	10 ,, 15	

The proportion varies according to mode of growth, soil, climate, &c. The manner in which the plant takes up the carbonic acid, the water and the ammonia, by the roots and leaves, regulated by light and heat, will be considered at the next meeting. The proximate elements thus produced, having contributed to the support of one generation of animals, by decomposition become the substances suitable for the food of plants, which are again devoured by the animal, and in this manner the chain of creation is kept up.

In the ultimate analysis of the organic constituents of plants, we arrive but at one result, the oft-told tale of carbon, oxygen, hydrogen and nitrogen; but in the proximate analysis we arrive at an infinite variety of substances, in which the fecundity of nature, in producing from four elements so great a diversity of distinct bodies, is powerfully shown. By burning and other destructive means the ultimate elements are separated; but to procure the proximate elements, much milder processes are adopted. As an illustration of the ordinary methods adopted, the examination of the composition of wheat flour may be taken. If this be put in a muslin bag, and agitated in water, it will be seen that a white powder, which is the starch, will separate from it and fall to the bottom of the water, whilst a peculiar adhesive fibrous substance will be left in the bag, resembling birdlime. This, which is termed gluten and on the relative quantity of which in flour its value as food depends, instead of being a simple substance, is a very compound one; for hot alcoho digested on it, takes up some substances and leaves fibrin, as it cools it deposits caseum, and if evaporated, will leave glutine. Ether digested on this, dissolves from it some fat. The water in which the flour was washed holds gum and sugar in solution, and after filtration from the starch, on boiling, a substance is separated analogous to white of egg, termed albumen. In this manner can be separated, from an apparently homogeneous substance, the following proximate elements;—gluten, fibrin, caseum, glutine, fat, starch sugar, gum, and albumen. In this manner are the processes condncted for separating organic substances into their several proximate parts. These may be grouped under four heads, according to their ultimate elements.

Class I. Where the carbon has hydrogen and oxygen in the exact proportion for forming water.

Class II. Where the oxygen is in excess over this proportion.

Class III. Where the hydrogen is in excess.

Class IV. Where, in addition to the carbon, hydrogen, and oxygen, nitrogen forms a part.

The first class, which may be considered as composed of carbon and water, contains gum, sugar, starch, wood, and other neutral bodies.

The second class, in which there is excess of hydrogen, contains the resinous bodies, such as resin, wax, oil, fat, &c.

The third class, with excess of oxygen, contains the vegetable acids.

The fourth class, characterized by the presence of nitrogen, contains the alcaloids, gluten, albumen, gelatine, &c.

The peculiarities of each group must be next considered. The first group can be converted the one into the other slightly by art, but readily by nature. And when the similarity of their chemical composition is considered, their easy convertibility is not surprising, though their physical properties appear so essentially different. Their composition is given below:—

	Pe cent		Or, taking their carbon as a fixed quantity.	
	Carbon.	Water.	Carbon.	Water.
Cane sugar. . . .	—	—	12	11
Grape sugar . . .	40	60	12	12
Starch	41	59	12	10
Gum	42	58	(12, bracketed with Starch)	(10, bracketed with Starch)
Acetic acid . . .	47	55	12	9
Wood	50	50	12	8

Sugar is characterized by its solubility in water and alcohol, by its sweet taste, by being soluble in alkalies, and by its crystallizing readily. There are several varieties of sugar, but the two principal are cane and grape sugars, the latter being that which gives the sweetness to fruits, as to grapes, plums, pears, apples, figs, &c. Although the difference between cane and grape sugar in composition is merely that the latter contains one atom more water, yet the former possesses sweetening properties in a much more eminent degree. Unfortunately for domestic economy the sweeter sugar can be artificially converted into the one less sweet, but not vice versa. These sugars can be distinguished from each other by the action of acids and alkalies. Sulphuric acid completely decomposes cane sugar, leaving nothing but a carbonaceous mass, whilst it but slightly colours grape sugar. Honey, which consists principally of grape sugar, is merely rendered into a fluid like treacle, whilst a solution of sugar candy is acted on very strongly, little else but a mass of charcoal being left. Alkalies have a contrary effect, acting strongly upon grape sugar, and but slightly on cane. There are several other means of distinguishing between various sugars, and amongst the best is their action on sulphate of copper.

Gum, which belongs to this group, is soluble in water and insoluble in alcohol, and hence comes a ready method of separating sugar and gum when dissolved in water; it is only necessary to add alcohol, and the gum is precipitated. This method is frequently resorted to in analysing substances for food. There are several modifications of gum, differing from each other in some of their properties, and as types of three kinds may be taken, gum tragacanth, the gum which exudes from the cherry and plum trees, and gum arabic. Some of these gums can be converted into other kinds with great facility. Immersed in boiling water, gum tragacanth swells considerably; boiled for a long time, it passes, through cherry-tree gum, into gum arabic.

Woody fibre is insoluble in nearly all menstrua. When a piece of wood has been subjected to the action of water, dilute acids and alkalies, everything soluble is dissolved out, and a fine white powder is left, which is the woody fibre or lignin, and is that part of the vegetable which is worked up into paper. There are several varieties or modifications of this, forming both elder pith and the hardest wood.

Starch, unlike the other proximate elements of plants, has an organized structure. When examined by a microscope before removal from the plant it is seen in the cells of the wood growing like a fruit or berry, having a spot on the granule supposed to be a point of attachment. It is composed of concentric layers, with a fluid in the interior soluble in cold water, but which is protected by the exterior, which is not soluble till immersed in hot water, when, bursting, the whole forms the well known gelatinous mass. A beautiful and delicate test is used for starch, viz, a solution of iodine. Several varieties of starch are known, amongst which the best known are potatoe starch and wheat starch. One lately introduced, called tous les mois, consists of very large grains. Starch is very abundant in most vegetable substances used for food, and is essential for nutrition. To ascertain the presence of starch, pour on the substance a solution of iodine in water, and a beautiful blue iodide of starch is formed if it is present. A cut potatoe or a slice of bread shows this exceedingly well.

The transmutation of this class of substances takes place very readily. Starch or wood are easily converted into gum or sugar. Cotton or sawdust, stirred up with a little sulphuric acid, is reduced to a gummy mass; this, boiled for 24 hours, is converted into sugar, which may be separated from the acid by the addition of chalk, and filtering the sweet liquid from the sulphate of lime thus formed. It may then be crystallized. But the sugar thus obtained is grape sugar, which has but little sweetening power. Cane sugar boiled with acid is in a similar manner converted into grape sugar. Starch is very easily transmuted. If it be carefully heated to a point short of charring, it is converted into a kind of gum, known as dextrine. It has then lost the property of forming a blue with iodine, and is readily soluble in cold water. It is manufactured largely in France, and is used there to stiffen ribbons. It is also the principal ingredient in the cement at the back of the postage stamps, as it is very adhesive.

The second group, having excess of hydrogen, consists of resins, oils, fat, &c. They are present in nearly all our food. The greater number of them are found to consist of two substances, termed by chemists, elaine and stearine, the latter being the solid principle. In the solid fats these may be separated by pressure, as in the manufacture of linseed, cocoa nut, olive, and other oils. There is a dispute at present in the scientific world, whether animals have or have not the power of forming fat in their system from food which does not contain it, but all agree that when present in the food the animal can treasure it up in certain parts of the body.

The third group, containing oxygen in excess, embraces, with one exception, the whole of the acids in vegetables which have no nitrogen; this exception, which is acetic acid or the acid of vinegar, is never obtained except by decomposition. These acids are abundantly secreted in some plants, and are also said to be excreted by the roots of most plants. Wood is converted partly into acetic acid when it is distilled at a strong heat, and in this manner most of the vinegar used at table is obtained. Sugar is also converted into vinegar very readily; a little vinegar added to a large quantity of sugar and water, causes the whole of the sugar to disappear, and acetic acid is found in its stead. Tartaric is one of the commonest vegetable acids, being present in nearly all sour-leaved plants. It obtains its name from being the acid in the tartar of wine. When tartaric acid is neutralized by potash, it forms a very soluble substance, but when the acid is in excess, the compound is very insoluble, and is precipitated as cream of tartar, or bitartrate of potash. It is from this deposit taking place more largely in the juice of the grape which renders it so fit to make the best wine; other juices, retaining this acid in solution, produce consequently sour wines. In forming these acids, the plant is absorbing oxygen from the air instead of yielding it, and in the growth of such fruits as lemons, the amount absorbed must be considerable.

Lecture IX.

The fourth section of proximate principles, or those containing nitrogen, are considered as being the most essential to animal life, they going to form new flesh in the animal, whilst all the other principles are supposed to be consumed during respiration, principally in order to maintain the heat of the body. When the gum, starch and sugar were washed out from wheat flour, an adhesive fibrous substance was left called gluten. This contains all the nitrogenous substances in the flour, not being a simple principle, but a mixture of three or four; one is like cheese, one like white of egg, but all contain nitrogen. They are characterised by their action towards various solvents, but as they are very similar in composition, they are not worth separating, when considered as food for animals. It has been lately shown by Mulder, that when deprived of extraneous salts, and of a little sulphur and phosphorus, they exactly resemble the nitrogenous principles of animals, that, in fact, they have exactly the same composition, whether derived from animal or vegetable, and are only modifications of one principle, to which he has given the name of proteine. They may therefore be represented as follows:—

Albumine, Fibrine, Caseine, Glutine } Carbon 84 + Hydrogen 36 + Nitrogen 6 + Oxygen 15.

It is essential that an exact mode of ascertaining the quantity of nitrogen present in a substance should be known; and there has lately been proposed by Will and Varrentrap, a very delicate method of effecting this. When an organic substance is mixed with caustic potash or soda, and lime, and then heated, the whole of the nitrogen present is driven off as ammonia, which may be ascertained by its smell, by its action on moistened litmus paper, and by the fumes formed by holding a rod dipped in muriatic acid over it. If this is collected by being passed into muriatic acid, sal-ammoniac, or chloride of ammonium is formed; when to this is added a solution of platinum, a copious brown precipitate is formed, consisting of the ammonio-bichloride of platinum. This dried and weighed, will indicate the quantity of ammonia or nitrogen evolved from the heated organic substance, 225 grains of it containing 17 of ammonia, or 14 of nitrogen. Or, it may be decomposed by a red heat, and 14 grains of nitrogen reckoned for every 99 grains of platinum that is left, as its following composition will prove:—

Ammonio-bichloride of platinum,

Platinum	99	171 Bi-chloride of platinum.
2 Chlorine	72	
Hydrogen	1	37 Hydrochloric acid.
Chlorine	36	
3 Hydrogen	3	17 Ammonia.
Nitrogen	14	

The value of various substances as food for animals being considered to be according to the quantity of nitrogen they contain, lists have been drawn up to show their comparative richness in nitrogen. In the following list, the numbers attached show the quantity of the various substances that is necessary to yield an equal amount of nitrogen:—

Hay	10	Pea straw	6	Peas and beans	8
Clover hay	8	New potatoes	28	Wheat and oats	5
Vetch hay	4	Old potatoes	40	Barley	6
Wheat straw	52	Turnips	60	Maize	6
Barley straw	52	Carrots	35	Oil cake	2
Oat straw	55	Cabbage	30		

It follows, as a necessary consequence, that when animals are fed on substances poor in nitrogen, they must eat more of such food than would be requisite were they fed on richer food. Thus vegetable feeders eat a greater quantity than do animal feeders; men fed on fish, potatoes, or rice, require to eat more in proportion. But neutral substances, also, such as gum, sugar, &c., are required for the sustenance of life, and consequently we find in milk, the liquid prepared by nature for the food of the young animal, a proper admixture of all these requisites. In 1000 parts of milk are found, according to analysis,

Caseine	45	to	90
Sugar	36	„	50
Butter	27	„	35
Phosphate of lime and other salts	9	„	10
Water	883	„	815
	1000		1000

The various processes of decay, such as fermentation, putrefaction, and eremacausis, (the latter term being the one now fashionable to describe the slow decay of woody substances) may all be considered as the return of complex substances to those more simple in composition. The fibrin, &c., consist of high numbers, but in putrefaction they are reduced to substances with low numbers, passing off as carbonic acid, water, and abundance of ammonia. In the vinous fermentation, the alcohol is a tertiary compound, carbonic acid a binary one. In eremacausis, all the compounds are given off as carbonic acid, water, and a little ammonia. Thus they all pass into air.

To ascertain how the proximate elements are produced and changed in plants, the germination of the seed must be watched. Although there is an infinite variety in the appearance of seeds, and consequently they might be supposed to differ a great deal, yet all agree in containing but two essential parts, the germ, and food for it to consume before it has put forth roots to gather it for itself. In the cocoa nut, these are covered by a outer fibrous coat, then a hard woody one, then the food or albumen of the seed, as it is termed, buried in which, at the soft end of the husk, is the embryo. It is similar to this in the smallest seed. In the chesnut, when the husk is removed, a mealy matter is seen, in the small end of which is the germ. When the germ grows, great changes take place in the seed, for which water, air, and a certain temperature are requisite, but no light, it being detrimental to a growing seed. If one of these conditions is absent, the seed will not grow. If they are present, provided the seed has not lost its vitality, it is sure to grow. Seeds differ very much in their power of retaining vitality, some remaining dormant in the soil for years, not germinating until the soil should by chance be turned up, they either wanting air or heat. Clayey soils, by enveloping the seed, prevent the air from getting to it. For want of moisture seeds lie dormant but still not dead, as is proved by a crop now growing from seed taken from Egyptian tombs. With the requisite circumstances, seeds swell, soften, and burst their membranes, the germ puts forth its radicle, which pierces the earth and sends out rootlets, after which the stem shoots up, and forms branches. At first the seed, feeding on the carbonaceous matter stored up, abstracts oxygen from the air, and evolves carbonic acid, but its province afterwards, when it has formed roots and leaves, is to decompose the carbonic acid of the air and to liberate oxygen. The roots of plants are said to throw out acetic acid; when they have been grown in powdered marble, acetate of lime has been found. Liebig and others insist much on this point, considering that it is by this means that plants render insoluble substances soluble. During germination, a portion of the gum and starch in the seed is converted into sugar, which is called the process of saccharification. In growing plants a substance called diastase is formed, which has the remarkable property of being able to convert many times its weight of starch or gum into sugar, and it is in this manner that seeds whilst growing become so sweet. This is seen beautifully in the process of malting, which consists in allowing the barley to grow until its maximum of sugar is formed, which is just when the plumule begins to show, and then stopping it by drying. If the diastase had been previously washed out with water it would have been spoilt for malt, as saccharification would not have taken place. For beer making, the malt is bruised in hot water, and the action of the diastase goes on, the mucilage and starch is converted into sugar, and this again is decomposed into alcohol and carbonic acid.

When the young plant has exhausted the storehouse nature has provided it with, it is strong enough to derive its food by its roots and leaves, until which time no true wood is formed. The stem of a plant may be seen to consist of several parts, the centre portion, or pith, becoming obliterated as the plant grows; the wood is of two kinds, the old or heart wood, and the new wood or alburnum; in like manner the bark is of two kinds, the newer being termed the liber. The bark is connected with the pith by layers running from it, called the medullary rays, forming in timber the silver grain. The branches are but extensions of the stem, the smallest fibre resembling the wood of the stem. So, also, are the roots; but as they taper off the pith disappears, and at length the wood and bark, only cellular matter being at the extreme points; these are the spongioles, and in these the power of absorption resides; it is on account of the injury inevitably done to these that transplanting is so dangerous an operation. These absorb the water in the soil holding saline substances and carbonic acid in solution. The question has been raised, can the roots of plants select their food? and although there have been many experimenters, the evidence is very contradictory. Dr. Daubeny made some experiments on barley and peas with a solution of strontia, and found that they would not take it up. Saussure obtained similar results with acetate of lime and common salt. But their selective power is at all events limited, as they have been made to absorb solutions of arsenic, corrosive sublimate, opium, and tobacco, and their effects are said somewhat to resemble those on animals. The excretory function of the root was once supposed to be the reason of the necessity of a rotation of crops, as a plant was said to throw out substances which were poisonous to plants of the same kind. Now, however, it is explained by saying that each plant requires particular inorganic food, and if one crop has removed all of that kind from the soil, of course a similar crop could not thrive. Thus turnips will grow after wheat, because, as they require different constituents, the wheat has not removed those which the turnip requires.

The power of the root to absorb liquids from the soil is generally attributed to two actions, endosmose and capillary attraction. Endosmose, or the property of thin fluids to pass through porous bodies if thicker fluids are on the other side, is well illustrated by immersing the ends of three tubes tied round with membrane into water, having previously poured into them solutions of gum, sugar, and some alcohol. The water passing through will cause the level of the thicker fluids to be considerably raised. The capillary action of porous bodies is seen when the end of a cane is dipped into spirits of turpentine; it rises up through the length and may be lighted at the other end. The sap in a plant decidedly circulates, and its course has been distinctly traced. It ascends from the root by the outer layer of wood to the leaves, there, being spread over a large surface gives up a great quantity of water, is acted on by light, and flowing down the inner bark, much thickened, deposits new wood in its course. Thus each year a ring of new wood and new bark is formed, and by counting the rings of wood in the section of a tree, its age may be ascertained.

Lecture X. and last.

The direction of circulation of the sap when it forms new wood, may be rendered evident by ringing the bark of a tree; it will be found that the new wood will always be deposited from the upper part of the cut, showing that in the bark it is travelling downwards. The force with which the sap rises is very great, and experiments have been made by cutting a branch in the spring time, and so confining it in a tube with mercury that the force with which it rises can be measured. An application of this has been recently made to the preserving timber by means of impregnating it with various saline fluids. The fresh cut stem is immersed in the fluid, with the leaves and branches still attached; evaporation going on at the surface of the leaf, the fluid is drawn into every part much more thoroughly than can be done by other means. The circulation is never stopped in a tree, for though it is much less in winter, it still goes on. A thermometer placed in the interior of a tree shows it to be a little warmer than the air; this is easily accounted for; the earth being warmer than the air, the sap drawn from it must necessarily be so also. This is exceedingly useful, as it prevents it from freezing, and cracking its delicate vessels.

The leaf, which is a flat expansion of the wood and bark, contains vessels which bring the sap in, and others which carry it out and down into the inner bark. Few have an idea of the enormous transpiration continually taking place from the surface of leaves. Dr. Hales found that a sunflower exhaled from 20 to 30 oz. of water in a warm day, and 5 oz. at night. In dewy or damp weather it did not exhale any. By this means the sap, which enters it watery and insipid, goes out from it much thicker and sapid. This also is the reason why leaves yield so much more ash than any other part. The organs of the leaves are very delicate, and few can bear the soots, ashes, acids, &c., which load the air of London. Some, however, can, and a list of them has been published by Mr. M'Cullock. Green-house plants are delicate, and sometimes fall victims to injurious vapours diffused through the house. At Godsden, some pipes had been covered with a paint containing coal tar; almost every plant was injured or killed. This proves that plants can absorb vapours by their leaves, as they show the effects before it has time to get to the roots. The mischief that cold easterly winds cause to the leaves is as great as though they were placed before a fire.

These are merely the mechanical powers of the leaf; the chemical are powerful and astonishing. They can be explained, but difficultly imitated. The chemist, for instance, can readily make carbon into carbonic acid, but he can scarcely get the carbon out again: this the plant is always doing, evolving the oxygen. This is the general result, though at times it is slightly different, when, for instance, the sap is to be acid, the oxygen must be retained. When it is to be resinous, as in fir trees, excess of hydrogen is wanted; deriving this principally from water, oxygen must be liberated from this source, as well as during the formation of wood. The rapidity with which the leaves of a tree deprive the air of its carbonic acid is no chemical fiction, as there are abundance of experiments on record to prove it. Boussingault brought the limb of a vine into a jar, and found that it deprived the air of carbonic acid and evolved oxygen as fast as he carried a tolerably rapid current through it. For this it requires a bright sun, and that is why plants grow so quickly in a tropical climate. Decandolle immersed aquatic plants in water impregnated with carbonic acid, and found that they deprived the water of the gas, replacing it with oxygen. Thus they perform for fishes what land plants do for land animals. Dr. Gilly made a mixture of gases having a great excess of carbonic acid, and immersed a turf of grass therein; after four hours' exposure to sunshine, he got the following result:—

	Before	After
Nitrogen . .	105	105
Carbonic Acid .	57	4
Oxygen . .	28	78
	190	187

With the exception of a little loss of oxygen, the whole of the carbonic acid absorbed was replaced by that gas. Saussure obtained the same result from Lythrum salicaria, and Vinca minor. Priestley, long ago, placed sprigs of mint, whilst growing, in air which had been destroyed by a mouse or a candle, and found that it restored it to a proper state. It was then supposed to be due to the mint sending out an agreeable odour; but he proved that plants with a disagreeable odour would do the same. In his correspondence with Franklin, given in the Philosophical Magazine, he says that he hopes the knowledge of this will prevent persons from cutting trees growing near houses. Other remarkable changes can be proved to be effected by plants. The little water cress, as well as many other plants, has the power of decomposing sulphuric acid, retaining the sulphur, and liberating the oxygen; other plants, in like manner, decompose phosphoric acid.

Dumas has drawn up a very ingenious contrast between animals and vegetables.

Vegetables.		Animals.	
Produce	Azotised principles. Starch, sugar, oils, &c.	Consume	Azotised principles. Starch, sugar, oils, &c.
Decompose	Carbonic acid Water Ammonia	Produce	Carbonic acid Water Ammonia
Evolve	Oxygen	Absorb	Oxygen
Absorb	Heat	Evolve	Heat
Are an apparatus of de-oxidizement.		Are an apparatus of oxidizement.	
Are stationary.		Are locomotive.	

These are not true of the petals, &c., of blossoms, which act like animals, sometimes evolving ammonia, always absorbing oxygen, and occasionally producing very great heat.

When the bark of a plant is green, it acts like the leaf, therefore in herbaceous plants the whole surface acts alike. In the cactus there are no true leaves, the stem supplying its place. The bark of the root, in some cases, secretes a substance not found elsewhere. Phloridzin is thus found beneath the bark of the root of apple and pear trees.

The circumstances which influence and modify the growth of plants, are chemical and mechanical. At the head of the chemical must be placed light. By analysing rays of light it has been found that the violet or chemical rays are those in which the power of light on plants resides. Mr. E. Solly, of the Horticultural Gardens, has made experiments on the action of various coloured glasses on the light for plants, and he has obtained very excellent results by the use of violet glass, that is, by cutting off all the rays of light but the violet. The influence of mineral manures has been shown to be twofold, by passing into the roots, and also by yielding parts of themselves, as in the case of the nitrates. Phosphorus is indispensable for wheat, silica for grass. Lime acts on crops by inducing changes in the organic matter, by neutralizing acids, by decomposing inorganic salts, and by liberating ammonia from its combinations, as, for instance, from rain water. In tracing the growth of vegetables, their power of absorbing, changing, and recombining, the materials obtained from the soil and the air, has been seen, as also their influence when they are returned to the soil, acting as manure, loosening the soil, and returning to it its inorganic salts. The parts of the plant thus used for manure has great influence; thus the leaves are much better than sawdust. There are also advantages attending ploughing it in in a green state; this is frequently done by agriculturists, as, after fermenting, it yields a rich mould. For this reason it is judicious to gather together the hedge-row weeds, and bury them in the soil. Vineyards can be manured by their own cuttings, and for a length of years will scarcely require any other manure. This method has been revived of late, but it was a practice resorted to by the Romans. The same principle will apply to most crops, as by green crop ploughing both the organic and inorganic constituents are returned.
