THE Board of Agriculture has published colour-printed geological maps of Worms Head (Sheet 246). The map is issued in two editions (price 1s. 6d. each), on one of which (the solid edition) glacial deposits are omitted, while on the other (the drift edition) such deposits are indicated by colour. The scale is 1 inch to the mile.

THE latest list issued by Messrs. Voigtländer and Son, of 12 Charterhouse Street, E.C., is a handsome production. It contains numerous examples of photographs taken with various types of lenses made by this firm, and is in addition provided with an excellent introduction by Dr. H. Harting on the selection of photographic lenses and cameras.

THE Livingstone College Year-book for 1907 contains the annual report, extracts from letters from old students, hints on diet and hygiene in the tropics, &c. The college gives a training in elementary medicine and surgery to missionaries, and is doing much good work.

DR. M. MOSZKOWSKI has translated into German Prof. T. H. Morgan's work on "Regeneration," and the volume is published by Mr. W. Engelmann, Leipzig, at the price of twelve marks. Prof. Morgan has provided his translator with new material relating to facts and theories of scientific importance published since the first or English edition appeared in 1901, and this has been incorporated in the German edition. At the end of the chapter on the theories of regeneration, Prof. Morgan states the views he now holds concerning some questions of fundamental interest.

OUR ASTRONOMICAL COLUMN.

COMET 1907*d* (DANIEL).—Several observations of this comet are recorded in No. 4188 of the *Astronomische Nachrichten* (p. 207, July 4). Observing at Kremsmünster on June 24, Prof. Fr. Schwab saw a nebulous body of about 2′ diameter with a bright nucleus; the comet disappeared in the dawn simultaneously with stars of the ninth magnitude. Herrn van Biesbroeck, with the 15-inch refractor at Uccle, found the magnitude to be 8·5 for the whole comet, on June 19, this being decidedly brighter than on the previous day. On June 27 Prof. Hartwig saw a bright centrally-placed condensation. On July 4, Dr. Lappa, observing at Rome, found the magnitude of the nucleus to be between 6.0 and 7·0.

This object now rises about midnight, about four hours before the sun, and may be seen with a good field-glass.

COMET 1907*c* (GIACOBINI).—Dr. Strömgren continues his daily ephemeris for comet 1907*c* in No. 4189 (p. 223, July 6) of the *Astronomische Nachrichten*, and carries it forward to July 31. This object is now travelling in a south-easterly direction through the constellation Virgo, and its brightness is only about half that at the time of discovery, its magnitude then being 13·0.

THE ORBIT OF α CENTAURI.—Finding that his second set of elements does not represent the angles measured at periastron passage, and having many more observational results on which to base his calculations, Prof. Doberck has re-investigated the orbit of α Centauri, and publishes the result in No. 4189 (p. 209, July 6) of the *Astronomische Nachrichten*. In the new set of elements (iv) the eccentricity is given as 0·5057 and the period as 78·81 years. There are still differences between the observed and calculated positions which must be accounted for either by unusually large constant errors in the measures or by the presence of an invisible third body, the effect of which, in this case, would be enhanced on account of the large eccentricity of the orbit; an ephemeris for 1907·5–1936·5 accompanies the paper.

COMPARISON OF THE SPECTRA OF THE LIMB AND CENTRE OF THE SUN.—In No. 5, vol. xxv. (p. 300, June), of the *Astrophysical Journal*, Prof. Hale publishes an important paper showing the results of a comparison of the spectrum of the central parts of the sun's disc with that of the sun's limb. In 1879–80, Prof. Hastings showed that the modifications of the Fraunhofer spectrum at the limb were similar to those which obtain when a spot spectrum is examined, but were much less in degree. Recent work at Mount Wilson confirms this, and shows that the effect is greater than was previously expected.

The differences between centre and limb are plainly shown in three sets of spectra which Prof. Hale reproduces. All winged lines such as H, K, $H\gamma$ and the lines of the *b* group lose, to a great extent, their hazy borders, the latter, for example, appearing as comparatively hard, well-defined lines. Other lines, *e.g.* $\lambda\lambda$ 5156·823, 5219·875, 5426·474, which are intensified in passing from the Fraunhofer to the spot spectrum, are intensified at the limb, whilst still others, generally "spark" lines, are weakened at the limb as they are in spots.

There are, however, as shown by the preliminary examination, important differences in the changes undergone. Perhaps the most striking is in the winged lines the borders of which, at the limb, are universally contracted, whereas in spots the wings on the strong lines in the more refrangible portion of the spectrum are intensified rather than diminished. Another anomaly is that at the limb the lines of V and Ti, certainly the most affected in spots, are not so strongly affected as those of Mg, Fe, Ca, &c. Again, in spots, $H\alpha$, like all the other H lines, is thinned, whereas at the limb this line is actually widened and perhaps strengthened.

The thinning of the spark lines is strikingly shown in a table in which the behaviour at the limb of twenty-seven of the more prominent enhanced lines of Fe, Ti, and V, as given by Sir Norman Lockyer, is exhibited. All these lines are considerably weakened in passing from centre to limb, and the majority of them have been observed similarly affected in spots.

A discussion of these results in their bearing on the solar theory is promised in a later paper.

THE ORBIT OF ι ORIONIS.—A note by Mr. Plaskett in No. 3, vol. i. (p. 206, May–June), of the Journal of the R.A.S. (Canada) mentions the preliminary results obtained from the radial-velocity measurements of the spectrum of ι Orionis. These show that the eccentricity of the orbit is 0·75, greater than that of any other yet known spectroscopic binary, and that the period is about 29·12 days.

METEOR AND FIREBALL OBSERVATIONS.—*Astronomische Nachrichten*, No. 4187 (p. 183, June 29), contains an account by Mr. Denning of a first-magnitude Leonid observed on November 17 last. This meteor travelled along a visible path more than ninety-one miles in length at a velocity of thirty miles per second, a considerably lower velocity than that usually attained by Leonids. The height at the beginning of the flight was seventy-seven miles, at the end sixty-six miles, so that the path was very long and nearly horizontal, facts which may account for the low velocity, as the body would thus encounter considerable atmospheric resistance.

A fireball, observed over Yorkshire on November 23, 8h. 5m., was brighter than Venus, and appears to have proceeded from a radiant at $46°+5°$, a position near α Ceti. From previous observations there appears to be a shower of long duration, or a succession of showers, from this radiant, Cetids having been observed in September, October, and November, those in November furnishing the most brilliant examples. The mean position of the radiant is $43°+5°$.

THE ROYAL SOCIETY OF CANADA.

THE annual sessions of this society, the premier scientific society in Canada, were held, as usual, in the capital city of Ottawa on May 13–16. The society, which was founded twenty-five years ago by the Duke and Duchess of Argyll (the Princess Louise and the then Marquis of Lorne), combines the features of the Royal Society of London and the French Academy. The number of fellows is very limited, and there are four sections, viz. French literature and history, English literature, &c., physics and chemistry, and biology and geology. There was an unusually large attendance from all parts of the vast Canadian dominion, and in Sections iii. and iv. the meetings were regarded as the best ever held.

Dr. Wm. Saunders, C.M.G., president of the society for 1906–7, and head of the Government Experimental Farms, gave his presidential address on the evening of May 14 in the presence of a distinguished audience, including Sir Sandford Fleming, Sir James Grant, Profs. Ramsay Wright, Penhallow, Prince, and Clark Murray, and representatives from most of the universities of Canada. The subject was "The Development of Agricultural Science," and it consisted of a masterly review of the history of farming from classical times to our own day.

The ancient Hebrews and Egyptians were the most proficient tillers of the soil in those distant ages, and the latter race was the first to raise domestic cattle. Amongst the Romans, agriculture was highly esteemed, and when luxury brought demoralisation, the noblest minds reverted to farming. "The earth," said one of these old Romans, "gives back what it receives with usury, and nothing can be more profitable or beautiful than a well-kept farm."

During the Middle Ages, only the wealthy ate wheaten food; the poorer classes used rye, barley, and oats. But in the sixteenth century Raleigh introduced the potato into Ireland. However, when the Queen of England wanted a salad for luncheon, she had still to despatch a messenger to Holland.

Up to the eighteenth century land was sown until exhausted. By that time farmers had learned the alternate crop plan of conserving the strength of the soil, and at the opening of the nineteenth century they understood the value of manure as a fertiliser.

"It is highly probable," declared Dr. Saunders, "that the plant-life will always supply enough food for mankind, and the supposition sometimes advanced, that the rapidly increasing population will not find sufficient nourishment, seems far remote from probability."

Twenty-three years ago farming was in a very depressed condition in Canada. In 1884 a select committee of the Canadian House of Commons investigated the causes of this depression, and found it was due, not to poor soil or idleness, but to a lack of knowledge and skill in the farmers, and the committee recommended the establishment of experimental farms to promote agriculture and instruct the farmers. Accordingly, in 1886 a central farm was started near Ottawa, with four other branch farms in other parts of Canada. In agriculture, Canada is now preeminent among the nations, and even Egypt, the ancient farming land, is asking for samples of Canadian products that she may emulate this country in the pursuit of the farming industry.

Prof. Rutherford, F.R.S., was president of Section iii. (Physics), and gave an address on the life-history of radium, and other fellows of the society presented twenty-five original communications, while Prof. Edward E. Prince, Chief Commissioner of Fisheries, delivered an address, as president of Section iv. (Biology and Geology), on marine biology in Canada. Prof. Prince is the head of the three biological stations carried on by the Government on the Atlantic, the Pacific, and the Great Lakes shores, and his account of the progress of zoological research and of the investigations at the stations proved exceptionally interesting. Twenty-seven papers were read and discussed, including one, the first ever presented to the society by a lady, the subject being "The Islets of Langerhans in the Pancreas of Certain Fishes," by Prof. Swale and Mrs. Thompson, of Winnipeg. Prof. Adami, McGill University, gave a paper upon certain curious cases of vertebrate teratology recently studied by him, and Prof. A. B. Macallum, F.R.S., described some new cells with protruding tail-like processes occurring in the mesoglœa of Aurelia and other Medusæ.

The popular evening lecture, which is always an important feature of the Canadian Royal Society's annual meeting, was delivered to a crowded assembly in the large hall of the Normal School by Prof. Ernest Rutherford. The subject was "Recent Results of Researches on Radium." In a graphic manner, the lecturer explained his famous "disintegration" theory, the transformation of chemical elements, the marvellous phenomena of radiant matter, and illustrated his remarks by striking experiments. He aroused much interest by stating that in Canada there were probably more rocks containing radium than in any other territory on the globe, and he had found, by suspending a wire in the open air in Montreal during a shower of rain, that radium collected on the wire. Many brilliant social functions took place during the meetings, including a large garden party by Dr. and Mrs. Saunders at their official residence; dinners given by the president-elect, Dr. S. E. Dawson; luncheons by Sir James Grant, former president; and other entertainments.

THE ROYAL VISIT TO THE UNIVERSITY COLLEGE OF NORTH WALES.

IN last week's NATURE, a short account was given of the visit of the King and Queen to Bangor to lay the foundation stone of the new buildings of the University College of North Wales. A few particulars relating to the origin and work of the college, and some thoughts suggested by speeches made at last week's ceremony, may be of interest as a supplement to the report that has already appeared.

The University College of North Wales was founded in 1884, and is at present located in the buildings of the former Penrhyn Arms Hotel. It has been enlarged by the addition of laboratories and lecture rooms for the faculty of science, which includes departments of agriculture and electrical engineering. The former was the first institution of its kind in Great Britain, and has been adopted as the model of similar agricultural departments started elsewhere. Its operations have been extended by the foundation in 1904 of a school of forestry under the auspices of the Board of Agriculture, one of two in the United Kingdom. The electrical engineering department is maintained by an annual grant from the Drapers' Company. If its resources in the matter of equipment have not been on a lavish scale, the training it has afforded has been of a high character and has probably possessed advantages which an over-elaborate plant might not afford. Still, much apparatus is badly needed before the condition of maximum efficiency can be reached. Another feature is the fisheries department, which has performed useful work in developing the fishing industry of North Wales, an industry which is capable of being greatly developed by the diffusion of practical scientific knowledge in the fishing districts. Although the present notice necessarily deals primarily with the scientific aspect of the work of the college, allusion must be made to the day training department, the courses in secondary education, and the facilities for kindergarten training afforded by the establishment of a preparatory school under the auspices of the college.

The new college will consist, when finished, of two quadrangles. At present it is only intended to erect the arts and administrative buildings, and it is to be hoped that by the time this has been done the building fund will admit of the science buildings being commenced. The library is very inadequately housed, and when we point out that only about 10*l.* a year is available for the purchase of books in such a subject as pure and applied mathematics combined, physics or chemistry, it will be seen that the present college staff is doing good work under difficulties which would not exist in a similar institution in Germany or America.

At the public luncheon, the Right Hon. D. Lloyd George, M.P., gave some interesting statistics showing the liberality and enthusiasm of the people of North Wales in matters relating to education. The contributions for university and technical education are six times, and to secondary education nine times, as high as in England, and the contributions of the town and suburbs of Bangor to the college alone represent the proportional equivalent of a sum which for a town of the size of Liverpool and its suburbs works out to 1,750,000*l.* In regard to the question of Government assistance, Mr. Lloyd George thought that waiting for Governments was like waiting for sunshine, and that the college afforded a grand opportunity for a millionaire to earn gratitude and fame.

But where is Mr. Lloyd George going to find his millionaire? A country which raises a protective tariff against millionaires in the form of death duties is scarcely a promising field. When we take account of the heavy losses North Wales has sustained by the death of a number of its most influential and prominent landowners during the last decade, the progress of the new college buildings will be found to represent a widespread feeling of munificence and loyalty towards the cause of higher national education far in advance of anything that exists in America. But in the race between British and American universities, Great Britain is heavily handicapped, with the result that, in spite of all the efforts we are putting forward, we are rapidly falling further and further behind. The inevitable result is that the responsibilities which the acquisition of wealth entails will be pressed more and more heavily every year on our Governments, and unless they can supply the extra few rays of sunshine we shall be less and less able every year to raise up the intellectual produce necessary to enable us to compete with the foreign producer.

The problem was solved long ago for Germany by her system of State universities. That Germany owes her national prosperity in no small measure to the principle of *Lehrfreiheit*, which has been adopted as the fundamental law governing the relations of the university professors with the State, is a fact which every German citizen knows well. It is no trifling thing to say that there is probably not a single university college in the United Kingdom the council and senate of which are more thoroughly imbued with the spirit of the German ideal than the University College of North Wales. In the large industrial centres of South Wales there exists an unfortunate conflict of rival factions, and it is sad to notice that many people only associate themselves with university education in order to acquire a cheap reputation by belittling the academic element, making unjustified and vexatious attacks on its representatives, and hampering the progress of the nation whose interests they falsely profess to have at heart. We refer in particular to the state of affairs which culminated some years ago in the premature death of the late Principal Viriamu Jones, and has continued to exist ever since. In North Wales the ardent Welsh nationalist, and the scientific worker who believes that "he is the greatest patriot who has the world for his nation," all realise that they are working together for a common cause.

G. H. BRYAN.

THE ALDROVANDI CELEBRATIONS AT BOLOGNA.

IT is not improbable that some of the delegates appointed to represent foreign universities and learned societies at the tercentenary of the death of Ulisse Aldrovandi (1522–1607) were insufficiently acquainted with the works of this great naturalist to appreciate thoroughly the importance of the occasion. The international gathering at Bologna (June 11–13) has been the means of rescuing from partial obscurity the memory of one of the many pioneers in the study of nature which Italy has produced. Bologna, the birthplace of universities and the *alma mater* of not a few students whose names occupy a prominent place in the history of the natural sciences, is an ideal meeting place of the nations to do homage to one of the fathers of scientific investigation. The numerous coats of arms which decorate the walls of the old university buildings bear witness to the hospitality of Bologna to students from all parts of the world, and the celebration which has now been brought to a successful conclusion testifies to the continuance of a spirit of hospitality after the lapse of centuries.

Aldrovandi's works, including several volumes published after his death, are in themselves a striking monument to his prodigious industry and encyclopædic knowledge; his wealth and long life were given up to an attempt to realise his ideal—"nothing is sweeter than to know all things."

The committee appointed under the patronage of the King to carry out the arrangements for the Aldrovandi celebrations had as honorary presidents the Marchese Tanari (Prosindaco del Commune) and the Rector of the University, Prof. Puntoni. Prof. Capellini, whose geniality is well known to many English friends, filled the office of acting president, and it is mainly to his labours and to those of the general secretary, Sig. Sorbelli, that the success of the meeting is due. On arriving at Bologna delegates were met at the station by members of the reception committee, from whom they received useful literature and information as to the lodgings provided for them. A general meeting was held in the Archiginnasio in the afternoon of June 11, at which Prof. Capellini welcomed the guests and gave an account of the order of procedure; in the evening a conversazione was given by the Marchese Tanari in the municipal buildings. The morning of June 12 was devoted to the most important business of the meeting; the delivery of discourses by Prof. Capellini, the Minister of Public Instruction and Agriculture, Prof. Costa and others, was followed by the presentation of addresses, accompanied by a few remarks by selected delegates. A feature of special interest was a speech by Count Luigi Aldrovandi—connected through fourteen generations with his illustrious ancestor. Prof. Ferguson, of Glasgow, was chosen by the British delegates as their spokesman. Oxford University was represented by Mr. Ashburner; Cambridge University, the Royal Society, the Linnean and Geological Societies of London, by Prof. Seward; St. Andrews, by Dr. Steele; and Glasgow University by Prof. Ferguson, who had previously taken part in the celebration of the octocentenary of the Bologna University. Among other delegates who spoke were Prof. Pélissier, of Montpellier; Prof. Schück, of Upsala; Dr. Wieland, of Newhaven; Prof. Entz, of Budapest; Prof. Richter, of Kolozsvar; and Prof. Brusini, of Zagabria (Agram, Croatia). The unveiling of a memorial tablet to Aldrovandi in the courtyard of the Archiginnasio terminated a somewhat lengthy programme.

In the evening delegates were afforded an opportunity of seeing the new Italian Opera—"John the Baptist"—in the Municipal Theatre. A cordial reception was given to the composer, a young priest from Turin, as he appeared before the curtain with those who took the parts of Christ, John the Baptist, Herod, and Salome. On June 13 the delegates were present at the inauguration of the Aldrovandi Museum. This was the most striking event during the meeting. A large collection of well-executed wood-blocks, together with the original specimens, shelves filled with volumes of unpublished manuscripts, a collection of coloured drawings of natural objects, and a series of herbaria formed a most impressive demonstration of the industry and whole-hearted devotion with which Aldrovandi applied himself and his means to the pursuit and organisation of knowledge. The fact that a catalogue of the unpublished manuscripts, specially printed for the celebrations, consists of 300 pages affords some measure of what Aldrovandi accomplished. Each delegate received a bronze medal bearing a bust of Aldrovandi and the following inscription on the reverse:—

Cui natura parens
Quaerenti tota refulsit

Virum post tria saecula meritas et gloria florentem
civitas et universitas
Bononiensis doctorum totius orbis adsensu rite
concelebrant. Prid. id. iun. MDCCCCVII.

In the afternoon a visit was paid to the Istituto Rizzoli at San Michele, in Bosco. Within the building devoted to orthopædic treatment were seen strange machines in motion to which were attached patients in various attitudes. The view from the grounds of the institute of Bologna and the plain beyond could not easily be surpassed.

An enjoyable banquet at the Hotel Brun in the evening brought the celebrations to a conclusion.

The presentation of several specially compiled volumes to those attending the meeting afforded another proof of the pains taken to render the meeting a success, and supplied a permanent interest to a thoroughly enjoyable reunion of nations. The volumes included "Intorno alla vita e alle opere di Ulisse Aldrovandi—Studi di A. Baldacci, E. de Toni, M. Gortani, F. Morini, A. C. Ridolfi, A. Sorbelli"; "Chartulorum Studii Bononiensis"; "Catalogo dei Manoscritti di U. Aldrovandi a Cura di Ludovici Frati con la collaborazione di A. G. e Albano Sorbelli.'"

NATIONAL POULTRY CONFERENCE AT READING.

THE second national poultry conference was held at University College, Reading, last week, July 8–12, under the presidency of Sir Walter Palmer, Bart.

In addition to papers and discussions, there was an exhibition of pairs of about 150 breeds of poultry, both English and foreign. Several breeds of the latter had not been seen in this country previously.

Mr. C. C. Hurst read a paper on Mendel's law of heredity and its application to poultry breeding. After briefly alluding to Mendel's work on peas, he went on to describe the Mendelian pairs of characters in fowls, such as rose and single comb, white and coloured plumage, colours of legs, and others. The "law of segregation" was then explained and illustrated by reference to crosses between rose-combed Hamburgh and single-combed Leghorn, and between white Leghorn and black Minorca and other coloured varieties.

The rose-combed are dominant over the single-combed varieties, and the first cross are all rose-combed birds. Bred among themselves they produce on the average three rose-combed chicks to one single-combed bird. The latter mated with a similar one breeds true. The nature of the blue Andalusian fowl was then discussed, and the want of fixity of colour, in spite of more than fifty years of breeding and separation of "rogues," was pointed out. Pedigree "blue" birds produce only one-half blue like the parents, the remainder being black and splashed white birds in equal proportions. The black and white breed true, but when crossed produce all "blue" birds. The necessity of the determination of what characters are Mendelian was emphasised, and the practical value of Mendel's law in enabling breeders to calculate what the results of particular crosses will be was referred to in conclusion.

The next paper in the section dealing with breeding problems was by Dr. J. Llewelyn Thomas, on "Hybridisation Experiments with the Ceylon Jungle-fowl." These experiments were undertaken in 1903–4 with the view of solving the following questions:—(1) Will the Ceylon jungle fowl (*Gallus stanleyii*) breed with the domestic fowl? (2) Will the hybrids breed with the jungle fowl and with the domestic fowl? and (3) will the hybrids breed among themselves? The view that the black-breasted jungle fowl of India (*Gallus bankiva*) is the parent stock of the domestic game fowl is generally accepted, and Darwin, in his "Animals and Plants under Domestication," says that the Ceylon jungle fowl "may in all probability be rejected as one of the primitive stocks of the domestic fowl," a statement which he based on information supplied by a Mr. Mitford that two hybrids raised by the latter proved sterile. It was felt that the evidence just mentioned was not sufficient to establish a conclusion one way or the other, and experiments were undertaken to obtain further information on the matter. Wild Ceylon jungle fowls were obtained after much trouble and placed in specially built runs with domestic fowls in various parts of the island.

The mating of jungle hens with the domestic cock was a complete failure. The jungle cock, however, mated readily with domestic hens! The eggs laid proved fertile, and about thirty chicks were raised from them. The hybrid cock crossed with the domestic hen gave fertile eggs, and the offspring was fertile not only with the domestic parent, but also with the hybrid parent and with one another. No chickens were obtained from the crosses

(1) hybrid cock × jungle hen, (2) hybrid hen × domestic cock, (3) hybrid hen × jungle cock.

From the cross-bred cock × hybrid hen several addled eggs were obtained, four more had chicks dead in the shell, and from two of the eggs live chickens were hatched out. The latter were apparently sturdy and robust enough for a short time, but died on the twelfth and eighteenth day respectively after hatching. The sterility of the hybrids cannot, therefore, be adduced as evidence that the Ceylon jungle fowl is not a parent stock of the domestic fowl. It was pointed out that the Ceylon jungle fowl has a reddish-brown breast, and when reversion occurs among domestic fowls, even those of pure bred black-breasted types, the males usually have red or brown breasts and not black like *Gallus bankiva*.

Mr. F. V. Theobald gave an account of a parasitic liver disease in fowls, specimens of which had been sent to him during the last three or four years. Although previously unrecorded, it is probably quite common, and due to a protozoon *Amoeba maleagridis*, Sm. Diagnosis is somewhat difficult, but the *post-mortem* appearances of the liver with yellow spots along with swollen cæca are characteristic. The life-cycle of the parasite is not yet fully worked out.

Mr. Theobald incidentally referred also to an infectious disease among poultry in South America, produced by a Spirochæte, which passes part of its life-cycle in a fowl tick (*Argas miniatus*). J. P.

HYDROLOGY IN THE UNITED STATES. PURIFICATION OF SEWAGE.

WE have on several previous occasions noticed the papers issued by the United States Geological Department on Water Supply and Irrigation.[1] Recently we have been favoured by the receipt of nineteen further papers bearing on this subject.[2]

The greater part of these, although containing a great deal of information bearing on water supply, are yet chiefly of local interest.

Paper No. 180 of the series now sent deals with the efficiency of turbine water-wheels, and consists of a compilation of data derived from tests and from manufacturers' power tables of American stock sizes, and is intended principally for the use of the hydrological surveyors in cases where the turbine is used for gauging streams.

Paper No. 179 gives an account of investigations carried on for the purpose of discovering means for preventing the pollution of streams by distillery refuse. Paper No. 189 further deals with the disposal of the waste liquors resulting from the manufacture of strawboard, an important problem connected with the prevention of stream pollution in the districts where this industry prevails.

Paper No. 187 deals with the measurement of streams when they are frozen over, and with the modifications of the ordinary methods of gauging these streams when they are covered with ice.

Paper No. 182 describes the various wells in use for municipal or domestic supply in Michigan, and the means adopted for raising the water from these wells.

Paper No. 185, on investigations into the purification of Boston Sewage, with a history of the sewage disposal problem, is of much more general interest, and contains a great deal of information of value to sanitary engineers and chemists engaged in sewage disposal. It therefore deserves a more extended notice in this Journal.

The origin of the paper was as follows:—An anonymous friend of the Massachusetts Institute of Technology, moved by the magnitude and gravity of the sewage disposal problem as it concerns householders and communities, in 1902 presented to the institute a sum equal to 1000*l.* a year for three years, afterwards extended to five years, for the purpose of making experiments on sewage purification and giving the widest possible publicity to means or methods by which the present too often crude and imperfect systems may be improved.

The report now under review, which contains 162 octavo pages, has been drawn up by Messrs. Winslow and Phelps in consonance with the wishes of the donor, and consists of a popular statement of the history of the several methods that have been tried for the purification of sewage, and a record of the results obtained at the laboratory of the Massachusetts Institute. It is claimed by the authors that the paper is written in a popular style and in language so simple that citizens, boards of health, and sewerage commissions may readily avail themselves of the information contained in it.

The sewage experimental station at the institute is situated adjacent to the City of Boston, U.S.A. Within the last few years the whole of the sewage of this city has been collected into two large main outfall sewers, and is discharged into the harbour on the ebb tide. The station is connected with one of these outfall sewers. The sewage is pumped directly from the sewer through $2\frac{1}{2}$-inch galvanised pipes into a series of twenty-five tanks having an area of 24 feet each, the depths varying from 3 feet to 6 feet. In these tanks the sewage is treated by intermittent sand filtration; the septic process; contact filtration through coke, stone, and brick of various diameters; and by trickling filters. The result of the effluent from the different tanks, as obtained by analysis, is given.

Under the conditions of these experiments crude sewage has been successfully filtered through a 2-feet bed of sand with an effective size of 0·14 millimetre at a rate of 0·4 million gallons per acre per day, divided into four doses in the twenty-four hours. The effluents were clear, bright, and well purified.

With single contact beds of stone $1\frac{1}{2}$ inches in diameter, passed at the rate of 1·2 million gallons per acre per day, the effluent of the crude sewage was only partially purified. The beds clogged rapidly, and the surface required much attention.

The double contact system in primary beds of 2-inch material, and secondary beds of $\frac{1}{2}$ inch, yielded a fairly well-purified and stable effluent at the rate, on the combined double system, of about 0·7 million gallons per acre per day with beds 6 feet deep.

The most practical of the methods that have been studied appears to be the treatment of the sewage either sedimented or subjected to a very short period of septic action in double contact beds.

The process of trickling filtration remains to be considered in a further report, but, so far as the present experiments indicate, this method will probably prove superior to any so far tested.

In the report is also given a summary of the history of sewage purification in England, Germany, the United States, and other countries, and the gradual development of the processes at present in operation. Starting from the discharge of the crude sewage into the sea or rivers, broad irrigation or sewage farming is described, and also chemical precipitation, intermittent filtration through sand, septic tanks, contact process in beds of coarse material, and continuous trickling over coarse material.

With regard to the first, it is shown that, although where the conditions are favourable sewage may be discharged into the sea without creating a nuisance, there yet remains to be considered its effect on shell-fish. With regard to the discharge into rivers, the conclusion arrived at by the River Pollution Commission of 1874 is given, that sewage mixed with twenty times its volume of pure

[2] Reports issued by the Department of the United States Geological Survey. Water Supply and Irrigation Papers. (Washington: Government Printing Office, 1906.) No. 185, Purification of Boston Sewage; No. 179, Prevention of Stream Pollution by Distillery Refuse; No. 180, Turbine Water Wheel Tests and Power Tables; No. 159, Summary of Underground Water Resources of Mississippi; No. 161, Quality of Water in the Upper Ohio River Basin; No. 162, Destructive Floods in the United States in 1905; No. 164, Underground Waters of Tennessee and Kentucky; No. 172, Progress of Stream Measurements, Missouri River; No. 174, Progress of Stream Measurements, Western Gulf of Mexico; No. 175, Progress of Stream Measurements, Colorado River; No. 177, Progress of Stream Measurements, California; No. 179, Means of Preventing Pollution of Streams by Distillery Waste; No. 181, Geology and Water Resources of Owens Valley; Nos. 182 and 183, Flowing Wells and Municipal Water Supplies in the Southern Peninsula of Michigan; No. 184, Underflow of South Platte Valley: No. 187, Determination of Stream-flow during the Frozen Season; No. 188, Water Resources of the Rio Grande Valley in New Mexico; No. 189, The Prevention of Stream Pollution by Strawboard Waste.

water would be two-thirds purified in flowing 168 miles at the rate of one mile an hour. With regard to broad irrigation, the conclusion generally arrived at is that sewage farms can never be expected to show a profit if interest on capital is included in the expenditure, and the experience is that there need be no serious danger of the spread of disease from irrigated crops, but that fruits and vegetables so grown should never be eaten without being cooked. With chemical precipitation the great difficulty is the disposal of the sludge, which amounts to twenty to twenty-six tons per million gallons of sewage. The disposal of this sludge generally involves considerable expense, it being found by practice to be of no value as manure. In fact, in some places, after being compressed into cakes, it is burnt or buried in the ground.

The result of the other processes has already been dealt with in the experiments conducted by the Massachusetts Institute.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Liverpool.—The annual exhibition of antiquities arranged by the Institute of Archæology, illustrating excavations in Upper Egypt 1906–7, was inaugurated at Burlington House, London, W., on Tuesday, July 16, and will remain open until July 30. The exhibits include scarabs, ornaments, and inscriptions of 2000 B.C. to 1200 B.C., and stelæ of Ptolemaic and later dates, recently discovered by Prof. Garstang, Mr. E. Harold Jones, and the Hon. R. H. Trefusis.

Manchester.—By the will of the late Mr. Mark Stirrup the university has received the following bequests:—Specimens of volcanic rocks and fossils; 1000*l.* for the maintenance of a geological and palæontological collection; 1500*l.* for the foundation of a palæontological scholarship, tenable for two years by anyone who has studied geology in the university.

Mr. J. W. Bews has been appointed to the newly instituted post of lecturer in economic botany.

Oxford.—In a convocation to be held on September 30, the degree of D.Sc. *honoris causa* will be conferred upon Prof. Charles Barrois, Lille; Prof. A. Heim, Zürich; Prof. A. Lacroix, Paris; Prof. A. Penck, Berlin; Dr. Hans H. Reusch, Norway; Prof. F. Zirkel, Leipzig.

Dr. George Dreyer, lecturer in general and experimental pathology in the University of Copenhagen, has been elected to the newly established professorship of pathology.

Sheffield.—The University has just issued its list of results of examinations, and we observe that three students have obtained the new degree of Bachelor of Metallurgy (B.Met.), viz. R. Mather, Z. T. K. Woo, and G. S. Ludlam. It seems only appropriate that the University's first three graduates should have taken their degree in metallurgy, as this department has for many years upheld a high standard of training in the metallurgy of iron and steel compatible with the ancient fame of the city as the home of the manufacture of high-class and special steels. It may not be inappropriate to note, in connection with the present trend of affairs in the East, that one of the honour graduates is a native of China.

Private enterprise has succeeded in founding, with the sanction of the Ministry of Education, confirmed by the Czar, an Institute of Archæology and Archæography in Moscow. The institute, which has just obtained its charter, ranks with a university, and is open to all graduates of Russian or foreign universities. Its aim is to prepare qualified archæologists and "archæographists." The latter term is applied to persons skilled in the preservation and use of historical archives, libraries, museums, and other collections, public and private, demanding special knowledge. The Moscow Institute of Archæology is the first institution in Russia founded on autonomous principles; it has the right to elect its own staff of professors, and generally to conduct its own internal affairs, subject only to a possible veto of the Minister of Education in certain cases. The course is a three years' one, the final year of which must be spent in practical work either in archæological expeditions and research among the monuments of antiquity as yet so little studied in Russia, or in similar special work at home or abroad. The institute grants the degree of doctor of archæology or archæography. Among those connected with the new institute whose names are favourably known outside Russia may be mentioned Dr. Uspensky, director of the institute, the author of fifty capital monographs in Russian; Dr. Fleischer, who was associated with English and American archæologists in recent excavations in Persia; Prof. Grot, and other Moscow professors. Privat-docent Visotsky has been appointed secretary to the institute.

The first meeting of the governing body of the Imperial College of Science and Technology was held on July 12 at the Victoria and Albert Museum, South Kensington. Mr. R. McKenna, M.P., President of the Board of Education, who was accompanied by Sir Robert Morant, opened the meeting. The following members of the governing body were present:—The Earl of Crewe, Sir F. Mowatt, Sir Julius C. Wernher, Sir W. H. White, Principal MacAlister, Mr. A. H. D. Acland, Mr. F. G. Ogilvie, Mr. J. C. G. Sykes, Dr. Glazebrook, Sir E. H. Busk, Prof. Capper, Prof. Farmer, Sir A. W. Rücker, Mr. A. Acland Allen, M.P., Mr. H. Percy Harris, Sir C. Kinloch-Cooke, Mr. R. A. Robinson, Mr. J. T. Taylor, Sir J. Wolfe-Barry, Sir Owen Roberts, Sir W. S. Prideaux, Viscount Esher, Sir A. Geikie, Prof. Tilden, Prof. Gowland, Prof. Dalby, Sir Alexander Kennedy, Mr. T. Hurry Riches, Mr. R. K. Gray, Sir Hugh Bell, Dr. Elgar, Prof. Divers, Mr. A. Sopwith, and Mr. W. McDermott, with Mr. F. E. Douglas as secretary (*pro tem.*). Mr. McKenna, in opening the meeting, took the opportunity to explain the arrangements which would have to be made for the transfer of the Royal College of Science and Royal School of Mines to the control of the governing body, and referred to the importance of the work which lay before the governing body in connection with the provision and organisation of advanced technical education within the Empire. On the motion of Viscount Esher, seconded by Sir Alexander Kennedy, Lord Crewe was unanimously elected chairman. On Lord Crewe taking the chair, Mr. McKenna handed to him the Letters Patent containing the Grant of the Charter of the Imperial College. Provisional committees (including a finance committee, of which Sir F. Mowatt was appointed chairman) were appointed to deal with preliminary matters and to report to the next meeting of the governing body, which was fixed for July 19.

A recent issue of the Journal of the Department of Agriculture and Technical Instruction for Ireland contained an exhaustive article on technical instruction in Belfast, by Mr. F. C. Forth, the principal of the municipal technical institute in the city. This account has now been published in a separate form. In the inauguration of the scheme of technical instruction the Corporation had as the chief object the provision of instruction in the principles of those arts and sciences bearing upon the trades and industries of Belfast. The success of the trade classes has been due in great measure to the enlightened view which officers of trade societies in Belfast have taken of the operations of the technical institute and to the encouragement which has been given by employers. In 1900 it was decided to build the excellent technical institute which has now been practically completed at a cost of 100,000*l.* The Belfast Corporation was, it is satisfactory to note, well advised, and as the work of each department developed sufficiently to warrant such a step, a principal teacher for it was appointed, and his first duty was to superintend the equipment of the department allotted to him in the new building and to be responsible for the expenditure of his share of the 40,000*l.* set aside for the equipment of the new institute. Before the building was out of the contractor's hands a number of classes were transferred to it, and useful experience was gained which led to some modifications in arrangements before the building was completed finally. The great bulk of the equipment is now installed, and it is hoped that when the date for the formal opening arrives, the building and its contents will be complete. Belfast is to be congratulated upon the provision the Corporation has made for providing young men and women with a modern and thorough type of technical education.

SOCIETIES AND ACADEMIES.

London.

Zoological Society, June 18.—Mr. G. A. Boulenger, F.R.S., vice-president, in the chair.—The growth-forms and supposed species in corals: Dr. F. W. **Jones**. The author showed that the growth-form of the colony was the outcome of the conditions of the environment, and was not a specific character. The growth-form was largely the result of the method of division of the zooids of the colony, and different external conditions produced different methods of division, so that almost any coral could show almost any method of division.—The lizard of the Ionian Islands which had been named *Lacerta ionica* by Herr Philip Lehrs: G. A. **Boulenger**. The author stated his opinion that this lizard was not entitled to specific rank, and that it was merely a variety of *Lacerta taurica*, Pallas.—Neotropical Lycænidæ: H. H. **Druce**. A large number of new forms were described, and the synonymy of many others discussed.—Descriptions of *Velifer hypselopterus* and of a new fish of the genus Velifer: C. T. **Regan**.—The anatomy, classification, and systematic position of the teleostean fishes of the suborder Halotriognathi: C. T. **Regan**. The paper showed that the Lamprididæ, Veliferidæ, Trachypteridæ, and Lophotidæ formed a natural group closely related to the Beryciformes, from which they differed especially in the structure of the mouth.—Monkeys of the genus Cercopithecus: R. I. **Pocock**. All the known forms of this genus may be arranged into groups typified by the following species:—*patas*, *aethiops*, *petaurista*, *cephus*, *nictitans*, *leucampyx*, *albigularis*, *mona*, *neglectus*, *l'hoesti*, and *diana*.—Some African species of Felis, based upon specimens exhibited in the society's gardens: R. I. **Pocock**. Special attention was directed to some interesting points connected with *F. nigripes*, *F. serval* and *servalia*, and *F. aurata* (=*chrysothrix*). A specimen of the last-named species from Sierra Leone changed from red to dusky grey while living in the gardens, thus proving that the differences in colour between individuals of this species were not of specific or subspecific value.—The jelly-fish of the genus Limnocnida collected during the third Tanganyika expedition: R. T. **Günther**. The material was obtained on four distinct dates in September, November, and February, by Dr. W. A. Cunnington, and therefore during the season of the great rains. The greater number of specimens in all the collections showed a vigorous growth of young medusa-buds on the manubrium, and that therefore the theory that asexual reproduction occurred during the dry season only, which was propounded by Mr. Moore, must be abandoned. Dr. Cunnington's material threw new light upon the order and succession in which the tentacles developed, and had enabled the author to record all the stages of tentacle development as exhibited by individuals ranging from 2 mm. to 22 mm. Certain variations in the arrangement of radial canals and of sense-organs were discussed. So large a percentage as 24 per cent. were found to possess five or more radial canals, the greatest number being seven instead of the normal four. The Victoria Nyanza form of Limnocnida collected by Sir C. Eliot, which was also dealt with in the paper, was believed to be a variety, which differed from the Tanganyika form in that the tentacles were more deeply embedded in ridges of jelly of the exumbrella than in the Tanganyika form. All the individuals in a collection from the Victoria Nyanza were females. The result of a re-investigation of both Limnocnida and Limnocodium led the author to the conclusion that both genera were to be referred to the Trachomedusæ, in spite of the fact that no other known trachomedusan had gonads on the manubrium. Reasons for this view were given, as also for the association of both fresh-water medusæ with the Olindiadæ. It was considered exceedingly doubtful whether either Limnocodium or Limnocnida ever passed through a hydroid stage at all.

Geological Society, June 19.—Dr. Aubrey Strahan, F.R.S., vice-president, in the chair.—The Inferior Oolite and contiguous deposits of the Bath-Doulting district: L. **Richardson**. In this paper a detailed description is given of the Inferior Oolite of the country between Doulting and Bath. It is shown that there is within the area no Inferior Oolite deposit of earlier date than the Upper Trigonia Grit—a deposit of Garantianæ hemera. In one appendix Mr. S. S. Buckman indicates the deposits in Dorset equivalent to those studied; in another the late Mr. J. F. Walker and Mr. Richardson deal with the Brachiopoda of the Fullers' Earth, naming seven new species; and in a third Mr. Richardson describes a new Amberleya and Spirorbis. The micro-fauna of the upper coral bed is dealt with by Mr. C. Upton, who obtained from material furnished him from Midford and Timsbury Sleight most of the micro-brachiopoda such as were found by Charles Moore at Dundry Hill.—The Inferior Oolite and contiguous deposits of the district between the Rissingtons and Burford: L. **Richardson**. This paper is presented with the preceding, because there are several points of similarity between the two districts described. Both are near lines of country along which movements of upheaval were frequent during the time of formation of the Inferior Oolite rocks.—The flora of the Inferior Oolite of Brora (Sutherland): Miss M. C. **Stopes**. This paper is to place on record the discovery of a bed containing impressions of plants, which represent a flora bearing a strong likeness to that of the Inferior Oolite of the Yorkshire coast. Previously, but one species and a second doubtful one were known from these coal-bearing beds. The bed in which the plants were found was a thin shale-band cropping out below high-tide level on the coast, about $1\frac{1}{4}$ miles south of Brora.—The constitution of the interior of the earth as revealed by earthquakes (second communication): some new light on the origin of the oceans: R. D. **Oldham**. The attempts which have been made to account for the oceans and continents are all subject to an uncertainty, in that we have had no means of knowing whether it is a mere irregularity of form that has to be accounted for or whether this irregularity is but the expression of a deep-seated difference in the constitution of the earth. The paper is an attempt to clear up this uncertainty by a comparison of the European records of the San Francisco and Colombian earthquakes of April 18 and January 31, 1906. The general conclusion is drawn that oceans and continents are not mere surface irregularities of the earth's form, but are accompanied by, and probably related to, differences in the constitution of the earth beneath them, which extend to a depth of about one-quarter of the radius. It is not possible to state exactly in what this difference consists, beyond that it causes the rate of propagation of the second-phase waves to be less, in comparison with that of the first-phase waves, under the oceans than under the continents.—The Swansea earthquake of June 27, 1906: Dr. C. **Davison**. With the exception of the Hereford earthquake of 1896, the Swansea earthquake was the strongest which has been felt in this country for more than twenty years. It disturbed an area of 66,700 square miles, reaching from Rochdale on the north to Penzance on the south, and from beyond Maidenhead on the east to Waterford on the west. The centre of the isoseismal 8 lies about three miles west of Swansea, the longer axis of the curve being directed E. 5° N. and W. 5° S. At Swansea, Neath, &c., the total number of chimneys thrown down or damaged must have amounted to several hundred. The shock consisted of two distinct parts, the first part being much weaker than the second, except at places within an oval area lying some miles to the east of the Swansea epicentre. The existence of a secondary focus beneath this area is also indicated by the relative positions of the isoseismal lines, the isoseismal 8 being much nearer the isoseismal 7 at the western than at the eastern end. Observations, fifty-three in number, were obtained from thirty-nine pits, distributed over an area forty-nine miles in length, from near Kidwelly to near Pontypool. The shock was, as usual, less strongly felt in pits than on the surface, and, the sound was more uniform and monotonous underground. Both shock and sound were observed in pits over about the same area. The originating fault in the neighbourhood of Swansea must run from E. 5° N. to W. 5° S., heading to the south, and passing not far from the line joining Llanelly to Neath, which is five or six miles to the north of the great east-and-west fault under Swansea Bay.—The Ochil earthquakes of September, 1900, to April, 1907: Dr. C. **Davison**. During this interval a series of slight shocks was felt chiefly in the villages of Blairlogie, Menstrie, Alva, and Tillicoultry, lying between the Ochil Hills and the river Forth. There were four shocks in 1900, one in 1903, ten in 1905, nineteen in 1906, and eight up to the end of April, 1907. The strongest shock of the series occurred on September 21, 1905; its intensity was 6, and it disturbed an area of about 1000 square miles. The originating fault must be directed from about E. 27° N. and W. 27° S., hading to the north, and passing not far from the villages mentioned above. It cannot therefore be identified with the great Ochil fault, which in the district referred to runs from about E. 13° N. to W. 13° S., and near Dollar hades to the south, although it is possible that some or many of the slighter shocks may have been due to slips along this fault.

Linnean Society, June 20.—Prof. W. A. Herdman, F.R.S., president, in the chair.—The distribution of conifers in China and neighbouring countries: the late Dr. M. T. **Masters.**—A group of papers on the collections of H.M.S. *Sealark*: J. Stanley **Gardiner.** A group of papers on collections obtained during the cruise of the yacht *Silver Belle*.—The pre-Glacial flora of Britain: Mr. and Mrs. Clement **Reid.**—Species and ovicells of Tubucellaria: A. W. **Waters.** The collections dealt with were from the Red Sea, Zanzibar, and the Atlantic.—Cephalopoda of the Sudan: Dr. W. E. **Hoyle.**—Triassic species of Zamites and Pterophyllum: E. A. N. **Arber.**—Plants collected on Mt. Ruwenzori by Dr. A. F. R. Wollaston (1906): E. G. **Baker,** S. L. **Moore,** and A. B. **Rendle.** The plants from the Ruwenzori range were collected from two camps, one at about 3500 feet above sea-level on the south-east slopes of the range between the mountains proper and Lake Ruisamba, the other at 6500 feet in the Mubuku Valley on the east side of the range. Expeditions were made to intermediate and higher altitudes, the highest camp being at about 12,500 feet, whence plants were collected up to the snow-level at about 14,500 feet on the east side. The time of year was January to July. Dr. Wollaston gives notes on the vegetation at different altitudes from 3000 feet to 15,000 feet, and has brought back some photographs showing the nature of the country and different aspects of the vegetation. The plants at the lower elevations include some common tropical weeds, with a fair percentage of more localised species and some novelties. Cultivation ceases above 7000 feet, and at from 7000 feet to 8000 feet is found the largest forest of the range; a large Dombeya is noticeable, and one of the finest trees is a Podocarpus. Above 8000 feet the forest thins out, and is gradually replaced by a belt of small tree-heaths and Podocarpus. The bamboo zone begins on the east side at about 8500 feet, and continues up to 10,000 feet. The big tree-heaths begin about 9500 feet, at which level a number of terrestrial orchids were found, with numerous ferns. From 10,000 feet to 11,000 feet moss is plentiful on the ground and trees, forming cushions 2 feet deep; here were found two tree Lobelias. In the next thousand feet Helichrysums, Lobelias, tree-heaths, and tree Senecios are the most conspicuous plants. The heaths cease about 12,500 feet, but the Senecios continue almost to 14,000 feet. Another Lobelia appears at about 12,500 feet, and is found on the steepest slopes almost to the snow-line. Helichrysums, sometimes forming bushes 4 feet or 5 feet high, grow luxuriantly. A small Arabis was found at 14,000 feet, and a rush, a grass (a new species of Poa), and mosses were found growing up to the level of permanent snow.—The anatomy of the Julianiaceæ: Dr. F. E. **Fritsch.**—Certain critical fresh-water algæ: G. S. **West.**

Faraday Society, June 25.—Prof. S. P. U. Pickering, F.R.S., in the chair.—The thermochemistry of electrolytes in relation to the hydrate theory of ionisation: W. R. **Bousfield** and Dr. T. M. **Lowry.** The process of ionisation of a neutral salt in aqueous solution "*is usually attended with a development of heat*" (Nernst, "Theoretical Chemistry," 1904, 659), *e.g.* $KCl \rightarrow \overset{+}{K} + \overset{-}{Cl} + 250$ cal. (Arrhenius, *Zeit. phys. Chem.*, 1889, iv., 106). It is pointed out that the decomposition of potassium chloride into molecular potassium and molecular chlorine involves an absorption of 105,600 cal., and that a further absorption must accompany the decomposition of the molecules into atoms. The electrification of the atoms is also probably an endothermic action, and the change represented by the above equation, so far from involving the liberation of 250 cal., must actually involve the absorption of more than 100,000 cals. The process of ionisation must therefore involve some powerful exothermic action not shown in the ordinary scheme, and it is suggested that this is supplied by the combination of the charged atoms or "ionic nuclei" with the solvent to form hydrated ions.—Influence of non-electrolytes and electrolytes on the solubility of gases in water. The question of hydrates in solution: Dr. J. C. **Philip.** The author supported the view according to which the diminished power of a solution to dissolve hydrogen and oxygen as compared with pure water is due mainly to the hydration of the solute and the consequent diminution of the "free" solvent.—Hydrates in solution: discussion of methods suggested for determining degree of hydration: Dr. G. **Senter.** It is pointed out that recent attempts to account for the properties of aqueous solution on the basis of association alone have not only proved inadequate to afford a quantitative representation of the facts, but in some respects do not appear to be even in qualitative agreement with experiment. The different methods of investigation indicate that the degree of hydration varies with the atomic weight; for example, in the case of the chlorides of the alkalis, the hydration decreases with increasing atomic weight of the alkali metals. From a quantitative point of view our knowledge of hydration is much less satisfactory, and the results so far obtained must be regarded as of a preliminary character.—The stability of hydrates as indicated by equilibrium curves: Dr. A. **Findlay.**

Chemical Society, July 4.—Sir Alexander Pedler, F.R.S., vice-president, in the chair.—*iso*Nitroso- and nitro-dimethyldihydroresorcin: P. **Haas.** The first of these substances is obtained by treating the potassium salt of dimethyldihydroresorcin with potassium nitrite in acid solution, and it is converted into the nitro-compound by treatment with nitrous gases in ether solution.—The structure of carbonium salts: F. **Baker.** *p*-Rosaniline and its monohydrochloride give absorption spectra conforming to the two types characteristic of carbonium salts such as the triphenyl- and trianisyl-carbinol sulphates, whence it is concluded that the magentas are carbonium salts.—Studies of dynamic isomerism, part vi., the influence of impurities on the muta-rotation of nitrocamphor: T. M. **Lowry** and E. H. **Magson.** The view previously arrived at that the mutarotation of nitrocamphor in solvents is conditioned by the presence of alkaline impurities is confirmed.—The relation between absorption spectra and chemical constitution, part viii., the phenylhydrazones and osazones of α-diketones: E. C. C. **Baly,** W. B. **Tuck,** Miss G. **Marsden,** and Miss M. **Gazdar.** Examination of the absorption spectra shows that these substances, in neutral solution, possess the ketonic structure, whilst phenylhydrazones in alkaline solution tend to assume the enolic configuration.—Permanganic acid: M. M. P. **Muir.** A solution containing 17 per cent. of this acid can be obtained by adding the calculated quantity of dilute sulphuric acid to a solution of barium permanganate and concentrating the filtrate in a vacuum.—Methyl dicarboxyaconitate: S. **Ruhemann.** Descriptions are given of additive and condensation products obtained by the interaction of this ester with (*a*) phenylhydrazine and (*b*) aniline. The action of heat on αα′-hydroxycarboxylic acids, part iii., αα′-dihydroxysebacic acid and its diacetyl derivative: H. R. **Le Sueur.** Both these compounds are decomposed at 250°–270° with the formation of carbon monoxide and the dialdehyde corresponding to suberic acid.—Dihydroxyadipic acids: H. R. **Le Sueur.** Two dihydroxyadipic acids are formed when the bromine atoms in αα′-dibromoadipic acid are replaced by hydroxy-groups. These are probably stereoisomerides.—The relation between absorption spectra and optical rotatory power: A. W. **Stewart.** The absorption spectra of racemic acid in concentrated solution differ from those of the optically active tartaric acids, but on dilution approximate to them in character, indicating that the acid breaks down into its two optical antipodes.—Experiments on the synthesis of the terpenes, part xi., synthesis of 4:*iso*propylidene*cyclo*-

hexanone and its derivatives: W. H. **Perkin**, jun., and J. L. **Simonsen**.—Purification of acetic ester: J. K. H. **Inglis** and Miss L. E. **Knight**.—Solubility of lead sulphate in concentrated solutions of ammonium acetate: J. J. **Fox**.—Researches on morphine, part iii.: F. H. **Lees**. By the hydrolysis of chloromorphide a second isomeride of morphine, neo*iso*morphine, has been obtained which on methylation furnishes the substance already known as *pseudo*codeine.

Association of Economic Biologists, July 4.—Mr. A. E. Shipley, F.R.S., president, in the chair.—Some notes on ticks: Cecil **Warburton**. The author dealt with the classification and means of identification, and discussed the leading generic characters.—Results of experiments with the spruce-gall and larch-blight disease: E. R. **Burdon**. The results showed that a paraffin emulsion applied early in the year, before the buds open and whilst the insects are still hibernating, is most effective.—The Cecidomyidæ or gall midges: W. E. **Collinge**. The author gave an account of his work, and appealed to entomologists and others for assistance in working out the life-histories, &c., of this very difficult family of Diptera.—A disease of bees in the Isle of Wight: Prof. A. D. **Imms**.—The American gooseberry mildew and the proposed legislative measures: E. S. **Salmon**.—The bionomics of the calypterate Muscidæ and their economic significance: C. G. **Hewitt**.—The next meeting will be held at Edinburgh about Easter, 1908.

Göttingen.

Royal Society of Sciences.—The *Nachrichten* (physicomathematical section), part i. for 1907, contains the following memoirs communicated to the society:—

July 28, 1906.—Measurements of the vertical electric current in the atmosphere, I.: H. **Gerdien**.

January 12.—A characteristic property of the *Klassenkörper*: Ph. **Furtwängler**.—A convergence theorem: E. **Landau**.—The most general conception of the plane continuous curve: A. **Schoenflies**.—The occurrence of genera and groups of Ammonites in the several zones of the Lower Chalk of Germany: A. **von Koenen**.

February 9.—The composition of quadratic forms: H. **Weber**.

February 23.—Researches from the Göttingen University chemical laboratory: O. **Wallach**. (1) Carbon acids of cyclic carbohydrates; (2) the behaviour of the nitrites of primary bases, and on the enlargement of the "ring" of carbocyclic systems.—(1) The Jacobian transformation of the quadratic forms of an infinite number of variables: (2) the transformation of assemblages of bilinear forms of an infinite number of variables: O. **Toeplitz**.

March 9.—Orthogonal systems of functions: F. **Riesz**.

Paris.

Academy of Sciences, July 8.—M. A. Chauveau in the chair.—Endosmosis between two liquids of the same chemical composition at different temperatures: G. **Lippmann**. If two volumes of pure water, one hot, the other cold, be separated by a porous membrane, there is endosmosis from the latter to the former. This phenomenon is adapted to very delicate thermometry.—Thermoendosmosis of gases: G. **Lippmann**. Between air at different temperatures there is endosmosis from cold to hot, more rapid than in the previous case of water.—The spontaneous combustion of balloons at ordinary atmospheric pressure: W. **de Fonvielle**. In the case of a recent explosion, the cause lay in a discharge of electricity between the earth and clouds. In previous instances the explosion was caused by an accumulation of positive electricity of the atmosphere in the metal of the valve.—The use of radiometry for the observation of low pressures in gases: application to researches on gaseous products emitted by radio-active bodies: Sir J. **Dewar**. Experiments show that by the use of a torsion balance or bifilar suspension radiometry can be used for quantitative researches at low pressures.—Polarisation by refraction, and the propagation of light in a non-homogeneous medium: Ch. **Fabry**. Light, passing through a medium the refractive index of which varies continuously, gives rise neither to any appreciable reflection nor in consequence to any polarisation.—The optical analysis of pyroxyles: M. **de Chardonnet**.—The electrolytic oxidation of platinum: C. **Marie**.—The sulphides, selenides, and tellurides of thallium: H. **Pélabon**.—On the preparation and properties of the borides of iron, Fe_2Bo and $FeBo_2$: Binet **du Jassonneix**.—The direct oxidation of toluene by catalysis: Paul **Woog**. Oxides of iron, nickel, copper, and manganese can be used as catalytic agents.—A new method of preparation of amino-primary alcohols: H. **Gault**. The action of halogen derivatives of ketones on some aromatic amines: A. **Richard**.—Complete analysis of the fruit of *Lycopersicum esculentum*: J. M. **Albahary**.—A proximate analysis of egg-yolk: N. A. **Barbieri**.—Photographic pelliplanimetry, a new method of rapidly measuring the surface of the living human body: B. **Roussy**.—The ferments in diseases of wine, especially *Coccus anamalus*: P. **Mazé** and P. **Pacottet**.—The extension of the Trias into the south of Tunis: A. **Joly**.—The Empidæ of Baltic amber: Fernand **Meunier**. DILLENIAN MEMORIALS AT OXFORD.

The Dillenian Herbaria: an Account of the Dillenian Collections in the Herbarium of the University of Oxford, together with a Biographical Sketch of Dillenius, Selections from his Correspondence, Notes, &c. By G. Claridge Druce. Edited, with an introduction, by Prof. S. H. Vines, F.R.S. Pp. cxii+258. (Oxford: The Clarendon Press, 1907.) Price 12*s*. 6*d*. net.

THIS volume is a valuable contribution to the history of the botanic preeminence of Oxford in the first half of the eighteenth century. It is significant that the three men Carl Linnæus visited in 1736 were Sir Hans Sloane, Philip Miller, and Dillenius. His credentials to the first were a commendatory letter from Boerhaave; but Sloane was then seventy-six, he had seen the rise and fall of many botanic arrangements, was a follower of our own John Ray, whose system he had adopted when indexing his large collections of plants, and was averse to further change. To him the young Swede of twenty-nine, with a brand new scheme of his own, was a visionary to be dismissed with speed, and therefore, with a few cold compliments, Linnæus departed. With Philip Miller, the gardener to the Company of Apothecaries at Chelsea, he became acquainted, bringing with him letters from his patron Clifford, and a mutual appreciation was the result. The residence of Dillenius at Oxford was the chief attraction which drew Linnæus to that place; there he stayed a month, and might have shared the liberal offer of Dillenius to divide the emoluments of the professorship between them had he so wished.

At this time Dillenius had been only two years installed as Sherardian professor, though he had received the stipend from the death of William Sherard. His tenure of the chair from 1734 to his death in 1747 was a bright interlude between two uneventful periods.

Mr. Druce has drawn up this account of the collections left by Dillenius, and has critically examined the specimens preserved as vouchers, illuminating many doubtful passages in the third edition of Ray's "Synopsis," and practically disposing of the dubious entries which have troubled many subsequent botanists. For studies of this character the facilities offered at the Botanic Garden, Oxford, are extremely good, and only to be excelled by the Sloane volumes in the department of botany, Cromwell Road. Mr. Druce has performed a labour of love in bestowing the work of years on these collections, and should be encouraged to persevere until all the more important of the pre-Linnean herbaria at Oxford are enumerated in similar detail. It should not be forgotten that the types of Sibthorp's splendid "Flora Græca" are also preserved at Oxford.

The introduction by Prof. Vines is an appreciative essay on the position of Dillenius as regards his contemporaries; then, with a single page of preface, Mr. Druce gives a life of Dillenius and bibliography, a full selection from his extant correspondence (the letters from Linnæus have, unhappily, disappeared), and thus, after an ample preamble, the principal portion of this volume begins.

Part v. opens with the collation of the Dillenian edition of Ray's "Synopsis" issued in 1724, with the plants preserved in that special herbarium. This edition was practically the chief guide of British botanists for something like forty years, in fact until Hudson's "Flora Anglica" superseded the Raian method by the Linnean system and nomenclature. We have for the first time an authoritative statement of what is in the herbarium, and what stands there for any given name.

Next and in similar fashion we find an account of the specimens representing the plates and descriptions in the "Hortus Elthamensis," that account of the garden of James Sherard the plates of which were etched by Dillenius. Following this we come to the great work of the author, the "Historia Muscorum," with a prefixed statement of the authorities whose determinations are the basis of the modern reductions; errata and index close this interesting volume.

The temptation to dwell longer on this theme is strong, but must be resisted; the book vividly recalls days spent long ago amongst these very plants and manuscripts, and this notice must end with the hope that another instalment from this treasure house may in due time be forthcoming.

B. D. J.

THE FOURTH INTERNATIONAL ORNITHOLOGICAL CONGRESS.

Proceedings of the Fourth International Ornithological Congress, London, June, 1905, forming Vol. xiv. of the "Ornis." Edited, under the direction of the President, Dr. R. Bowdler Sharpe, by the Secretaries, Dr. Ernst J. O. Hartert and J. Lewis Bonhote. Pp. 696; with 18 plates. (London: Dulau and Co., 1907.) Price 21*s*. net.

AS in many other branches of science, the ornithologists have established an international congress, and the official account of their fourth meeting, held in London in June, 1905, is now before us. It forms a handsome and well-illustrated volume of 696 pages, and constitutes also the fourteenth volume of *Ornis*, the official journal of the association, which accompanies the presidency of the congress when it is moved from one country to another.

The first meeting of the International Congress of Ornithologists was held at Vienna in April, 1884, under the presidency of Dr. Gustav Radde, of Tiflis, and owes its inception, more or less, to the ill-starred Crown-Prince Rudolph of Austria, who had a certain amount of interest in natural history, inspired chiefly, we believe, by one of the Brehms, his personal friend and companion. The meeting at Vienna was a success to a certain extent, and was followed seven years later by the second meeting, which took place at Budapest in 1891. This congress was very well attended, and was carried out with great *éclat* by the enthusiastic naturalists of the Hungarian capital. English ornithology was represented by the late Mr. Danford and by Dr. Bowdler Sharpe, who read there an important paper on the classification of birds. The presidents on this occasion were Prof. Victor Fatio, of Geneva, and Dr. Otto Herman, of Budapest. The next meeting of the congress was deferred for several years from various causes. But the difficulties were at length surmounted, and the ornithologists of every part of the world were invited to assemble at Paris in June, 1900, under the presidency of the late Dr. Oustalet, the head of the magnificent collection of birds in the Jardin des Plantes. Although ornithologists are not numerous in France, the meeting in Paris was very well attended, and included visitors from all parts of the world. Many excellent communications were made to it. At the close of the *séances* it was resolved that the next (fourth) meeting of the congress should take place in England in 1905, and Dr. R. Bowdler Sharpe, the well-known head of the Bird Department at the Natural History Museum, South Kensington, was selected as its president. The present volume gives us a full account of the proceedings of this meeting, which was held in London in June, 1905, and was attended not only by the English devotees of ornithology, but by representatives of that science from France, Germany, Austria, Hungary, Italy, Holland, Belgium, Russia, Sweden, Switzerland, the United States, Canada, and Australia.

The fourth congress was opened at the Imperial Institute, South Kensington, on June 12 by a few words from the outgoing president, Dr. Oustalet, who then vacated the chair in favour of Dr. Sharpe, the new president. Dr. Sharpe gave a most interesting and instructive address on the origin and progress, from 1753 to the present time, of the national bird-collection in the British Museum, which is now by far the finest and most nearly complete of its kind in the world. This address, which is printed in full in the present volume, gives particulars of the additions made to the great collection year by year since its foundation, together with details on its mode of arrangement and government. By bequest, purchase, and presentation, Dr. Sharpe tells us, nearly every large private collection of birds made in England has ultimately passed into the British Museum, including those of the late Marquess of Tweeddale, Mr. Seebohm, Mr. Crowley, Mr. Allan Hume, Dr. Sclater, Mr. Osbert Salvin, Dr. Godman, and other well-known naturalists.

After the president's address the present volume is mainly occupied with the papers read at the meetings of the congress and at its various sections. These sections were five in number—systematic ornithology and distribution; migration; biology and nidification; economic ornithology; and aviculture. Excellent communications, altogether forty in number, were made on all these subjects. They are mostly of a somewhat technical character, but we may direct attention to Mr. Walter Rothschild's paper on extinct and vanishing birds, which was splendidly illustrated by the large series of specimens and drawings shown to the ornithologists when they made their excursion to Tring. We may also invite notice to Mr. Pycraft, who writes on the origin of the differences between the various kinds of nestlings, and seeks to justify his ingenious theory that all birds "were originally arboreal."

Those who require information on the eleven Acts for the Protection of Wild Birds passed by our Parliament may refer to Sir Digby Pigott's paper on this difficult subject read before the economic section, while those who keep birds in aviaries should not fail to study Mr. D. Seth-Smith's address on the importance of aviculture as an aid to the study of ornithology. The numerous and interesting facts ascertained by the votaries of this new branch of science are well set out in Mr. Seth Smith's contribution to the present volume.

THERMODYNAMICS.

Thermodynamics: an Introductory Treatise dealing mainly with First Principles and their Direct Applications. By Prof. G. H. Bryan, F.R.S. Pp. xiv+204. (Leipzig: B. G. Teubner; London: D. Nutt; Williams and Norgate, 1907.)

PROF. BRYAN has not been content in this work to follow closely the beaten track, but has given us the results of much original research. The fundamental conceptions of energy, available or unavailable, of entropy, and of temperature are given in their simplest form (see the general summary at end of the book).

As the conception of temperature is for the most part new, and throws much light on the subject, it is well to set out the author's definition. The absolute temperature of a body M is to be understood, and can be defined, only with reference to another standard body N. It is the ratio between the quantities of heat respectively taken from M and imparted to N, when M is used as reservoir, N as refrigerator in a reversible Carnot cycle. This, of course, is, and is intended to be, a theoretical definition only; and a theoretical definition is needed. Similarly, the entropy of a body cannot be defined as an absolute quantity. We can only say that in certain circumstances it increases or diminishes. In all irreversible transformations it increases by an amount equal to the available energy transformed into unavailable energy. Two definitions of entropy are given at p. 58.

Prof. Bryan encounters the usual difficulty in defining temperature, density, &c., *at a point* in a molecular medium. Given a continuous medium, we say that (for instance) the density at P is the limiting ratio of quantity to the containing volume when that volume (which contains P) becomes infinitely small. That definition is irreproachable, but, as applied to a medium consisting of discreet molecules, wholly devoid of meaning. It is possible to give a logical definition by proceeding to the limit in the other direction. But in practice—and Bryan follows the practice—it is usual to define density as the number of molecules in an element of volume at P—large compared with molecular dimensions, it being assumed for the purpose of the definition that the density may be taken without sensible error as constant throughout small distances near P. The same method applies *mutatis mutandis* to temperature.

The chapter on the diffusion of gases from the point of view of thermodynamics requires more explanation than the author has directly given. He says (p. 125):—

"When two gases at equal temperature and pressure mix by diffusion, the gain of entropy is the same as would occur if each were to expand by escaping into vacuum till it occupied the volume of the mixture."

To this Advocatus Diaboli would say, If instead of two gases you have two quantities of the same gas, oxygen, *caeteris paribus*, the whole system remains throughout in the same physical state, and, therefore (art. 86 [2]), there is no gain of entropy. What difference can it make that one volume of oxygen is replaced by nitrogen?

I think Prof. Bryan would justify his statements thus:—He asserts, art. 124 (*a*), "as two gases at equal pressure and temperature in general tend to mix by diffusion and not to separate, the process of diffusion is irreversible." And he implies (*b*) that every irreversible process necessarily involves increase of entropy. If these principles (*a*) and (*b*) be granted, 125 is probably justified. But they are both very questionable.

It is not possible within the limits of this notice adequately to discuss either (*a*) or (*b*). I would, however, point out that in diffusion, as in all motions of gases, if at any instant the velocities of all the molecules were reversed the system, if isolated, would retrace its course. Does not this fact make a broad distinction between diffusion of gases and irreversible processes usually admitted as such?

S. H. BURBURY.

VOLCANOES.

I Vulcani Attivi della Terra. Morfologia—Dinamismo—Prodotti Distribuzione Geografica-Cause. By G. Mercalli. Pp. viii+421; illustrated. (Milano: Ulrico Hoepli, 1907.) Price 10 Lire.

THIS history of the study of volcanoes may be divided into three periods; the earliest is covered by the fragmentary remains of the writings of classical philosophers and the sporadic records of great eruptions of Vesuvius and Etna during the Middle Ages; the second commenced with the eruption of Vesuvius in 1631, which gave rise to over 200 publications, and from this date on we have a fairly complete record of the activity of Vesuvius and Etna; in the third period, observation became systematised, and vulcanology, as a science, may be said to date from Spallanzani's study of Stromboli in 1788. In the nineteenth century the science expanded its boundaries, volcanoes in other parts of the world besides Italy began to be studied, experimental methods were applied to elucidating the mechanism of eruptions and the formation of volcanic rocks, and the microscope to the investigation of their composition and structure.

As a consequence of this expansion of the science it has come to pass that we have had to look, not to Italy, but to other countries, and especially to England, for a general handbook; Prof. Mercalli has rectified this, and the country where the study of volcanoes, and the science of vulcanology, took their birth has produced the best and most complete guide to their pursuit. In the compass of a moderate sized book, we have a remarkably complete, well-balanced review of the subject, which commences with the final result of volcanic activity, in an account of the rocks produced, and works back through the forms of volcanoes, their dynamics, and distribution, to the cause of volcanic activity.

The longest and most generally interesting chapter in the book is doubtless that dealing with the dynamics of volcanoes. Fissure eruptions and the outflow of lava without the formation of a volcanic cone are recognised, and in the classification of volcanic explosions we come across a third type—in addition to the familiar vulcanian and strombolian types—in what are termed plinian eruptions. This name is applied to the violent explosive eruptions, like that of Vesuvius in 79 A.D., of Bandaisan and of Krakatoa, which follow prolonged periods of repose, are of extraordinary violence, are accompanied by comparatively little or no outpouring of lava, while causing the ejection of large volumes of previously solidified material, and are succeeded by another period of repose. The eruptions of Pelée and St. Vincent in 1902 are regarded as differing in degree only, not in kind, from other known eruptions; the celebrated spine of Pelée, which was thrust up to 1000 feet above the crater, was an extreme case of extrusion of solidified lava, and the "black cloud" an extreme case of the avalanches of incandescent ashes which are a not uncommon accompaniment of great eruptions.

In dealing with the cause of volcanic activity, Prof. Mercalli favours the view, first propounded by Seneca, that it is produced by the access of sea water to highly-heated material in the interior of the earth, resulting in the production of high-pressure steam; but here, as elsewhere throughout the book, the theory is not pressed, and alternative explanations are fairly stated. A word, too, may be said for the illustrations, which are numerous and excellent.

OUR BOOK SHELF.

Shaft Sinking in Difficult Cases. By J. Riemer; translated from the German by J. W. Brough. Pp. xii+122; with 18 illustrations and 19 folding plates. (London: Charles Griffin and Co., Ltd., 1907.) Price 10s. 6*d*. net.

MR. RIEMER is one of the leading German authorities on sinking, and a translation of his valuable treatise forms an addition to English technical literature that is specially welcome in view of the fact that shaft sinking, the most complicated of all mining problems, is necessarily dealt with in a brief manner in the standard works on coal-mining. The volume is confined to a description of means that have to be resorted to when ordinary methods of sinking cannot be applied on account of excessive influx of water, the means described being shaft sinking by hand, boring shafts, the freezing method of sinking, and the sinking-drum method.

The particulars given relate exclusively to recent practice in Germany, where, unfortunately for the colliery owners, the subject of shaft sinking in circumstances of special difficulty has necessarily received special attention. Some of the difficulties recorded are appalling. For example, the sinking of a shaft at the Rheinpreussen colliery occupied twenty years, and at the Friedrichshall shaft sinking thirty-four yards cost no less than 437*l.* a yard with the shaft-boring process, whilst the unsuccessful attempt to sink ten yards by pumping cost 1563*l.* per yard. The author favours the Kind Chaudron method of sinking by the process of boring, a method that has never been known to fail. The freezing process, which was devised in 1883, has been applied in sixty-four cases, the deepest being at the Schieferkaute mine, where the ground had to be frozen to a depth of 240 yards. The depths that can be dealt with by this process are limited by the plasticity of ice.

The value of the author's detailed descriptions is greatly enhanced by the large-scale dimensioned drawings of the various shafts. On the whole, the volume furnishes those in charge of mining undertakings with a review of the various methods that may be used in difficult cases of sinking, so that the selection of the best method for any particular case is facilitated. It is not a book for elementary students, but one that deserves the careful study of advanced students and of experienced engineers. The translation has been carefully made, and a bibliography and index, that are wanting in the German edition, are undoubtedly valuable additions.

Die philosophischen Grundlagen der Wissenschaften. by Prof. B. Weinstein. Pp. xiv+543. (Leipzig and Berlin: B. G. Teubner, 1906.) Price 9 marks.

This volume contains a series of thirty-five lectures originally delivered in the University of Berlin. A wide range of subjects is treated—from sense-perception to time, space, causality, substance, hypothesis, explanation. As the lecture form is preserved, the discussion never becomes crabbed or too compressed—a great virtue in a book—and the author moves naturally and easily whithersoever the topic leads him. He touches no subject without elucidating it, and the hope expressed in the preface that the work will be of some value alike to specialists and ordinary readers will, we are sure, be amply fulfilled. In particular the work may be heartily recommended to young philosophical students with some knowledge of German who are trying to crack some of the nuts of psychology and metaphysics. Had Prof. Weinstein but added at the end of each chapter a short list of other discussions of his subject that might profitably be consulted, our gratitude would have been even greater than it is.

A few indications of the author's standpoint and mode of treatment must be given. The attempt to "explain" phenomena of consciousness by physical terms like attraction, pressure, vibration of molecules, and the like is well characterised on p. 54, where it is pointed out what utter folly it would be thought to "explain" in the same way the inertia of lifeless substances as caused by vibrations of the substance. How competing perceptions are unified is a topic that occupies several excellent pages. We see things upright, although the retinal image really shows the object in an inverted form. Prof. Weinstein is at pains to contest the view that this takes place because the judgment of the sense of touch is so powerful as to overwhelm that of the sense of sight. He points out, for example, that all orientation in space takes place with reference to our bodies, and we judge according to the movements which we perform with parts of our bodies. "Below" means what we have to bend our bodies to touch; "above" what we must stand on tip-toe to touch. If we saw everything inverted, according to the information supplied by the retinal image, we should see our bodies as well in an inverted position. Hence the sense of touch, and the sense would always give harmonious judgments. The treatment of the *a priori* nature of Zeitlichkeit and of the whole subject of causality leaves little to be desired, and atomism and æther have a few illuminating paragraphs. It is an excellent volume in every way.

The Toxins and Venoms and their Antibodies. By Em. Pozzi-Escot. Authorised translation by Dr. Alfred T. Cohn. Pp. vii+101. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1906.) Price 4*s.* 6*d.* net.

We regret that we are unable to speak favourably of this little book. In 100 short pages an attempt is made to survey the whole domain of toxins, bacterial, vegetable, and animal, of the venoms and of antitoxins, with the result that it is superficial and sketchy. It teems with errors in spelling, and with curious sentences, probably due to faulty translation, *e.g.* Micocher for Miescher, Rauson for Ransom, tumors for humors, Chauvée for Chauveau, Zalnosky for Zalensky, methylotoxin for mytilotoxin, &c.; mussels are spoken of as crustacea, and scorpions as insects; it is stated that "toxins act as toxic agents only when in a condition to be introduced into the circulation sub-cutaneously," "the action of bee poison is very often benign," "*in vitro* it (antivenine) acts quite as well preventively as therapeutically," and so on. R. T. Hewlett.

Everyman's Book of the Greenhouse (Unheated). By W. Irving. Pp. 247. (London: Hodder and Stoughton, n.d.) Price 5*s.* net.

The designation "unheated" is a convenient term to denote a greenhouse in which there is no set heating apparatus. A small stove that will keep out the frost adds materially to the utility of a greenhouse, as it is thus possible to provide a winter domicile for half-hardy plants, besides enabling the possessor to force plants into growth and prepare plants for window boxes or house decoration.

The author has extended the limits of his selection to include alpine plants and others that are especially suitable to pot culture. The directions as to choice and management are based on Mr. Irving's long experience at Kew, and are simply and clearly expressed. The longer paragraphs, such as that on the genus Primula, are the most instructive, and since it is easier to grow a few kinds well, these might have been amplified to the exclusion of certain of the less important genera. The numerous photographs are very effective and fascinating, but the coloured plates are not attractive.

"Mephistopheles." The Autobiography and Adventures of a Tabby Cat. By Keiro (Charles Yates Stephenson); with illustrations by Louis Wain. Pp. 158. (London: Jarrold and Sons, n.d.) Price 2*s.* 6*d.*

An interesting account is given of the episodes in the life of a cat possessed by Mr. Stephenson for more than eighteen years. The narrative and the excellent illustrations will both appeal to young people.

Healthy Boyhood. By Arthur Trewby; with an introduction by Sir Dyce Duckworth, and a Foreword by Earl Roberts. Pp. viii+63. (From the author.) Price 1*s.* 6*d.*

This booklet contains useful advice to boys, expressed is a temperate manner; it may be commended to the attention of parents and schoolmasters.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of Radium.

IN replying to Mr. Soddy's communication published in NATURE of June 13 (p. 150) I cannot refrain from expressing my regret on learning that he has apparently taken my paper in the *American Journal of Science* for December, 1906, as such a serious "criticism" and "imputation" on my part in dealing with his paper on "The Production of Radium from Uranium." It was my intention merely to point out certain conditions of experiment which appeared to me to be quite essential to the solving of the problem of the growth of radium in uranium compounds, conditions which had apparently been neglected in his own experiments, and to show that where these conditions had been fulfilled the results were not in agreement with those which had been obtained by him. I was then, and am still, of the opinion that the experimental procedure which Mr. Soddy adopted was not suited to give conclusive results of either a positive or negative character, and this opinion is certainly strengthened by the fact that, under very similar conditions of experiment, Prof. Rutherford was unable (Bakerian Lecture, Phil. Trans., 204, 218) to observe the growth of radium in a solution of Giesel's "emanating substance," although he has since concluded that radium was actually being produced in quite notable quantities.

My suggestion of the "accidental and unconscious introduction" of radium salts during Mr. Soddy's tests was only one of a number of possible sources of error to which I have already directed attention. That the other suggestions have not met with his disapproval, and that he is at least convinced of the necessity of starting with purified uranium salts, would seem probable from his statement that he is now continuing the investigation with purified uranium compounds. I am very glad to learn that the results which he has now obtained entirely confirm and extend the results which I have already published. It may be of interest to add that my original solution of one hundred grams of *purified* uranium nitrate has recently been tested and found, after a period of more than two and one-half years, to contain less than 10^{-11} gram of radium.

"The experiments described in this paper are considered to indicate that the results obtained by Mr. Soddy are without significance and that one or more products of a slow rate of change intervene between uranium and radium." This is the particular paragraph to which Mr. Soddy now raises an objection. I fully realise that this statement is open to criticism; it was an unsuccessful effort at brevity. A longer but more satisfactory summary would perhaps have been:—The results of the experiments described in this paper are in support of the hypothesis that one or more products having a slow rate of change intervene between uranium and radium, and indicate that the results obtained by Mr. Soddy are without quantitative significance in so far as they relate to the production of radium by uranium.

"Commercial salts" of uranium may contain, and usually do contain, quite appreciable amounts of every constituent of the minerals from which they have been prepared. The presence in such salts of a small proportion of the immediate parent substance from which radium is derived is therefore in itself no indication of any genetic connection whatever between uranium and radium. My observation of the growth of radium in actinium preparations, even if it has served no other useful purpose, has certainly indicated where the immediate parent of radium is to be sought. To judge from the results which I have obtained in recent experiments along the same lines it would appear that, unless the rate of disintegration of radium now assumed is greatly in error, the chemical process outlined in my "Note on the Production of Radium from Actinium" is capable of effecting the essentially quantitative separation of the radium parent from most of the other substances present in a uranium mineral.

In conclusion, it may be desirable to direct attention to the fact that the only evidence we now have that radium is a disintegration product of uranium is the constancy of the ratio between the quantities of these two elements in the natural minerals, a relation which was first pointed out in these columns by the writer.

BERTRAM B. BOLTWOOD.

Yale University, New Haven, Conn., June 29.

The "Double Drift" Theory of Star Motions.

I HAVE been greatly interested in Mr. Eddington's account in NATURE of July 11 (p. 248) of Prof. J. C. Kapteyn's investigations of this subject. Although I do not quite follow his argument for the existence of two overlapping systems of stars (more dramatically termed "two Universes" by Prof. Turner), I yet venture to suggest an explanation of the apparently (perhaps really) opposite "drifts," which seems to me to agree sufficiently with the observed facts.

If we adopt Lord Kelvin's postulate of a single vast stellar universe very slowly condensing towards its common centre of gravity, we might expect that the component stars would move for the most part in ellipses or spirals of very varying degrees of eccentricity and of inclination to the mean orbit—perhaps indicated by the Milky Way. If we further postulate (what is very generally admitted) that our sun is situated towards the central rather than towards the outer portion of the whole system, then, just as the planets, through differential angular motions as regards the earth, appear sometimes to move in a retrograde direction or to be quite stationary, so a certain proportion of the stars might be expected, at any given period, to exhibit the same phenomena.

But further, considering the enormous distances that are known to separate the stars and star-groups from each other and the extreme slowness of their angular motions, there seems no reason why their respective orbits should not be almost as frequently in a right-hand as in a left-hand direction in regard to the central plane of general motion.

Our knowledge of the actual motions of the stars may not inaptly be compared to what astronomers would possess of the solar system supposing the whole of their observations had been limited to a period of about twenty-four hours, and that the sun was invisible. The motions of the planets and their satellites thus determined would seem as strange and incomprehensible as do those of the stars at the present time, our accurate observations of which have been limited to a few centuries.

It will probably be of interest to many of your readers (as it certainly will be to myself) if some of your mathematical correspondents will explain why, and in what way, some such system as is here suggested is incompatible with the facts set forth by Prof. Kapteyn and others.

ALFRED R. WALLACE.

IN the article to which Dr. A. R. Wallace refers, and elsewhere, I have confined myself to attempting to establish the result that the stars distribute themselves into two systems according to their motions, abstaining as far as possible from defining what physical connection is implied by the rather vague word "system." Whether the two systems are comparatively permanent and have come together from different parts of space, or whether they may have been evolved from a single system, is, in the present state of our knowledge, a somewhat speculative question, and it is with some reluctance that I enter upon it. Still, without asserting that the hypothesis of two *permanent* systems is the only possible one, I know at present of no other satisfactory explanation. In the system suggested by Dr. Wallace (in which the stars move about the centre of the universe in ellipses, some forward and some retrograde, with all sorts of eccentricities) the motions would be for our purposes haphazard. Thus the system would form a single and not a double drift; the extremely eccentric orbits form a perfect transition between the direct and retrograde orbits. To account for two drifts, it is not sufficient to show that some stars move forward and some backward; it must be shown that there is a concentration of the motions about two definite velocities (definite in magnitude and direction), and it does not appear to me that the suggested system provides for this. In fact, it is difficult to see how gravitation towards the centre of the universe could separate the motions of the stars into two systems, if they originally formed one system.

A. S. EDDINGTON.

Royal Observatory, Greenwich, July 18.

The Dental Formula of Orycteropus.

NORMALLY the adult Orycteropus has in each jaw but five teeth, though frequently, especially in young animals, a number of smaller teeth are found further forward. In 1890, Mr. Thomas discovered in both the upper and lower jaws of fairly large fœtal specimens a number of milk-teeth, seven in the upper and four in the lower jaw. So far as I am aware, nothing further has been discovered regarding the dental succession.

In the skull of a newly-born specimen which I have been enabled to study through the kindness of Dr. Perinquey, of the S. African Museum, I have been fortunate in finding a full set of milk-teeth in both upper and lower jaws. In the upper are three minute but calcified incisors, one canine and six premolars. Of these only the last five premolars probably cut the gum, and only the fourth and sixth are large enough to be functional to a slight extent. Succeeding teeth are found under the third, fourth, fifth and sixth premolars, and possibly under the second. Beyond the sixth premolar there is evidence of at least four true molars. In the lower jaw there are also three minute calcified incisors, one minute canine, and six milk-premolars. Of these the second, third, fourth, fifth, and sixth premolars probably cut the gum, and are slightly functional. The germs of replacing teeth are found in connection with all the premolars except the first. Behind the last premolar are evidences of five true molars. The dental formula of Orycteropus may thus be taken to be :—

Incisors	Canine	Premolars	Molars
		?2 3 4 5 6	1 2 3 4 5
1 2 3	*1*	*1 2 3 4 5 6*

		2 3 4 5 6	1 2 3 4 5

This dental formula is quite unlike that in any living mammal, but if we assume that the ancestor of Orycteropus had functional succeeding incisors, and canines, it would have had a formula not at all unlike that found in many of the Mesozoic mammals. Elliot Smith suggests that it may have branched off very early from the subungulate stem. Kitchen Parker was more impressed with the resemblances of the skull to that of the marsupials and lower insectivores.

Some further light may be obtained by a careful microscopic examination of the developing teeth, which I hope to undertake immediately.

R. BROOM.

Victoria College, Stellenbosch, June 25.

THE RADIO-TELEGRAPHIC CONVENTION.

THE report of the select committee appointed to consider the radio-telegraphic convention drawn up by the Powers in November last has just been published as a parliamentary paper. The committee recommends, by a majority of five to four, the ratification of the convention, a result which will hardly surprise those who have followed the evidence given before the committee, though the narrowness of the majority may be difficult to understand.

The provisions of the convention have already been summarised in NATURE (vol. lxxv., p. 59, November 15, 1906), so that it will not be necessary to repeat them here. It will be recollected that it was then pointed out that the provision of prime importance, and the only one likely to lead to opposition to the ratification of the convention, was the one requiring that "coast stations and ship stations are bound to exchange radio-telegrams reciprocally without regard to the particular system of radio-telegraphy adopted by these stations." The necessity for this provision and the highly beneficial results likely to accrue from its enforcement to civilisation and maritime interests were described, and the hope was expressed that the private interests of the Marconi Company would not stand in the way of its adoption.

A study of the evidence presented to the committee and clearly summarised in its report shows that the only opposition to ratification came from those representing the interests of the Marconi Company. They, having already secured what amounts to a practical monopoly so far as Great Britain, Italy, and Canada are concerned, are not unnaturally desirous of maintaining and increasing that monopoly. Whether the policy of not ratifying the convention which they support is likely to lead to such a result seems more than doubtful. The evidence shows that, so far as the world as a whole is concerned, the Marconi Company do not possess even a majority of existing stations, but only about one-third of the total number.

The ratification of the convention by all the signatory Powers except Great Britain would inevitably lead to a growth of other systems at the expense of Marconi stations: existing Marconi stations under their control would necessarily be discontinued unless they consented to acquiesce in the provision for intercommunication. The numerous stations existing along the south coast of England, if they refused to intercommunicate, would be useless for the shipping of foreign nations using other systems, and the necessity for the erection of other stations in their place on the north coast of the Continent would arise. If these, as is probable, interfered with the working of the English stations, protest would be useless from a country outside the convention. From almost all points of view it seems, as a matter of fact, that the Marconi Company stands to gain rather than to lose by the adoption of the convention by Great Britain.

Of the technical objections raised by the Marconi Company little need be said. Since the representatives of all the other systems were agreed that there exist no real difficulties in intercommunication from the technical standpoint, one is compelled to the conclusion that these objections are biassed by other considerations, unless, indeed, the Marconi system is so inferior to all others that it alone possesses this great disadvantage.

It will be recollected, probably, that great stress was laid by many writers in the daily Press at the time of the international Conference on the naval and military aspects of the convention, and Great Britain was represented by some as handing herself over bound to the Powers. That these contentions were entirely without foundation was pointed out in NATURE (*loc. cit.*), and would have been clear to anyone who took the pains to study the actual provisions of the convention. The section of the report of the select committee dealing with this aspect of the question should be sufficient to dispel any lingering doubts which may still remain.

Wireless telegraphy has been very much before the public for the past ten years. In sensational achievement much has been accomplished, and of recent years it has figured somewhat largely as an international bone of contention. But the practical commercial development has been disappointingly slow. It is to be hoped that with the ratification of the convention a period of peaceful progress may ensue, and that some of the well-deserved fruits of many years of patient experimenting may be gathered by the numerous inventors who have been working in this field.

MAURICE SOLOMON.

THE LIFE OF ST. PATRICK SCIENTIFICALLY TREATED.[1]

PATRICIUS MAGONUS SUCATUS, the Roman-Briton from South Wales who became the apostle and patron saint of Ireland, was a great man, who occupies a large place in history, and Prof. Bury has presented us with a great biography, worthy of the subject and of the brilliant equipment brought to bear on it.

Our "fabulous" lives of saints are full of facts, often strangely disguised and misplaced. The venerable records deserve the most thorough scientific treatment, of which this book is a noble illustration. Our remarks by way of review will be confined to some points of interest to astronomers and archæologists.

We were curious to learn when and how St. Patrick's Day, March 17, became a fixed festival. It is with Patrick, as with many another saint, that while the circumstances of his death are very obscure, the day stands forth with a positiveness which at once challenges inquiry. The saint died in 461 A.D. He was "buried quietly in an unmarked grave." "The pious excitement about his bones arose long after his death." In searching this book for information about the day, a very curious state of things discloses itself. The author says that the legendary date of the saint's death "had become vulgar in the seventh century," but the earliest reference we can find is the statement of a scribe who died in 846 A.D., a postscript to a copy of Patrick's "Confession." "Huc usque uolumen quod Patricius manu conscripsit sua: septem decima Martii die translatus est Patricius ad cælos" (p. 227). That was written 385 years after the saint's death. Though we should have liked to have the matter more clearly explained, we make it no point to doubt that March 17 was observed before the ninth century. What strikes us is the fact that in 846 A.D. that was the date of the vernal equinox. It is hard to believe that the Irish of the ninth century could have celebrated St. Patrick's Day without noticing the coincidence.

Turning to the legend of the saint's death, we find him converted into a solar hero. An angel predicted that his death would "set a boundary against night that no light might be wasted on him: Up to the end of the year there was light, that was a long day of peace" (p. 264). Another version has it that "after his death there was no night for twelve days, and the folk said that for a whole year the nights were less dark than usually." The one version seems to refer to the equinox, and the other to the summer solstice when for twelve days before and twelve days after the sun's declination is within its highest northward degree.

It is of interest to note that our two native British patron saints, Patrick and Dewi, seem to have been made solar heroes. In the legend of the death of Dewi, or David, we have a midsummer festival described in Christian terms, and there is ample evidence that Dewi's day was June 24 before it was fixed on March 1.

When Patrick became a solar hero, assuming that he did, he became entitled to the shamrock. About the only thing one finds it hard to forgive in our author is that he never mentions the shamrock. How can we think of Patrick and March 17 without the shamrock? We must have it brought in. The story of how Patrick utilised the popular triadic herb to teach the Irish the fundamental dogma of his faith bears the stamp of truth as clearly as anything known of him. He found the plant in great popularity among the "pagan" Irish, as well as among his Brythonic countrymen. The Welsh bards used to decorate their spring Gorsedd with the trefoil, and, as we shall see, Patrick had a great deal to do with the Gorsedd. To Celts, who thought in threes, the plant had possibly no rival as an emblem.

We have now associated an equinox and solstice date, a solar hero, and a Gorsedd emblem which our modern bards state was used at the equinox. But our modern bards have evidently changed the order of festivals, substituting the solstitial quarter days for those of the May-year. The shamrock must have belonged originally to the May-day festival, as February would be too early for it. Patrick found in Ireland the May-year in its glory, and he set about changing it into the Church-year, as part of his mission. Legend represents him lighting a fire on Easter Eve in open defiance of the fire lit on the selfsame night at Tara in connection with a high pagan festival. Our author rightly interprets the legend.

"The idea is that Easter is to replace Beltane, the Church to overcome the heathen fire, and it is a matter of no importance that the day of Beltane was the first day of summer, which could never fall on Easter Eve" (p. 107).

"We can detect here, in the very act as it were, the process by which pagan superstitions which insisted on surviving were sometimes adapted into the Christian calendar" (p. 108).

The legend of the saint's death has quite a Beltane setting. "A thorn-bush burst into flame on the wayside and was not consumed. And an angel spoke and turned him back" to Saul, to die there rather than at Armagh. A thorn-bush bursting into flame, *i.e.* flowers, before March 17 reminds us of the Glastonbury thorn-bush flowering at Christmas. There is also a legend of an Irish saint presenting a queen with a dish of blackberries at the Easter festival. Over and over again the early Church festivals are spoken of in Beltane and All Hallows terms. The chief reason seems to be that for a long time the early British and Irish Christians had no effective substitutes for the May-year festivals.

Descriptions of British pagan and early Christian festivals should be read with the aid of whatever light the bardic Gorsedd, which was once common to all parts of the British Isles, can lend us. Where Patrick lay dead, angels who kept watch over his body diffused "sweet odours of wine and honey," which is dangerously like representing the angels holding a typical Irish wake. The angels are the bards who, dressed in white, presided over the ceremonies of the Beltane feast, and wine and honey were their customary dues on such an occasion, liberal quantities of which consumed at the feast diffused sweet odours. The legend strives to harmonise the pagan feast, the Church festival, and the anniversary of Patrick's death.

This brings us to a very instructive episode in the saint's life, his attack on the "King Idol of Erin." In the plain of Slecht was a famous idol, "apparently of stone covered with silver and gold, standing in a sacred circuit, surrounded by twelve pillar stones." "It was told in later times that the firstlings, even of human offspring, used to be offered to this idol, in order to secure a plenteous yield of corn and milk, and that the high kings of Ireland themselves used to come at the beginning of winter to do worship in the plain of Slecht." Our author thinks that "the story is based on a genuine fact, but that the later accounts impute to it a significance which it did not possess." The story relates that Patrick struck down the idol with his staff, which, Prof. Bury observes, he could not have done without the consent of secular powers.

[1] "The Life of St. Patrick, and his Place in History." By Prof. J. B. Bury. Pp. x+404. (London: Macmillan and Co., Ltd., 1905.) Price 12s. net.

It is the clear truth of the setting of the story that strikes us most. What Patrick attacked was a pagan Gorsedd, and the incident is of great value as showing the use of the stone circle in the fifth century. We seem to see it in use in the earliest of Welsh tales, but we cannot assign definite periods to the incidents recorded. Here, however, we have a fairly historical episode, which should be read with Geoffrey of Monmouth's account of the May festival at Stonehenge, also in the fifth century. The Slecht Gorsedd was the same in plan as the present Welsh one—a large stone surrounded by twelve other stones. The disappearance of the former goes far to prove the truth of the history. In Wales the Gorsedd was not suppressed in the interests of Christianity. It actually received Christian baptism. The first Gorsedd after the introduction of Christianity among the Welsh is called in the bardic records "Cadair Fedydd," baptismal chair. It is an expression that explains how in

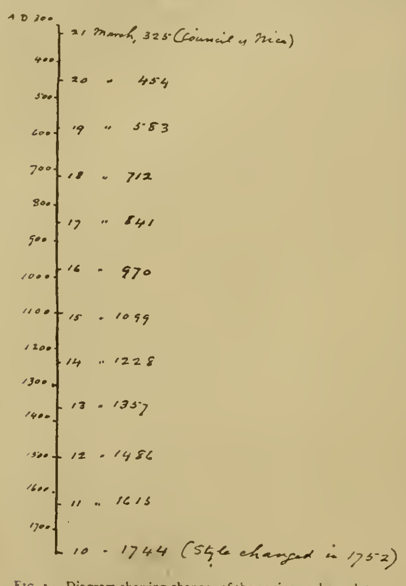

Fig. 1.—Diagram showing changes of the equinox-solstice date.

Wales it is unreasonable to look for any gap in the history of the Gorsedd there.

Our author has narrowed the inquiry into the birthplace of Patrick to the Severn estuary. Had he used some Welsh traditions about Patrick in Glamorgan he might have settled the question for good. There is a persistent tradition that Patrick was kidnapped by "pike-bearing" Irishmen from Llantwit-Major, in that county, and Mr. T. C. Evans (Cadrawd) has found three Banwens in that neighbourhood, either of which would suit for the Bannaventa mentioned as Patrick's home.

The accompanying diagram (Fig. 1) embodies the method by means of which Sir Norman Lockyer was able to note the equinoctial significance of St. Patrick's Day, before the facts mentioned by the present writer were available. Such a diagram may prove very useful to the historian. The changes in date have been calculated as from the Council of Nice, and each change represents an error of a day in 129 years. By a similar calculation as from B.C. 46, the beginning of the Julian Year, the 17th was an equinox date from A.D. 728 to 859, covering the whole period during which the particulars about Patrick were put together for an ecclesiastical purpose.

The present writer has found the following working hypothesis very useful in determining the significance of anomalous or irregular fair days. Any dates between the 10th and the 20th in March, June, September, and December may be suspected to be arrested solar days. When other evidence confirms such a supposition, the period of the institution of the fair or festival may be found by means of the above diagram. The process of arrest referred to is very evident in the case of fairs. In 1824 there were two three-days' fairs held at Bradford. One was on December 9, 10, and 11, being the dates of the fair before the change of style. The other fair was on June 17, 18, and 19. If the last figure is to be regarded as the solstice, we are taken back to 600 A.D. But it would be safer to regard the 17th as being the first of the three solstitial days, and that in the ninth century. The 17th is an important fair day, and it happens that St. Alban's Day is given in English calendars as June 17. The Welsh bards have somehow introduced the name Alban as that of a solstitial quarter day. That would naturally be suggested if Alban's Day at any time fell on the solstice, which may very well have happened in the ninth century. In an old Welsh calendar of about 1471 A.D., Alban's Day is June 22, when the date of the solstice was the 13th. That, however, does not dispose of our theory. By regarding the 22nd as the middle solstice day preceding the Council of Nice, we get the very period of the British proto-martyr. It was when the 21st was a solstice date that the earliest Christian calendar in the West was compiled, and it is possible that Alban's Day was fixed from the very first on the 22nd. The 21st is still called St. Alban's Eve. The question, therefore, is, Have we in the case of Alban's Day two arrested solar dates?

John Griffith.

NOTES.

Sir Henry Roscoe, F.R.S., and Sir William Ramsay, K.C.B., F.R.S., have been nominated foreign members of the Accademia dei Lincei, Rome.

The Vienna Academy of Sciences has awarded the Baumgarten prize to Prof. E. Ritter v. Schweidler, for his work on the phenomena of dielectrics; the Lieben prize to Prof. H. Benndorf, for his work on the transmission of earthquake waves in the interior of the earth; and the Haitinger prize to Dr. Robert Kremann, for his work on the esters.

We learn with regret of the death of Prof. Egon von Oppolzer at the early age of thirty-seven. Dr. von Oppolzer, who was a son of the celebrated Theodor von Oppolzer, was born at Vienna in 1869, and was educated at the universities of Vienna and Munich. In 1897 he became an assistant in the observatory at Prague, where he discovered in 1901 the variability in the brightness of the planet Eros. In the latter year he was appointed extraordinary professor of astronomy at Innsbruck, where he remained until his death. Among the subjects on which he wrote are astronomical refraction, solar physics, and the application of physical theory to stellar problems. He also made contributions to meteorology. A new form of zenith telescope was constructed by him, as well as a photometer of novel design. The variability of the minor planets, which has recently become a subject of very great interest, has naturally been investigated with the greatest success by the aid of photography, and it is worthy of note that Dr. von Oppolzer's important discovery in this branch of research was established by visual observations.

A MEETING of the Institution of Mechanical Engineers will be held on July 30–31, in the Mitchell Hall of the University, Aberdeen. The following papers will be read:—Aberdeen Harbour, by Mr. R. G. Nicol; cableways used on shipbuilding berths, by Mr. J. M. Henderson; portable pneumatic tools, by Mr. H. Bing; granite quarrying in Aberdeenshire, by Mr. W. Simpson; an electrically-controlled single-lever testing-machine, by Mr. C. E. Larard; observations on present-day practice in jute preparing and spinning, by Mr. D. J. MacDonald.

AFTER the current year the *Journal of Anatomy and Physiology* will be issued in two independent parts, one to be devoted to anatomical, histological, morphological, and embryological subjects, and the other to contain papers on subjects of physiological interest (including physiological histology and physiological chemistry). The acting editor of the anatomical part will be Prof. D. J. Cunningham, with whom will be associated Sir William Turner, K.C.B., Prof. A. Macalister, and Prof. G. S. Huntington. The acting editor of the physiological part will be Prof. E. A. Schäfer, with whom will be associated Profs. F. Gotch, W. D. Halliburton, C. S. Sherrington, and E. H. Starling.

THE Red-Hills Exploration Committee has issued an interim report for 1906. The committee is a joint committee of the Essex Archæological Society and the Essex Field Club appointed to make a systematic study of the red-hills, of which there are probably several hundreds on the coast of Essex alone. Work was commenced in the parish of Langenhoe, and three mounds have been examined thoroughly, particulars concerning which are given in the interim report. The red-hills vary in size from a few rods to several acres; they date from a remote period, and some at least are prehistoric. By some they have been regarded as salt works; by others as cattle shelters, human habitations, potteries, or glass factories. The object of the committee is to decide the question of their origin and significance, and an appeal is made for funds. Donations may be sent to Mr. H. Wilmer, St. Alban's Crescent, Woodford Green, Essex.

THE seventy-fifth annual meeting of the British Medical Association will be held at Exeter from July 27 to August 2. The president, Dr. R. A. Reeve, will deliver his address on July 30. The address in medicine, on "A Plea for Accuracy of Thought in Medicine," will be delivered on July 31 by Dr. W. H. White; that in surgery, on "The Contagion of Cancer in Human Beings, Auto-inoculation," on August 1 by Dr. H. T. Butlin; and the popular lecture, on "Weather, Climate and Health," on August 2 by Sir John W. Moore. There will be thirteen sections, and the names of these, with that of the president in each case, are as follows:—Pathology, Dr. R. Moore; medicine, Dr. W. Gordon; diseases of children, Mr. A. H. Tubby; psychological medicine, Dr. T. C. Shaw; electrical section, Dr. H. L. Jones; tropical diseases, Mr. J. Cantlie; surgery, Prof. G. A. Wright; ophthalmology, Mr. L. H. Tosswill; larynology, otology, and rhinology, Dr. R. McKenzie Johnston; dental surgery, Mr. J. McKno Ackland; obstetrics and gynæcology, Mr. E. H. Tweedy; State medicine, Dr. A. Newsholme; and naval and military, Dr. J. Porter.

ON Friday last, July 19, the new laboratory buildings erected by the Royal Horticultural Society in their gardens at Wisley, Surrey, were declared open by Lord Avebury in the presence of a large and distinguished assembly interested in the development of horticulture and in horticultural education in this country. The company was entertained to luncheon in the gardens by the council of the society, and the speakers after lunch included, in addition to Lord Avebury, Sir Trevor Lawrence, K.C.V.O. (president of the society), Lord Balfour of Burleigh, Sir William Chance, Sir Thomas Elliott, K.C.B., Prof. Michael Sadler, Sir William Vincent, and Sir John T. Dillwyn-Llewelyn. The laboratory buildings, which are the first in this country erected for the specific purpose of prosecuting research in horticultural science, include a research laboratory, a greenhouse for experimental work, a photographic dark-room, an office and store-room, and a students' laboratory accommodating twenty-four students at a time. The latter is equipped with all the necessary appliances for the study of plant life and its relationships to external conditions, and is excellently lighted and furnished with water and acetylene gas supply to the benches, &c. The subjects upon which the first researches are to be carried out are soil sterilisation and the etherisation of plants. The director of the laboratory is Mr. F. J. Chittenden, who was until recently a staff instructor in biology at the technical laboratories at Chelmsford.

THE following additional papers have been promised for reading before Section A of the British Association at the Leicester meeting: On the motions of ether produced by collision of atoms or molecules, containing or not containing electrons, Lord Kelvin; on variability in the products resulting from changes in radium emanation, Sir W. Ramsay, K.C.B.; on the production and origin of radium, Prof. E. Rutherford; the effect of high temperature on the activity of the products of radium, Prof. E. Rutherford and Dr. J. E. Petavel; Helium and radio-activity in common ores and minerals, Hon. R. J. Strutt; the transmission of the active deposit from radium emanation to anode, S. Russ; the absorption of gases by charcoal, Miss I. Homfray; on a theoretical method of attempting to detect relative motion between the ether and the earth, A. O. Rankine; the ultimate efficiency of illuminants, C. V. Drysdale; the variability in light of Mira Ceti and the temperature of sun-spots, Rev. A. L. Cortie; (1) on improving the plate constants of the astrographic catalogue, (2) on the determination of periodicity from a broken series of maxima, Prof. H. H. Turner; (1) some new results in the theory of functions of a real variable, (2) on the introduction of the mathematical idea of infinity, W. H. Young; the teaching of the elements of analysis, C. O. Tuckey.

IN the *Strand Magazine* for June, Mr. J. J. Ward, with the aid of numerous excellent photographs, tells the life-history of the goat-moth in a remarkably graphic manner.

IN the report of the Rugby School Natural History Society for the past year, attention is directed to the gift by Miss Loveday of a large collection of shells. Although these have been safely stored, the society lacks a conchologist capable of arranging the specimens in proper order.

THE second number of *British Birds* contains, as frontispiece, a striking portrait of the late Prof. Alfred Newton, reproduced from a photograph by Mayall. The publishers, Messrs. Witherby and Co., have also issued this photogravure in a large size suitable for framing. Mr. P. H

Bahr continues his account of the life of the osprey; while Messrs. Witherby and Ticehurst discuss additions made to the British bird-list since 1899.

Reports of papers and discussions on museum-fittings and the difficulties experienced by curators owing to reflection from the glass in exhibition galleries occupy a considerable space in No. 12 of the *Museums Journal* for the current year. Reflection is considered to present an insurmountable difficulty, which might, however, have been mitigated in many museums had more attention been paid to the needs of the exhibits when the buildings were designed. The same issue contains reprints of two addresses sent by the Trustees of the British Museum (natural history) to Upsala on the occasion of the recent celebrations in honour of Linnæus.

We are indebted to the author, Mr. Henri Piéron, of the physiological laboratories at Sorbonne, for copies of several papers from the *Comptes rendus de la Société de Biologie* dealing with experiments to determine the nature of the factors which induce sleep. In the first of these the nature of the experiments to be instituted on dogs for this purpose is discussed, while in the later ones such results as have at present been obtained are noticed. From the same author we have also received a paper from the Bulletins of the Institut général psychologique dealing with the "psychophysiology" of the sea-anemone *Actinia equina*.

Conchologists will be interested in two papers by Mr. Burnett Smith in the May issue of the Proceedings of the Philadelphia Academy. In the first the author discusses the genus Pyrula, which has existed since the late Eocene, and is now distributed in nearly all shallow tropical seas, a distribution suggesting that these seas had much freer intercommunication than is at present the case. Some of the Tertiary gastropods formerly included in Volutilithes, but now separated by the author as Athleta, form the subject of the second paper, in which the early stages of growth of these shells are discussed in detail.

A prosperous year in all branches is recorded in the report of the Yorkshire Naturalists' Union for 1906. An important piece of work undertaken by the geological section is the zoning of the Carboniferous rocks, which was inaugurated at the Ingleton meeting. The collection of photographs of important local rock-sections also continues to receive special attention. It is satisfactory to learn that the pair of peregrine falcons has continued to breed on Bempton Cliffs, although this is somewhat discounted by the driving away of a second pair which attempted to nest at Ingleboro'. Fortunately, in both instances public opinion is strongly in favour of protective legislation.

At the close of an article in the *American Naturalist* for June on the perception of colour by the eye, Mr. J. M. Dane summarises the three chief theories which have been proposed to explain the phenomenon. According to the first of these, all colours may be received by each cone of the retina; the second claims that not more than two colours can be impressed on any one cone; while the third admits the reaction of only one colour on a single cone, so that there are separate blue, red, yellow, and other cones, and corresponding transmission-fibres in the optic nerve. According to this third hypothesis the mixing of sensations, which gives rise to shades and tints, must take place in the brain. Evidence in favour of the same view is afforded by the fact that no nerve is known to respond to impulses of distinct kinds; but it should be borne in mind that no corroborative evidence is at present afforded by anatomy. Attention may also be directed to a paper in the same issue by Mr. A. B. Wright on a graphic method of correlating the environment and distribution of fishes.

Despite a falling-off in the number of papers read, the South London Entomological and Natural History Society, of which the report for 1906–7 is now before us, has to record a successful year's work. One of the features of the year was an exhibition of natural history objects held in the society's rooms in March last, which attracted a large number of visitors. The report is illustrated by several interesting photographs, from among which we are enabled, by the courtesy of the editor, to reproduce one illustrating a marvellous protective resemblance of a moth to its surroundings. So closely, indeed, do the colouring and contour accord with the bark upon which the insect is resting that it requires somewhat minute examination to detect the presence of the latter. A second, although

A specimen of the moth *Xylina ornithopos* reposing on oak-bark in the New Forest. From Report of S. London Entomological and Nat. Hist. Society, 1906–7.

somewhat less striking, case of the resemblance of a moth to its surroundings is shown in another photograph, where a specimen of *Aplecta nebulosa* is depicted on oak-bark at Leith Hill.

The second edition of the volume of the official guide to the museums of economic botany at Kew, devoted to dicotyledons and gymnosperms, has been out of print for some years, and is now replaced by a third edition, that has been carefully revised and considerably augmented, from which the gymnosperms have been excluded. Besides furnishing a guide to the collections at Kew, the book provides a valuable authority on the popular and scientific names of economic products and their sources.

The floras of the small islands known as sand keys, lying to the westward of Key West off the coast of Florida, also of the Marquesas and Tortugas groups, are graphically shown in a series of maps prepared by Mr. C. F. Millspaugh as publication No. 118 of the Field Columbian Museum. The mangrove vegetation in which *Rhizophora mangle* is the dominant species is an almost universal feature; an association of *Uniola paniculata* and *Euphorbia buxifolia* is commonly found, and a characteristic growth of *Suriana maritima* occurs on two of the Tortugas keys.

A systematic attempt is now being made to catalogue the flora of the county of Glamorgan. The work was done partly by the late Mr. John Storrie, but the new catalogue is being compiled by Prof. Trow, of the University College, Cardiff, assisted by a number of competent members of the Cardiff Naturalists' Society, and with the advice and help of Mr. A. Bennett, of Croydon. The catalogue will appear in the Transactions of the Cardiff Naturalists' Society, and is not expected to reach the complete form for another four years.

In the botanical section of the Philippine Journal of Science, vol. ii., No. 1, contains a collation of Philippine Cyperaceæ founded on the material in the Kew Herbarium by the late Mr. C. B. Clarke, and a short list of Philippine myxogastres named by Mr. G. Massee. In connection with an account of the pteridophytes collected by Mr. E. D. Merrill on Mt. Halcon, in Mindoro, Prof. E. B. Copeland, who is responsible for the identifications, notes the predominance of the Celebes element over the Bornean. The collection includes a large number of species of Polypodium, several of which are new, four new species of Diplazium, *Tmesipteris tannensis*, and a new species of Lycopodium.

The first number of vol. ii. of the botanical memoirs of the Department of Agriculture in India relates to diseases of cereals caused by *Sclerospora graminicola*, a member of the Peronosporeæ. While dealing with a matter of economic importance, the author, Dr. E. J. Butler, also gives consideration to the teratological aspect. The most interesting alteration occurs in the central prolification of the floral axis with the suppression of the pistil. The mycelium attains its maximum development in the leaves, and the reproductive organs are only produced there. The conidia arising on short, stout stalks germinate in water and give rise to zoospores; oogonia are formed in the leaf tissues at a later stage. Sclerospora disease has also been observed in India on *Sorghum vulgare* and Italian millet.

In a reference to the sixth report of the Woburn Experimental Fruit Farm (Nature, July 4, p. 231), Mr. F. V. Theobald stated that it had been found that "lead arsenate wash badly scorches the leaves under certain conditions and at certain strengths." Mr. Spencer Pickering informs us that the results obtained at the Woburn Fruit Farm do not lead to this conclusion; and upon referring the point to Mr. Theobald we find that the word "badly" written by him in his article should have been "slightly."

In the *Philippine Journal of Science* for May there are an address delivered by Dr. Paul Freer, on modern theories of immunity; a preliminary communication, by M. Mirjajima, on the cultivation of a bovine piroplasma, in which it is shown that the *Piroplasma parvum* of cattle in a blood-broth culture medium seems to develop into trypanosomes; and an exhaustive article, by Messrs. Ashburn and Craig, on dengue fever.

We have received a copy of the special bulletin of the State Board of Health containing a summary of the sanitary legislation in the United States enacted during 1906. Among others, we note that Massachusetts and Rhode Island have passed Acts to prohibit the misuse of vessels used in the sale of milk; Mississippi has passed an Act requiring the disinfection of public buildings, railway depôts, railway coaches, and sleeping cars; New Jersey an Act to provide for locating and abolishing mosquito-breeding places; and Virginia an Act prohibiting spitting in public places.

We have received from the Count Camillo Raineri-Biscia a copy of a reprint of the work entitled "Fior di Pensieri sulle Pietre Preziose di Armed Teifascite" (Bologna: L. Andreoli, 1906), translated from the Arabic and annotated by Antonio Raineri-Biscia. The translation was published originally in 1818, the translator being the eminent professor of Oriental languages at the University of Pisa, who died in 1839. A biography of the translator is given, and of his numerous works there recorded none is of greater interest than this translation of the Arabic manuscript on precious stones by Ahmed Teifascite, preserved in the Royal Library at Florence. The work is divided into twenty-five chapters, each dealing with the formation, occurrence, properties, and value of a different mineral. Some of the minerals are somewhat difficult to identify with certainty, but they appear to be as follows:—pearls, hyacinth, emerald, topaz, balas ruby, amethyst (*benfesc*), garnet, diamond, cat's eye, turquoise, carnelian, onyx, magnetite, corundum, fluorspar (*dahnag*), lapis lazuli, coral, agate, heliotrope (*giemest*), jet (*khamahan*), jasper, rock crystal, and talc. The translation is admirably reproduced, and forms a valuable contribution to mineralogical history.

As might have been expected, Sir H. Risley's theory that the Bengalis represent a blend of Dravidian and Mongoloid elements with a strain of Indo-Aryan blood in the higher groups has been contested by those members of that enterprising race who claim a higher ethnical origin. The latest critic of this school, Rama Prasad Chanda, deals with the subject in the April number of *East and West* (Bombay). Admitting, as he is compelled to do, that the Bengalis are brachycephalic, he urges that the inclusion in the anthropometrical statistics of partially assimilated races, like the Mals, Koch, and Maghs, unduly increases the ratio of brachycephaly. He proposes a new ethnical classification of the Indian races, including in what he calls the "Outlandic" group tribes of such varied character as Pathans, Baloches, Bengalis, and some races of the Brahmaputra valley, with the population of Coorg and Bellary in South India, all distinguished by round or medium heads, regular features, and moderate stature. In thus excluding a Mongoloid element from Bengal and associating the Bengali with the Turko-Iranian tribes of the North-western Frontier, his views are not likely to be received favourably by competent Indian ethnologists.

A select list of books, with references to periodicals, relating to iron and steel in commerce in the Library of Congress has been compiled by Mr. A. P. C. Griffin (Washington: Government Printing Office, 1907). The list, which covers twenty-four pages, is in no sense exhaustive. It forms, however, a handy guide to the most recent accessible literature of the subject.

In view of the recent discussion of matters connected with Belgium's exploitation of the Congo, a well-informed paper on the railways of the Upper Congo, by Mr. D. C. Boulger, in the *Engineering Magazine* (vol. xxxiii., No. 4), deserves careful attention. It is a friendly estimate of Belgian enterprise and achievement in pushing the railway across Africa from the western coast towards the great north and south artery of the Cape to Cairo line. The excellent reproductions of photographs illustrating the article show the difficulty encountered in cutting the track through the dense forest.

The following interesting details, referring more particularly to the telegraphic weather service of the United States, are taken from the annual summary, 1906, of the *Monthly Weather Review*. The Weather Bureau officials issue forecasts for thirty-six and forty-eight hours in advance daily for each State; the materials necessary for this service, including observations from about twenty stations in the Atlantic and Western Europe, are received by telegraph from about 200 stations in the morning, and from a lesser number in the evening. Storm-warning telegrams are sent to lightships and vessels from all wireless telegraph stations of the navy department along the coasts of the Atlantic, Pacific, and Gulf of Mexico; a similar service has also been inaugurated with the Marconi Company. The immense amount of information received from some 4500 stations of different classes is exhibited to the public in various ways. The daily issue of weather maps in Washington is about 1625 copies; there are also 105 other places, which issue an aggregate of 25,000 maps daily. The number of ships cooperating with the Bureau in the department of marine meteorology was 1771 during the year in question.

The Munich central meteorological station has for the first time published the preliminary results of the observations made in unmanned balloons in Bavaria in connection with the international ascents. The observations refer to the year 1906, and were made under various conditions, including periods of Föhn winds. The results will be classified for the different types of weather in a later discussion. Below 3000 metres the mean gradient (Δt/100 m.) was $-0^{\circ}.57$ C., which seems to point to a cooling effect of the mountains on the surrounding air. The largest gradients, $-0^{\circ}.71$, occurred at altitudes of 6000–8000 metres. The lowest point at which the upper inversion occurred was 8000 m., during a barometric depression; the highest point was 13,300 m., during an anticyclone. With one exception the temperature of the warm current in the upper inversion lay between -51° and -58° C. On December 5, in cyclonic conditions, a temperature of $-72^{\circ}.5$ was recorded at 13,270 m.; above this altitude an inversion occurred, and at the highest point, 14,170 m., a temperature of $-63^{\circ}.5$ was registered.

The extensive use of flexible cord in electric light fittings at the present time makes it of prime importance that definite tests of the rubber on which their insulation depends should be instituted. Prof. A. Schwartz has collected together a large amount of information on the subject, and has added the results of his own experiments in his paper on "Flexibles" in the July number of the Journal of the Institution of Electrical Engineers. He considers that the diagram connecting stress and strain for a complete cycle of stresses applied, which he calls a "hysteresis" diagram, furnishes a better criterion of the character of the rubber than any other test in common use. He is in favour of the use of pure as against vulcanised rubber in flexible cords.

The hope that the work of Dr. J. A. Harker at the National Physical Laboratory, and of Drs. L. Holborn and F. Henning at the Reichsanstalt, had definitely fixed 1710° C. as the melting point of platinum, has been rudely shaken by the appearance of additional work by Messrs. C. W. Waidner and G. K. Burgess in the May Bulletin of the United States Bureau of Standards, and by Drs. L. Holborn and S. Valentiner in the *Annalen der Physik* (vol. xxii., p. 1). The former, by the optical pyrometer method, find the point is 1753° C., while the latter, by a comparison of the optical scale with the nitrogen scale up to 1600° C., have assigned 1789° C. to the point. These discrepancies show the necessity for further work before the scale can be considered definitely fixed at these high temperatures.

The current number of the *Quarterly Review* contains two articles of interest to scientific readers. The first, under the title "The Case for the Goat," urges the value of the goat as a producer of milk. "It is not only that the goat produces a relatively large quantity of milk, and exceptionally rich milk, but . . . this milk may be drunk practically without any risk of tubercular infection." The second article, "Magic and Religion," by Mr. Edward Clodd, gives in the form of a review of a number of recent works on anthropology, an interesting summary of the growth of the science, explaining by the way how other branches of natural knowledge have assisted its growth, and enumerating the more recent contributions to the study.

The Carnegie Institution of Washington has published an "Index of Economic Material in Documents of the States of the United States: Maine, 1820–1904." The work was prepared for the department of economics and sociology of the institution by Mr. Adelaide R. Hasse, of the New York Public Library. The purpose of the volume is to furnish a guide to the economic material contained in the printed reports of administrative affairs, legislative committees, and special commissions of the State of Maine and in the messages of the governors to the legislature of that State. The present volume will be followed by others, each devoted to a single State.

Several new editions of important German scientific works have recently been received. Prof. Otto Lummer has a volume on optics in Müller-Pouillet's "Lehrbuch der Physik und Meteorologie," the tenth revised edition of which is in course of publication, under the editorship of Prof. L. Pfaundler. The new edition is to be completed in four volumes, and Prof. Lummer's work (price 15 marks), though it runs into nearly nine hundred pages, is only the third book of the first part of the second volume. The publishers are Messrs. F. Vieweg and Son, Brunswick. A second revised edition of "Die Kathodenstrahlen," by Prof. G. C. Schmidt, has also been published by Messrs. Vieweg and Son. The original work was briefly noticed in Nature of June 9, 1904 (vol. lxx., p. 124); its price is 3 marks. The fifth revised edition of Prof. A. Engler's "Syllabus der Pflanzenfamilien" has been published by Messrs. Borntraeger Bros., Berlin. Two volumes in the Philosophische Bibliothek have been received from the Dürr'schen Buchhandlung, Leipzig; No. 35 is the sixth edition of the German translation of Hume's "Enquiry concerning Human Understanding," edited by Raoul Richter, and No. 113 is a commentary on Kant's "Kritik der reinen Vernunft," by Prof. H. Cohen. Another philosophical work is "Das Weltproblem von positivistischen Standpunkte aus," by Joseph Petzoldt, published by B. G. Teubner, Leipzig. From the same publisher we have received a small volume by Prof. P. Maas, entitled "Lebensbedingungen und Verbreitung der Tiere." Two papers by A. S. Marggraf and F. C. Achard, founders of the beet sugar industry, form No. 159 of Ostwald's "Klassiker der exakten Wissenschaften," published by W. Engelmann, Leipzig.

OUR ASTRONOMICAL COLUMN.

Comet 1907*d* (Daniel).—The following set of elements and an ephemeris for comet 1907*d* have been computed by Herr H. H. Kritzinger, of Berlin, from places observed on June 15 and 24 and July 4, and are published in Circular No. 99 from the Kiel Centralstelle:—

Elements.

T = 1907 Sept. 4·168 (M.T. Berlin)

$$\left.\begin{aligned} \omega &= 293^\circ\ 49'\cdot16 \\ \Omega &= 143\ \ \ 2\cdot45 \\ i &= \ \ 8\ \ 56\cdot37 \end{aligned}\right\} 1907\cdot0$$

$$\log q = 9\cdot71590$$

An extract from the ephemeris is given below:—

Ephemeris 12h. (M.T. Berlin).

1907	α (true) h. m.	δ (true) ° ′	Brightness
July 24	3 20·7	+13 37·1	
26	3 37·5	+14 21·5	9·84
28	3 54·8	+15 2·5	
30	4 12·8	+15 39·4	11·81
Aug. 1	4 31·4	+16 11·3	
3	4 50·1	+16 37·5	13·81

The brightness at the time of discovery is taken as unity, and it is very probable that the comet will become an easy naked-eye object during August. On July 18 it was easily seen by Dr. W. J. S. Lockyer, at South Kensington, with a small telescope of about $1\frac{1}{4}$ inches aperture and 11 inches focal length, the brightness on that date, according to the above ephemeris, being 6·38.

According to the ephemeris, the comet on August 1 will be 47s. east and 18′ 8″ north of Aldebaran, and will rise four hours before the sun.

Anomalous Refraction.—No. 18 of the Miscellaneous Scientific Papers of the Alleghany Observatory contains a note by Messrs. Schlesinger and Blair on the effects of anomalous refraction on meridian-observation results. They show, from a discussion of the results obtained at the international latitude stations, that, at a properly chosen station, the effect is far less than the errors of observation in the best work that can at present be done. Incidentally, their computations indicate very strongly that the Kimura term in the latitude variation is real, and is not due, as has been suggested, to anomalous refraction.

Italian Observations of the Total Solar Eclipse of August, 1905.—The various reports which have from time to time appeared in the *Memorie della Società degli Spettroscopisti Italiani*, dealing with the results of the Italian eclipse expedition to Alcalà de Chivert in August, 1905, are now collected into one volume as the complete "Rapporto della Commissione Italiana . . ." With photographs of the instruments in position, reproductions of the solar photographs obtained, and the full discussion of the astronomical and meteorological results, the volume is a valuable addition to eclipse records. Prof. Riccò discusses the colours of the prominences, the heights of the "reversing layer" and of the chromosphere, the white prominences, the corona, the spectra, &c., whilst the discussion of the meteorological results is due to Dr. Chistoni.

Micrometer Measures of Jovian Features.—In No. 4190 of the *Astronomische Nachrichten* (p. 225, July 11) Dr. H. E. Lau gives the results of the observations of Jupiter made at the Urania Observatory, Copenhagen, during the opposition of 1906–7. The measurements of the five bands are first given, and are followed by the dimensions and positions of various "spots" in each band, the longitude and the motion of each feature, at a definite epoch, being appended. For the middle of the Great Red Spot Dr. Lau found the value of μ to be $+0^\circ\cdot071$.

July and August Meteors.—Some valuable hints to meteor observers are given in the July number of *Knowledge and Scientific News* (vol. iv., No. 7, p. 150) by Mr. Denning. The article deals principally with the Aquarid and Perseid showers, both of which should now be active. The former apparently form a fixed radiant point, near to δ Aquarii, from about July 23 to August 23, but this needs substantiating by further careful observations. Mr. Denning suggests that observers should record, very carefully, the exact data for each individual object, and afterwards seek to determine the radiant points quite independently. For the Perseids, and for the Aquarids at their maximum during the last few days of July, the radiant should be obtained separately from each night's observations.

For the minor showers the radiants have never been adequately studied, and many more observations are desirable, whilst even in regard to the Perseids it is probable that a number of important features yet remain to be detected or confirmed. No moonlight will interfere during the maximum of the present apparition.

Orbits of Binary Stars.—No. 5, vol. xxv. (June), of the *Astrophysical Journal* contains discussions of the orbits of κ Cancri and β Arietis by Mr. N. Ichinohe and Herr Ludendorff respectively.

From the discussion of twenty-five plates taken at the Yerkes Observatory, the former observer found the period of κ Cancri to be 3·393 days, whilst the eccentricity of the orbit is 0·149, and the length of its semi-major axis 5,890,000 km.

Seventy-six plates of β Arietis were examined by Herr Ludendorff, but only two lines on each, Mg λ 4481 and Hγ, could be employed in the discussion. The duplicity of the Mg line could not be detected on seventy-four plates, although, as mentioned in a previous paper by Dr. Vogel, it certainly does appear double on the other two. The writer of the present paper suggests that this doubling may be due to special disturbances in the atmosphere of the star. The results of the investigation show that the period of this binary is 107·0 days, the length of the semi-major axis of the orbit is 22,880,000 km., the total mass of the system, assuming that the masses of the components are equal, is 0·34 that of the sun, and that the eccentricity of the orbit has the extraordinarily large value 0·88. No other known spectroscopic binary orbit has an eccentricity greater than 0·55, although the values for several visual binaries exceed 0·80, but in these cases the periods are very much greater.

SCIENTIFIC WORK IN THE SEA-FISHERIES.[1]

In the first lecture the earlier history of the pre-scientific period was alluded to, from the third century onward, and even in those early times fears as to the permanence of the sea-fisheries were prevalent, as shown by regulations as to meshes of nets, small or immature fishes, and other features. Indeed, ever-recurring fears as to the decline of these fisheries have been conspicuous. Inquiries and commissions were numerous, and in the seventeenth century many protective Acts were passed, and companies floated to encourage the struggling sea-fisheries, whilst in the eighteenth century the bounty system was instituted and was only abolished in 1830.[2] The Commission of 1833 reported that the fishes of the British Channel had declined since the peace of 1815, and that the fishermen and their families were dependent on the poor-rates for support. It is clear that at that time the finny wealth of the Channel was unknown. The Commission of 1866, on the other hand, came to the conclusion that the supply of sea-fishes was increasing, and admitted of progressive increase. Then the United States Fish-Commission came into existence, from the complaints as to the diminution of the fishes on the American fishing-grounds, and artificial hatching of sea-fishes commenced in 1878. In Britain, again, a commission of two reported in 1878 much as that of 1866 had done.

Lord Dalhousie's Commission of 1883–5 was due to the complaints of the liners against trawling, and it introduced scientific investigation into the subject for the first time. This investigation was made by the same eye and the same hand on sea and on land; a method of dealing with the fishes was adopted, and subsequently followed

[1] Abstract of two lectures delivered at the Royal Institution on May 4 and 11, by Prof. W. C. McIntosh, F.R.S.

[2] An interesting historical account of the sea-fisheries, by T. Fulton, from which part of the foregoing is taken, was given in the *Fish Trades' Gazette* for 1893.

in the case of the *Garland's* work under the Scotch Fishery Board. This scientific report gave an account of beam-trawl fishing; the kinds and proportions of saleable and unsaleable fishes; the proportions of the living and the dead and of the immature fishes; the development and growth of the food-fishes; and the universal presence of floating eggs in all the ordinary food-fishes, except the herring and the wolf-fish. It showed that no noteworthy destruction of the spawn of food-fishes occurred, and that the small or immature fishes from the deeper waters consisted chiefly of dabs and long-rough dabs. It gave the distribution of the food-fishes on the various grounds, and the relative condition of the districts; a list of unsaleable fishes (chiefly frog-fishes); the fauna of the trawling grounds—surface and bottom; the food of fishes; temperature of the air; temperature of the surface and bottom water, and other points, including the satisfactory condition of the fishes themselves, and the effects of frequent hauls of the trawl on the same ground. It demonstrated that the inshore was dependent on the offshore for the supply of eggs and young of various fishes; that a gradual passage of the eggs and young shorewards, and of the growing fishes at a later stage seawards, took place. Further, that in a bay like St. Andrews Bay, constant and long-continued trawling did not exhaust the fishes, and that the men invariably kept the same line (by fixed land-marks) in their operations, a feature which at once disposed of the fears as to "trawling out." No interference with well-conducted modes of fishing was suggested.

The scientific report further recommended the establishment of experimental sea-fish hatcheries, the closure of certain areas for experiments, and the keeping of records by all fishermen of the ground, weather, depth, and nature of the fishes. Statistics were put on an improved footing in Scotland. The Fishery Board for Scotland received increased powers and funds, and carried out the trawling experiments in the closed areas, but it did not follow the advice given as to ship, staff, apparatus, and regularity of work. The Board proceeded further to close other areas, such as the Moray Firth, but upon data which science rejects. The Parliamentary Committee of 1893 followed, but the scientific evidence as to diminution was founded on data supplied by the Scotch Fishery Board, and, unfortunately, the faulty method of handling the statistics misled all as to the supposed decrease of flat-fishes. Carefully checked subsequently, the work of the Board's ship *Garland* showed that no increase of fishes had occurred in the closed areas, that the fish-fauna at the end of the ten years' experiments stood very much as at the beginning, and that, on the whole, the marine food-fishes were able to withstand man's interference. Other committees, such as that on the "Immature Fishes Bill" and the "Ichthyological Committee," were also dealt with. Sea-fish hatching was shown to be inconclusive up to date, whilst the enormous numbers of young fishes in the sea rendered the procedure of doubtful advantage.

The whole history of the subject, including the most recent work and statistics in America, Canada, Japan, Newfoundland, Norway, St. Andrews Bay, and elsewhere, showed that it was neither scientific nor practical to doubt the permanence of the British marine food-fishes or the marvellous resources of nature in the sea. Even the lobster (a form supposed to be diminishing) had been shown by Prof. Prince, of Canada, to be able to hold its own in the most rigorously fished district of western Nova Scotia. If such a species can do so, how much more the food-fishes, which survive notwithstanding the distrust of the public and the fishermen, and the fears of the learned as to man's upsetting the balance of nature.

LECTURE II.

In taking a broad survey of the reasons which prompted our country to join in the International Investigation of the Sea, it would appear that the main object was the prospective benefit to the British fisheries, though the testing of the antagonistic views, viz. of the "Resources of the Sea" and the "Impoverishment of the Sea," may have influenced the decision. The lines upon which such work should be carried out had been laid before the Ichthyological Committee, and subsequently published.[1] It is difficult to ascertain what the British investigators expected to discover, but, briefly, one of their tasks was to find out "whether the quantity and consumption of fish taken from the North Sea and neighbourhood are in proper proportion to the production." To this the observers added the exploration of the small fish grounds. The ambiguity on the subject is apparent from the mention of the "publication of annual results," of "discoveries of practical importance to the fisheries," and of "recommendations for international action."

One department, viz. hydrography, made itself prominent from the beginning, but a study of its work in the German ship *Pommerania* in 1872, of the efforts to connect temperatures with the captures of fishes in 1884, of the observations of the Scotch Board in the eastern and western waters of North Britain, of the International Survey of the North Sea (in which the same Board joined) in 1893–4, gave reasons for reserve. The present results of hydrography in connection with the fisheries in the international investigations emphasise this reserve.

We now turn to the work of the senior naturalists whose efforts were to be directed to the elucidation of fisheries' problems, such as the present condition of the food-fishes of the North Sea, and to prove the "impoverishment of the sea." Briefly, the Marine Biological Association, in the southern area of the North Sea, announces that "facts have been obtained upon which a proper understanding of the yield of the sea must in future be based," and that this pregnant statement rests on the results of experiments with marked plaice. From the numbers subsequently captured three important conclusions are drawn, viz.:—"(1) the migrations of the species, (2) the rate of growth, and (3) the intensity of fishing." Marking of plaice has long been carried out by the Scotch Board, by the Americans with cod, and by the Germans and Dutch in the international work also on the plaice. A simple method of tattooing is suggested as more likely to place the fishes (plaice) on a normal footing than the present somewhat rough one of silver wire and buttons. The data are yet too few and the time too short for a trustworthy conclusion, and British and German observers disagree. The second head has long been studied, and the present observations relate rather to the proportional rate of growth in connection with locality. Thus plaice transplanted from the Horn reef to the Dogger shoal grew faster than would have been the case had they remained, but this increase was exceeded in the Scager Rack. Transplantation is thus suggested by Dr. Garstang, as the Danes have done for some years in the Lim Fjord. So far as experience goes, however, there is little fear of suitable areas off our open shores being left unoccupied by such fishes as the plaice. The third head is apparently considered important by the Marine Biological Association, the percentage captured in the offshore waters being 20 and in the inshore 10, so that it is concluded that a limit has been reached in sea-fishing, and that it is no longer an uncertain pursuit (in the hands of the association). But this conclusion is not supported by long experience in St. Andrews Bay, nor by the history of the plaice-fishery of the Cattegat, nor by the work on the old trawling grounds on the east coast. The international observers, again, differ amongst themselves, the number experimented with being too few for a conclusion so important.

In the northern section hydrographical work is again too prominent, and surprise was felt that a new and original series of fisheries' investigations, based on a well-considered plan, was not forthcoming. The statistics of commercial trawling vessels and their treatment have little real bearing on the present inquiry, even though they are portioned out in Fulton's squares, yet it is asserted "that by these methods, if we only had statistics enough, we should mark down accurately for each fish the time of the coming at every position in the North Sea, and then weaving all the facts together show the route followed in the migration of any species." A tribute may be paid to this enthusiasm, but the importance of all these pages of tables and curves is doubted.

A contribution of a different type is that of the Scotch

[1] "A Second Decade of the Sea-Fisheries," 1903.

Board on "The Distribution and Seasonal Abundance of the Flat-fishes in the North Sea," by Dr. Fulton. This is also largely a statistical paper, and somewhat overlaps Henking's work in the North Sea and the Cattegat, and Dr. Heincke's, so far as flat-fishes are concerned. A main point is the "complementary and compensatory fluctuations" in the statistics, *e.g.* the "witch" or pole-dab in square xiv., near the Fair Isle, taking, during the winter, the place of dabs, lemon dabs, and plaice. Uncertainty, however, exists, as no other method of fishing than trawling was used on the same ground to make sure the other forms were not there. This condition is well known to fishermen. In regard to the maximum of the captures in each fish, it is found that it corresponds to the spawning season. While this paper likewise does not deal directly with the great question handed over to the Scotch Board to solve, it indirectly supports the "Resources of the Sea" in so far as the total average of lbs. per hour of fishing was greater (in flat-fishes) in 1903 than in 1901.

One of the most important papers is that of Dr. H. M. Kyle, who shows that the quantity of fish of all kinds landed in the North Sea ports, and especially of flat-fishes, was greater in 1903 than in 1902. This is clearly substantiated by Johansen's observations on Danish plaice. Hjort's work, again, removes any fear of diminution of round fishes for the supply of the North Sea.

While, therefore, the work of the British international observers up to date does not show an answer to the fundamental question submitted by the Government, yet it inadvertently supports the "Resources of the Sea," and is fairly compatible with the safety of the fishes in the North Sea. Finally, a separate English Fisheries Board, as Lord Dalhousie recommended, was suggested.

NEW ZEALAND PETROGRAPHY.[1]

THE first volume of this work was reviewed in NATURE of January 4, 1906, vol. lxxiii., pp. 234, 235. We noticed in that place the reasons which led to these Cape Colville rocks being selected for special study, and also the circumstances which made it necessary to call in extraneous aid for the descriptive part of the work. Of the volume now before us, the first two-thirds, to which alone the title of the book is properly applicable, completes the account of the volcanic rocks of the Cape Colville Peninsula. As before, the petrographical descriptions are by Prof. Sollas, and the notes relative to locality and occurrence by Mr. McKay, who also furnishes a clear geological map of the district. The details of mineralogical composition and micro-structure do not include much that is new, though we may mention the occurrence of a felspar of the anorthoclase type in some of the rhyolites, the frequent association of hornblende (or its pseudomorphs) with hypersthene in the andesitic rocks, and the presence of olivine in certain basic hypersthene-andesites or hypersthene-basalts. The interest of this collection of Tertiary andesites, dacites, and rhyolites lies, not so much in any novelty which they present, as in the close resemblance of the whole assemblage from this "petrographical province" to familiar types from better-known areas, such as Hungary and the Great Basin of North America.

The lack of arrangement and some minor blemishes, on which we will not insist, are drawbacks doubtless incidental to the conditions under which the work was carried out, by the cooperation of a petrologist in England with a field-geologist at the Antipodes. When this investigation was taken in hand, Mr. McKay, we believe, embodied in his own person the Geological Survey of New Zealand, and the work must be considered a notable production in these adverse circumstances. The re-organised Geological Survey, under the directorship of Dr. J. M. Bell, has begun operations with greater advantages, and two important memoirs of the new series have already appeared.

A special feature of the present work is the profusion of plates. This was not, we understand, a part of the original design, but it greatly enhances the value of the book. In the two volumes more than two hundred full-page plates are devoted to the illustration of the volcanic rocks of the Cape Colville Peninsula alone. The thin slices have been photographed with polarised light, usually with an amplification of sixty diameters, and most of the plates are very successful in rendering the micro-structure of the rocks selected. Such a collection of illustrations is welcome independently of the immediate object of the book, and the fact that most of the rocks belong to types of world-wide distribution is, from this point of view, an advantage.

The latter part of this volume is devoted to the description and illustration of various rocks from numerous places in New Zealand. Some of these, from the Kaimanawa Mountains and other localities in the North Island, are volcanic rocks generally comparable with those of Cape Colville. Other descriptions are included here, without regard to relationship, to fill out the volume, and the want of any orderly arrangement gives a somewhat confused appearance to this section. Some remarkable teschenites are described from the east coast of Wellington Province. They appear to occupy the neck of an old volcano, and it is noteworthy that, like the similar rocks from some European localities, they are referred to a Cretaceous age. Special interest attaches to a collection of crystalline schists from Westland Province, on the west side of the South Island. In addition to garnetiferous mica-schists, epidote-amphibole-schists, and other ordinary types, there occurs a series of schistose ultrabasic rocks composed of serpentine, talc, tremolite, calcite, &c. Through the same district there runs also a belt of massive ultrabasic rocks, viz. fresh and altered dunites. The geological relations of these two very interesting groups are only briefly touched in this work, but they are fully discussed in the first Bulletin (new series) of the Geological Survey, already mentioned.

Prof. Sollas's investigations, while devoted mainly to the exhaustive description of one group of rocks, afford also a glimpse of the rich variety of material which New Zealand offers to the petrographer. When we recall further the widely different "petrographical province" of Dunedin, characterised by highly alkaline rock-types, some of which have recently been described by Dr. Marshall, we may expect that a more comprehensive examination of the igneous and crystalline rocks of the colony will result in further important additions to petrological science.

A. H.

[1] "The Rocks of Cape Colville Peninsula, Auckland, New Zealand." By Prof. Sollas, F.R.S.; with an Introduction and Descriptive Notes by Alexander McKay. Vol. ii. Pp. 215; with geological map and 133 photographic plates of rock-sections. (Wellington, N.Z.: J. McKay, 1906.)

UNSOLVED PROBLEMS IN THE DESIGN AND PROPULSION OF SHIPS.[1]

THERE are but few problems in the design of ships, as in most other branches of engineering, that can be exactly or completely solved in the full scientific meaning of the word, and those are of a secondary character. The primary or fundamental problems of safety, strength, speed, and steadiness at sea are far too complicated to bring under anything like general mathematical treatment. The results obtained by the most advanced calculations cannot be applied directly to the real conditions of a ship at sea. After all is said and done, they merely relate to hypothetical cases which are simple in character and are amenable to mathematical treatment. Some of these calculations are very elaborate, and their elaboration may sometimes tend to magnify their importance. The real problem is often very imperfectly dealt with after they are made, and it can only be solved approximately for working purposes by accepting the results of calculation for what they may be really worth, judging of the allowances required for their incompleteness, and using them in a scientific way and a scientific spirit to arrive at safe conclusions. We are obliged to come to a conclusion somehow, because we have to build ships as well as we can, whether we can solve exactly all the problems that arise in their design or not; and we have to take the responsibility of guaranteeing results, however difficult to obtain, or of declining to do so, within the time allotted for the preparation of

[1] Abridged from the "James Forrest" Lecture, delivered before the Institution of Civil Engineers on June 18, by Dr. Francis Elgar, F.R.S.

designs and tenders, which is often very short. This is of the nature of engineering work of all kinds.

The nature of some of the principal problems that arise in the design of ships, and the extent to which their solutions are scientific, empirical, or merely tentative, will be indicated in some degree as I go on. I pass over what I venture to call the secondary problems of mensuration and hydrostatics—which relate to bodies floating in equilibrium in still water, and constitute the bulk of the ship-designer's purely scientific stock-in-trade—and will endeavour to direct attention to some of the fundamental problems of a ship's behaviour at sea. I do not underrate, however, the great importance of those passed over, for it is the results of mathematical and physical research into the still-water properties and conditions of floating bodies which enable us, with the aid of observation and experience, to judge the probable qualities and behaviour of ships at sea. They also furnish the best data for comparisons between ships of varying dimensions and forms.

The class of problems that demand attention first are those which bear the most directly upon safety at sea. These are very general and comprehensive in character, and are impossible of anything like complete solution from the purely scientific side; but they are of vital importance, and solutions of them, which will be upon the right side, have to be found somehow for every ship that is built.

The first in natural order of the problems that relate to safety is the maximum depth of safe loading, or the minimum sea-going freeboard for a ship of any given size or type.

The losses of cargo-steamers, and of lives at sea, became so serious twenty-five to thirty years ago that many attempts were made to get a law passed for limiting depth of loading. The great difficulty and complexity of the problem resisted for a long while all efforts to deal satisfactorily with it. It was considered by many authorities, upon all sides, to be impossible of solution; and yet individual shipowners, or shipping companies, were obliged to regulate the loading of their own ships in some way, and upon some system, or make it the duty of others to do so. It followed, therefore, that if the knowledge and experience of those separately responsible for the loading of the various types of vessels could be brought together and analysed, it ought to be possible to frame rules and tables of freeboard which would embody the results of safe loading, and prevent steamers being sent to sea in a dangerously overladen condition.

The present Board of Trade freeboard rules and tables, which limit, by an Act of Parliament passed in 1890, the depth of loading of British ships, were arrived at in this manner. The first official tables were prepared in 1885 by a committee appointed by Mr. Chamberlain when he was President of the Board of Trade.

The close attention paid during recent years to the protection of openings in the weather-deck, in association with the strict limitation of loading now enforced by the Board of Trade freeboard tables, has resulted in an extraordinary diminution of losses at sea. The effect upon safety of the present regulations, and of the improvement all round in the size, strength, and equipment of ships is shown by the yearly statistics of losses, and it is well that the figures relating to these should be known. In the three calendar years 1881–3 there were 1982 of the British ships registered in the United Kingdom, exclusive of fishing-vessels, lost at sea from all causes—foundering, stranding, collision, and missing—and 5599 lives of crew in them, besides 332 passengers. For the three years ending June 30, 1906, the corresponding figures were 654 ships, 1394 lives of crew, and 133 passengers—and more than 100 of these passengers were lost in the channel steamer *Hilda*, on her passage to St. Malo in November, 1905. The number of lives of crew lost at sea has thus been reduced to one-fourth of what it was twenty-five years ago, while not more than thirty passengers, besides the unfortunate victims of the *Hilda* disaster, lost their lives in all the vessels, large and small, that were lost at sea during the three years ending June 30, 1906.

An important element of safety at sea is the division of the hull into separate water-tight compartments. A collision with another ship may occur, and it is necessary to provide, in such case, against being sent quickly to the bottom. Much attention has been given to this point during recent years, especially in large passenger liners. The number and positions of the water-tight bulkheads in these are often regulated so as to carry out the recommendations of the Board of Trade Bulkheads Committee, presided over by the late Sir E. J. Harland in 1891.

Compliance with the Bulkhead Committee's rules is optional on the part of shipowners, but, although they may be sometimes used as a guide in fixing the position of bulkheads, full compliance with their requirements is by no means general, even in the highest class of steamers.

The next point of vital importance to safety at sea is stability. The stability of a ship when floating in equilibrium in still water is readily calculated, and is represented graphically by curves which show at any angle of inclination what the righting moment is which operates to move her back towards the upright position supposing her to have been forcibly inclined away from it. It is thus determined very completely for the assumed still-water conditions, but the designer, although he is obliged to trust to his judgment for making it satisfactory for sea-going purposes, often knows little of what it may become under working conditions upon a voyage. I made two voyages in a large ocean liner not long ago, the metacentric height of which is about 7 inches when light and 18 inches when filled up with passengers, stores, fresh water, coals, and a homogeneous cargo of such density as completely fills all the cargo spaces and immerses her to her load draught. The metacentric height was 2 feet 2 inches at sailing upon the first voyage; at the middle of the voyage it was 21 inches, and at the end 20 inches. Upon the second voyage the metacentric heights were 2 feet 10 inches at starting, 16 inches in the middle of the voyage, and 20 inches at the end. The irregularities in the metacentric height from day to day were largely due to the manner in which the water-ballast was used. This was the case of an ocean liner, in which the weights carried were about one-half the fixed weight of the hull and machinery. In a large cargo-steamer, where the weights carried may amount to twice the weight of the hull and machinery, it will be seen how much the stability on service depends upon those who regulate the loading, and how little upon the designer.

The ship-designer requires to decide, of course, what metacentric height to give a ship in the circumstances to which his calculations apply, but it is only by comparison with other ships of similar types that have been found satisfactory after passing into the hands of their owners that he can properly fix the exact figure.

The question of stability was raised before the Loadline Committee of 1885 in connection with the regulation of freeboards, and has often been revived since. It has been felt, however, that stability is so intimately related to stowage, and so much in the hands of those who regulate it, that it would be impossible to treat stability satisfactorily as a mere factor of depth of loading. Nothing can make a ship safe if her stability is not secured by proper stowage; but when vessels will obviously admit of being loaded with homogeneous cargoes, so as to have their stability dangerously reduced at sea, the official bodies who assign load-lines should look for proof that the danger is understood, and that proper measures will be taken in regulating the stowage to guard against it. I understand this is the course taken by the Board of Trade and the authorities who assign freeboards when cases of such a nature come before them.

One of the most important elements of safety at sea is structural strength, and there is no more intricate or difficult problem which we have to consider. Mercantile steamers have been made what they are, in respect of design and strength of structure, chiefly by observation and experience of the effects of straining action at sea. The usual calculations of strength of structures do not carry us very far by themselves in shipbuilding, and although much attention has been given to these by ship-designers they cannot be greatly relied upon in practice. As a matter of fact, the arrangement of material shown upon the transverse section of a ship, and the sizes of the various parts, are practically what they have been made from time to time by Lloyd's Register Society. Classification at Lloyd's is so important in the mercantile marine for purposes of insurance that the design of a ship's structure is usually little, if any, more than compliance with Lloyd's rules and tables. These rules have been modified as ships have increased in size and varied in type; and when exceptional ships not directly provided for by the rules have to be classed, the structural design is specially dealt with by Lloyd's; but the governing principle throughout is experience of the behaviour of ships at sea.

Lloyd's Register Society has also done, and is still doing, much in the way of scientific research. It has a highly trained technical staff which has conducted and published some of the most valuable investigations yet made of the structural strength of ships; but the general problem of how to obtain the requisite strength of structure with the minimum weight of material is extremely difficult of approach from the scientific side. The usual calculations of structural strength are based upon still-water conditions. The most important are those which relate to longitudinal strength, because the greatest stresses that can come upon a ship are in the longitudinal direction. In these calculations the structural portion of the hull is regarded as a steel girder supported over the whole of its length by the upward pressure of the water.

In order to approximate somewhat to the worst conditions at sea, the maximum stresses at the top and bottom are calculated for two hypothetical cases of support upon a wave surface. The surface usually taken is that of a trochoidal wave of the same length as the ship, the height of which is one-twentieth of its length. The vessel is first considered in equilibrium upon a wave-crest with her bow and stern in the adjacent hollows, and next to be supported at the ends upon two wave-crests with her midship part in the hollow between them. The whole system of wave-water is supposed, for the purposes of the calculations, to be fixed for the moment, and the ship to be floating upon it in statical equilibrium.

It is not known how nearly the results given by calculations, which rest upon assumptions that differ so widely from the real circumstances, correspond with the maximum stresses really brought to bear at sea, but it is certain that they are often much in excess of the truth. In the new big Cunarders, *Lusitania* and *Mauretania*, the limiting stress accepted by Lloyd's as determined by calculation was 10 tons per square inch for mild steel the ultimate tensile strength of which is 28 to 32 tons per square inch. This gives an apparent factor of safety of only 3.

Many vessels have been running for years in which the figures, obtained by similar calculations, for the maximum stresses would amount to 10 tons per square inch. This must be largely in excess of the truth, and it is impossible to say exactly by how much.

The quantitative values of the calculated stresses are thus extremely doubtful. Even in comparing them with figures obtained in a similar way for other ships, it is necessary to be careful not to press the comparison too far. Attempts have been made to measure the actual stresses at sea upon portions of a ship's structure by means of strain indicators. Extensive experiments were carried out in H.M.S. *Wolf* a few years ago by an Admiralty Committee with Stromeyer's indicators, which gave some interesting results; but very little real progress has yet been made towards a quantitative solution of the strength problem.

The *Great Eastern* proved, by her Atlantic voyages to New York and Quebec, and her subsequent experiences in the trying work of cable-laying in the Atlantic, that she was quite strong enough for anything required of such a ship; and if we compare her structure with that of the standard ship of her dimensions and type to-day, which embodies the results of fifty years' more experience than her designer had at command, it appears very remarkable. Sir W. White came to the conclusion, which I believe is right, that after making full allowance for features of modern designs, that involve additional weight, which the *Great Eastern* did not possess, her structure was lighter than that of the corresponding ship of to-day, although the ship of to-day is built of steel 50 per cent. stronger than the iron plates of the *Great Eastern*, and the riveting of the edges and butts of plating is much more extensive and efficient, and is performed by hydraulic power in those parts where strength is most important.

The difference in principle between the two designs is so great, and the comparison of the weights of material they require is so much in favour of the *Great Eastern*, that there certainly seems to be a case for careful investigation, and for seriously considering whether a radical change in the structural design of large ocean liners might not be made with advantage. Novel structural arrangements are constantly being introduced into the design of cargo-steamers in order to give large open holds and to facilitate stowage. Some of these are now being built of large size and depth, with only a single strongly plated deck at the top, and there seems no reason why this principle should not be applied to large passenger vessels. Any saving of weight thus effected would not only be a saving of cost, but would better enable the difficulties of draught of water in harbour and docks for the largest ships to be overcome.

The problem of speed has always been a very vexed and difficult one, and there is none which has caused more trouble, or given rise to more fallacies in theory and errors in solution. I cannot even direct attention to the numerous theories and the various approximate formulas that have been invented and employed from time to time for explaining and solving the speed problem. These formulas are generally so restricted in their range of application, and require so much knowledge of their limitations and the conditions under which they can alone be relied upon for results that will be approximately near the truth, as to prove dangerous traps to the unwary and ill-informed. The man who can use these intelligently and safely, and with full knowledge of their limitations and their tendencies to error, is able to deal with the speed problem much more completely and effectively—and I shall confine my remarks to the way of doing that.

The practical solution of the speed problem was effected by the late Mr. William Froude when he discovered the law of similitude or comparison which enables the resistance of a model, as ascertained by experiment, to be used for calculating the resistance of another model upon a different scale, or that of a full-sized ship of similar form. His analysis of the separate elements of resistance, showing that the two great ones, friction and wave-making, varied independently of each other, and the latter in a very irregular manner, explained why simple approximate formulas are so untrustworthy.

What is wanted for the practical purposes of a designer is the means of ascertaining the resistance of a ship of given dimensions at any desired speed; and also of readily determining the precise form or degree of fineness of under-water body that would enable the maximum of carrying power to be obtained at a moderate rate of fuel consumption. It is one thing to know exactly what power is required to give a ship of given dimensions and form the speed asked for or promised, and quite another to determine what are the dimensions, form, and degree of fulness that will give the maximum passenger and freight-carrying capacity with moderate engine power and expenditure of fuel.

In order to exhaust the problem of the best form of ship to meet the requirements of any particular trade or service, considerable investigation is required. This can only be made satisfactorily by testing the resistances of models in an experimental tank upon the late Mr. Froude's system.

That method is unfortunately impracticable, however, for ship-designers in this country, because there is no experimental tank here available for general use. The very few that exist belong either to the Admiralty or to private shipbuilders, and are confined exclusively to the work of their respective owners. I have had experiments made occasionally for my own purposes, but had to go abroad for them. The experiments required by Mr. Yarrow for his valuable investigations into the effect of shallow water upon speed were made in the North German Lloyd tank at Bremerhaven, where other experiments have also been made for him. A British shipbuilder can only get such experiments made by setting up an independent establishment for himself or going abroad. Now an experimental tank, with its equipment and a competent staff for working it, is very costly to create and to maintain; and over and above the cost of construction, and of running it, there is the all-important question of the quality of the results it will produce. It is not enough to procure a tank with all its apparatus and appliances and to attach to it a staff of scientific men to run models and take records of their speed and resistance. The work is of so delicate and intricate a nature that the personal qualities of the experimenters count for very much in it. The results obtained by the late Mr. W. Froude and the present Mr. R. E. Froude owe much of their value to the exceptional qualifications of those eminent men for scientific research, especially upon the experimental side. It is the men, and not the tools, who constitute the most important factor in work such as this, and the right men for it are very difficult to obtain and to keep.

An attempt has recently been made to provide an experimental tank at the National Physical Laboratory, to be worked by members of the staff there, at which ship models might be tested for resistance, but up to now this has been without result. There is another way of dealing with the matter, however, and a readier one for the ordinary purposes of the ship-designer, which has been initiated by Mr. R. E. Froude, that promises to overcome the difficulty in a satisfactory manner. Mr. Froude read a paper at the Institution of Naval Architects, three years ago, upon "Some Results of Model Experiments," in which he gave results of a series of general experiments on systematic variations in form of hull, the variations consisting of six different sets of typical lines, varied in proportion by independent variations of length, beam, and draught. The resistance data given by these experiments are published in the paper in such a form that the resistance of a ship of any dimensions, the lines of which are similar to the typical ones, which are also given, can be readily taken out. The types dealt with have block coefficients, or ratios of displaced volume to product of length, breadth, and draught, varying from 0·4865 in the finest to 0·541 in the fullest. Now this covers a very important class of mercantile steamers—that of fast Channel boats—and the designer of such a boat could have nothing better for his speed calculations than the data in this paper. He has only to refer to Mr. Froude's tables and diagrams in order to determine at once the proportions and form that will best suit the circumstances, and to construct the lines of his boat.

If similar data could be obtained for other forms of ships, say for the fast-liner type, with block coefficients varying from about 0·6 to 0·7, the designer of that class of vessels would indeed have cause to be grateful. The best practical solution of this long-vexed problem of the relation of power to speed appears to be an extension of Mr. Froude's system to vessels of the fast-liner type, and to others with which the ship-designer ordinarily has to deal, leaving those of abnormal proportions or form, and also the work of general research, to a public experimental tank—if ever we find enterprise enough among those interested to get one set up in this country.

The resistance of a ship may be estimated to a close degree of accuracy in the manner mentioned, but the determination of the engine power required to overcome that resistance involves the important consideration of screw-propeller efficiency. The problem of the most efficient design of propeller for any given size and form of ship and rate of turning of shaft is as yet far from practical solution. Model experiments have been carried out at Haslar with a large number of propellers of varying pitch, diameter, and developed area, but these model screws have been very small, as the size and speed at which they could be worked were limited by the stresses the experimental mechanism is capable of bearing.

Further advance might be effected by carrying out experiments on a larger scale than those already made, and with stronger appliances than those now used for the purpose in the Admiralty tank. A still more effective means, which I hear is under consideration by Mr. Froude, would be to build an experimental launch for the purpose, to be run in open water and propelled by machinery of considerable power. The propelling machinery could be so arranged that the thrust of the screws and the torque on the shaft would be automatically recorded, as in the case of tank experiments. With such an arrangement screws up to 3 feet in diameter could be experimented with—a great advance on anything that could be hoped for in the tank—and the important problem of propeller efficiency might thus be brought much nearer to a practical solution.

We now come to the greatest problem of all with regard to the propulsion of ships, and that is the form which propelling machinery is likely to take in the immediate future. Already an important change is in progress from the ordinary reciprocating marine engine to the steam turbine, and the question is not only how far that change will extend, but whether the whole of the cumbrous apparatus required for producing steam may not before very long be swept out of mercantile steamers, and the power be obtained from some form of internal-combustion engine. Very few ocean steamers have been fitted with turbine machinery or are being so fitted, and although this may not cause surprise in the case of cargo-boats and other vessels of low or even moderate speeds, it may appear strange that liners of high speeds are still being fitted with reciprocating engines, and that the bold lead given by the Cunard Company with their two fastest new boats and the *Carmania* should not be generally followed.

The chief reason for hesitation to put turbine machinery into ocean liners is the doubt which exists as to coal consumption. The amounts at stake are so large in these costly vessels when experiments with novel propelling machinery are tried that everybody prefers to see someone else make them. The Cunard Company is making the crucial experiment upon the largest scale that is now possible, and everyone interested in progress must wish those responsible for it all the success they hope for and deserve; but the result is to some extent uncertain, and the immediate future of the turbine in fast liners depends greatly upon it.

In warships the consumption of coal has been brought down to about 1·7 lb. per equivalent I.H.P. of reciprocating engines per hour, and the same in mercantile boats of cross-Channel type. That is as good as can be obtained with reciprocating engines in the same classes of vessels, as weight has to be kept down as much as possible in these by shortening the stroke, and using high mean pressures of steam in the cylinders, in order to get all the power that is practicable out of a moderate size and weight of machinery. It pays better, in these cases, to stop somewhat short of the maximum efficiency that is attainable than to carry the additional weight which the increase would involve. In ocean liners the conditions are different, and economy of consumption is there the chief point aimed at. Their consumption with quadruple-expansion engines and a boiler pressure of 210 lb. to 220 lb. per square inch has been brought down to 1·3 lb. of coal per I.H.P. per hour for all purposes. The substitution of turbines for reciprocating engines in ocean vessels depends chiefly upon whether the consumption with turbines can also be brought down to this low figure, and there is no satisfactory evidence that this is now practicable. It appears probable that the marine turbine may ultimately be so improved as to beat the best reciprocating engines in economy of consumption in ocean liners, but no proof is forthcoming that it can yet be relied upon to do it.

The correct measurement of the power given out by turbine machinery is a practical problem of great importance. Considerable success has been achieved with a telephonic recording apparatus for indicating the twist of a shaft over a given length, and thus giving a measure of the torque. The record is not always, however, so definite and accurate as could be desired. A satisfactory solution of this problem is much required by ship designers.

The question of some form of internal-combustion marine engine suitable for large ocean vessels is still about where it was when Mr. Milton's paper was read and discussed here last January, and I do not feel able to add anything with advantage now to that paper and discussion. I will therefore merely enumerate the conditions, most of which were mentioned by Mr. Milton, that must be satisfied by a successful marine engine of any type whatever:—

(1) The engine must be reversible.

(2) It must be capable of being stopped quickly, and of being started quickly either ahead or astern.

(3) It must be capable of being promptly speeded to any desired number of revolutions between dead slow and full speed, and of being kept steadily at the required speed for any length of time. "Dead slow" ought not to be faster than one-quarter of full speed, and should be less in very fast vessels.

(4) It must be capable of running continuously for long distances, with but short intervals between the runs, without risk of stoppage or breakdown.

(5) It must be capable of working well, not only in smooth water, but also in heavy weather in a seaway, where the varying immersion of the propeller causes rapidly changing conditions of resistance.

(6) All working parts must be readily accessible for overhauling, and all wearing surfaces must be capable of being promptly and easily adjusted.

(7) The engine must be economical in fuel, especially at its ordinary working speed.

(8) It must be compact, light in weight, and well balanced so as not to cause vibration.

(9) It must not involve any risk of accumulation of gas in the ship such as could form an explosive mixture.

(10) It is a *sine qua non* that it must be capable of using a fuel the supply of which at moderate price is practically unlimited, and that could be obtained readily in whatever part of the world a ship might happen to be.

Engineers and metallurgists may together succeed in overcoming some day the difficulties of producing large cylinders which will stand the high impulses and great and rapid variations of temperature that occur with internal combustion, but until that is accomplished no great step ahead can be taken. There are no two opinions, however, as to the advantages that would be gained by doing away with the present boilers and their appurtenances, and abolishing with them much of that very arduous and disagreeable class of labour known as marine stoking.

The subject of oil fuel for marine boilers is interesting, but I have no time to say more than that great practical advance has been made with it during the last decade, and a consumption as low as 0·9 lb. per I.H.P. per hour has been regularly realised in mercantile vessels which employ the system of spraying the liquid for combustion by means of hot air. American steamships have used oil fuel largely during the last three years, under a combined system of high and low pressure air respectively for desiccating or pulverising the oil before combustion and for assisting the combustion afterwards. This system has proved highly successful and economical. Vessels of 14,000 tons displacement belonging to the Shell Transport Company have made voyages regularly and successfully from Singapore to this country by the long route of the Cape of Good Hope, and still larger vessels have made equally successful voyages from New York to San Francisco *viâ* Cape Horn.

The securing of all the comfort that is possible for passengers on board ship is a modern idea. Formerly it was thought sufficient to take them safely, and without much regard even to time, to their destination, and very little attention was paid to comfort. Now it is the chief object of the best shipping companies to leave and arrive in port on fixed days, and even at fixed hours, and to make the life of passengers on board ship as comfortable and luxurious as on shore.

Much of the comfort and luxury now in such demand by passengers is provided by those who manage the ships, and not by their designer. There is one very important element of comfort, however, which the designer can do much to supply, and to which increasing attention is given. I refer to steadiness at sea, and freedom from heavy rolling and pitching. But whatever may be done by the designer to give a metacentric height favourable to steadiness, its proper regulation at sea by suitable stowage of cargo and stores in the first instance, and by the judicious use of water ballast afterwards, requires the careful and close attention of the ship's officers if unpleasant rolling is to be kept at a minimum. About 18 inches of metacentric height appears to give a satisfactory combination of resistance to inclination in large ships with a long rolling period.

After reducing the tendency to roll as much as possible by suitable regulation of the metacentric height, the next thing is to increase the resistance to whatever rolling there may be. This is done chiefly by means of bilge keels, which oppose the whole of their surface to the motion of rolling, and are very effective in reducing its extent when they are of sufficient depth. In ships I have known that have been fitted after they were built with bilge keels suitably formed and placed, the extreme angles of rolling have been reduced to one-half. Their steadying effect is now well known and admitted in the mercantile marine.

Other devices have been considered, and some have been tried for still further increasing the resistance to rolling. Sir Philip Watts described in the Transactions of the Institution of Naval Architects for 1883 and 1885 the trials in H.M. ships *Inflexible* and *Edinburgh* of free water in large chambers that extended right across the lower deck, the transverse motion of which, as the ship rolled, was regulated by the shape of the water-chamber and the depth of the water, so that it would operate as a drag or brake upon the rolling motion. The same device was tried in a small passenger ship, the *Ohio*, in 1887, and in the *City of New York* and *City of Paris* in 1889. In the two last-named ships the chamber was upon the orlop deck. These water-chambers appear to have given good results within certain limits of rolling and when the motion of the water in them was well timed, but the action upon the rolling depended very much upon the way in which the water was regulated. Whether it was on account of this or because of the space occupied, or other objections that exist to the free motion from side to side of large quantities of water in a ship, I do not exactly know, but whatever the reason may be the idea has been dropped.

A proposal has recently been made by M. Victor Cremieu, of Paris, to check rolling by means of a heavy pendulum of long period that would oscillate in a closed chamber filled with viscous fluid, and he has contributed a paper upon the subject to the Académie des Sciences. His idea is to make the length of pendulum and its weight such as would give it an angular moment up to possibly one-tenth that of the ship. The clearances between the pendulum and the sides of the chamber, and the degree of viscosity of the liquid—M. Cremieu suggests oil, or a mixture of water and glycerin—would be so arranged as to make the energy of the pendulum most effective in offering resistance to rolling. A simplification of the apparatus is suggested by substituting for the pendulum a weight that would move backwards and forwards upon a curved path in a transverse chamber or tube filled with the viscous liquid. In both cases the principle is that of opposing the rolling of the ship by the statical moment of the oscillating weight, and reducing the energy of motion by generating heat in the fluid through which the weight moves.

Sir John Thornycroft described an automatic steadying apparatus in 1892, which was fitted in his steam-yacht *Cecile* with some success. It consisted of a most ingenious controlling gear which regulated the motion from side to side of a heavy weight in opposition to the rolling motion. It was very cleverly worked out, and destroyed much of the rolling in a vessel of great metacentric height and very short period. This idea also has not been followed up.

A device which appears promising for increasing the resistance to rolling is one that has been ingeniously and effectively worked out by Dr. Otto Schlick, of Hamburg, a very eminent marine engineer. It depends upon gyroscopic action, and its principle was fully described by Dr. Schlick at the Institution of Naval Architects in 1904. This principle appears to deserve serious consideration, and is already ripe for application to the smaller classes of steamers. I am informed that an apparatus is being manufactured for placing in the Hamburg-American Company's passenger-boat *Silvana*, of about 1000 tons, which runs between the Elbe and Heligoland, and that Dr. Schlick is designing a standard gyroscope that will be suitable for boats of about 1200 tons to 2000 tons displacement. This standard gyroscope will be electrically driven, except in cases where there is not a sufficient margin of electric power available in a ship, when it would be driven by a steam turbine. An apparatus for vessels of the displacement named would be applicable to the class of Channel steamers, and we may perhaps see it tried before long in some of them.

What I have said with regard to making ships steady at sea has had reference only to rolling motion; but many persons consider it is not rolling that affects them so much as pitching, or as the skew motion near the ends of a ship that is neither rolling nor pitching, but an unpleasant combination of the two. There is also sometimes a vertical or heaving oscillation when large waves are passing a ship broadside on which may rise to an amplitude of several feet when the wave-period approximates to the period of her own dipping oscillations, but it is probably seldom that the motion from this cause is great. Pitching is often the chief cause of trouble and discomfort, and the motion due to it may be greater and more violent than any other, especially near the ends of the ship. The pitching period is sometimes as short as four seconds, so that there may be three or four pitches to one roll; and the vertical distance moved through near the ends in pitching is very much greater than at the ship's side during a roll.

After all has been done in the way of making the forward transverse sections of a ship such as will best resist plunging into the sea, and by good stowage, there still remains considerable tendency to pitch in certain conditions of sea which cannot be removed. The best way to avoid the ill effects of pitching is to get as near as possible to the axis of rotation, the position of which varies considerably according to the nature and direction of the seas which cause the pitching, but is, on the average, not far from the centre of length. The modern large steamers which have their first-class passenger accommodation upon three or four decks in the middle third of a ship's length are generally found to be the most easy and comfortable at sea. That is no doubt largely because the greatest vertical distance moved through in pitching in the passenger accommodation is only one-third of what it is at the ends of the ship. It is to this concentration of passenger accommodation near the middle of a ship's length that we have to look chiefly for neutralising the trying effects of pitching.

One of the chief causes of discomfort and distress to passengers on shipboard is vibration. This may be due to one or more of several causes, to which much attention has been given during recent years. The effect of reciprocating engines in causing vibration has been investigated by Dr. Schlick, Mr. Yarrow, Mr. Mallock, Prof. Dalby, and others, who have demonstrated the manner in which such engines operate to cause vibration, and how to reduce this effect to a minimum by suitable design, and by balancing the principal working parts. There is little to choose, in a strongly built ship, between modern well-balanced reciprocating engines and steam turbines as regards smoothness of running and absence of unpleasant vibration. Vibration is often due to the action of the propellers, and when these have to run at very high speeds, as with fast-running turbines, a certain amount of vibration is sometimes unavoidable. Apart from the essential conditions of trueness of propeller blades and exact balance of the propellers upon their shafts when turning, there is the action of the ends of the blades upon the water adjacent to the stern-plating where they pass nearest to it in revolving, which causes a hammering effect that is sometimes very great. The vibration and tremor of this plating may be quite local, and may be readily checked by strong bracket frames at the part where it is greatest; or it may be communicated throughout the hull, and set up sympathetic vibrations in large flat areas of plating, such as decks, straight side-plating, bridges, &c. These difficulties can generally be overcome by careful attention to the surfaces that vibrate, and by stiffening or supporting them at a few critical points by struts or brackets. There appears no reason why ships should not now be kept free from all unpleasant vibration, whether as regards the working of the main engines or the action of the propellers.

The tendency to increase the size of ships is strong and continuous. It has long been known, and experience proves that the power required to drive a ton of a ship's displacement at a given speed diminishes, and the working expenses become less per ton all round, with increase of size.

There is a size and speed of ship that is most appropriate and profitable for each line of steamers, or each trade, and it varies greatly in different trades. It is the managers of the various lines who know best what dimensions and speed are likely to be most profitable in their respective trades, and what are the maximum number of passengers and quantities and descriptions of cargo likely to be forthcoming. The approximate size, and the speed, of mercantile steamers depend upon commercial and economic considerations which the ship-designer usually has but an imperfect knowledge of. His part consists in producing a design that will fulfil the necessary conditions of size, draught of water, speed, carrying capacity, and accommodation for passengers in the most efficient manner and at the minimum of cost. There is one point, however, which is so important in considering further large increases of speed in ocean liners generally that I would like to direct attention to it.

Speed is limited in passenger liners, altogether independently of size, by economic considerations. High speed at sea is a costly luxury. It can be obtained by paying for it—up to 25 knots, as we see by the latest Cunard liners—but it has to be paid for by somebody. The extra cost cannot be got out of cargo freight, for as speed is increased the proportion of space available for carrying cargo becomes reduced by the increase of boilers and machinery, and therefore less cargo is carried relatively to the size of the ship. This reaches an extreme limit in the fastest Atlantic liners, the holds of which are as full as they can be stowed of engines, boilers, and coals for the voyage—their speeds only being limited by the impossibility of getting more boilers in—and it is only a few odd spaces which cannot be utilised for other purposes that are available for carrying a little cargo. In these cases cargo is reduced almost to a negligible quantity.

It may be said generally, as regards any line of steamers, that if speeds of more than 12 to 13 knots are desired the extra expenditure involved by such increase must be looked for outside the cargo. This element of earning power does not bear an increase of rate of freight. There are only two sources from which payment of the extra cost of increased speed can come. One is from passengers and the other from a mail subsidy. No mail subsidy that could be proposed would pay more than a small proportion of this extra cost; the greater part of it must come from passengers. What passengers have to pay for high speeds at sea may be seen by the rates charged in the fastest Atlantic steamers. Apart altogether from special cabins, or apartments de luxe, for which almost any prices are paid, the cost of a single first-class passage to New York varies from 22*l.* 10*s.* to 48*l.* 10*s.* for a run of six days, in one of the fastest liners, according to the position of the cabin in the ship and the time of year, or from $1\frac{3}{4}d.$ to nearly 4*d.* per mile travelled. The prices have risen rapidly during recent years as speed has been increased, and passengers across the Atlantic appear to be forthcoming in ever-increasing numbers who are ready to pay them. If that were not the case such high speeds could never have been reached. No great improvement of speed is to be looked for upon the other main lines of ocean traffic, unless some revolutionary change is made in the mode of propulsion which will cut down the cost, or a sufficient number of passengers are found, as in the Atlantic trade, who will pay the higher rates it necessitates.

I have not done anything this evening towards reducing the number of the many and difficult unsolved problems that trouble the mind and tax the skill and judgment of the ship-designer, but if I have succeeded in conveying some idea to you of their nature, and of the interdependence of science and engineering in all wise attempts at their solution, I shall have accomplished my object.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LIVERPOOL.—Mr. J. Mercer has been appointed assistant lecturer in mathematics and Mr. T. E. Gardner assistant lecturer in organic chemistry.

A lectureship in plant physiology has been established in the botanical department through the generosity of Mr. W. P. Hartley (the donor of the laboratories).

Prof. Ronald Ross has been granted leave of absence for five months to enable him to report on measures for the prevention of malaria in Mauritius for the Colonial Office.

Prof. A. W. Mayo Robson will deliver the Mitchell Banks Memorial Lecture during the session 1907–8.

At the graduation ceremony held in St. George's Hall on July 13, *ex officio* degrees were conferred on several members of the staff, including Emeritus Prof. Paul, Dr. E. A. Browne, Prof. Watkinson, Mr. J. Wemyss Anderson, Associate Profs. Aspinall, Brodie, and Bromley Holmes. The dean of the faculty of science (Prof. Harvey-Gibson) presented the following for the degree of Doctor of Science, *honoris causa*, viz.:—Prof. A. R. Forsyth, Prof. F. Gotch, Sir Oliver Lodge, Sir Henry Roscoe, Sir William Ramsay, Sir John Murray, Prof. Ostwald, Prof. Osler, and (*in absentia*) Dr. C. L. A. Laveran. Sir Alexander Kennedy was presented for the degree of Doctor of Engineering by Prof. Watkinson.

MR. ADAM SEDGWICK, F.R.S., has been elected professor of zoology and comparative anatomy in the University of Cambridge in succession to the late Prof. Newton.

SIR DOUGLAS FOX will deliver the inaugural address of a nature-study course for women, to be held at the Horticultural College, Swanley, from Saturday, July 27, to Saturday, August 10.

THE council of the City and Guilds of London Institute has conferred the fellowship of the institute upon Mr. Alfred E. Young, chief surveyor of the Federated Malay States, for his original and valuable work in the trigonometrical survey of the Malay States.

THE annual meeting of the Midland Agricultural and Dairy College will be held on Monday, July 29, at 3.15 p.m., when the report on the year's work will be presented. Sir John Rolleston will address the meeting and present the certificates gained during last session.

AT Bedford College for Women (University of London) the following courses, open free to teachers in secondary and elementary schools in the county of London, will be given in the Michaelmas term:—"Geology for Teachers of Physical Geography," by Dr. C. A. Raisin, beginning Wednesday, October 9, 6 p.m.; "The Organisation of Nature-study Courses in London Schools," by Miss M. R. N. Holmer, beginning Saturday, October 5, 10.30 a.m. Syllabuses of the lectures can be obtained on application to the principal.

THE East London College, which has gradually been evolved from the educational work connected with the "People's Palace," has been accorded the position of a school of the University of London by the Senate of that body. It has long been felt that there should be a school of the University in the eastern half of London; and for this position the East London College is admirably suited. The chemical department, under the charge of Dr. J. T. Hewitt, has done valuable work. Prof. C. H. Lees, F.R.S., was recently appointed head of the physics department, and the laboratories have been re-equipped and extended, while large grants have been made for the mechanical and electrical engineering departments by the Drapers' Company. Much research work has been accomplished under the professor of electrical engineering, Prof. J. T. Morris, and mathematics is showing signs of considerable development at the college.

THE need of reform at Oxford is urged in a letter signed by leading advocates of progressive learning in Wednesday's *Times*. It is pointed out that many members of the University are of the opinion:—(1) That the constitution and machinery of Oxford, both legislative and executive, need revision; (2) that the relations between the University and its colleges, both constitutional and financial, require modification; (3) that a central direction of our studies is required enabling the faculties to have the authority assigned to them in other seats of learning; (4) that the studies of the University are themselves too narrow in scope and that fresh endowments of various branches of study are necessary, and especially that a greater encouragement should be given to research, which at Oxford is probably to a larger extent divorced from teaching than in any other great university. As attempts at reform have again and again proved abortive, the signatories consider that either a fresh commission, or, if that suffices, legislation by the King in Council, as contemplated by the last commission, are the only practical ways of carrying out the necessary changes.

"THE influence of a body of thoroughly competent, zealous, and conscientious teachers in our public elementary schools may plainly be an important factor in our national life," says Sir Robert Morant in his prefatory memorandum to the new regulations (Cd. 3597) for the training of teachers and for the examination of students in training colleges. The general spirit of the regulations is likely to encourage work which will produce teachers of the right kind. The time for training is at best short, and it is important that the essential needs of the future teacher should receive primary consideration; the Board rightly warns college authorities against undertaking any too ambitious scheme. Where a university course of work is permitted to a student training to become an elementary-school teacher, the regulations insist that it shall not be at the sacrifice of some fundamental study or of facilities for obtaining practice in the art of teaching. Following the regulations of previous years, the necessity for inculcating the scientific method in the teaching of all subjects, and not confining such attempts to the instruction in science, is insisted upon. The memorandum admirably urges also that:—"The study of natural objects . . . should be so conducted as to encourage accurate observation and the careful recording of what is seen, with a view to the growth of an independent habit of thought, and the furnishing of a well-defined field of knowledge derived from immediate observation by the scholar." The necessity for lessons in elementary schools designed to familiarise children with the chief laws of health is now recognised by everyone, and great importance is to be attached by the Board to the education in this subject received by the student in training. The regulations as a whole will be read with satisfaction by all who have at heart the educational welfare of elementary-school children.

IN the third of the annual Harvard lectures, delivered at Yale University last April, Prof. A. Lawrence Lowell, the lecturer for the year, dealt with the subject of American universities. These lectures are the outcome of a fund provided by an anonymous Harvard graduate. In his lecture, which is published in *Science* for June 28, Prof. Lowell raises many points of wide interest. After directing attention to the value to civilisation of the great European universities at the close of the Middle Ages, he said that American universities are not only growing larger, but their influence is extending more widely through the body politic. In addition to being training places for young men, the universities in the States aim at diffusing learning directly or indirectly through all strata of society, helping to bring light to anyone who wants it. It is being more fully understood, too, that a university should not be merely a local institution, but one bringing together students from all parts of the country. As Prof. Lowell remarked, "should a general custom arise for every man to attend exclusively the university in his own neighbourhood, it would be a great misfortune to education in America." Referring to the two classes of universities in the United States, Prof. Lowell instituted an interesting comparison between State universities and those not supported by taxation. He comes to a similar conclusion to that arrived at by President Pritchett in the first bulletin of the Carnegie Foundation, that the most vigorous of the State universities have been, as a rule, those which have thrown themselves most completely upon the State and obtained the smallest fraction of their support from private benefaction. We commend this experience to British statesmen in the hope that American experience of the great value to the community of universities endowed from State funds may lead them to emulate American practice in this respect.

THE regulations for secondary schools (Cd. 3592) issued by the Board of Education, to come into force on August 1, mark a distinct advance in educational administration. More elasticity is to be allowed in the Board's dealings with secondary schools; more encouragement is to be given to local initiative and local effort; and certain defective features in older regulations are removed. The additional funds now available for secondary education have made it possible to abolish the limited four years' course on which alone grants have been paid hitherto. A uniform grant will in future be paid on pupils between twelve and eighteen years of age who are following an approved curriculum, and, what is of prime importance from the point of view of the schoolmaster, the term instead of the year is to be taken as the unit in assessing grants. The subjects to be studied and the time to be devoted to each has in the past been prescribed by the Board; for the future the head teacher and local authorities are to be encouraged to submit to the inspector for approval courses of work designed precisely to suit local needs and conditions. In the payment of grants it is interesting to note that the Board is prepared in certain cases to augment the grant due to a school by a further sum towards meeting expense incurred by the school in respect of approved educational experiments. There is ground for hope that this arrangement may hasten the methodical building up of a science of education. This adoption of the plan followed in all other scientific work of basing conclusions upon experiment and observation should lead to many improvements, and it is to be hoped that much thought and the best talent will be devoted to the inauguration of the age of scientifically arranged experiments in education. The regulations will, if sympathetically and intelligently interpreted, greatly improve English secondary education.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 6.—"The Mechanical Effects of Canal Rays." By A. A. Campbell **Swinton**. Communicated by Sir William Crookes, F.R.S.

This investigation was undertaken in order to discover whether the so-called canal rays, which at suitable pressures can be seen streaming through the apertures in a perforated kathode, backward away from the anode, share with kathode rays the property of causing small and light mill-wheels to rotate.

Experiments were conducted with tubes in which there were a number of perforations in the kathode, so that the canal rays, after passing through these, impinged on the vanes of a mill-wheel of screw-propeller form, and also with other tubes in which there was only a single perforation in the kathode, and the canal rays acted on the vanes of a mill-wheel of water-wheel type. In both these forms of tubes mill-wheels with vanes of mica, as also with vanes of aluminium, were employed, and in every case rapid rotation of the mill-wheel occurred at suitable pressures in the direction corresponding with that of the canal rays. That this was due to the canal rays was proved by closing the apertures in the kathodes by means of aluminium shutters, when rotation could not be produced, as also by subjecting the tube to a powerful magnetic field so as to deflect to one side all direct or reflected kathode rays.

Experiments were also made with screw-propeller mill-wheels mounted in front of the kathode. In this case, when the vanes of the mill-wheel were of mica, the rotation obtained always corresponded with the result being due to bombardment by kathode rays proceeding away from the kathode; whereas, when the vanes were of aluminium, rotation in the contrary direction invariably took place, this corresponding with the effect being due to canal rays proceeding towards the kathode.

It was further ascertained by means of two thermo-junctions of Constantan copper—one on each side of a mica vane, arranged so as to oppose their E.M.F.'s, and connected to a mirror galvanometer—that under canal-ray bombardment the two sides of a mica vane may acquire differences of temperature amounting to as much as 200° F. It is suggested that the heat insulating properties of mica and the high thermal conductivity of aluminium have probably an important bearing on the divergent results obtained with these two materials, as mentioned above.

Physical Society, June 28.—Prof. W. E. Ayrton, F.R.S., past-president, in the chair.—Experiments on the production of sand ripples on the sea shore: Mrs. **Ayrton**. The sand-ripples of the sea-shore, although parallel to the line of the breakers, are not produced by their edges, but entirely under water. The long see-saw motion of the water produces the ripples, as was observed in 1882 by Mr. A. Hunt. To show this, a glass trough, in which was level sand, covered with a foot of water, was pushed to and fro on rollers. This motion set the water oscillating, and soon small ridges were seen in the sand, at nearly equal distances from one another, growing larger as the oscillation continued. By deduction from the shape of certain sand vortices, it appears that every ridge in otherwise smooth sand must produce two other ridges, one on either side of the first, and that these two give rise to two other ripples, until the whole becomes ripple-marked. Experiments were shown to demonstrate this fact. To show that the vortices generated by the original ripple swept out those succeeding, an artificial barrier was put across the trough to increase the size of the vortices, a handful of moist black pepper was thrown in, and the water oscillated. Immediately the actual process by which the water started and built up the ripples was shown. The way was illustrated in which the ripples on the sea-shore could be imitated, even when the water ran in one direction alone, if only the sand were sloped so that the water ran up it, and if, by means of a paddle, a series of waves were sent along the water in the direction in which it was running. The whole of the sandy shore is ripple-marked when the tide is high, but the waves at the edge of the retreating tide wipe out the ripples except where there is a pool, so that the water is left over the ripples until after the sea has retired. The greatest depth at which ripple-mark can be formed at the bottom of the sea depends on the violence of the motion of the water. At depths of 60 feet or 70 feet the sand is said to have been found ripple-marked. If the depth of a vessel is large compared with its cross-section, a depth of water can be found beneath which no sand-ripples can be formed. On sprinkling a little sand in the water in a small trough, and rocking it to and fro, the sand was seen to assemble quickly in a straight line across its middle. Watching these grains, it was noticed that the result arose from every swing carrying each grain on one side of the centre nearer to the middle than the next swing carried it away again. Each ripple as a whole tends to move towards the middle of the trough. In troughs, the water was kept oscillating so as to form a stationary wave twice the length of the trough, and the place where the heap of sand was formed was where the level of the water changed least, and its horizontal velocity was the greatest. Referring to the Goodwin Sands, Mrs. Ayrton said she found it impossible to avoid recognising the resemblance between the hillocks and hollows of these sands and those made in her glass troughs, and it seemed possible that they were also produced by stationary waves.

CAMBRIDGE.

Philosophical Society, May 20.—Dr. Hobson, president, in the chair.—Exhibition of photomicrographs of wood-sections made by Mr. J. A. Weale: E. R. **Burdon**.—Parasitic trees of southern India: C. A. **Barber**. The sandal tree, *Santalum album*, was discussed; although a large tree with abundant foliage and thick stem, it is dependent for its water and mineral salts on the roots of other plants. The disease called locally "spike" was illustrated by a series of lantern-slides. Four genera of Olacaceæ, Olax, Ximenia, Opilia, and Cansjera, large green climbers or shrubs, are now known to be parasitic like the sandal. The arrangement of the subgroups of the Olacaceæ has been unsatisfactory for a long time. The study of the haustoria endorses the arrangement proposed by Van Tieghem whereby the Opilieæ are transferred to near the Santalaceæ. Special attention was directed to the presence of a complicated gland in the haustoria of *Santalum album* not hitherto described in any root-parasite. The gland is present in most, if not all, of the haustoria dealt with. Diagrams were shown of the haustoria of *Thesium Wightianum*, *Buckleya Quadriala* from Japan, *Osyris arborea*, *Cansjera Rheedii*, *Ximenia americana*, *Olax scandens*, and *Opilia amentacea*.—Physiology of plants in the tropics: A. M. **Smith.** (*a*) The internal temperature of leaves under tropical insolation. In still air, with black bulb vacuum thermometer at from 55° C. to 62° C., the air temperature in the shade being from 25° C. to 28° C., and the humidity about 70 per cent., leaves, whether thick and fleshy, or thinner and coriaceous, or thin and pliable, when placed normal to the sun's rays reach a temperature of 15° C. above that of the surrounding air, a temperature often considered injurious to the functions carried on in the leaf. In the shade the internal temperature varies from 1°·5 below to 4° above that of the surrounding air. Breezes reduced the temperature in the sun by amounts varying from 2° C. to 10° C. An attempt was made to estimate the magnitude cooling due to transpiration. Two leaves with stomata outwards were consistently lower in temperature than two with their stomatal surfaces facing each other. The difference was on an average 2°·5 C. Investigations into leaves with red or red-brown colouring matters showed that the red pigment raised the internal temperature of the leaf from 2° C. to 4° C. above that of similar leaves which were white or nearly so. (*b*) Periodicity of growth in Ceylon. Monthly observations showed that there was the largest amount of young growth in February, the driest month of the year. The theory is suggested that only then is there sufficient transpiration to supply the necessary mineral food for rapid growth. (*c*) Respiration of *Hydrilla verticillata*, a tropical water-weed. Values for the respiration from 7° C. to 50° C. were obtained. These when plotted produce a curve which shows increase of respiration with temperature according to the van 't Hoff rule, the coefficient for an increase of 10° C. being 2·2. The values go on increasing up to the death-point of the plant.—Notes on the parasitism of Botrytis: F. T. **Brooks.** The conidia of Botrytis are unable to infect healthy green leaves, whereas if a young mycelium, nourished saprophytically, is placed upon a normal leaf of such a plant as lettuce, infection rapidly spreads. Experiments have been undertaken to ascertain whether the conidia can cause the infection of weakened plants. Lettuce plants were grown in sterilised sand, watered from time to time with mineral solutions. After these plants had been growing six weeks the conidia had no power of infecting them. By tearing healthy green leaves of lettuce plants direct infection is caused by placing the spores upon the torn portion. The conidia are able also to infect leaves just beginning to turn yellow.—A representation of the exponential function as an infinite product: G. B. **Mathews.**—Some theorems on integral equations: H. **Bateman.**—The theory of the rotation of the plane of polarisation by solutions: Prof. **Thomson.**

EDINBURGH.

Royal Society, June 10.—Dr. Robert Munro, vice-president, in the chair.—A contribution to the craniology of the natives of Borneo, the Malays, the natives of Formosa, and the Tibetans: Sir William **Turner.** The paper contained a full discussion of the characters of the skulls of the various peoples and races inhabiting the regions named; and one fact of general significance was the prevalence of the dolichocephalic type in the people of the interior of Borneo, Sumatra, Formosa, and the Philippines, and in the inhabitants of eastern Tibet, while the brachycephalic skull was characteristic of the sea-board peoples.—The histology of the Ephedreæ, with special reference to the value of histology for systematic purposes: R. J. D. **Graham.** The primary structures of sixteen species or varieties were examined. The outer walls of the epidermal cells have a middle stratum containing crystals of calcium oxalate. Certain papillose epidermal cells act as ocelli, giving the light-spot and image described by Haberlandt for leaves. The cortex is differentiated into an outer palisade and inner lacunar chlorenchyma. The stereon system is built on a girder principle, the outer flanges of each girder hypodermal, the inner pericyclic. Tannin sacs occur in the pith and cortex. The stelar system resembles somewhat that of Equisetæ, but differs in each leaf having two bundles which extend through two stem internodes. The characters which the author regarded as of use in determining subgeneric groups and in distinguishing varieties were the stereon distribution and degree of development, the distribution of the tannin sacs, and partially the character of the stelar system taken at a given level (the second internode below the apical bud).—The variation of Young's modulus under an electric current: H. **Walker.** Wires of steel, iron, platinum, and copper were heated by an electric current of gradually increasing and decreasing strength, and corresponding measurements of Young's modulus made. In steel, iron, and copper there was a decrease in the modulus for weak currents, then an increase to a maximum as the current increased and the temperature rose, finally falling off again as higher temperatures were reached. The return for decreasing currents followed a somewhat similar course, but not coincident with the course of the change during the increasing current. In the case of platinum, there was no initial decrease of the modulus for weak currents.

June 17.—Prof. A. Gray, F.R.S., vice-president, in the chair. At the request of the council, Baron **Kikuchi** gave an address on Japanese national development, more especially with reference to education. The main purpose of the address was to show that the Japanese national spirit, which consisted of intense love of country and reverence for the Imperial house, had remained intact through the long centuries of change and growth, largely influenced as these had been by Chinese literature and philosophy, Indian religion, and in later days by Western learning.

June 24.—Dr. R. H. Traquair, F.R.S., in the chair.—The evolution of the eyebrow region of the forehead, with special reference to the significance of its excessive development in the Neanderthal race: Prof. D. J. **Cunningham.** The usual types of supra-orbital arch in recent man are what are seen in the baboon. The Neanderthal type, which approximates to that of the anthropoid apes, is also to be found, but rarely in a highly developed state, in individual members of certain races such as the Aboriginal Australians and New Guineans, and the Maories. These facts, which have an important bearing on Schwalbe's recent theories, were fully demonstrated from specimens by means of ordinary photographs and Röntgen-ray photographs.—The origin of the amnintic and allantoic fluids: Prof. D. Noel **Paton** and Dr. B. P. **Watson.** Anatomical, pathological, and experimental evidence was brought forward in support of the view that both fluids are derived from the fœtus and not from the maternal blood vessels, and as a result of an extensive series of chemical examination of the fluids it was concluded that they are both derived from the fœtal kidneys.—The application of a differential densimeter to the study of some Mediterranean waters: J. J. **Manley.** The instrument is an adaptation of Hare's hydrostatic method for comparing the densities of two liquids, and was found to be capable of great accuracy. A series of results showed the effects of variation of temperature upon the relative densities of normal sea water.—The electric conductivity and angles of minimum deviation of ninety samples of sea water, and a comparison of these with the salinity and density: Prof. E. G. **Hill.** The purpose of the comparison was to see if these physical properties could be used for measuring the salinity and density. The conclusion was that, though the physical properties were not exact measures of the chlorine in sea waters, the differences between the values for chlorine calculated from the physical constants and that measured by titration were so small that for purposes of oceanography it may be assumed that the values are identical.

July 2.—Prof. Crum Brown, F.R.S., in the chair.—Address on the work at the solar observatory, Kodaikánal, S. India: Prof. C. Michie **Smith.** The address began with a discussion of the conditions which must be fulfilled by a good solar observatory, and of the practical difficulties in the way of realising these conditions. Kodaikánal, from its steady climatic conditions and its elevation, was probably on the whole as well fitted for this kind of work as any other single observatory. In some years there was sunshine for 346 days out of the year. The general arrangements of the observatory were described, but especially the methods for conducting solar research. A series of spectroheliograms showing the distribution of calcium vapour in the sun's atmosphere was exhibited; also photographs of the sun's disc and of the marginal prominences. Some interesting questions were touched upon as to the interpretation of certain markings in the spectroheliograms.

Dublin.

Royal Dublin Society, June 18.—Dr. J. H Pollok in the chair.—Injurious insects and other animals observed in Ireland during the year 1906: Prof. G. H. **Carpenter.** In addition to records of well-known orchard and forest pests, this paper gives an account of damage to barley by maggots of the small fly *Elachyptera cornuta*, and to young cabbage plants by grubs of the beetle *Psylliodes chrysocephala*.—The densities and specific heats of some alloys of iron: W. **Brown.** The author has investigated the change in the densities and specific heats of about fifty different specimens of iron alloyed with various percentages of carbon, manganese, nickel, tungsten, silicon, copper, chromium, cobalt, and aluminium. The more important results are graphed, and the effect of adding 1 per cent. of an element to iron estimated.—A simple and rapid method of determining the rate of absorption of oxygen by polluted waters: Dr. W. E. **Adeney.**

Paris.

Academy of Sciences, July 16.—M. A. Chauveau in the chair.—The structural stability of ethylene oxide: Louis **Henry.**—How far it is possible to justify the use of the arithmetic mean in calculations on the results of observations: Giovanni **Schiaparelli.** A report on the scientific mission to the gardens and public zoological establishments of the United Kingdom, Belgium, and Holland: Gustave **Loisel.**—The method of M. Loewy for the study of divided circles: MM. **Gonnessiat** and **Drayet.** Results show that it would be a mistake to limit the use of the division to entire degrees, leaving the remainder to a simple interpretation; this would involve, even in the mean of six microscope readings, errors of more than $0''\cdot2$.—The surfaces generated by a circular helix: M. **Barré.**—Remarks on the theorem of Jensen: C. **Carathéodory** and L. **Féjer.**—A fundamental problem in the theory of elasticity: A. **Korn.**—The difference of potential in an arc running continuously between metallic electrodes: C. E. **Guye** and L. **Zébrikoff.**—The influence of pressure on the absorption spectra of gases: A. **Dufour.** Some rays remain of the same wave-length under increased pressure; others are displaced in the spectrum towards the red, according as the pressure is increased. All sensible rays under pressure show the Zeeman effect to a very feeble extent.—Synchronising in multiple reflections: Henri **Abraham.**—The valency of the molecule in salt solutions deduced from the dispersive properties of the solution and the theory of electrons: C. **Chéneveau.**—The origin of series spectra: W. **Ritz.**—The scale of molecular weights of gases: Daniel **Berthelot.** The table of molecular weights defined by the densities of gases only represents a system of numbers, and must be fixed by relation to a gas of reference.—Some new characteristic constants of oils: E. **Louise** and E. **Sauvage.** Observation of the miscibility with acetone gives rapid determining characteristics for many oils. The hydrolysis of iron perchloride: G. **Malfitano** and L. **Michel.** It is probable that the hypothetical products $FeCl_2(OH)$ and $FeCl(OH)_2$ exist, while $Fe(OH)_3$ can only exist temporarily in solution.—The production of high temperatures in laboratory research: C. **Chabrié.**—The analysis of selenium hexafluoride: Paul **Lebeau.**—Ethyl hexahydrobenzoylacetate: A. **Wahl** and A. **Meyer.** The action of diazo-chlorides on γ-chloro-aceto-acetic esters: G. **Favrel.**—Triphenylcarbinol. The action of malonic and cyanacetic acids: R. **Fosse.**—The oxidation of oxyhæmoglobin: I. **Szreter.**—A contribution to the study of the brandies of Charentes: E. **Kayser** and A. **Demolon.**—The neo-volcanic formations anterior to the Miocene in the north-west of Sardaigne: M. **Deprat.** The first eruptions were characterised by the emission of rhyolites, but the greater part of the region is marked by the presence of the less acid trachytes and andesites.—An investigation on the foreign fats in lard: Alexandre **Leys.** The fraudulent addition of oil to genuine lard only changes the melting point, without reducing the specific gravity.—The separation of odorous principles in plants: Eug. **Charabot** and G. **Laloue.** Some new observations on the Carboniferous earths of the Sahara: G. New South Wales.

Royal Society, May 1.—Prof. T. P. Anderson Stuart, president, in the chair.—Presidential address: Prof. T. P. Anderson **Stuart.** The address reviewed matters chiefly connected with medical questions. The true value of the Danysz rabbit experiments was set out, showing that, even if successful to the fullest possible extent, this method of coping with the pest could never be more than auxiliary to the methods already known and in use. The Danysz rat-virus, and its complete failure under the most favourable conditions, in New South Wales, was next described, and the question asked—if this virus has been such a failure what grounds have we for expecting a better result with the rabbit-virus? The bubonic plague was referred to in connection with the recent report of the Indian Plague Commission, and the apathy of the people in Sydney as regards the destruction of rats was condemned. In connection with the death of Schaudinn, the discoverer of the *Spirochaeta pallida*, the long-sought virus of syphilis, the most successful experience of an entirely free and unrestricted treatment of female patients suffering from contagious diseases in Sydney was described. Reference was now made to the opsonin treatment, and to its introduction in Sydney at the Royal Prince Alfred Hospital. The movement for establishing a school of tropical medicine in Australia was fully discussed and commended.

ZOOLOGY AS AN EXPERIMENTAL SCIENCE.

Experimental Zoology. By Prof. Thomas Hunt Morgan. Pp. xii+454; illustrated. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1907.) Price 12*s.* net.

THIS welcome book may be regarded as a landmark, since it vindicates the position of zoology as an experimental science. It is the modern successor of Semper's famous "Animal Life," and it has had its forerunners in various smaller books, such as De Varigny's "Experimental Evolution." But it is, we believe, the first scholarly and critical review of a large part of the enormous mass of experimental investigations which have been a feature of zoological science during the last fifteen years. Thus it gives the student a comprehensive and orderly survey (with well-selected bibliography) of a widely-scattered scientific literature; it enables him rapidly to bring himself up to date as regards experiments on the influence of environment, on hybridising, on inbreeding, on the conditions of growth and reproduction, on the determination of sex, and so on; and the data are presented in a manner so critical and stimulating that the book is bound to have a great influence in promoting experimental research, which is likely to be prominent in zoological laboratories for centuries to come. For

"while the historical study of zoology must always remain a legitimate field for activity, as human history has been a time-honoured study, there can be little doubt that the more promising and searching method of zoological study in the future will be found in experiment."

To have furthered this movement is sure to be the reward of Prof. Morgan's book, which is at once a careful balance-sheet of past results and an incentive to add to them. The author has made all zoologists his debtors, for the work is uncommonly well done. It is an interesting sign of the times that the author is "professor of experimental zoology" in one of the leading universities of the world.

The author's general point of view is thus indicated:—

"The branches of biology that have made most extensive use of the experimental method are physiology, bacteriology, and physiological chemistry. The zoologist and the embryologist have also to deal with physiological problems, and already the beginning of important experimental work has been carried out in this field; but *the most distinctive problem of zoological work is the change in form that animals undergo, both in the course of their development from the egg (embryology) and in their development in time (evolution).*"

It is to an examination of the experimental study of these changes in form that the book is mainly devoted.

"Experimental morphology would perhaps nearly indicate the field to be examined; but since the line between experimental physiology and experimental morphology is often hard to draw, and since I shall not hesitate at times to enter upon the physiological side of many problems, I have chosen the somewhat broader title of Experimental Zoology to include the subjects to be treated."

The principal topics discussed fall under six headings:—evolution, growth, grafting, the influence of the environment on the life-cycle, the determination of sex, and the secondary sexual characters; and if there are any zoologists who have not been following the recent development of experimental work, they will be amazed at the amount of profoundly interesting work that has already been done. New vistas are being opened out on all sides, and zoology is entering upon a fresh and most promising phase. It should be noted, too, that Prof. Morgan tells his tale in a style so lucid and graphic that even the uninitiated cannot fail to follow what is certainly one of the most fascinating zoological books ever published.

The main theme of the book is "the central problem of morphology—the causes of the changes in form, or at least the determination of the conditions under which changes in form occur." It must be noted, however, as the author is well aware, that the title "Experimental Zoology" is much wider than the contents of the book. He has deliberately refrained from discussing, (*a*) recent experimental work on the psychical aspects of vital phenomena as dealt with in recent works by Loeb, Lloyd Morgan, Jennings, Bethe, and others; (*b*) the study of regeneration (to which he devoted a previous excellent treatise); and (*c*) experimental embryology, which has also received comprehensive treatment in more than one recent volume. The exclusion of the last-named department is especially regrettable, though it is ungracious to say so. For, after all, the central problem of morphology is not so much concerned with the environmental production of modifications, or with the Mendelian phenomena of inheritance, or with the determination of sex, but with *morphogenesis.* Thus a treatise on experimental zoology which refrains from a thorough-going discussion of the fundamental researches of men like Roux and Wilson, Driesch and Herbst, illustrates what the experimentalists have called "autotomy." Let us hope that in subsequent editions the missing parts—absolutely necessary to completeness—may be regenerated. The author's competence to secure this is well known. Of course, a book should always be received with due consideration of the author's aim and prescribed limits, and what we have ventured to say is in no sense intended as criticism, but we may further remark that under the title of "Experimental Zoology" we may justly include not only experiments bearing on morphogenesis (individual and racial), but also those which enable us better to understand the daily life of the fully formed creature. Much of the work that has been done in comparative physiology and psychology is definitely experimental, and just as essential to an all-round outlook as the work of Mendel and de Vries.

It is of course impossible to give a summary of the author's conclusions, but we may give two or three samples.

"The experimental evidence in favour of the inheritance of acquired characters is unsatisfactory." "Used with discretion Mendel's law may still unlock many

P

problems, but if attempts are made to force it to interpret cases that do not belong to its proper field of action, especially in regard to dissociation in the germ-cells, harm rather than good may temporarily result." "It seems arbitrary to speak of unit characters as immutable and quite unnecessary to make this idea a cardinal point of the mutation theory." "On the mutation theory selection destroys species; it does not originate them." "Admitting that all eggs and all sperm carry the material basis that can produce both the male and female, the two conditions being mutually exclusive when development occurs, the immediate problem of sex determination resolves itself into a study of the conditions that in each species regulate the development of one or the other sex. It seems not improbable that this regulation is different in different species, and that, therefore, it is futile to search for any principle of sex determination that is universal for all species with separate sexes; for while the fundamental internal change that stands for the male or the female condition may be the same in all unisexual forms, the factor that determines which of the alternate states is realised may be very different in different species."

We may be allowed to compliment the author on his highly successful execution of an arduous task; his workmanship is marked by carefulness, lucidity, and impartiality, by the salt of good-tempered criticism, and by a stimulating suggestion throughout that the whole business of experimental zoology is only beginning.

J. A. T.

BOOKS ON PATENT LAW.

(1) *The Inventors' Guide to Patent Law and the New Practice.* By J. Roberts. Pp. viii+109. (London: John Murray, 1906.) Price 1s. net.

(2) *Notes on the New Practice at the Patent Office.* By J. Roberts. Pp. 32. (London: Eyre and Spottiswoode, Ltd., n.d.) Price 1s.

(1) THIS book is intended to give inventors an explanation of the law and rules relating to the grant of patents in the United Kingdom, and information as to the proper manner of protecting inventions. The book is to a great extent an abstract from the larger book of Mr. Roberts, and, as a guide to the student of patent law, should be extremely useful. In addition to the parts of the book dealing directly with the Patent law, information is given specially for the use of an inventor who is in possession of an invention which he considers it desirable to protect; but the ordinary inventor, even with this book in his hand, would meet with considerable difficulty in drafting his specification in the best manner. It is frequently noticed that inventors themselves are quite unable to appreciate and describe what is the real point of their invention; and this difficulty cannot be met by any guide-book. The various matters dealt with in the book comprise practically the whole of the Patent Law, and the questions of the application for a patent, and procedure at the Patent Office, as well as proceedings for infringement, and other proceedings, on a patent already granted, are all referred to, and references given to other works in which fuller information is contained.

It is, of course, impossible in such a small space—about one hundred pages—to give any full account of the Patent Law, and Mr. Roberts has perhaps given as much information as possible in the space at his disposal. The reader, however, will have to refer to the larger works to get any clear ideas on the different points dealt with. It is impossible, for instance, to explain the difference between patentable and non-patentable inventions in a few pages. Every particular case must be judged on its own merits, and reference to a few cases is of little or no use on the question of sufficiency of invention.

At the end of the book, the Patents Act, 1902, is fully set out, together with the rules made under the Act. An index is given which appears to be fairly complete.

(2) This publication deals shortly with the alterations in the Patent Law introduced by the Patents' Act of 1902, and the rules made under that Act. The effect of the new provisions is given very clearly, and certain controversial points arising on the construction of the Act and the rules are very fully dealt with. Among these may be mentioned the question of post-dating the specification, which is the subject of Rule 5 of 1905. This rule gives the comptroller power to post-date the application, and this power, if used against the applicant, is no doubt outside the scope of the Act of 1902. There is, however, little reason to suppose that the rule will be exercised by the comptroller to the prejudice of an applicant, and in practice the applicant may find the power of the comptroller to post-date extremely convenient in cases where he is unable to meet the Patent Office objections within the prescribed time.

Another point very fully dealt with is the question of the meaning to be given to the words "in part described" in Section 1 of the Act of 1902. The author suggests that these words should be narrowly read, and that the words "partly described" should mean that part of the invention as claimed by the applicant has already been described, so that one claim at least includes what is old. This is a reasonable construction, and is practically that adopted by the Office under the new practice.

The author also deals with the question of the compulsory insertion of references at the instance of the comptroller, and the form in which the reference is to be inserted. In the Act of 1902 there is an ambiguity as to whether the comptroller should have power to settle the form of the reference or whether he could decide only what specifications should be referred to. The view taken by the Patent Office is that they are entitled to settle the form, but the author does not consider they are justified in this interpretation. The official view, however, does not really cause any hardship to the patentee, as if there is really an invention the specification can be quite well drafted in such a way that all necessity for the compulsory reference is avoided, and the officials at the Patent Office always give great facilities for amendment to define the invention more clearly, if there is any invention of any sort contained in the application.

Mr. Roberts's notes give a very clear idea of the changes introduced in the Patent Law by the new Act and rules.

OUR BOOK SHELF.

The Efficient Life. By Dr. Luther H. Gulick. Pp. xvi + 195; illustrated. (London: W. Heinemann, 1907.) Price 3*s.* 6*d.* net.

THE "Efficient Life" is a useful addition to our stock of knowledge of how to maintain health and vigour under the conditions of the present-day manner of living. Man has become in civilised countries mostly a dweller in cities during the past fifty years, and even the small portion of human beings who follow a country life is tinged by the customs and ways of the city.

Dr. Gulick applies himself to telling us how to counteract the deteriorating effects of (town) life, and he has executed his task well. It is an artificial life we lead, and the means of ameliorating its evils must necessarily be by artificial devices. Following the chase and tilling the soil were the natural avocations of man, but these natural means of physical development cannot be followed by the majority nowadays, and we have to be content with bodily exercises, breathing exercises, games, and such substitutes as we can devise to make up for nature's plan. That we are to succeed is another question, but if we are it is by following the ideals and methods Dr. Gulick has set before us. In "The Efficient Life" the author deals with almost every phase of our daily round of life. Food, drink, fatigue, sleep, exercise, baths, and general physiological states are dealt with in an attractive and masterly style which everyone can understand and no one can study without benefit.

Although by neither proverbial quotations nor by lectures can we gain health, yet, by dint of persistence in teaching the public by means of these, great good may come; and in time the thoughts they give rise to come to be, imperceptibly perhaps, part and parcel of our daily life. In this way a better perception of how to counteract the deteriorating effects of the modern manners of living may be attained, and with such efficient guides before us as the one given by Dr. Gulick, the end may be hoped to be attained, gradually, perhaps, yet none the less surely.

Flowers of the Field. By the Rev. C. A. Johns. Revised and edited by C. Elliott. Pp. xx + 316. (London: G. Routledge and Sons, Ltd., 1907.) Price 7*s.* 6*d.* net.

JUDGING by the useful purpose it has served in the past, Johns's "Flowers of the Field" may almost be regarded as a "classic," and now it shares with the classics the fate of being produced in two versions. The opinion is often expressed that the editions bearing a date antecedent to 1899 were excellently adapted to the use of amateur collectors of flowers, but the publishers, considering it advisable to bring the book up to date, remodelled it at the same time. In the version now before us, Mr. Elliott claims that the old form is maintained except for revision, the augmentation of descriptions and the addition of new coloured plates. It is evident that the text has been subjected to considerable revision, especially in the matter of rearranging the species of some of the larger genera, but there are other places where emendations were required, such as assigning Paris to the Trilliaceæ and Acorus to the Orontiaceæ, retaining the genera Apargia and Fedia, and the binomial *Lactuca alpina.* Where the present edition differs from, and falls short of the original work is in the size and number of the cuts, and the elimination of guiding headlines under the large genera. The coloured plates are good reproductions, but in many instances the drawings are scrappy and attenuated. An apparently unimportant and yet important change is the increase in size and bulk of the volume. While recognising that Mr. Elliott has made changes for the better in the text, mistakes such as "aureole," "Hiberna," "paralias," are not infrequent. It is probable that the botanist who possesses an old edition of the book will be satisfied with his antique.

Cyclopedia of American Agriculture. Edited by L. H. Bailey. In four volumes. Vol. I.: Farms. Pp. 618 + xviii. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1907.) Price 21*s.* net.

CYCLOPEDIAS seem to be coming into fashion again; Morton's "Cyclopedia of Agriculture" was one of the best books dealing with the old high farming of the middle of the last century, but it has found no successor, though we understand one is under preparation at the present time, and now we receive the first instalment of a monumental work from America. The book opens with a description of the various districts into which the continent may be divided, the cotton States, the corn-belt States, the arid States, &c., each section being contributed by a writer specially acquainted with the locality in question. Then follows an exceedingly interesting and valuable chapter on planning, stocking, and equipment of various types of farm, with a discussion of the capital required in each case. Other sections of this chapter deal with water supply, farm buildings, and machinery, this latter an article that would be of service to the English farmer. Further chapters treat of soils and fertilisers, and are of a more ordinary text-book type, as again is the last chapter dealing with the atmosphere. This, indeed, is too much a general essay on meteorology, and not at all of a character to draw the farmer to a more intelligent personal study of the weather and the forecasting which is within his own power.

The book is profusely illustrated with wood-cuts and process blocks, but while many of the photographs are of interest and are necessary to develop the text, a great many seem to have been inserted on the general encyclopedia principle of stick a picture in wherever you can, however diagrammatic and irrelevant it may be. Indeed, we are at times reminded of the delicious illustrations to "Wisdom while you wait." While we cannot recommend this cyclopedia to the English farmer, so different is the agriculture of the two countries, it should find its place on the shelves of the teacher, who can obtain from it a good many hints and suggestions for application on this side.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Root Action and Bacteria.

THE experiments mentioned by Mr. F. Fletcher in NATURE of July 18 (p. 270) bear only on the functioning of roots once they have come into activity, not on their passage from the dormant to the active condition.

The probable analogy between the bursting of a dormant root-bud and the germination of a seed has led me to investigate the latter, and some of the results already obtained tally exactly with those obtained with trees. Seeds of *Lolium perenne*, sterilised by carbon disulphide, were planted in soil or sand which had been previously treated in various ways; the water-contents of the medium were the same in every case, and re-inoculation from the air was prevented. All the experiments were made in duplicate, and all the duplicates were remarkably concordant. The results were, that seeds in unheated earth began to germinate on the ninth day, the total germination being 65 per cent.; in earth heated to 250°, 150°, 95°, and 80°, no germination has occurred yet, although twenty-two days have now elapsed, while in the case of earth heated to only 60°, germination did not occur until the eighteenth day, and the total germination is only 30 per cent.

Dr. Russell mentioned that in his experiments he had not noticed any retardation to be produced by the sterilisation of the soil; but in his experiments, as well as in my own with apple trees, no steps were taken to guard against re-inoculation from the air, and such re-inoculation would be very easy in the case of seeds just below the surface of the soil. Another explanation may be that we have not used similar seeds; and from some experiments with mustard, now in progress, it is evident that different seeds behave differently, though the difference may be due to the imperfect sterilisation of the seeds themselves in some cases. Dr. Russell has been good enough to examine my experiments whilst in progress, and I believe that he is satisfied with the results so far as they go at present.

There is not sufficient evidence yet to show whether the bacterial action is a direct one on the seeds, or whether it is an indirect one, as Dr. Russell suggested, modifying some chemical change produced in the soil by heating. The very low temperature (60°) which suffices to affect the germination tells against the view that chemical change is one of the governing factors, as also does the fact that the results obtained with sand are similar to those obtained with earth. On the other hand, it was found that with soil which had been heated to 150°, and then re-inoculated, germination was much retarded, and was very feeble, this pointing to some chemical change which was not counteracted at once by the re-inoculation.

The view that plants in growing charge the soil with something which is toxic to other plants was put forward a year or two ago by Dr. Whitney, but the evidence adduced for it seems to have been very inconclusive; the details of Mr. Fletcher's results in this direction will, therefore, be expected with considerable interest. We have, during the last three years, been endeavouring to ascertain whether any action of this sort can account for the effect of grass on trees, trees having been grown in earth or sand in pots and watered with leachings from earth or sand in which grass was growing. The results, however, have been entirely negative.

SPENCER PICKERING.

Biological Expedition to the Birket el Qurun.

THE lake in the Fayum province of Egypt known as the Birket el Qurun has a very unique interest as the remains of the historic Lake Moeris, which was used as an artificial regulator of the Nile floods by the monarchs of the twelfth dynasty. During the last few years a good deal of attention has been paid to the lake and the whole Fayum province by Captain Lyons, F.R.S., and the staff of the Egyptian Survey Department. No detailed examination of the flora and fauna had, however, been undertaken, and it was to furnish the desired biological information that we were invited to make investigations in the spring of this year.

The Birket el Qurun is now reached with great ease from Cairo, as the railway comes within a distance of some seven miles. Consequently we had no difficulties of transport to contend with, and began our work on the lake shore on March 26. During a period of eight weeks we made careful collections in a number of different parts of the lake, and being provided with a sailing-boat of moderate size we were able to make our way about by water, camping in a number of likely places on the shore sufficiently far apart.

The lake seems to be remarkable more for the quantity of life which its waters contain than for the number of different species inhabiting it. The tow-net revealed immense swarms of entomostraca—mostly copepods and cladocera—as well as vast numbers of rotifers, while the smaller organisms form the food supply of the fish, which occur in astonishing abundance. Although the tow-nettings usually afforded a plentiful supply of the smaller animals, they contained relatively little in the way of phyto-plankton. Algæ were collected from the rocks and stones and the submerged stems of plants, while the larger representatives of the flora were also collected.

The fish were for the most part obtained from the native fishermen, and while some thirteen different species were brought home, the overwhelming majority of those taken belong to two species of the genus Tilapia. A large specimen of the Nile perch (*Lates niloticus*) was examined, which measured 120 cm. and weighed 54 lb. Only a few species of mollusca were found, with but a single lamellibranch amongst them, while the worms are represented by certain small oligochætes. The collection contains a polyzoan with circular lophophore, while among the hydrozoa, Cordylophora is found growing abundantly. Perhaps the most interesting discovery is that of a medusa, and the hydroid form with which it is associated. While the water of the lake is now slightly brackish, there is evidence that it was perfectly fresh even in historic times, so that the existence of this form here is rendered more than ever remarkable. It is a typical anthomedusan, and finds its nearest ally in the marine genus Sarsia. There are several animal groups apparently unrepresented in the Birket el Qurun which we might well expect to find, since they are common in the Nile, with which the lake is in direct communication. Such are the crabs, prawns, and sponges, of which no specimens were procured. Similarly we obtained no examples of argulidæ, leeches, or turbellaria.

In addition to the actual collecting, certain physical observations were made. The seiche alterations in water-level appear to be very slight, as is only natural where the greatest depth is but four or five fathoms. A number of readings of the water temperature were taken which prove unexpectedly interesting. The temperatures recorded show a maximum of 94°·2 in very shallow water close to shore about 2.0 p.m., and a minimum of 54°·8 as a surface reading in the early morning. The difference between the surface temperature and that of the water below may also be very considerable, as was shown in one case by a difference of 8°·8 between the reading at a fathom and that at the surface. All these figures are doubtless explained by the shallowness of the lake and the extremes of heat and cold to which it is often exposed.

C. L. BOULENGER, King's College, Cambridge.

The Atomic Weight of Cobalt.

IT has recently been suggested by Prof. J. J. Thomson that the accepted atomic weight of cobalt, namely 59·0, is probably too high, and that the true atomic weight of cobalt is less than that of nickel. Prof. Thomson's suggestion was founded on the results observed with secondary radiation.

We have made an attempt to determine the atomic weight electrolytically by direct comparison with silver, and obtain as the mean of fifteen determinations a value of 57·7 for the atomic weight.

We have also attempted to compare the atomic weights of cobalt and nickel directly with each other and with that of silver by placing three voltameters in series and passing the same current through them, but on account of unexpected difficulties due to secondary reactions in the case of nickel we have not yet obtained satisfactory results.

We hope later to complete the investigation and give details of the experiments.

One of us ("F. H. P.") has also compared the absorption of cobalt and nickel for the β radiation from uranium, and the results indicate a smaller atomic weight for cobalt than for nickel.

Physical Laboratories, Woolwich Polytechnic.

SINGLE-PLATE COLOUR-PHOTOGRAPHY.

THE desire has often been expressed to have a sensitive plate that might be exposed in any ordinary camera, and that would yield what has so often been called a photograph "in natural colours." Such plates are now on the market in France, and will doubtless be obtainable in this country as soon as the makers are able to meet the demand for them. It has taken the enterprising firm of Messrs. Lumière more than three years to perfect their invention and reduce the manufacture of the plates into a system suitable for the factory.

Colours are reproduced by these plates only in that limited sense which applies to all three-colour processes. The natural colours are imitated by tints, which, if successfully produced and seen by a suitable light, are not distinguishable by the unassisted eye from the original. The accuracy of the imitation depends on the choice of the dyes used, and also on the colour-sensitiveness of the emulsion taken in conjunction with the compensating screen used to reduce its excessive sensitiveness to the more refrangible light that characterises all photographic plates.

In the ordinary methods of three-colour photography the three colours are separately photographed, using coloured media that transmit only the light required, a print from each negative is obtained in its proper colour, and the three prints are superposed. For one plate to contain in itself the necessities for such a process it is obvious that its surface must be divided among the three colours, and that the separate patches of each must be so small that, as ordinarily viewed, they are not distinguishable, must be comparable, in fact, to the lines in a wood cut or the dots or grain in a photomechanical print. Further, if the print is to be complete in itself, the three colours must be an integral part of it, and not, as in Prof. Joly's method, form a separate "viewing screen."

The new plates fulfil these conditions. The coloured grained screen that has the three colours in invisibly small patches, forming a tricolour mosaic with the three colours so proportioned that the general impression they give is a neutral grey, is obtained by means of starch granules. These are selected of fairly uniform size, and dyed in separate quantities red, green, and violet. The three lots are mixed as thoroughly as possible, and in such proportions that no colour predominates, and spread upon glass as a film one layer thick. The interstices between the rounded granules are filled up by pressing and more or less crushing the grains, an improvement on the original method of filling them up with a black pigment. This three-coloured irregular mosaic is varnished, and a specially sensitised emulsion is spread on the top of it. The plate is then ready for the camera.

The exposure is made with a suitable colour screen at the lens so that the red, green, and violet lights may act upon the plate in their proper proportions in spite of the want of orthochromatism of the emulsion. The glass side of the plate is presented towards the lens, so that the light that forms the image passes first through the layer of dyed starch granules. The sensitive layer will obviously be affected behind each coloured granule so far as the light from the object is of the same colour as the granule. After development the image has to be reversed, or changed from the negative first produced into a positive. Therefore, instead of fixing in the ordinary way, the metallic silver image is dissolved out by an acid oxidising solution, and the remaining silver bromide is reduced to the metallic state by a developer. Intensification may be necessary. The result is a three-coloured grained transparency in which the truth of the colours depends upon the conditions stated above.

It is obvious that such plates must be comparatively costly, but then only one is required, while some methods of colour photography need six, or even more. The reversal of the image is more trouble than simple fixing, but only one plate has to be dealt with instead of many. The image is granulated, while other methods give results free from grain. It is therefore impossible to say much as to the practical advantage of the method until the plates can be put to actual use. There can, however, be very little doubt that this method, or a modification of it, has a future of usefulness, and no doubt at all as to the ingenuity of the idea that has given rise to it, and the admirable perseverance that has overcome innumerable difficulties in practically working it out.

C. J.

CENTENARY OF THE GEOLOGICAL SOCIETY.

IN September next the Geological Society will celebrate its hundredth birthday. In honour of this interesting occasion preparations have for some time been in progress. Invitations to the celebration have been issued to all the foreign members and foreign correspondents of the society; the various geological surveys all over the globe, universities having chairs of geology or mineralogy, scientific academies, societies and museums at home and abroad have been invited to send delegates to London. The large number of acceptances already received include the names of many of the most distinguished geologists of the present day, both in the old and the new world.

It has been arranged that a series of excursions to various parts of this country shall take place before the centennial meeting, under the conduct of fellows of the society conversant with the geology of the several selected districts. These excursions will begin on Wednesday, September 18, and the excursionists will all be back in London by the evening of September 25. The celebration of the centenary, which will extend over three days, will begin on Thursday, September 26, at 11 o'clock, in the Hall of the Institution of Civil Engineers, when the chair will be taken by Sir Archibald Geikie, who has been elected president of the society for the second time in order that he may preside on this occasion. The foreign members and foreign correspondents, and the delegates from institutions at home and abroad, will then be received by him, and will present their addresses. In the afternoon, at 3 o'clock, in the same hall, the president will deliver an address, while in the evening a banquet will be given by the society to its colonial and foreign guests.

Friday, September 27, will be chiefly devoted to visits to museums, galleries, &c., concluding with an evening reception. On Saturday, September 28, short excursions have been projected to places of geological interest within easy reach of London. On Monday, September 30, the visitors will be divided into two sections, one of which will go to Oxford, the other to Cambridge. It is understood that the universities will confer honorary degrees on some of the more distinguished geologists from beyond the seas, and that college hospitality will be as abundant and hearty as usual, while those visitors who may still have energy enough left for field-work will be taken on geological excursions from both the university towns. This well-planned combination of scientific intercourse with social pleasure can hardly fail to have a lasting effect in forming and confirming friendships by bringing the geologists of many different countries into close personal relations with each other.

DR. AUGUST DUPRÉ, F.R.S.

A WELL-KNOWN name vanishes from the list of living analytical chemists by the death of Dr. A. Dupré, which occurred at Sutton on July 15.

Like a number of chemists whose names readily come to mind—Hoffmann, Schorlemmer, and Lunge, for example—Dupré was born and educated in Germany, but in early manhood crossed the North Sea to seek a sphere for his talents in England. He had studied chemistry under Bunsen; and in 1855, at the age of twenty, he graduated at Heidelberg with the degree of Ph.D. Coming soon afterwards to this country, his first appointment of importance was that of lecturer in chemistry at Westminster Hospital, in 1864. Two years later he became a naturalised British subject. Concurrently with his lecturing duties, Dupré also undertook those of chemical referee to the medical department of the Local Government Board and public analyst for Westminster; and for many years he was chemical adviser to the explosives department of the Home Office, a position which he held at the time of his death.

As might be expected, Dupré's original work in chemistry bore chiefly upon points arising in his own domain of chemical analysis. Some two dozen communications appeared during the period 1876–1902 in the *Analyst*, the Journals of the Chemical Society and the Society of Chemical Industry, and in the Proceedings of the Royal Society. None were epoch-making, but all were useful; their general character will be shown by the titles of a few of them:—"The Composition and Analysis of Butter Fat" (1876); "On Copper in Food" (1877); "The Estimation of Urea by Means of Hypobromite" (1877); "On the Estimation of Dissolved Oxygen in Water" (1885); "Changes in the Proportion of Acid and Sugar present in Grapes during Ripening"; "The Specific Heat and other Physical Characters of Mixtures of Methyl Alcohol and Water"; "The Explosion of Potassium Chlorate by Heat" (1902). In addition, Dupré made various reports upon explosives, and was joint author with Drs. Thudichum and Hake respectively of two well-known treatises, viz., "The Origin, Nature, and Varieties of Wines," and "A Short Manual of Inorganic Chemistry."

The crown of Dupré's professional career was his election to the Royal Society in 1875. To the general public, however, he was probably best known as the analyst whose dangerous duty it was to examine the explosives used in the Fenian scares of a generation ago—notably the one in which nitroglycerine was found in process of manufacture on a large scale at Birmingham in 1883.

Concerned chiefly with the practical applications of chemistry, Dupré was no leader in its philosophy, but his name is honourably associated with the advancement in this country of the profession he adopted when making this country his home.

C. S.

THE BRITISH ASSOCIATION AT LEICESTER.

THIS week sees the opening of the seventy-seventh annual meeting of the British Association, and there are indications that at Leicester the Association will receive the heartiest of welcomes, and that the deliberations of its members will be followed with deep interest by the inhabitants generally. The financial position must be very gratifying to all concerned; the whole of the promised subscriptions are in the bank, and have earned quite a good sum as interest. When it is borne in mind that no public appeal has been made, but that the money has readily been subscribed, this happy result speaks highly as to the generosity of the townspeople and the manner in which they have been approached.

The Mayor (Sir Edward Wood) is most anxious that Leicester should prove its full appreciation of having been chosen as this year's meeting place, and that the many visitors to the ancient borough should carry away a lasting impression of its hospitality and desire for comfort. The local programme tells of Sir Edward Wood's wish to come into as close touch as possible with every visitor, in its record of an evening *fête* in the Abbey Park at which it is anticipated 3000 will be present. His Worship is supplementing this by entertaining on the following evening the officials of the Corporation, the teachers of the town, infirmary nurses, &c., and he has invited the old people from the Trinity Hospital, almshouses, the cripples of the town, and others, to meet him in the same park on the Saturday—all this in commemoration of the visit—which he desires should be a lasting, pleasurable recollection.

We have already spoken of the excellent arrangements made by the local executive, with Mr. Alfred Colson as its chairman, of the sectional meetings, interesting excursions and visits to works planned to add to the enjoyment of the men of science. Each member attending the meeting is to receive a copy of the special edition of "Glimpses of Ancient Leicester," a book written by a Leicester lady, and also to have a capital guide to Leicester and neighbourhood, with a map, prepared under the direction of the publications subcommittee, and containing specially written articles by experts on Charnwood Forest; stone roads, canals, edge-railways, outramways, railways, &c., of Leicestershire; geology; the pre-Cambrian rocks; palæontology, cryptogamic flora of Leicestershire; botany; zoology; entomology; and a bibliography of town and county. These, it is hoped, will serve as memoirs of the town's welcome and a most successful week's work.

The Mayor, Recorder, Town Clerk, and others will attend the official service at St. Martin's Church on the Sunday morning, at which the Bishop of Southwark (Dr. Talbot) will preach. The Bishop of the diocese (Dr. Carr Glynn) is giving an address at St. Peter's Church, and other eminent men are preaching at various churches and chapels, so that the harmony of religion and science will doubtless receive every justice. The leading clubs of the town have freely opened their doors to "temporary members," and the full advantages of golfing and bowls are offered to all interested.

The tramcar service of the town is a most complete one, and every facility for quick transit is given. A favourite daily rendezvous will undoubtedly be the "loggia" erected adjacent to, and connected with, the town museum buildings, and here, if the weather is fine, a quiet rest, a cup of tea, and the music of the band of the Seaforth Highlanders will prove thoroughly enjoyable, and a relief to the heavier work of the sectional meetings.

Next year the Association is to meet at Dublin, and by a happy thought a deputation of the following gentlemen, Sir Howard Grubb, F.R.S., Rev. Dr. W. Delaney, and Prof. W. H. Thompson, will be the guests of the local executive at Leicester.

We hope that in a future issue we may be able to congratulate the Association on the complete success of its last annual meeting, the large attendance of its members, the high quality of the papers read and discussed and lectures given; and Leicester upon its generous welcome and hospitality.

INAUGURAL ADDRESS BY SIR DAVID GILL, K.C.B., LL.D., D.Sc., F.R.S., HON. F.R.S.E., &c., PRESIDENT OF THE ASSOCIATION.

TO-NIGHT, for the first time in its history, the British Association meets in the ancient city of Leicester; and it now becomes my privilege to convey to you, Mr. Mayor, and to the citizens generally, an expression of our thanks for your kind invitation and for the hospitable reception which you have accorded to us.

Here in Leicester and last year in York the Association has followed its usual custom of holding its annual meeting somewhere in the United Kingdom; but in 1905 the meeting was, as you know, held in South Africa. Now, having myself only recently come from the Cape, I wish to take this opportunity of saying that this southern visit of the Association has, in my opinion, been productive of much good: wider interest in science has been created amongst colonists, juster estimates of the country and its problems have been formed on the part of the visitors, and personal friendships and interchange of ideas between thinking men in South Africa and at home have arisen which cannot fail to have a beneficial influence on the social, political, and scientific relations between these colonies and the mother country. We may confidently look for like results from the proposed visit of the Association to Canada in 1909.

One is tempted to take advantage of the wide publicity given to words from this chair to speak at large in the cause of science, to insist upon the necessity for its wider inclusion in the education of our youth and the devotion of a larger measure of the public funds in aid of scientific research; to point to the supreme value of science as a means for the culture of those faculties which in man promote that knowledge which is power; and to show how dependent is the progress of a nation upon its scientific attainment.

But in recent years these truths have been prominently brought before the Association from this chair; they have been exhaustively demonstrated by Sir William Huggins from the chair of the Royal Society, and now a special guild [1] exists for their enforcement upon the mind of the nation.

These considerations appear to warrant me in following the healthy custom of so many previous presidents—viz., of confining their remarks mainly to those departments of science with which the labours of their lives have been chiefly associated.

The Science of Measurement.

Lord Kelvin in 1871 made a statement from the presidential chair of the Association at Edinburgh as follows: "Accurate and minute measurement seems to the non-scientific imagination a less lofty and dignified work than the looking for something new. But nearly all the grandest discoveries of science have been the reward of accurate measurement and patient, long-continued labour in the minute sifting of numerical results."

Besides the instances quoted by Lord Kelvin in support of that statement, we have perhaps as remarkable and typical an exemplification as any in Lord Rayleigh's long-continued work on the density of nitrogen which led him to the discovery of argon. We shall see presently that, true as Lord Kelvin's words are in regard to most fields of science, they are specially applicable as a guide in astronomy.

One of Clerk Maxwell's lectures in the Natural Philosophy Class at Marischall College, Aberdeen, when I was a student under him there, in the year 1859, ran somewhat as follows:—

"A standard, as it is at present understood in English, is not a real standard at all; it is a rod of metal with lines ruled upon it to mark the yard, and it is kept somewhere in the House of Commons. If the House of Commons catches fire there may be an end of your standard. A copy of a standard can never be a real standard, because all the work of human hands is liable to error. Besides, will your so-called standard remain of a constant length? It certainly will change by temperature, it probably will change by age (that is, by the rearrangement or settling down of its component molecules), and I am not sure if it does not change according to the azimuth in which it is used. At all events, you must see that it is a very impractical standard—impractical because, if, for example, any one of you went to Mars or Jupiter, and the people there asked you what was your standard of measure, you could not tell them, you could not reproduce it, and you would feel very foolish. Whereas, if you told any capable physicist in Mars or Jupiter that you used some natural invariable standard, such as the wave-length of the D-line of sodium vapour, he would be able to reproduce your yard or your inch, provided that you could tell him how many of such wave-lengths there were in your yard or your inch, and your standard would be available anywhere in the universe where sodium is found."

That was the whimsical way in which Clerk Maxwell used to impress great principles upon us. We all laughed before we understood; then some of us understood and remembered.

Now the scientific world has practically adopted Maxwell's form of natural standard. It is true that it names that standard the metre; but that standard is not one-millionth of the earth's quadrant in length, as it was intended to be; it is merely a certain piece of metal approximately of that length.

It is true that the length of that piece of metal has been reproduced with more precision, and is known with higher accuracy in terms of many secondary standards, than is the length of any other standard in the world; but it is, after all, liable to destruction and to possible secular change of length. For these reasons it cannot be scientifically described otherwise than as a piece of metal whose length at 0° C. at the epoch A.D. 1906 is =1,553,164 times the wave-length of the red line of the spectrum of cadmium when the latter is observed in dry air at the temperature of 15° C. of the normal hydrogen-scale at a pressure of 760 mm. of mercury at 0° C.

This determination, recently made by methods based on the interference of light-waves and carried out by MM. Perot and Fabry at the International Bureau of Weights and Measures, constitutes a real advance in scientific metrology. The result appears to be reliable within one ten-millionth part of the metre.

The length of the metre, in terms of the wave-length of the red line in the spectrum of cadmium, had been determined in 1892 by Michelson's method, with a mean result in almost exact accordance with that just quoted for the comparisons of 1906; but this agreement (within one part in ten millions) is due in some degree to chance, as the uncertainty of the earlier determination was probably ten times greater than the difference between the two independent results of 1892 and 1906.

We owe to M. Guillaume, of the same International Bureau, the discovery of the remarkable properties of the alloys of nickel and steel, and from the point of view of exact measurement the specially valuable discovery of the properties of that alloy which we now call "invar." He has developed methods for treatment of wires made from this alloy which render more permanent the arrangement of their constituent molecules. Thus these wires, with their attached scales, may, for considerable periods of time and under circumstances of careful treatment, be regarded as nearly invariable standards. With proper precautions, we have found at the Cape of Good Hope that these wires can be used for the measurement of base lines of the highest geodetic precision with all the accuracy attainable by the older and most costly forms of apparatus; whilst with the new apparatus a base of 20 kilometres can be measured in less time and for less cost than one of a single kilometre with the older forms of measurement.

The Great African Arc of Meridian.

In connection with the progress of geodesy, time only permits me to say a few words about the Great African arc on the 30th meridian, which it is a dream of my life to see completed.

The gap in the arc between the Limpopo and the previously executed triangulation in Rhodesia, which I reported to the Association at the Johannesburg meeting in 1905, has now been filled up. My own efforts, at

[1] The British Science Guild.

6000 miles distance, had failed to obtain the necessary funds, but at Sir George Darwin's instance contributions were obtained from this Association, from the Royal Society and others, to the extent of half the estimated cost; the remaining half was met by the British South Africa Company. But for Darwin's happy intervention, which enabled me to secure the services of Captain Gordon and his party before the Transvaal Survey Organisation was entirely broken up, this serious gap in the great work would probably have long remained; for it is one thing to add to an existing undertaking of the kind, it is quite another to create a new organisation for a limited piece of work.

Since then Colonel (now Sir William) Morris has brought to a conclusion the reductions of the geodetic survey of the Transvaal and Orange River Colony, and his report is now in my hands for publication.

Dr. Rubin, under my direction, at the cost of the British South Africa Company, has carried the arc of meridian northwards to S. latitude 9° 42′, so that we have now continuous triangulation from Cape L'Agulhas to within fifty miles of the southern end of Lake Tanganyika; that is to say, a continuous geodetic survey extending over twenty-five degrees of latitude.

It happens that, for the adjustment of the international boundary between the British Protectorate and the Congo Free State, a topographic survey is at the present moment being executed northward along the 30th meridian from the northern border of German East Africa. A proposal on the part of the Royal Society, the Royal Geographical Society, the British Association, and the Royal Astronomical Society has been made to strengthen this work by carrying a geodetic triangulation through it along the 30th Meridian, and thus adding $2\frac{1}{2}°$ to the African arc. These Societies together guarantee 1000*l.* towards the cost of the work, and ask for a like sum from Government to complete the estimated cost. The topographic survey will serve as the necessary reconnaissance. The topographic work will be completed by the end of January next, and the four following months offer the best season of the year for geodetic operations in these regions.

There is a staff of skilled officers and men on the spot sufficient to complete the work within the period mentioned, and the Intercolonial Council of the Transvaal and Orange River Colony most generously offers to lend the necessary geodetic instruments. The work will have to be done sooner or later, but if another expedition has to be organised for the purpose the work will then cost from twice to three times the present amount. One cannot therefore doubt that His Majesty's Government will take advantage of the present offer and opportunity to vote the small sum required. This done, we cannot doubt that the German Government will complete the chain along the eastern side of Lake Tanganyika, which lies entirely within their territory. Indeed, it is no secret that the Berlin Academy of Sciences has already prepared the necessary estimates with a view to recommending action on the part of its Government.

Captain Lyons, who is at the head of the survey of Egypt, assures me that preliminary operations towards carrying the arc southwards from Alexandria have been begun, and we have perfect confidence that in his energetic hands the work will be prosecuted with vigour. In any case the completion of the African arc will rest largely in his hands. That arc, if ever my dream is realised, will extend from Cape L'Agulhas to Cairo, thence round the eastern shore of the Mediterranean and the islands of Greece, and there meet the triangulation of Greece itself, the latter being already connected with Struve's great arc, which terminates at the North Cape in lat. 70° N. This will constitute an arc of 105° in length—the longest arc of meridian that is measurable on the earth's surface.

The Solar Parallax.

Much progress has been made in the exact measurement of the great fundamental unit of astronomy—the solar parallax.

Early in 1877 I ventured to predict [1] that we should not arrive at any certainty as to the true value of the solar parallax from observations of transits of Venus, but that the modern heliometer applied to the measurement of angular distances between stars and the star-like images of minor planets would yield results of far higher precision.

[1] "The Determination of the Solar Parallax," the *Observatory*, vol. i. p. 280.

The results of the observations of the minor planets Iris, Victoria, and Sappho at their favourable oppositions in the years 1888 and 1889, which were made with the cooperation of the chief heliometer and meridian observatories, fully justified this prediction.[1] The Sun's distance is now almost certainly known within one-thousandth part of its amount. The same series of observations also yielded a very trustworthy determination of the mass of the Moon.

The more recently discovered planet Eros, which in 1900 approached the Earth within one-third of the mean distance of the Sun, afforded a most unexpected and welcome opportunity for re-determining the solar parallax—an opportunity which was largely taken advantage of by the principal observatories of the northern hemisphere. Unfortunately the high northern declination of the planet prevented its observation at the Cape and other southern observatories. So far as the results have been reduced and published [2] they give an almost exact accordance with the value of the solar parallax derived from the heliometer observations of the minor planets, Iris, Victoria, and Sappho in 1888 and 1889.

But in 1931 Eros will approach the Earth within one-sixth part of the Sun's mean distance, and the fault will rest with astronomers of that day if they do not succeed in determining the solar parallax within one ten-thousandth part of its amount.

To some of us who struggled so hard to arrive at a tenth part of this accuracy under the less favourable geometrical conditions that were available before the discovery of Eros, how enviable seems the opportunity!

And yet, if we come to think of it rightly, the true opportunity and the chief responsibility is ours, for *now* and not twenty years hence is the time to begin our preparation; *now* is the time to study the origin of those systematic errors which undoubtedly attach to some of our photographic processes; and then we ought to construct telescopes specially designed for the work. These telescopes should be applied to the charting of the stars near the path which Eros will describe at its opposition in 1931, and the resulting star-coordinates derived from the plates photographed by the different telescopes should be rigorously inter-compared. Then, if all the telescopes give identical results for the star-places, we can be certain that they will record without systematic error the position of Eros. If they do not give identical results, the source of the errors must be traced.

The planet will describe such a long path in the sky during the opposition of 1931 that it is already time to begin the meridian observations which are necessary to determine the places of the stars that are to be used for determining the constants of the plates. It is desirable, therefore, that some agreement should be come to with respect to selection of these reference-stars, in order that all the principal meridian observatories in the world may take part in observing them.

I venture to suggest that a Congress of Astronomers should assemble in 1908 to consider what steps should be taken with reference to the important opposition of Eros in 1931.

The Stellar Universe.

And now to pass from consideration of the dimensions of our solar system to the study of the stars, or other suns, that surround us.

To the lay mind it is difficult to convey a due appreciation of the value and importance of star-catalogues of precision. As a rule such catalogues have nothing whatever to do with discovery in the ordinary sense of the word, for the existence of the stars which they contain is generally well known beforehand; and yet such catalogues are, in reality, by far the most valuable assets of astronomical research.

If it be desired to demarcate a boundary on the Earth's

[1] "Annals of the Cape Observatory," vol. vi., part vi., p. 29.
[2] Monthly Notices R.A.S., Hinks vol lxiv. p. 725; Christie, vol. lxvii. p. 382.

surface by astronomical methods, or to fix the position of any object in the heavens, it is to the accurate star-catalogue that we must refer for the necessary data. In that case the stars may be said to resemble the trigonometrical points of a survey, and we are only concerned to know from accurate catalogues their positions in the heavens at the epoch of observation. But in another and grander sense the stars are not mere landmarks, for each has its own apparent motion in the heavens which may be due in part to the absolute motion of the star itself in space, or in part to the motion of the solar system by which our point of view of surrounding stars is changed.

If we desire to determine these motions and to ascertain something of the general conditions which produce them, if we would learn something of the dynamical conditions of the universe and something of the velocity and direction of our own solar system through space, it is to the accurate star catalogues of widely separated epochs that we must turn for a chief part of the requisite data.

The value of a star-catalogue of precision for present purposes of cosmic research varies as the square of its age and the square of its accuracy. We cannot alter the epoch of our observations, but we can increase their value fourfold by doubling their accuracy. Hence it is that many of our greater astronomers have devoted their lives chiefly to the accumulation of meridian observations of high precision, holding the view that to advance such precision is the most valuable service to science they could undertake, and comforted in their unselfish and laborious work only by the consciousness that they are preparing a solid foundation on which future astronomers may safely raise the superstructure of sound knowledge.

But since the extension of our knowledge of the system of the universe depends quite as much on past as on future research, it may be well, before determining upon a programme for the future, to consider briefly the record of meridian observation in the past for both hemispheres.

The Comparative State of Astronomy in the Northern and Southern Hemispheres.

It seems probable that the first express reference to southern constellations in known literature occurs in the Book of Job (ix. 9): "Which maketh Arcturus, Orion, and Pleiades, and the chambers of the south." Schiaparelli's strongly supported conjecture is that the expression "chambers of the south," taken with its context, signifies the brilliant stellar region from Canopus to α Centauri, which includes the Southern Cross and coincides with the most brilliant portion of the Milky Way.

About the year 750 B.C. (the probable date of the Book of Job) all these stars culminated at altitudes between 5° and 16° when viewed from the latitude of Judæa; but now, owing to precessional change, they can only be seen in a like striking manner from a latitude about 12° further south.

The words of Dante have unquestionably originated the wonderful net of poetic fancy that has been woven about the asterism, which we now call Crux.

> To the right hand I turned, and fixed my mind
> On the other pole attentive, where I saw
> Four stars ne'er seen before save by the ken
> Of our first parents—Heaven of their rays
> Seemed joyous. O thou northern site! bereft
> Indeed, and widowed, since of these deprived.

All the commentators agree that Dante here referred to the stars of the Southern Cross.

Had Dante any imperfect knowledge of the existence of these stars, any tradition of their visibility from European latitudes in remote centuries, so that he might poetically term them the stars of our first parents?

Ptolemy catalogues them as 31, 32, 33, and 34 Centauri, and they are clearly marked on the Borgian globe described by Assemanus in 1790. This globe was constructed by an Arabian in Egypt: it bears the date 622 Hegira, corresponding with A.D. 1225, and it is possible that Dante may have seen it.

Amerigo Vespucci, as he sailed in tropical seas, apparently recognised in what we now call Crux the four luminous stars of Dante; for in 1501 he claimed to be the first European to have looked upon the stars of our first parents. His fellow-voyager, Andrea Corsali, wrote about the same time to Giuliano di Medici describing "the marvellous cross, the most glorious of all the celestial signs."

Thus much mysticism and romance have been woven about this constellation, with the result that exaggerated notions of its brilliancy have been formed, and to most persons its first appearance, when viewed in southern latitudes, is disappointing.

To those, however, who view it at upper culmination for the first time from a latitude a little south of the Canary Islands, and who at the same time make unconsciously a mental allowance for the absorption of light to which one is accustomed in the less clear skies of Northern Europe, the sight of the upright cross, standing as if fixed to the horizon, is a most impressive one. I at least found it so on my first voyage to the Cape of Good Hope. But how much more strongly must it have appealed to the mystic and superstitious minds of the early navigators as they entered the unexplored seas of the northern tropic! To them it must have appeared the revered image of the Cross pointing the way on their southward course—a symbol and sign of Hope and Faith on their entry to the unknown.

The first general knowledge of the brighter stars of the southern hemisphere we owe to Frederick de Hautman, who commanded a fleet sent by the Dutch Government in 1595 to the Far East for the purpose of exploring Japan. Hautman was wrecked and taken prisoner at Sumatra, and whilst there he studied the language of the natives and made observations of the positions and magnitudes of the fixed stars of the southern hemisphere.[1]

Our distinguished countryman Halley visited St. Helena in 1677 for the purpose of cataloguing the stars of the southern hemisphere. He selected a station now marked Halley's Mount on the Admiralty chart of the island. I have visited the site, and the foundations of the observatory still remain. Halley's observations were much hindered by cloud. On his return to England, Halley in 1679 published his "Catalogus Stellarum Australium," containing the magnitudes, latitudes, and longitudes of 341 stars, which, with the exception of seven, all belonged to the southern hemisphere.

But the first permanently valuable astronomical work in the southern hemisphere was done in 1751–2 by the Abbé de Lacaille. He selected the Cape of Good Hope as the scene of his labours, because it was then perhaps the only spot in the world situated in a considerable southern latitude which an unprotected astronomer could visit in safety, and where the necessary aid of trained artisans to erect his observatory could be obtained. Lacaille received a cordial welcome at the hands of the Dutch governor Tulbagh: he erected his observatory in Cape Town, made a catalogue of nearly 10,000 stars, observed the opposition of Mars, and measured a short arc of meridian all in the course of a single year. Through his labours the Cape of Good Hope became the birthplace of astronomy and geodesy in the southern hemisphere.

Bradley was laying the foundations of exact astronomy in the northern hemisphere at the time when Lacaille laboured at the Cape. But Bradley had superior instruments to those of Lacaille and much longer time at his disposal. Bradley's work is now the basis on which the fair superstructure of modern astronomy of precision rests. His labours were continued by his successors at Greenwich and by a long series of illustrious men like Piazzi, Groombridge, Bessel, Struve, and Argelander. But in the southern hemisphere the history of astronomy is a blank for seventy years from the days of Lacaille.

We owe to the establishment of the Royal Observatory at the Cape by an Order in Council of 1820 the first successful step towards the foundation of astronomy of high precision in the southern hemisphere.

Time does not permit me to trace in detail the labours of astronomers in the southern hemisphere down to the present day; and this is the less necessary because in a recent Presidential Address to the South African Philosophical Society[2] I have given in great part that history

[1] The resulting catalogue of 304 stars is printed as an appendix to Hautman's "Vocabulary of the Malay Language," published at Amsterdam in 1603.

[2] Trans. South African Phil. Soc., vol. xiv., part 2.

in considerable detail. But I have not there made adequate reference to the labours of Dr. Gould and Dr. Thome at Cordoba. To their labours, combined with the work done under Stone at the Cape, we owe the fact that for the epoch 1875 the meridian sidereal astronomy of the southern hemisphere is nearly as well provided for as that of the northern. The point I wish to make is that the facts of exact sidereal astronomy in the southern hemisphere may be regarded as dating nearly a hundred years behind those of the northern hemisphere.

The Constitution of the Universe.

It was not until 1718, when Edmund Halley, afterwards Astronomer Royal of England, read a paper before the Royal Society,[1] entitled "Considerations on the Change of the Latitudes of Some of the Principal Fixt Stars," that any definite facts were known about the constitution of the universe. In that paper Halley, who had been investigating the precession of the equinoxes, says: "But while I was upon this enquiry I was surprized to find the Latitudes of three of the principal Stars in heaven directly to contradict the supposed greater obliquity of the Ecliptick, which seems confirmed by the Latitudes of most of the rest."

This is the first mention in history of an observed change in the relative position of the so-called fixed stars—the first recognition of what we now call "proper motion."

Tobias Mayer, in 1760, seems to have been the first to recognise that if our Sun, like other stars, has motion in space, that motion must produce apparent motion amongst the surrounding stars; for in a paper to the Göttingen Academy of Sciences he writes: "If the Sun, and with it the planets and the Earth which we inhabit, tended to move directly towards some point in the heavens, all the stars scattered in that region would seem to gradually move apart from each other, whilst those in the opposite quarter would mutually approach each other. In the same manner one who walks in the forest sees the trees which are before him separate, and those that he leaves behind approach each other." No statement of the matter could be more clear; but Mayer, with the meagre data at his disposal, came to the conclusion that "the motions of the stars are not governed by the above or any other common law, but belong to the stars themselves."

Sir William Herschel, in 1783, made the first attempt to apply, with any measure of success, Mayer's principle to a determination of the direction and amount of the solar motion in space.[2] He derived, as well as he could from existing data, the proper motions of fourteen stars, and arrived by estimation at the conclusion that the Sun's motion in space is nearly in the direction of the star λ Herculis, and that 80 per cent. of the apparent motions of the fourteen stars in question could be assigned to this common origin.

This conclusion rests in reality upon a very slight basis, but the researches of subsequent astronomers show that it was an amazing accidental approach to truth—indeed, a closer approximation than Herschel's subsequent determinations of 1805 and 1806, which rested on wider and better data.[3]

Consider for a moment the conditions of the problem. If all the stars except our Sun were at rest in space, then, in accordance with Mayer's statement, just quoted, all the stars would have apparent motions on great circles of the sphere away from the apex and towards the antapex of the solar motion. That is to say, if the position of each star of which the apparent motion is known was plotted on the surface of a sphere and a line with an arrow-head drawn through each star showing the direction of its motion on the sphere, then it should be possible to find a point on the sphere such that a great circle drawn from this point through any star would coincide with the line of direction of that star's proper motion. The arrow-heads would all point to that intersection of the great circles which is the antapex of the solar motion, and the other point of intersection of the great circles would be the apex

[1] Phil. Trans., 1718, p. 738.
[2] *Ibid.*, 1783, p. 247.
[3] *Ibid.*, 1805, p. 233; 1806, p. 205.

that is to say, the direction of the Sun's motion in space.

But as the apparent stellar motions are small and only determinable with a considerable percentage of error, it would be impossible to find any point on the sphere such that every great circle passing through it and any particular star, would in every case be coincident with the observed direction of motion of that star.

Such discordances would, on our original assumption, be due to errors of observation, but in reality much larger discordances will occur, which are due to the fact that the other stars (or suns) have independent motions of their own in space. This at once creates a new difficulty, viz., that of defining an absolute locus in space. The human mind may exhaust itself in the effort, but it can never solve the problem. We can imagine, for example, the position of the Sun at any moment to be defined with reference to any number of surrounding stars, but by no effort of imagination can we devise means of defining the *absolute* position of a body in space without reference to surrounding material objects. If, therefore, the referring objects have unknown motions of their own, the rigour of the definition is lost.

What we call the observed proper motion of a star has three possible sources of origin:—

(1) The *parallactic motion*, or the effect of our Sun's motion through space, whereby our point of view of surrounding celestial objects is changed.

(2) The *peculiar* or particular motion of the star, *i.e.*, its own *absolute* motion in space.

(3) That part of the observed or tabular motion which is due to inevitable error of observation.

In all discussions of the solar motion in space, from that of Herschel down till a recent date, it has been assumed that the peculiar motions of the stars are arranged at random, and may therefore be considered zero in the mean of a considerable number of them. It is then possible to find such a value for the Precession, and such a common apex for the solar motion as shall leave the residual peculiar motions of the stars under discussion to be in the mean=zero. That is to say, we refer the motion of the Sun in space to the centre of gravity of all the stars considered in the discussion, and regard that centre of gravity as immovable in space.

In order to proceed rigorously, and especially to determine the amount as well as the direction of the Sun's motion in space, we ought to know the parallax of every star employed in the discussion, as well as its proper motion. In the absence of such data it has been usual to start from some such assumption as the following: the stars of a particular magnitude are roughly at the same distance; those of different classes of magnitude may be derived from the hypothesis that on the average they have all equal absolute luminosity.

The assumption is not a legitimate one—

(1) Because of the extreme difference in the absolute luminosity of stars.

(2) Because it implies that the average absolute luminosity of stars is the same in all regions of space.

The investigation has been carried out by many successive astronomers on these lines with fairly accordant results as to the position of the solar apex, but with very unsatisfactory results as to the distances of the fixed stars.[1] In order to judge how far the magnitude (or brightness) of a star is an index of its probable distance, we must have evidence from direct determinations of stellar parallax.

Stellar Parallax.

To extend exact measurement from our own solar system to that of other suns and other systems may be regarded as the supreme achievement of practical astronomy. So great are the difficulties of the problem, so minute the

angles involved, that it is but in comparatively recent years that any approximate estimate could be formed of the true parallax of any fixed star. Bradley felt sure that if the star γ Draconis had a parallax of $1''$ he would have detected it. Henderson by "the minute sifting of the numerical results" of his own meridian observations of α Centauri, made at the Cape of Good Hope in 1832–3, first obtained certain evidence of the measurable parallax of any fixed star. He was favoured in this discovery by the fact that the object he selected happened to be, so far as we yet know, the nearest sun to our own. Shortly afterwards Struve obtained evidence of a measurable parallax for α Lyræ and Bessel for 61 Cygni. Astronomers hailed with delight this bursting of the constraints which our imperfect means imposed on research. But for the great purposes of cosmical astronomy what we are chiefly concerned to know is not what is the parallax of this or that particular star, but rather what is the average parallax of a star having a particular magnitude and proper motion. The prospect of even an ultimate approximate attainment of this knowledge seemed remote. The star α Lyræ is one of the brightest in the heavens; the star 61 Cygni one that had the largest proper motion known at the time; whilst α_2 Centauri is not only a very bright star, but it has also a large proper motion. The parallaxes of these stars must therefore in all probability be large compared with the parallax of the average star; but yet to determine them with approximate accuracy long series of observations by the greatest astronomers and with the finest instruments of the day seemed necessary.

Subsequently various astronomers investigated the parallaxes of other stars having large proper motions, but it was only in 1881, at the Cape of Good Hope, that general research on stellar parallax was instituted.[1] Subsequently at Yale and at the Cape of Good Hope the work was continued on cosmical lines with larger and improved heliometers.[2] By the introduction of the reversing prism and by other practical refinements the possibilities of systematic error were eliminated, and the accidental errors of observation reduced within very small limits.

These researches brought to light the immense diversity in the absolute luminosity and velocity of motion of different stars. Take the following by way of example:—

Our nearest neighbour amongst the stars, α_2 Centauri, has a parallax of $0''\cdot 76$, or is distant about $4\frac{1}{3}$ light-years. Its mass is independently known to be almost exactly equal to that of our Sun; and its spectrum being also identical with that of our Sun, we may reasonably assume that it appears to us of the same magnitude as would our Sun if removed to the distance of α_2 Centauri.

But the average star of the same apparent magnitude as α_2 Centauri was found to have a parallax of only $0''\cdot 10$, so that either α_2 Centauri or our Sun, if removed to a distance equal to that of the average fixed star of the first magnitude, would appear to us but little brighter than a star of the fifth magnitude.

Again, there is a star of only $8\frac{1}{2}$ magnitude[3] which has the remarkable annual proper motion of nearly $8\frac{3}{4}$ seconds of arc—one of those so-called runaway stars—which moves with a velocity of 80 miles per second at right angles to the line of sight (we do not know with what velocity in the line of sight). It is at about the same distance from us as Sirius, but it emits but one ten-thousandth part of the light energy of that brilliant star. Sirius itself emits about thirty times the light-energy of our Sun, but it in turn sinks into insignificance when compared with the giant Canopus, which emits at least 10,000 times the light-energy of our Sun.

Truly "one star differs from another star in glory." Proper motion rather than apparent brightness is the truer indication of a star's probable proximity to the Sun. Every star of considerable proper motion yet examined has proved to have a measurable parallax.

This fact at once suggests the idea, Why should not the apparent parallactic motions of the stars, as produced by the Sun's motion in space, be utilised as a means of determining stellar parallax?

Secular Parallactic Motion of Stars.

The strength of such determinations, unlike those made by the method of annual parallax, would grow with time. It is true that the process cannot be applied to the determination of the parallax of individual stars, because the peculiar motion of a particular star cannot be separated from that part of its apparent motion which is due to parallactic displacement. But what we specially want is not to ascertain the parallax of the individual star, but the mean parallax of a particular group or class of stars, and for this research the method is specially applicable, provided we may assume that the peculiar motions are distributed at random, so that they have no systematic tendency in any direction; in other words, that the centre of gravity of any extensive group of stars will remain fixed in space.

This assumption is, of course, but a working hypothesis, and one which from the paper on star-streaming communicated by Prof. Kapteyn of Groningen to the Johannesburg meeting of the Association two years ago we already know to be inexact.[1] Kapteyn's results were quite recently confirmed in a remarkable way by Eddington,[2] using independent material discussed by a new and elegant method. Both results showed that, at least for extensive parts of space, there are a nearly equal number of stars moving in exactly opposite directions. The assumption, then, that the mean of the peculiar motions is zero may, at least for these parts of space, be still regarded as a good working hypothesis.

Adopting an approximate position of the apex of the solar motion, Kapteyn resolved the observed proper motions of the Bradley stars into two components, viz., one in the plane of the great circle passing through the star and the apex, the other at right angles to that plane.[3] The former component obviously includes the whole of the parallactic motion; the latter is independent of it, and is due entirely to the real motions of the stars themselves. From the former the mean parallactic motion of the group is derived, and from the combination of the two components, the relation of velocity of the Sun's motion to that of the mean velocity of the stars of the group.

As the distance of any group of stars found by the parallactic motion is expressed as a unit in terms of the Sun's yearly motion through space, the velocity of this motion is one of the fundamental quantities to be determined. If the mean parallax of any sufficiently extensive group or class of stars was known we should have at once means for a direct determination of the velocity of the Sun's motion in space; or if, on the other hand, we can by independent methods determine the Sun's velocity, then the mean parallax of any group of stars can be determined.

Determination of Stellar Motion in the Line of Sight.

Science owes to Sir William Huggins the application of Doppler's principle to the determination of the velocity of star-motion in the line of light. The method is now so well known, and such an admirable account of its theory and practical development was given by its distinguished inventor from this Chair at the Cardiff meeting in 1891, that further mention of that part of the matter seems unnecessary.

The Velocity of the Sun's Motion in Space.

If by this method the velocities in the line of sight of a sufficient number of stars situated near the apex and antapex of the solar motion could be determined, so that in the mean it could be assumed that their peculiar motions would disappear, we have at once a direct determination of the required velocity of the Sun's motion.

The material for this determination is gradually accumulating, and indeed much of it, already accumulated, is not yet published. But even with the comparatively scant material available, it now seems almost certain that the true value of the Sun's velocity lies between 18 and 20 kilometres per second;[4] or, if we adopt the mean value, 19 kilometres per second, this would correspond almost

exactly with a yearly motion of the Sun through space equal to four times the distance of the Sun from the Earth.

Thus the Sun's yearly motion being four times the Sun's distance, the parallactic motion of stars in which this motion is unforeshortened must be four times their parallax. How this number varies with the amount of foreshortening is of course readily calculated. The point is that from the mean parallactic motion of a group of stars we are now enabled to derive at once its mean parallax.

This research has been carried out by Kapteyn for stars of different magnitudes. It leads to the result that the parallax of stars differing *five* magnitudes does *not* differ in the proportion of one to ten, as would follow from the supposition of equal luminosity of stars throughout the universe, but only in the proportion of about one to five.[1]

The same method cannot be applied to groups of stars of different proper motions, and it is only by a somewhat indirect proof, and by calling in the aid of such trustworthy results of direct parallax determination as we possess, that the variation of parallax with proper motion could be satisfactorily dealt with.

The Mean Parallaxes of Stars of Different Magnitude and Proper Motion.

As a final result Kapteyn derived an empirical formula giving the average parallax for stars of different spectral types, and of any given magnitude and proper motion. This formula was published at Groningen in 1901.[2] Within the past few months the results of researches on stellar parallax, made under the direction of Dr. Elkin, at the Astronomical Observatory of Yale University, during the past thirteen years,[3] have been published, and they afford a most crucial and entirely independent check on the soundness of Kapteyn's conclusions.

In considering the comparison between the more or less theoretical results of Kapteyn and the practical determinations of Yale, we have to remember that Kapteyn's tables refer only to the means of groups of a large number of stars having on the average a specified magnitude and proper motion, whilst the latter are direct determinations affected by the accidental errors of the separate determinations and by such uncertainty as attaches to the unknown parallaxes of the comparison stars—parallaxes which we have supplied from Kapteyn's general tables.

The Yale results consist of the determination of the parallax of 173 stars, of which only ten had been previously known to Kapteyn and had been utilised by him. Dividing these results into groups we get the following comparison :—

Comparison Groups arranged in order of Proper Motion.

No. of stars	Proper Motion	Magnitude	Parallax		Yale—Kapteyn

These results agree in a surprisingly satisfactory way, having regard to the comparatively small number of stars in each group and the great range of parallax which we know to exist amongst individual stars having the same magnitude and proper motion. In the mean perhaps the tabular parallaxes are in a minute degree too large, but we have unquestionable proof from this comparison that our knowledge of stellar distances now rests on a solid foundation.

The Distribution of Varieties of Luminosity of Stars.

But, besides the mean parallax of stars of a particular magnitude and proper motion, it is essential that we should know approximately what percentage of the stars of such a group have twice, three times, &c., the mean parallax of the group, and what percentage only one-half, one-third of that parallax, and so on. In principle, at least, this frequency-law may be obtained by means of the directly determined parallaxes. For the stars of which we have trustworthy determinations we can compare these true parallaxes with the *mean* parallax of stars having corresponding magnitude and proper motion, and this comparison will lead to a knowledge of the frequency-law required. It is true that, owing to the scarcity of material at present available, the determination of the frequency-law is not so strong as may be desirable, but further improvement is simply a question of time and the augmentation of parallax-determination.

Adopting provisionally the frequency-law found in this way by Kapteyn,[1] we can localise all the stars in space down to about the ninth magnitude.

Take, for example, the stars of magnitude 5·5 to 6·5. There are about 4800 of these stars in the whole sky. According to Auwers-Bradley, about $9\frac{1}{2}$ per cent. of these stars, or some 460 in all, have proper motions between 0″·04 and 0″·05. Now, according to Kapteyn's empiric formula, the satisfactory agreement of which with the Yale results has just been shown, the mean parallax of such stars is almost exactly 0″·01. Further, according to his frequency-law, 29 per cent. of the stars have parallaxes between the *mean* value and double the mean value; 6 per cent. have parallaxes between twice and three times the mean value; $1\frac{1}{2}$ per cent. between three and four times the mean value. Therefore of our 460 stars 133 will have parallaxes between 0″·01 and 0″·02, twenty-eight between 0″·02 and 0″·03, seven between 0″·03 and 0″·04, and so on.

Localising in the same way the stars of the sixth magnitude having other proper motions, and then treating the stars of the first magnitude, second magnitude, third magnitude, and so on to the ninth magnitude in the same way, we finally locate all these stars in space.[2]

It is true we have not localised the individual stars, but we know approximately and within certain limits of magnitude the number of stars at each distance from the Sun.

Thus the apparent brightness and the distance being known we have the means of determining the light-energy or absolute *luminosity* of the stars, *provided it can be assumed that light does not suffer any extinction in its passage through interstellar space.*

On this assumption Kapteyn was led to the following results, viz., that within a sphere the radius of which is 560 light-years (a distance which corresponds with that of the average star of the ninth magnitude) there will be found :—

The Density of Stellar Distribution at Different Distances from our Sun.

Consider, lastly, the distribution of stellar density, that is, the number of stars contained in the unit of volume.

We cannot determine *absolute* star-density, because, for example, some of the stars which we know from their measured parallaxes to be comparatively near to us are in themselves so little luminous that if removed to even a few light-years greater distance they would appear fainter than the ninth magnitude, and so fall below the magnitude at which our data at present stop.

But if we assume that intrinsically faint and bright stars are distributed in the same proportion in space, it will be evident that the comparative richness of stars in any part of the system will be the same as the comparative richness of the same part of the system in stars of a particular luminosity. Therefore, as we have already found the arrangement in space of the stars of different degrees of luminosity, and consequently their number at different distances from the Sun, we must also be able to determine their relative density for these different distances.

Kapteyn finds in this way that, starting from the Sun, the star-density (*i.e.*, the number of stars per unit volume of space) is pretty constant until we reach a distance of some 200 light-years. Thence the density gradually diminishes until, at about 2500 light-years, it is only about *one-fifth* of the density in the neighbourhood of the Sun.[1] This conclusion must, however, be regarded as uncertain until we have by independent means been enabled to estimate the absorption of light in its course through interstellar space, and obtained proof that the ratio of intrinsically faint to bright stars is constant throughout the universe.

Thus far Kapteyn's researches deal with the stellar universe as a whole; the results, therefore, represent only the *mean* conditions of the system. The further development of our knowledge demands a like study applied to the several portions of the universe separately. This will require much more extensive material than we at present possess.

As a first further approximation the investigation will have to be applied separately to the Milky Way and the parts of the sky of higher galactic latitude. The velocity and direction of the Sun's motion in space may certainly be treated as constants for many centuries to come, and these constants may be separately determined from groups of stars of various regions, various magnitudes, various proper motions, and various spectral types. If these constants as thus separately determined are different, the differences which are not attributable to errors of observation must be due to a common velocity or direction of motion of the group or class of star to which the Sun's velocity or direction is referred. Thus, for example, the Sun's velocity as determined by spectroscopic observations of motion in the line of sight appears to be sensibly smaller than that derived from fainter stars. The explanation appears to be that certain of the brighter stars form part of a cluster or group of which the Sun is a member, and these stars tend to some extent to travel together. For these researches the existing material, especially that of the determination of velocities in the line of sight, is far too scanty.

Kapteyn has found that stars the proper motions of which exceed $0''{\cdot}05$ are not more numerous in the Milky Way than in other parts of the sky;[2] in other words, if only the stars having proper motions of $0''{\cdot}05$ or upwards were mapped there would be no aggregation of stars showing the existence of a Milky Way.

The proper motions of stars of the second spectral type are, as a rule, considerably larger than those of the first type; but Kapteyn comes to the conclusion that this difference does not mean a real difference of velocity, but only that the second-type stars have a smaller luminosity, the mean difference between the two types amounting to $2\frac{1}{2}$ magnitudes.[1]

The Future Course of Research.

In the last Address delivered from this Chair on an astronomical subject, Sir William Huggins, in 1891, dealt so fully with the chemistry of the stars that it seemed fitting on the present occasion to consider more especially the problem of their motion and distribution in space, as it is in this direction that the most striking advances in our knowledge have recently been made. It is true that since 1891 great advances have also been made in our detailed knowledge of the chemistry of the Sun and stars. The methods of astro-spectrography have been greatly improved, the precision of the determination of motion in the line of sight greatly enhanced, and many discoveries made of those close double stars, ordinarily termed spectroscopic doubles, the study of which seems destined to throw illustrative light upon the probable history of the development of systems from the original nebular condition to that of more permanent systems.

But the limitations of available time prevent me from entering more fully into this tempting field, more especially as it seems desirable, in the light of what has been said, to indicate the directions in which some of the astronomical work of the future may be most properly systematised. There are two aspects from which this question may be viewed. The first is the more or less immediate extension of knowledge or discovery; the second the fulfilment of our duty, as astronomers, to future generations. These two aspects should never be entirely separated. The first, as it opens out new vistas of research and improved methods of work, must often serve as a guide to the objects of the second. But the second is to the astronomer the supreme duty, viz., to secure for future generations those data the value of which grows by time.

As the result of the Congress of Astronomers held at Paris in 1887 some sixteen of the principal observatories in the world are engaged, as is well known, in the laborious task, not only of photographing the heavens, but of measuring these photographs and publishing the *relative* positions of the stars on the plates down to the eleventh magnitude. A century hence this great work will have to be repeated, and then, if we of the present day have done our duty thoroughly, our successors will have the data for an infinitely more complete and thorough discussion of the motions of the sidereal system than any that can be attempted to-day. But there is still needed the accurate meridian observation of some eight or ten stars on each photographic plate, so as to permit the conversion of the *relative* star-places on the plate into *absolute* star-places in the heavens. It is true that some of the astronomers have already made these observations for the reference stars of the zones which they have undertaken. But this seems to be hardly enough. In order to coordinate these zones, as well as to give an accuracy to the *absolute* positions of the reference stars corresponding with that of the *relative* positions, it is desirable that this should be done for *all* the reference stars in the sky by several observatories. The observations of well-distributed stars by Kustner at Bonn present an admirable instance of the manner in which the work should be done. Several observatories in each hemisphere should devote themselves to this work, employing the same or other equally efficient means for the elimination of sources of systematic error depending on magnitude, &c., and it is of far more importance that we should have, say, two or three observations of each star at three different observatories than two or three times as many observations of each star made at a single observatory.

The southern cannot boast of a richness of instrumental and personal equipment comparable with that of the northern hemisphere, and consequently one welcomes with enthusiasm the proposal on the part of the Carnegie Institute to establish a meridian observatory in a suitable

[1] *Ibid.*, April, 1892.

situation in the southern hemisphere. Such an observatory, energetically worked, with due attention to all necessary precautions for the exclusion of systematic errors, would conduce more than anything else to remedy in some degree that want of balance of astronomical effort in the two hemispheres to which allusion has already been made. But in designing the programme of the work it should be borne in mind that the proper duty of the meridian instrument in the present day is no longer to determine the positions of all stars down to a given order of magnitude, but to determine the positions of stars which are geometrically best situated and of the most suitable magnitude for measurement on photographic plates, and to connect these with the fundamental stars. For this purpose the working list of such an observatory should include only the fundamental stars and the stars which have been used as reference stars for the photographic plates.

Such a task undertaken by the Carnegie Observatory, by the Cape, and if possible by another observatory in the southern hemisphere, and by three observatories in the northern, would be regarded by astronomers of the future as the most valuable contribution that could be made to astronomy of the present day. Taken in conjunction with the astrographic survey of the heavens now so far advanced, it is an opportunity that if lost can never be made good; a work that would grow in value year by year as time rolls on, and one that would ever be remembered with gratitude by the astronomers of the future.

But for the solution of the riddle of the universe much more is required. Besides the proper motions, which would be derived from the data just described, we need for an ideal solution to know the velocity in the line of sight, the parallax, the magnitude, and the spectrum-type of every star.

The broad distinction between these latter data and the determination of proper motion is this, that whereas the observations for proper motion increase in value as the square of their age, those for velocity in the line of sight, parallax, magnitude, and type of spectrum may, for the broader purposes of cosmical research, be made at any time without loss of value. We should therefore be most careful not to sacrifice the interests of the future by immediate neglect of the former for the latter lines of research. The point is that those observatories which undertake this meridian work should set about it with the least possible delay, and prosecute the programme to the end with all possible zeal. Three observatories in each hemisphere should be sufficient; the quality of the work should be of the best, and quality should not be sacrificed for speed of work.

But the sole prosecution of routine labour, however high the ultimate object, would hardly be a healthy condition for the astronomy of the immediate future. The sense of progress is essential to healthy growth, the desire to know must in some measure be gratified. We have to test the work that we have done in order to be sure that we are working on the right lines, and new facts, new discoveries, are the best incentives to work.

For these reasons Kapteyn, in consultation with his colleagues in different parts of the world, has proposed a scheme of research which is designed to afford within a comparatively limited time a great augmentation of our knowledge. The principle on which his programme is based is that adequate data as to the proper motions, parallaxes, magnitudes, and the type of spectrum of stars situated in limited but symmetrically distributed areas of the sky, will suffice to determine many of the broader facts of the constitution of the universe. His proposals and methods are known to astronomers and need not therefore be here repeated. In all respects save one these proposals are practical and adequate, and the required cooperation may be said to be already secured—the exception is that of the determination of motion in the line of sight.

All present experience goes to show that there is no known satisfactory method of determining radial velocity of stars by wholesale methods, but that such velocities must be determined star by star. For the fainter stars huge telescopes and spectroscopes of comparatively low dispersion must be employed. On this account there is great need in both hemispheres of a huge reflecting telescope—six to eight feet in aperture—devoted almost exclusively to this research. Such a telescope is already in preparation at Mount Wilson, in America, for use in the northern hemisphere. Let us hope that Prof. Pickering's appeal for a large reflector to be mounted in the southern hemisphere will meet with an adequate response, and that it will be devoted there to this all-important work.

Conclusion.

The ancient philosophers were confident in the adequacy of their intellectual powers alone to determine the laws of human thought and regulate the actions of their fellow men, and they did not hesitate to employ the same unsupported means for the solution of the riddle of the universe. Every school of philosophy was agreed that some object which they could see was a fixed centre of the universe, and the battle was fought as to what that centre was. The absence of facts, their entire ignorance of methods of exact measurement, did not daunt them, and the question furnished them a subject of dispute and fruitless occupation for twenty-five centuries.

But astronomers now recognise that Bradley's meridian observations at Greenwich, made only 150 years ago, have contributed more to the advancement of sidereal astronomy than all the speculations of preceding centuries. They have learned the lesson that human knowledge in the slowly developing phenomena of sidereal astronomy must be content to progress by the accumulating labours of successive generations of men; that progress will be measured for generations yet to come more by the amount of honest, well-directed, and systematically discussed observation than by the most brilliant speculation; and that, in observation, concentrated systematic effort on a special thoughtfully selected problem will be of more avail than the most brilliant but disconnected work.

By these means we shall learn more and more of the wonders that surround us, and recognise our limitations when measurement and facts fail us.

Huggins's spectroscope has shown that many nebulæ are not stars at all; that many well-condensed nebulæ, as well as vast patches of nebulous light in the sky, are but inchoate masses of luminous gas. Evidence upon evidence has accumulated to show that such nebulæ consist of the matter out of which stars (*i.e.*, suns) have been and are being evolved. The different types of star spectra form such a complete and gradual sequence (from simple spectra resembling those of nebulæ onwards through types of gradually increasing complexity) as to suggest that we have before us, written in the cryptograms of these spectra, the complete story of the evolution of suns from the inchoate nebula onwards to the most active sun (like our own), and then downward to the almost heatless and invisible ball. The period during which human life has existed on our globe is probably too short—even if our first parents had begun the work—to afford observational proof of such a cycle of change in any particular star; but the fact of such evolution, with the evidence before us, can hardly be doubted. I most fully believe that, when the modifications of terrestrial spectra under sufficiently varied conditions of temperature, pressure, and environment have been further studied, this conclusion will be greatly strengthened. But in this study we must have regard also to the spectra of the stars themselves. The stars are the crucibles of the Creator. There we see matter under conditions of temperature and pressure and environment, the variety of which we cannot hope to emulate in our laboratories, and on a scale of magnitude beside which the proportion of our greatest experiment is less than that of the drop to the ocean. The spectroscopic astronomer has to thank the physicist and the chemist for the foundation of his science, but the time is coming—we almost see it now—when the astronomer will repay the debt by wide-reaching contributions to the very fundamenta of chemical science.

By patient, long-continued labour in the minute sifting of numerical results, the grand discovery has been made that a great part of space, so far as we have visible knowledge of it, is occupied by two majestic streams of stars travelling in opposite directions. Accurate and minute measurement has given us some certain knowledge as to the distances of the stars within a certain limited portion of space, and in the cryptograms of their spectra has been deciphered the amazing truth that the stars of both streams are alike in design, alike in chemical constitution, and alike in process of development.

But whence have come the two vast streams of matter out of which have been evolved these stars that now move through space in such majestic procession?

The hundreds of millions of stars that comprise these streams, are they the sole ponderable occupants of space? However vast may be the system to which they belong, that system itself is but a speck in illimitable space; may it not be but one of millions of such systems that pervade the infinite?

We do not know.

"Canst thou by searching find out God? canst thou find out the Almighty unto perfection?"

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. A. E. H. LOVE, M.A., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

I PROPOSE to use the opportunity afforded by this Address to explain a dynamical theory of the shape of the earth, or, in other words, of the origin of continents and oceans.

The theory which has for more than a century been associated with the phrase "the figure of the earth" is the theory of the shape of the surface of the ocean. Apart from waves and currents, this surface is determined by the condition that there is no up and down upon it. This condition does not mean that the surface is everywhere at the same distance from the centre of the earth, or even that it is everywhere convex, but that a body moving upon it neither rises against, nor falls in the direction of, gravity (modified by the rotation). A surface which has this character is called an equipotential surface, and the surface of the ocean coincides with part of an equipotential surface under gravity modified by the rotation. This particular equipotential surface runs underground beneath the continents. It is named the "geoid." The height of a place above sea-level means its height above the geoid. If we knew the distribution of density of the matter within the earth it would be a mathematical problem to determine the form of the geoid. As we do not know this distribution we have recourse to an indirect means of investigation, and the chief instrument of research is the pendulum. The time of vibration of a pendulum varies with the place where it is swung, and from the observed times we deduce the values of gravity at the various places, and it was shown many years ago by Stokes that the shape of the geoid can be inferred from the variation of gravity over the surface.

The question to which I wish to invite your attention is a different one. If the ocean could be dried up, the earth would still have a shape. What shape would it be? Why should the earth have that shape rather than some other? In order to describe the shape we may imagine that we try to make a model of it. If we could begin with a model of the geoid we should have to attach additional material over the parts representing land and to remove some material over the parts representing sea. Our model would have to be as big as a battleship if the elevations and depressions were to be as much as 3 or 4 inches. In thinking out the construction of such a model we could not fail to be impressed by certain general features of the distribution of continent and ocean, and we may examine a map to discover such features. Fig. 1 is a rough map of the world drawn in such a way that to every degree of latitude or of longitude there corresponds the same distance on the map. Certain very prominent features have often been remarked: the tapering of America and Africa towards the south, the disproportion between the land areas of the northern and southern hemispheres, the excess of the oceanic area above the continental area, which occupies but little more than one-quarter of the surface; the wide extent of the Pacific Ocean, which with the adjoining parts of the Southern Ocean covers nearly two-fifths of the surface. Another prominent feature is the antipodal position of continent and ocean. South America south of an irregular line which runs from a point near Lake Titicaca to Buenos Ayres is antipodal to a portion of Asia which lies in an irregular triangle with corners near Bangkok, Kiaochau, and Lake Baikal; but no other considerable parts of the continental system have continental antipodes. The Antarctic continent is antipodal to the Arctic Ocean, Australia is antipodal to the central Atlantic, and so on. Another notable feature is the skew position of South America to the east of North America; South America lies to the east of the meridian 85° west of Greenwich; most of North America lies to the west of it. But although we may observe prominent general features of the distribution, we should find it far from easy to attribute to the form of our imaginary model any-

Fig. 1.

thing that could be called a regular geometrical figure. When we begin to think about the removal of material from the parts of the model which are to represent oceans and seas, we require a map which gives information about the depth of the sea in different places. Around all the coasts there is a margin of not very deep water. If some part of the sea could be dried up, so that more land was exposed around all the coasts, the area of the surface of the sea would be diminished; and it is known that the depth of water that would have to be removed in order to make the area of the sea just half the total area is about 1400 fathoms. The contour-line at this depth would divide the surface into two regions of approximately equal area—the continental region and the oceanic region. Fig. 2 represents the contour-line at 1400 fathoms, or the

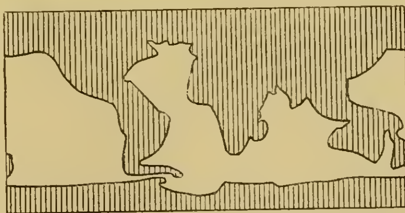

Fig. 2.

line of separation of the continental and oceanic regions. The continental region is shaded. In drawing this map I have omitted a number of small islands, and I have also omitted a few enclosed patches of deep water. Two of these are in the Mediterranean, one in the Arctic Ocean, and others are in the Gulf of Mexico and the Caribbean Sea. The Red Sea, the Mediterranean, and the Arctic Ocean belong to the continental region, and so do the Gulf of Mexico and the Caribbean Sea. At this depth Asia and North America are joined across Behring's Strait, and Europe is joined to North America across the British Isles, Iceland, and Greenland; Australia is joined to Asia through Borneo and New Guinea, and the Australasian continental region nearly reaches the Antarctic region by way of New Zealand. At this depth also South America does not taper to the south, but spreads out, and is separated from the Antarctic region by a very narrow channel. By going down to great depths our problem is very much simplified. We find that the surface of the earth can be divided into continental and oceanic regions of approximately equal area by a curve which approaches a regular geometrical shape. By smoothing away the irregularities we obtain the curve shown in Fig. 3, which exhibits the surface as divided up into a continuous continental region and two oceanic regions—the basin of the Pacific Ocean and the basin of the Atlantic and Indian Oceans. We may take our problem to be this: to account on dynamical grounds for the separation of the surface into a continental region and two oceanic regions which are approximately of this shape.

The key of the problem was put into our hands four years ago by Jeans in his theory of gravitational instability. If there are any differences of density in different parts of a gravitating body, the denser parts attract with a greater force than the rarer parts, and thus more and more of the mass tends to be drawn towards the parts where the density is in excess, and away from the parts where it is in defect. In every gravitating system there is a tendency to instability. In a body of planetary dimensions this tendency, if it were not checked, would result in a concentration of the mass either towards the centre or towards some other part. But concentration of the mass means compression of the material, and it cannot proceed very far without being checked by the resistance which the material offers to compression. There ensues a sort of competition between two agencies: gravitation, making for instability, and the elastic resistance to compression, making for stability. Such competing agencies are familiar in other questions concerning the stability of deformable bodies. A long thin bar set up on end tends to bend under its own weight. A steel knitting-needle a foot long can stand up; a piece of thin paper of the same length would bend over. In order that a body may be stable in an assigned configuration there must be some relation between the forces which make for instability, the size of the body, and the resistance which it offers to changes of size and shape. In the case of a gravitating planet we may inquire how small its resistance to compression must be in order that it may be unstable, and, further, in respect of what types of displacement the instability would manifest itself. If we assign the constitution of the planet, the inquiry becomes a definite mathematical problem. The greatest difficulty in the problem arises from the enormous stresses which are developed within such a body as the earth by the mutual gravitation of its parts. The earth is in a state which is described technically as a state of "initial stress." In the ordinary theory of the mechanics of deformable bodies a body is taken to be strained or deformed when there is any stress in it, and the strain is taken to be porportional to the stress. This method amounts to measuring the strain or deformation from an ideal state of zero stress. If the ideal state is unattainable without rupture or permanent set or overstrain, the body is in a state of initial stress. The commonest example is a golf ball made of india-rubber tightly wound at a high tension. Now the problem of gravitational instability can be solved for a planet of the size of the earth on the suppositions that the density is uniform and the initial stress is hydrostatic pressure. If the resistance to compression is sufficiently small the body is unstable, both as regards concentration of mass towards the centre and as regards displacements by which the density is increased in one hemisphere and diminished in the other. A planetary body of sufficiently small resistance to compression could not exist in the form of a homogeneous sphere. It could exist in a state in which the surface is very nearly spherical, and the mass is arranged in a continuous series of nearly spherical thin sheets, each of constant density; but these sheets would not be concentric. They would be crowded together towards one side and spaced out on the opposite side somewhat in the manner shown in Fig. 4. The effect would be a displacement of the centre of gravity away from the centre of figure towards the side where the sheets are crowded together. How small must the resistance to compression be in order that this state may be assumed by the body instead of a homogeneous state? The answer is that, if the body has the same size and mass as the earth, the material must be as compressible as granite. Granite, as we know it at the earth's surface, is not a typically compressible material. A cube of granite 10 feet every way could be compressed from its volume of 1000 cubic feet to a volume of 999 cubic feet by pressure applied to every part of its surface; but according to the recent measurements of Adams and Coker the pressure would have to be rather more than two tons per square inch. A homogeneous sphere of the same size and mass as the earth, made of a material as nearly incompressible as granite, could not exist; it would be gravitationally unstable. The body would take up some such state of aggregation as that illustrated in Fig. 4, and its centre of gravity would have an eccentric position.

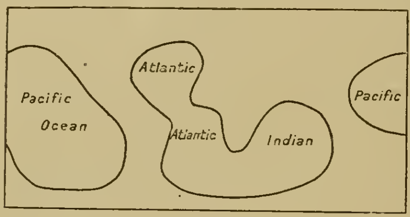

Fig.3

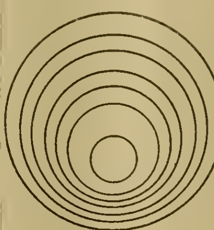

Fig.4.

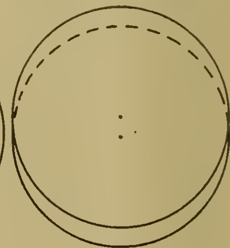

Fig.5.

Now how would an ocean rest on a gravitating sphere of which the centre of gravity does not coincide with the centre of figure? Its surface would be a sphere with its centre at the centre of gravity (Fig. 5). The oceanic region would be on one side of the sphere and the continental region on the other side. It was pointed out many years ago by Pratt that the existence of the Pacific Ocean shows that the centre of gravity of the earth does not coincide with the centre of figure. There is no necessity to invoke some great catastrophe to account for the existence of the Pacific Ocean, or to think of it as a kind of pit or scar on the surface of the earth. The Pacific Ocean resembles nothing so much as a drop of water adhering to a greasy shot. The force that keeps the drop in position is surface tension. The force that keeps the Pacific Ocean on one side of the earth is gravity, directed more towards the centre of gravity than the centre of figure. An adequate cause for the eccentric position of the centre of gravity is found in the necessary state of aggregation which the earth must have had if at one time it was as compressible as granite. The theory of gravitational instability accounts for the existence of the Pacific Ocean.

But we can go much further than this in the direction of accounting for the continental and oceanic regions. We keep in mind the eccentric position of the centre of gravity, and try to discover the effect of rotation upon a planet of which the centre of gravity does not coincide with the centre of figure. The shape of a rotating planet must be nearly an oblate spheroid; but the figure of the ocean would, owing to its greater mobility, be rather more protuberant at the equator than the figure of the planet on which it rests. The primary effect of the rotation of the earth upon the distribution of continent and ocean is to draw the ocean towards the equator, so as to tend to expose the Arctic and Antarctic regions. We have seen that both Arctic and Antarctic are parts of the continental region. But there is an important secondary effect. Under the influence of the rotation the parts of greater density tend to recede further from the axis than the parts of less density. If the density is greater in one hemispheroid than in the other, so that the position of the centre of gravity is eccentric, the effect must be to produce a sort of furrowed surface; and the amount of elevation and depression so produced can be described by an exact mathematical formula. It has been proved that this formula is a sort of expression which mathematicians name a spherical harmonic of the third degree.

The shape of the earth is also influenced by another circumstance. We know that at one time the moon was much nearer to the earth than it is now, and that the two bodies once rotated about their common centre of gravity almost as a single rigid system. The month was nearly as short as the day, and the moon was nearly fixed in the sky. The earth must then have been drawn out towards the moon, so that its surface was more nearly an ellipsoid with three unequal axes than it is now. The primary effect of the ellipsoidal condition upon the distribution of continent and ocean would be to raise the surface above the ocean near the opposite extremities of the greatest diameter of the equator. But, again, owing to the eccentric position of the centre of gravity, there would be an important secondary effect. The gravitational attraction of an ellipsoid differs from that of a sphere, and it may be represented as the attraction of a sphere together with an additional attraction. If the density was greater in one hemi-ellipsoid than in the other, the additional attraction would produce a greater effect in the parts where the density was in excess, and the result, just as in the case of rotation, would be a furrowing of the surface. It has been proved that the formula for this furrowing also is expressed by a spherical harmonic of the third degree.

We are brought to the theory of spherical harmonics and the spherical harmonic analysis. Spherical harmonics are certain quantities which vary in a regular fashion over the surface of a sphere, becoming positive in some parts and negative in others. I spoke just now of making a model of a nearly spherical surface by removing material from some parts and heaping it up on others. Spherical harmonics specify standard patterns of deformation of spheres. For instance, we might remove material over one hemisphere down to the surface of an equal but not concentric sphere (*cf.* Fig. 5) and heap up the material over the other hemisphere. We should produce a sphere equal to the original but in a new position. The formula for the thickness of the material removed or added is a spherical harmonic of the first degree. It specifies the simplest standard pattern of deformation. Again, we might remove material from some parts of our model and heap it up on other parts so as to convert the sphere into an ellipsoid. The formula for the thickness of that which is removed or added is a spherical harmonic of the second degree. Deformation of a sphere into an ellipsoid is the second standard pattern of deformation. The mathematical method of determining the appropriate series of standard patterns is the theory of spherical harmonics. Its importance arises from the result that any pattern whatever can be reached by first making the deformation according to the first pattern, then going on to make the deformation according to the second pattern, and so on. If we begin with a pattern, for instance the shape of the earth, which is not a standard pattern, we can find out how great a deformation of each standard pattern must be made in order to reproduce the prescribed pattern. The method of doing this is the method of spherical harmonic analysis. Except in very simple cases the application of it involves rather tedious computations. With much kind assistance and encouragement from Prof. Turner, I made a rough spherical harmonic analysis of the earth's surface. I divided the surface into 2592 small areas, rather smaller on the average than Great Britain. I gave them the value +1, or one unit of elevation, if they are above the sea, and the value −1, or one unit of depression, if they are below the 1400-fathom line. To the intermediate areas I gave the value 0. The distribution of the numbers over the surface was analysed for spherical harmonics of the first, second, and third degrees.

Any spherical harmonic of the first degree gives us a division of the surface into two hemispheres—one elevated, the other depressed. The spherical harmonic analysis informs us as to the position of the great circle which separates the two hemispheres, and also as to the ratio of the maximum elevation of this pattern to the maximum elevation of any other pattern. The central region of greatest elevation of this pattern is found to be in the neighbourhood of the Crimea, and the region of elevation

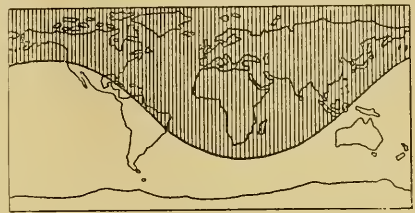

Fig. 6.

contains the Arctic Ocean and the northern and central parts of the Atlantic, Europe, Africa, Asia, most of North America, and a small part of South America. When the surface is mapped on a rectangle in the same way as before, the chart of the harmonic is that shown in Fig 6.[1] The actual disproportion between the amounts of continental area in the northern and southern hemispheres is associated with the result that the central region of elevation, as given by the analysis, is about 45° north of the equator; and the extension of the Pacific Ocean and adjoining Southern Ocean to much higher southern than northern latitudes is associated with the corresponding position of the central region of greatest depression about 45° south of the equator. In regard to harmonics of the second degree, the spherical harmonic analysis informs us as to the ellipticity of the equator and the obliquity of

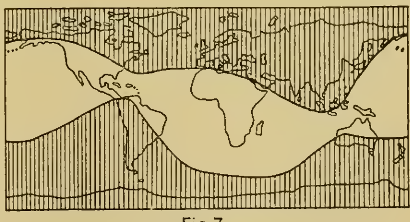

Fig. 7.

the principal planes of that ellipsoid which most nearly represents the elevation of the surface above or its depression below the surface of the ocean, or the geoid. The result is an equatorial region of depression, which spreads north and south unequally in different parts and forms a sort of immense Mediterranean, containing two great basins, and separating a northern region of elevation from a southern. The northern region of elevation occupies the northern part of the Atlantic Ocean and runs down to and across the equator in the neighbourhood of Borneo. The southern region of elevation occupies the southern part of the Pacific Ocean, and it runs up to and across the equator in the neighbourhood of Peru. The chart of the harmonic is shown in Fig. 7. The equatorial regions

[1] In this figure, and in the following figures, regions of elevation are shaded, and regions of depression are left blank.

of elevation given by the analysis are near the ends of a diameter, as we should expect.

It has not been necessary to enter into a minute description of the harmonics of the first and second degrees, because they represent very simple things—a shifting of the surface to one side and a distortion of it into an ellipsoid. The harmonics of the third degree are not so familiar. There are essentially four of them, each specifying a standard pattern of deformation. The first of these, the zonal harmonic, gives us a division of the surface into two polar caps and two zones by means of the equator and the parallels of latitude about 51° north and 51° south. Alternate zones are depressed and elevated, as shown in Fig. 8. The existence of an Antarctic continent and an Arctic Ocean is specially associated with the presence of this harmonic, and the disproportion of the continental areas in the northern and southern hemispheres is also connected with it. The second of the harmonics of the third degree, the tesseral harmonic of rank 1, gives us a division of the surface into six half-zones by means of a complete meridian circle and the parallels of latitude about 27° north and 27° south. Alternate half-zones are depressed and elevated as shown in Fig. 9. The combined effect represented by the zonal harmonic and the tesseral harmonic of rank 1 is a furrowed surface with an Arctic region of depression extending southwards in the direction of the Atlantic, a zone of elevation which runs across the Atlantic, South America, and Africa, and then turns northwards at either end, a zone of depression with the same kind of contour, and an Antarctic region of elevation which extends northwards in the direction of Australasia. These regions are shown in Fig. 10. I have recorded the result

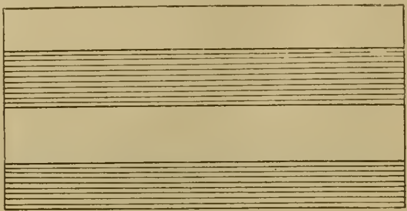

Fig. 8.

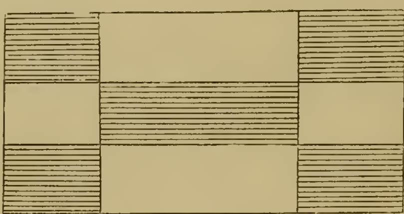

Fig. 9.

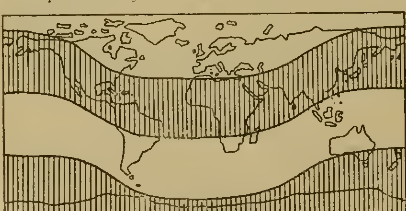

Fig. 10.

of combining these two harmonics because they represent the particular effects that would be produced by the interaction of two causes—the rotation, and the eccentric position of the centre of gravity. The third type of harmonics of the third degree, the tesseral harmonic of rank 2, gives us a division of the surface into octants by means of the equator and two complete meridian circles. Alternate octants are elevated and depressed as shown in Fig. 11. We can name the octants where there is elevation: Asia, Australasia, North America, South America. The harmonic of this type is certainly prominent. It is specially associated with the skew position of South America to the east of North America. The fourth type of harmonics of the third degree, the sectorial harmonic, gives us a division of the surface into six sectors by means of three complete meridian circles. Alternate sectors are depressed and elevated as shown in Fig. 12. The southward tapering of Africa is specially associated with the harmonic of this type. The combined effect of all the harmonics of the third degree is shown in Fig. 13. It represents the sphere deformed into a sort of irregular pear-shaped surface. The stalk of the pear is in the southern part of Australia and contains Australasia and the Antarctic continent. This is surrounded on all sides but one (towards South America) by a zone of depression, the waist of the pear. This, again, is surrounded on all sides but one (towards Japan) by a zone of elevation, the protuberant part of the pear; and finally we find the nose of the pear in the central Atlantic between the Madeiras and the Bermudas. I do not, however, wish to emphasise the resemblance of the surface to a pear or any other fruit, but prefer to describe it as an harmonic spheroid of the third degree. Another

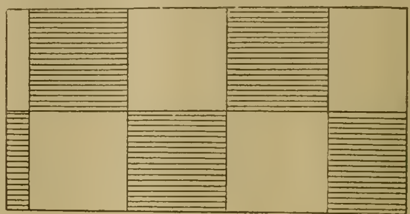

Fig. 11.

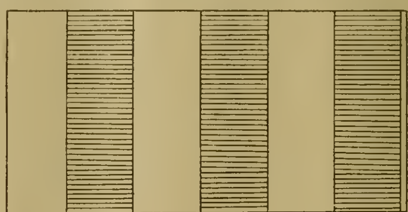

Fig. 12.

Fig. 13.

way of regarding it would be as a surface with ridges and furrows. From a place in the South Atlantic there run three ridges: one north-westwards across America, a second north-eastwards across Africa and Asia, and the third southwards over the Antarctic continent, continuing northwards across Australia nearly to Japan. From the Sea of Okhotsk there run three furrows: one south-westwards across Japan, the Malay Peninsula, and the Indian Ocean; a second south-eastwards across the Pacific; and the third northwards over the Arctic Ocean, continuing southwards by way of the Atlantic. Harmonics of the first and third degrees have in common the character of giving depression at the antipodes of elevation; the harmonics of the second degree give depression at the antipodes of depression and elevation at the antipodes of elevation. The maxima of the harmonics of the first and third degrees are found to be rather greater than the maximum of the harmonic of the second degree. Of three quantities to be added together the two larger ones agree in giving depression at the antipodes of elevation; a result which is in accordance with the fact that most continents have oceanic antipodes.

When we superpose the effects represented by all the various harmonics of the first, second, and third degrees, so as to make, as it were, a composite photograph of all the various elevations and depressions represented by them severally, each in its appropriate amount as determined by the harmonic analysis, we find the curve shown in Fig. 14 as the theoretical curve of separation between regions of elevation and depression which are approximately equal in area. I showed before a smoothed curve (Fig. 3) which I proposed to take as representing the facts to be

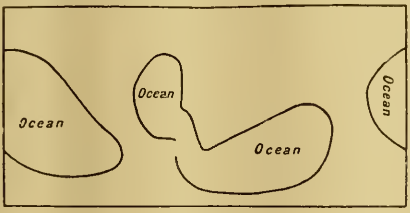

Fig. 14.

accounted for. The resemblance of the two curves seems to be striking. Incidentally it has been noticed how the prominent features of the distribution of continent and ocean are associated with the presence of various harmonics. As regards the contour of the great ocean basins, we seem to be justified in saying that the earth is approximately an oblate spheroid, but more nearly an ellipsoid with three unequal axes, having its surface furrowed according to the formula for a certain spherical harmonic of the third degree, and displaced relatively to the geoid towards the direction of the Crimea.

As regards the amount of elevation and depression in different parts, the agreement of the theory with the facts is not so good. The computed elevation is too small in Southern Africa, Brazil, and the southern part of South America, too great in the Arctic regions, to the south of of Australasia, and in the Mediterranean region. There are many reasons why we could not expect the agreement to be very good. One is the roughness of the method of harmonic analysis that was used. But there is also the fact that many causes must have contributed to the shaping of our actual continents and oceans besides those which have been taken into account in the theory. It appears, however, that the broad general features of the distribution of continent and ocean can be regarded as the consequences of simple causes of a dynamical character: eccentric position of the centre of gravity, arising from a past state of inadequate resistance to compression, an inherited tendency, so to speak, to an ellipsoidal figure, associated with the attraction of the moon in a bygone age, the rotation, and the interactions of these various causes.

In attempting to estimate the bearing of the theory on geological history we must be guided by two considerations. The first is that the earth is not now gravitationally unstable. From observations of the propagation of earthquake shocks to great distances, we can determine the average resistance to compression, and we find that this resistance is now sufficiently great to keep in check any tendency to gravitational instability. The eccentric position of the centre of gravity must be regarded as a survival from a past state in which the resistance to compression was not nearly so great as it is now. The second guiding consideration is that, according to the theory, the inequalities which are expressed by spherical harmonics of the third degree are secondary effects due to the interaction of the causes which give rise to inequalities expressed by harmonics of the first and second degrees. We should expect, therefore, that the inequalities of the third degree would be much smaller than those of the first and second degrees; but the harmonic analysis shows that the three inequalities are entirely comparable. We must conclude that the harmonics of the first and second degrees which we can now discover by the analysis are survivals from a past state, in which such inequalities were relatively more important than they are now. Both these considerations point in the same direction, and they lead us to infer that certain sæcular changes may have taken place in the past, and may still be going on. Sixty-nine years ago Charles Darwin wrote: "The form of the fluid surface of the nucleus of the earth is subject to some change the cause of which is entirely unknown, and the effect of which is slow, intermittent, but irresistible." Forty-two years later Sir George Darwin showed that any ellipsoidal inequality in the figure must be gradually destroyed by an irreversible action of the same nature as internal friction or viscosity. The same may be said of a state in which the centre of gravity does not coincide with the centre of figure when the resistance to compression is great enough to keep in check the tendency to gravitational instability. The state would be changed gradually in such a way as to bring the centre of gravity nearer to the centre of figure. A symptom of such changes might be the occurrence of great subsidences in the neighbourhood of the Crimea, where we found the maximum of the first harmonic. Such subsidences are supposed by geologists to have taken place in rather recent times. Symptoms of the diminution of the inequalities expressed by harmonics of the second degree would be found in the gradual disappearance of seas forming part of the great depression which was described above as a sort of immense Mediterranean (*cf.* Fig. 7), in the destruction and inundation of a continent in the northern Atlantic and in a gradual increase of depth of the Southern Pacific. The disappearance of seas from a vast region surrounding the present Mediterranean basin, and containing the Sahara and Southern Asia as far east as the Himalayas, is one of the best ascertained facts in geological history; and the belief in the destruction of a north Atlantic continent is confidently entertained. In parts of the Southern Pacific a depression represented by harmonics of the third degree is superposed upon an elevation represented by harmonics of the second degree, and we should therefore expect to find the depth of the ocean to be increasing gradually in this region. The region in question is that of the coral reefs and coral islands, such as Funafuti, and the result is in accord with Darwin's theory of the formation of coral reefs. So far as the general distribution of the mass within the earth is concerned, the reduction of the inequalities of the first and second degrees would seem to have already proceeded very far; for we are assured by geodesists that harmonics of the first degree, and those of the second degree which do not represent the effect of the rotation, are far from prominent in the figure of the geoid—much less prominent than we found them to be in the distribution of continent and ocean. We infer that the inequalities of the first and second degrees must have been progressively diminished in comparison with those of the third degree. The general result of such changes would be a gradual diminution of the depths and extents of the oceans which correspond with the harmonics of the first and second degrees, and a compensating increase in the depths and extents of the oceans which correspond with the harmonic of the third degree. To see the character of the changes which would thus be brought about, we may examine a figure which shows the composite elevations and depressions that are represented by harmonics of the first and second degrees, and, separately, those which are represented by harmonics of the third degree. In Fig. 15 the composite elevations of the first and second degrees are shaded vertically, and the elevations of the third degree are shaded horizontally. The deep parts of the Atlantic that border the coasts everywhere from Brazil to Ashanti are regions in which a depression represented by the third harmonic is superposed upon an elevation represented by the other two harmonics, and the same is true of the deep parts of the Indian Ocean which border the shores of Africa and Asia from Madagascar to Burmah. The deep parts of the Pacific that border the western coast of America from Alaska to Chile are regions in which an elevation represented by the third harmonic is superposed upon a depression represented by the other harmonics. These observations suggest that in the greater part of the Atlantic and the northern and western parts of the Indian Ocean the direction of sæcular change may have been that of an advance of the ocean to encroach upon the continental region, while in the Pacific Ocean on the American side the direction of sæcular change may have been that of a retreat of the ocean, permitting an extension of the continental region. This difference would lead us to expect different types of coast in the two regions, and such a difference has been observed. Whereas in the Atlantic region, with few exceptions, the coast cuts across the directions of the mountain chains, in the Pacific region on the American side the coast generally corresponds

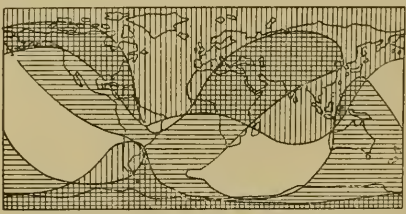

Fig. 15.

in direction with the neighbouring mountain chains of the continent. The deep parts of the Pacific which are nearest to the Asiatic coast from Kamchatka to Siam are regions where a moderate depression represented by the third harmonic is superposed upon a moderate elevation represented by the other harmonics. These shores of the Pacific are distinguished by the wide margin which separates the deep ocean from the coast of the continent. It might perhaps be desirable to recognise in this region a type of coast differing from the two main types associated with the Atlantic and the American side of the Pacific. The analysis does not represent South Africa or the southern parts of South America sufficiently well to warrant us in expecting these regions to exhibit one type rather than the other; but the way in which Australia is represented, as an elevation of the third degree superposed upon a depression of the first, suggests that the coasts of Australia, and especially the eastern coast where the elevation in question is greater, should be of the same type as the American shores of the Pacific; and it is the fact that the mountain chains of Queensland and New South Wales run parallel to the neighbouring coasts. There seems therefore to be much evidence to support the view that the direction of sæcular change has been that of diminishing the prominence of the inequalities of the first and second degrees in comparison with those of the third degree. The process by which such changes would be brought about would be of the nature of relief of strain, expressing itself in occasional fractures of no very great magnitude; and such fractures would be manifested at the surface as earthquakes. Seismic and volcanic activities constitute the mechanism of the process of change. These activities are spasmodic and irregular, but the effect of them is cumulative. For this reason they tend in the course of ages to transform the shape of the earth from one definite type to another. The diminishing speed of the earth's rotation is another cause of change which appears to produce an alternating rather than a cumulative effect. On the one hand it tends to diminish that tendency, which we noted above, to draw the waters of the ocean towards equatorial regions; on the other hand it must result in an actual reduction of the equatorial protuberance of the earth's figure. This reduction can only be effected by seismic activity expressed by subsidences in equatorial regions. The effect which would in this way be produced in the distribution of continent and ocean would appear to be that there would be long periods in which the ocean would tend to advance towards the Arctic and Antarctic regions, interrupted by shorter periods in which it would tend to retreat towards the neighbourhood of the equator.

The theory which I have tried to explain is a tentative one, and further investigation may prove it to be untenable; but it is to its credit that, besides tracing to dynamical causes the existing distribution of continent and ocean, it offers an explanation of the difference between the Atlantic and Pacific types of coast, it gives indications of a possible account of those alternations of sea and land which first led to the study of geology, and it suggests an origin for Charles Darwin's unknown force the operation of which is slow and intermittent, but irresistible.

NOTES.

Next year's meeting of the British Medical Association will be held at Sheffield under the presidency of Mr. Simeon Snell. This year's meeting is at present in progress at Exeter. On Tuesday last the president, Dr. Henry Davy, delivered his address, taking as his subject "Science in its Application to National Health."

The *Nimrod*, in which Mr. E. H. Shackleton's expedition will proceed to the Antarctic regions, sailed from the Thames on July 30 with Lieut. Rupert England in command. Lord Kelvin has presented to the expedition a standard compass and sounding instruments. The Admiralty is lending a compass, chronometers, charts, and sounding apparatus, as well as three Lloyd-Creak Dip instruments for the landing party. Watches are being supplied by the Royal Geographical Society, and, in addition, the vessel will be equipped with a liquid steering compass and a special pole compass. The members of the expedition on board the *Nimrod* are Mr. James Murray, the biologist of the expedition; Mr. W. A. Michell, surgeon and zoologist; and Mr. A. F. Mackay, the junior surgeon of the landing party, who will also engage in zoological work. At Lyttelton, New Zealand, the remaining members of the expedition will join the ship. These include, besides Mr. Shackleton, Mr. E. Marshall, senior surgeon of the shore party and cartographer of the expedition; Lieut. Adams, R.N.R., who will be in charge of the meteorological work; and Sir Philip Brocklehurst, for survey work and field geology. Dr. David, professor of geology in Sydney University, has arranged to accompany the expedition south to King Edward VII. Land.

The weather still continues very cool for the time of year, but on the whole the conditions lately have been somewhat dry. At Greenwich there has been no year since 1888 with so few warm days in July, and the thermometer has not once touched 80°. The total rainfall for the month is less than an inch, whilst the average for the past sixty years in July is 2·40 inches. The aggregate rainfall for the first eight weeks of summer, to July 27, is less than the average in the north-east, east, and south of England, and in the Channel Islands, but in every other district of the United Kingdom it is in excess of the normal. The greatest excess for the summer is 2·42 inches, in the north-west of England, whilst the greatest deficiency is 1·17 inches, in the east of England, the measurements being respectively 7·21 inches and 2·88 inches, and the rainy days respectively forty-one and twenty-six. Both the temperature and the sunshine for the summer have, so far, been below the average.

The experiments which have been in progress in the Congo State for some time past in training the African elephant for domestic work are progressing satisfactorily. During the first three months of the present year, eight young elephants were captured, bringing the stud up to a total of thirty. At first the wild elephants suffer in health on confinement, but this depression soon passes off. Similar experiments are being made in the British territory of Uganda, but so far the results there are uncertain.

As illustrating further the want of sympathy with scientific research shown by the Indian administrative authorities, to which Prof. Ronald Ross, F.R.S., directed attention in an exhaustive article contributed to our issue of June 13, an Indian correspondent writes concerning the rules of the India Office regulating the supply of apparatus to Government colleges. According to these rules, our correspondent states, any piece of apparatus of European manufacture—costing more than 3*l.* 7*s.*—can only be obtained by requisitioning through the Secretary of State. Requisitions are prepared once a year, and, as a rule, eighteen months elapse between writing a demand and the arrival of the apparatus. It is nearly impossible to foresee everything that may be required during the prosecution of a research, and it happens sometimes that a man of science must wait three years for necessary material. The reasonable contention is made that professors in India should be permitted to spend their laboratory funds themselves and to deal with manufacturers direct. It is surely not taking too much for granted to suppose that men in responsible positions, who presumably have been selected for their posts with great care, may be trusted to administer their funds honestly and to the best advantage of the institutions with which they are connected. The system of having to requisition scientific instruments and materials a year or more in advance is not confined to India, and it is both discouraging to scientific work and wasteful in practice.

It is interesting to find that the traditional date assigned to one of the great cycles of national legend is confirmed by independent evidence, and this in the case of the oldest existing literature of any of the peoples who dwelt to the north of the Alps. According to the native annals of Ireland, the Celtic heroes, Conchobar and Cuchulainn, flourished about the beginning of the Christian era, and though some authorities have supposed Cuchulainn to be a degraded Celtic god, there can be no reasonable doubt that he and his uncle lived and fought on earth. This traditional date is supported by the fact, already well recognised by scholars, that, though the poems were at a later date modified by their ecclesiastical transcribers, their spirit is essentially pagan. Prof. Ridgeway, in a paper recently submitted to the British Academy, has approached the problem from the point of view of the archæologist. From an elaborate investigation of the ethnology of this heroic race, their methods of fighting, their use of chariots—unknown to the later Ossianic poems—their arms and armour, and their dress and jewellery, as described in the Cuchulainn Epic, he is able by a comparison of remains of the La Tène period discovered in Ireland to decide that this cycle of culture is here represented; that, as is asserted in the Irish traditions, a tall, fair-haired, grey-eyed race of Celts, like those of Britain and the Continent, invaded Ireland in the centuries immediately before the birth of Christ, and that the poems themselves took shape when the La Tène form of culture was still flourishing in the country, which can hardly have been much later than 100 A.D. The evidence of tradition and archæology thus happily combines to establish the date of this important Saga literature.

According to the report of the Northumberland Sea-fisheries Committee for the past year, the prospects of the fisheries under its supervision are very satisfactory, the marked falling-off in the products of trawling, which has been so noticeable for many years, having at length given place to a distinct upward tendency. It was discovered some time ago that an extensive migration from the south of female crabs takes place during winter, and it is now ascertained that a similar state of affairs exists in the case of flounders, which travel when fully adult into Scotch waters. Means for extending the mussel-beds of the district have been carefully sought, but at present with no great success. The main reasons for the unsatisfactory state of the mussel-supply appear to be the crowded condition of some of the beds, the action of storms on others, and the destruction caused by whelks and starfishes.

Judging from the report for 1906, the Zoological Gardens at Giza, near Cairo, enjoy great popularity among native Egyptians, the number of visitors showing an increase of twenty-five per cent. on the previous year, which was itself a record season. At the close of last year the gardens contained a remarkably fine collection of African big game animals, inclusive of six Sudani elephants, nine beisa oryx, three addax, and three kudu.

The skeleton of a wonderful new horned rodent, *Epigaulus hatcheri*, from the Miocene of Kansas, is described by Mr. J. W. Gidley in the Proceedings of the U.S. National Museum, No. 1554 (pp. 627–636). The total length of the mounted skeleton in a straight line is about 14 inches. From the allied Ceratogaulus, the genus differs by the larger and more backwardly directed horns, the reduced molars, and larger premolars. Although presenting some resemblances to the beavers and squirrels, it appears to be most nearly related to the sewellels (Haplodontidæ). The paper concludes with speculations as to what possible use horns can be to a burrowing animal.

The porcupines of the Malay Peninsula and Archipelago form the subject of a paper by Mr. M. W. Lyon in the Proceedings of the U.S. National Museum, No. 1552 (vol. xxxii., pp. 575–594), in which the generic grouping is revised and several new forms are described. For the large Malay and Java porcupines, commonly known as *Hystrix brachyura* and *H. javanica*, F. Cuvier's genus Acanthion is reinstated. These porcupines differ from the typical Hystrix by the absence of a nuchal crest, the shorter quills, and much shorter nasal bones in the skull, which extend backwards only so far as the line of the lachrymals, instead of to the hind root of the zygomatic arch. A new species from Sumatra is made the type of a separate genus, as *Thecurus sumatrae*, differing from Acanthion by the smaller capsule-like extremities of the tail-bristles, often closed at the end, and the smaller quills, which are replaced on the lower part of the rump by grooved spines like those on the back. The remaining species are referred, as before, to the genera Atherura (or Atherurus) and Trichys.

From Prof. H. F. Osborn we have received copies of a number of papers published in the Bulletin of the American Museum of Natural History, *Science*, &c., from which the following are selected for notice. In vol. xxii., art. 13, of the first-named serial is described the milk-dentition of the hyracoid from the Egyptian Eocene known as Saghatherium, the teeth at that age serving to confirm previous conclusions as to the systematic position of the genus. A restoration of the skeleton and external form of the remarkable Permian reptile Naosaurus forms the subject of vol. xxiii., art. 14. The enormous neural spines of the dorsal vertebræ, armed with transverse spikes, are considered to have supported a sail-like expansion of skin, but no reference is made to the probable object of this structure; the creature measured about 8½ feet in length. A magnificent skeleton of the Columbian mammoth (*Elephas columbi*), discovered in Indiana in 1903, and now mounted in the American Museum of Natural History, is described in art. 12; the tusks are remarkable for their great curvature and the crossing of the tips. The extinct mammals of Patagonia, and American exploration in the vertebrate beds of the Fayum Eocene, form the subjects of two of Prof. Osborn's contributions to *Science*.

IN referring to a scientific expedition sent out by the University of Colorado to study the natural history of the north-eastern part of the State, it is mentioned that, owing to the diversity of climatic conditions, the flora of Colorado is only exceeded in numbers by the flora of the State of California, and possibly of Florida. The object of the expedition was to collect plants, birds, and fossils. Leguminous plants, notably *Psoralea tenuiflora* and species of Astragalus, were prolific in the dry localities. Varieties of Populus known as cotton wood were abundant along the streams. Details appear in vol. iv., No. 3, of the University of Colorado Studies, where Mr. F. Ramaley contributes a second article on the silva of Colorado, treating of the species of Populus.

AN official notice which has been issued by the Inspector-General of Forests in India, intimating that the series of Forest Bulletins initiated in 1905 will be superseded by two publications to be known as the Indian Forest Records and Indian Forest Memoirs, furnishes another proof of the recognition by the Government of India of the importance of the department. Similarly to the Records and Memoirs of the Geological Survey of India, the former, that will be issued as material accumulates, will be devoted to short articles, notes, and preliminary announcements; the latter will contain memoirs or monographs, and will also appear irregularly as occasion arises.

THE report for 1906 of the Director of Agriculture in the Federated Malay States has been received. In connection with rice cultivation, experiments have been instituted to test the value of rotation crops. The position of the rubber industry is reviewed, and the opinion is expressed in favour of pushing the manufacture of block rubber, since it approximates more nearly to the smoke-dried Brazilian product. On the subject of soils and the expense incurred by weeding, Mr. Carruthers recommends the cultivation of a suitable leguminous crop, such as *Mimosa rudica*, the sensitive plant, on rubber lands, that would not only increase the nitrogen in the soil, but would also tend to conserve the surface.

DR. J. C. WILLIS contributes a paper to the Annals of the Royal Botanic Gardens, Peradeniya (vol. iv., part i.), on the occurrence and origin of certain endemic plants on Mt. Ritigala in Ceylon and elsewhere, providing in his opinion strong evidence against the theory of the origin of species by natural selection of infinitesimal variations. Comparing a number of allied species, such as *Coleus elongatus*, an endemic on Mt. Ritigala, with *Coleus barbatus*, a plant widely spread through Ceylon and S. India, Dr. Willis controverts the view that the specific characters of the endemic have developed as adaptations by means of infinitesimal variations, and prefers the mutation theory as affording a more feasible explanation.

FRUIT enters largely into the dietary of Americans, and this wholesome practice has been encouraged by the United States Department of Agriculture by means of bulletins indicating the nutritive value of fruit to the consumer and the economic value as a crop to the farmer. A Farmer's Bulletin, No. 293, compiled by Mr. C. T. Langworthy, provides a rational summary of available data on the composition, food value, and place of fruit in the human diet.

A CATALOGUE of the plants of New Zealand, similar to the London catalogue of the British Isles, has been prepared by Mr. T. F. Cheeseman for the Education Department of that dominion. The arrangement is that of the author's recently issued "Manual of the New Zealand Flora"; the indigenous and naturalised plants are grouped separately, and the distribution is broadly indicated.

IN the Journal of the Royal Society of New South Wales (vol. xl.), Mr. R. H. Mathews gives some details of the organisation of the Kurnu tribe in the north-west of New South Wales, of their rules as to sharing food, of the organisation of the Chauan tribe near the north-east border of Western Australia, and of the language of tribes about Alice Springs; he also gives a Loritcha vocabulary and some details as to avenging parties in Victoria. We learn more as to the "blood" divisions of the Kurnu, of which Mr. Mathews was the discoverer; but an actual genealogy of a small tribe thus organised would be of far more value than many explanations, provided totems, phratries, classes, bloods, and shades were duly noted. It might also enable us to discover whether the present irregularity in marriage regulations is of old standing. The class system of the Chauan tribe seems to be aberrant, so far as the form of the names goes; only two show any close relation to those prevailing among the more easterly eight class tribes; the names are arranged by Mr. Mathews on the supposition that matrilineal descent prevails, but this assumption can only be substantiated by the discovery of phratry names for the two groups of class names, and all the phratry names so far recorded indicate that patrilineal descent is the rule in the north. Mr. Mathews has also published a paper on the Australian tribe in the *Zeitschrift für Ethnologie*, 1906, pp. 939–946. His contributions are now so numerous that he would do well to attempt a general review of the facts he has published, which are otherwise not easy to piece together. It is clear from a paper by Mr. Mathews in vol. xxxvii. of the *Mitteilungen* of the Vienna Anthropological Society that he hardly realises the importance of exhaustiveness or of the localisation of his facts; to take one example, the paper professes to deal with Australian ethnography; the shields described are those of south-east Australia, but there is not a hint that the statements are not true of the whole of the continent.

THE great accuracy which has been attained in the measurement of electric current by the current balance at the National Physical Laboratory will in all probability lead to a more extended use of balances depending on the attraction of co-axial solenoids. A valuable series of papers by E. B. Rosa and L. Cohen dealing with the mutual inductance, and therefore attraction, of such circuits, has appeared in the May Bulletin of the Bureau of Standards at Washington. In one of these the various expressions which have been given for the mutual inductance of co-axial solenoids, from that due to Maxwell to the one Mr. A. Russell gave in the April number of the *Philosophical Magazine*, are compared and tested. Unfortunately, none of them appears to be at the same time accurate and easy of numerical calculation, while in one or two of them the authors have detected small errors.

PUBLICATION No. 62 of the Carnegie Institution of Washington consists of an account by Prof. Carl Barus of the work he has done on the condensation of vapour as induced by nuclei and ions. The condensation is effected in a cylindrical glass fog chamber 6 inches in diameter and 18 inches long, by exhaustion into a vacuum chamber through a stop-cock 4 inches in diameter. The coronas produced in transmitted light by the fog are observed through a goniometer. Different gases have been tried as well as different saturating vapours. In all cases there appear to be three types of condensation nuclei, dust particles, transient bodies which when charged are the ions, and lastly, excessively minute and persistent "colloidal" nuclei, on which condensation only takes place at the higher exhaustions. Prof. Barus has not found any daily period in the number of colloidal nuclei present in the atmosphere which could be ascribed to cosmical radiation. In this respect they differ from the ions, which have been shown by Messrs. A. Wood and A. R. Campbell (NATURE, vol. lxxiii., p. 583) to be present to the maximum extent about 9 a.m. and noon, and to reach a minimum about 3 p.m.

DR. E. GRIMSEHL describes in the *Physikalische Zeitschrift* for July 15 a simple apparatus suitable for demonstrating the principal properties of electric oscillations. Condensers of various sizes are formed by placing two sheets of tinfoil between three sheets of ebonite and vulcanising the whole together, leaving metal ears projecting so that each condenser can be hung on two bare wires which form part of the circuit. Variable inductances are made of solenoids of hard copper wire, one end of each being fixed and the other attached to a slide which can move parallel to the axis of the solenoid, so as to vary the length. The spark gap is formed by two aluminium spheres at the ends of two brass screws which pass through opposite sides of an ebonite box. With this apparatus and, for waves in wires, a simple Hertz generator capable of being tuned, almost all the fundamental experiments on electric oscillations can be performed.

THE curious differences of colour exhibited by the thin films of gold produced on the surface of a glass plate near which a gold wire is slowly disintegrating owing to the passage of an electric current through it, have been explained by M. L. Houllevigue in a communication to the Société Française de Physique at the last meeting (July 15). Films which appear blue in transmitted light are composed of a hydride of gold, stable at ordinary temperatures, but unstable above 130° C., when it loses 7 per cent. to 8 per cent. of its weight. Such a film when heated is converted into the more commonly known form, which appears to be identical with beaten gold leaf, and is green in transmitted light. Several other properties of these films find a simple explanation in M. Houllevigue's discovery.

THE Board of Agriculture has issued the ninth part of the memoir descriptive of the South Wales coalfield (Memoirs of the Geological Survey, price 8*d*.). The volume covers fifty pages, and is an explanation of the new series map, sheet 246, which includes West Gower and the country around Pembrey. The report has been drawn up by Dr. A. Strahan, F.R.S., in part from notes by Messrs. B. S. N. Wilkinson, T. C. Cantrill, and E. E. L. Dixon. The dominant feature in the structure of the district is the anticline which throws up the Old Red Sandstone to form Cefn-y-Bryn. The Old Red Sandstone appears under an aspect that was quite unexpected. The red marls that form the lower half of the formation around most of the coalfield are absent in parts of Gower, whilst the conglomerates at the top attain a remarkable development, and Silurian rocks come to the surface as an inlier. The Carboniferous Limestone is well developed. On the coast between Llanelly and Pembrey, the lower part only of the Pennant series is exposed, but the whole of the Lower Coal series probably exists under the estuary of the Loughor. The probable effect of various anticlines and synclines upon the extent of the Coal-measures under that estuary is taken into consideration and illustrated in a map. The only coal seams hitherto worked are those which are developed in the Pennant series in the western part of the South Wales coalfield, and the value of the concealed and unproved coalfield is lessened by the fact that the strata are likely to be highly inclined and much disturbed. The superficial deposits include the Raised Beach, which is so finely exhibited in East Gower, and glacial deposits, both presenting features of great interest.

WE have received the eleventh of a series of bulletins published by the Engineering Experiment Station of the University of Illinois. It deals with the effect of scale on the transmission of heat through locomotive boiler tubes, and has been drawn up by Prof. E. C. Schmidt and Mr. J. M. Snodgrass. Of late years there has been much discussion on the subject, and statements as to the extent to which deposits of scale affect the conductivity of a tube or sheet have been made from time to time, and have differed widely. The results of the authors' tests lead to the following conclusions:—Considering scale of ordinary thickness, say of thicknesses varying up to $\frac{1}{8}$ inch, the loss in heat transmission due to scale may vary in individual cases from insignificant amounts to as much as 10 per cent. or 12 per cent. The loss increases somewhat with the thickness of the scale. The mechanical structure of the scale is of importance equal to or greater than the thickness in producing this loss. Chemical composition, except in so far as it affects the structure of the scale, has no direct influence on its heat-transmitting qualities.

WE have received from Mr. R. Lavachery, a Belgian engineer residing at Chapultepec, Mexico, drawings of an ingenious appliance invented by him for life-saving at sea. It consists of a rifled cannon from which a projectile is fired; to the projectile are attached a cable, an anchor, and a rocket. The mechanism is very simple, and for humanitarian reasons the inventor has not patented it.

BENJAMIN ROBINS, F.R.S., is remembered as the inventor of the ballistic pendulum and as the founder of the modern science of gunnery. As the details of his life and work are not generally known, opportunity is taken by *Engineering* (July 19), in the year of the 200th anniversary of his birth, to give detailed particulars of his career. Though he only lived to the age of forty-four, yet in that time Robins was in turn mathematical tutor, civil engineer, scientific experimenter, political pamphleteer, editor of "Anson's Voyages," and, at last, engineer-in-chief to the

East India Company. He was among the foremost mathematicians of his day, and had his life been prolonged he would undoubtedly have risen to greater fame.

No. 76 of the Publications of the Carnegie Institution contains an account of a series of researches by Prof. Theodore W. Richards, in conjunction with Messrs. W. N. Stull, F. W. Brink, and F. Bonnet, on the compressibility of a large number of the elements. A very ingenious apparatus was devised for making the measurements, and the results obtained show that the compressibility of an element is a periodic function of the atomic weight, and probably associated with the same causes which determine atomic volume and volatility.

The July number of the *Journal of Hygiene* (vii., No. 3) is devoted to reports on plague investigation in India. Further experimental evidence is detailed of the transference of plague through the intermediary of the flea. It is shown that close and continuous contact of plague-infected animals with healthy animals, if fleas are excluded, does not give rise to an epizootic among the latter, and that when fleas are present the epizootic, if it does start, varies in severity and rate of progress according to the season of the year and the number of fleas present. The season in which epizootics were readily produced experimentally, and spread rapidly, corresponds with that of the plague epidemic.

A second edition of vol. iii. of the "Descriptive and Illustrated Catalogue of the Physiological Series of Comparative Anatomy contained in the Museum of the Royal College of Surgeons of England" has been published. The volume is sold by Messrs. Taylor and Francis. It contains descriptions of the specimens in the section comprising the nerves of vertebrates not dealt with in vol. ii., and also those in the section including the organs of special sense.

The eleventh edition, revised, of Mr. W. T. Lynn's "Celestial Motions" has just been published by Messrs. Samuel Bagster and Sons, Ltd. The price of this handy little book of astronomy is 2s. net.

An interesting article, by Mr. E. V. Heward, upon the physical features of Mars, with particular reference to the habitability of the planet, appears in the August number of the *Fortnightly Review*.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in August:—

Aug. 1. 4h. Venus and Jupiter in conjunction. Venus 0° 18′ N.
,, Daniel's comet very near Aldebaran.
2. 12h. 6m. Central transit of Saturn's Satellite Titan.
4. 12h. Vesta in conjunction with the Moon. Vesta 0° 52′ S.
,, 15h. 38m. to 16h. 20m. Occultation of χ^1 Orionis (mag. 4·7).
,, Juno very closely S. of ϕ Virginis (mag. 4·9).
10. 14h. Mercury and Jupiter in conjunction. Mercury 2° 6′ S.
10–13. Epoch of August shooting stars, Radiant 45° + 57°.
11. Uranus 1° S of 28 Sagittarii (mag. 5·6).
14. Daniel's comet near γ Geminorum.
17. 16h. 53m. to 20h. 26m. Transit of Jupiter's Sat. III. (Ganymede).
18. 9h. 51m. Central transit of Saturn's Satellite Titan.
20. 12h. 42m. Minimum of Algol (β Persei).
23. 9h. 31m. Minimum of Algol (β Persei).

Daniel's Comet (1907*d*).—Herr Kritzinger's ephemeris for comet 1907*d* is extended to August 19 in No. 4191 (p. 259, July 23) of the *Astronomische Nachrichten*, and a part of it is given below:—

Ephemeris 12h. (M.T. Berlin).

1907	α (true) h. m.	δ (true) ° ′	log *r*	log Δ	Brightness
Aug. 3	4 50·1	+16 37·5	9·9453	9·8812	13·8
,, 5	5 8·9	+16 57·8			
,, 7	5 27·8	+17 12 0	9·9116	9 8878	15·6
,, 9	5 46·5	+17 20·0			
,, 11	6 4·8	+17 22·0	9·8763	9 9021	17·2
,, 13	6 22·8	+17 18·3			
,, 15	6 40·3	+17 9 3	9·8399	9·9234	18·5
,, 17	6 57·3	+16 55·6			
,, 19	7 13·6	+16 38 0	9·8036	9·9499	19·3

An observation made on July 19 gave corrections of +4s. and +1′·9 to the ephemeris, and on that date the magnitude of the whole comet was recorded as 4·0.

Apparent path of Daniel's Comet (1907*d*). August 1–19, 1907.

From the accompanying chart it will be seen that during the period August 1–19 the comet's apparent path lies between α Tauri and λ Geminorum, its declination varying but by a small amount. On the former date the comet will rise about four hours, and on the latter about three hours, before sunrise.

The Heliomicrometer.—For the purpose of determining the heliographic positions of flocculi on spectroheliograms, quickly and accurately, Prof. Hale has devised an apparatus which he calls the heliomicrometer, and of which he gives a preliminary description in No. 5, vol. xxv., of the *Astrophysical Journal* (p. 293, June).

Briefly, it is a modification of an earlier instrument in which the spectroheliogram was projected on to a bright globe divided by meridians of latitude and longitude, the positions of the flocculi being read off directly from the globe. The angular diameter of the latter as seen from the projecting lens was, essentially, equal to the angular diameter of the sun as seen from the earth.

In the present apparatus, images of the photograph and the globe are viewed with two similar telescopes, the two images being brought into the same eye-piece. Immediately in front of the plate to be measured cross-hairs are mounted, and their intersection may be set on the particular flocculus to be measured by the observer operating from the eye-piece; during this process the bright image of the globe is occulted. The image of the properly adjusted globe is then admitted, and, by means of fine motions—again operated from the eye-piece—the intersection of the central meridian and the equator is brought into coincidence with the intersection of the cross-hairs. The amount that the globe has been rotated in each coordinate is then read off from circles fitted with verniers, and thus the latitude and longitude of the flocculus are obtained directly without any computation.

In testing the heliomicrometer method against that of the ordinary measuring machine, it was found that the results were in good agreement, and that the actual operations occupied the same amount of time, thus saving, with the former, the time taken by the computations from the polar coordinates in the latter.

SEARCH-EPHEMERIDES FOR COMET 1894 IV. (E. SWIFT).—Owing to the possibility of its identity with the lost comet of De Vico, Swift's comet of 1894 is of particular interest.

During its return of February, 1901, it was very unfavourably placed for re-discovery, and was not seen, but in the hope that it may be re-discovered during its present return, Prof. Seares publishes two search-ephemerides in Bulletin No. 12 of the Laws Observatory, University of Missouri. The former is based on elements indicating July 9 as the time of perihelion passage, whereas the second takes July 25; both show that the comet will attain its maximum brightness, as seen from the earth, about the beginning of October. It is of interest to note that the present position of this comet is near to that of comet 1907*d* (Daniel), although there is no possibility of the identity of the two objects.

According to the ephemerides, the position of Swift's comet on August 1·5 (Berlin M.T.) will be (1) 2h. 25·7m., $+12° 31'$, or (2) 1h. 51·7m., $+8° 31'$.

A QUICKLY CHANGING VARIABLE STAR.—A star having the position α=9h. 45m. 39·8s., $\delta = +12° 20'·3$ (1900·0), and situated +12·1s. in R.A. and 1'·9 in dec. from B.D. + 12°.2105, has been found by Mr. Metcalf, of Taunton (Mass.), to change its magnitude from 13·5 to 11·5 in four days. The range of variability is confirmed by the Harvard plates of this region, but the exact period has not yet been ascertained. The designation of this object is 66.1907 Leonis. (*Astronomische Nachrichten*, No. 4191, p. 260, July 23).

THE VARIATION OF THE POLE.—The provisory results obtained by the International Latitude Service during the year 1906·0–1907·0 are published by Prof. Th. Albrecht in No. 4187 of the *Astronomische Nachrichten* (p. 177, June 29). The diagram giving the projected path of the pole from 1899·9 to 1907·0 shows that during the year 1906 a further diminution of the amplitude of the variation from the mean pole took place.

UNIVERSITY REFORM.

THE discussion in the House of Lords on July 24 concerning the present state of the Universities of Oxford and Cambridge serves again to bring prominently before the public the importance of well-equipped universities to the nation. The Bishop of Birmingham asked the Government to appoint a Royal Commission "to inquire into the endowment, government, administration, and teaching of the Universities of Oxford and Cambridge and their constituent colleges, in order to secure the best use of their resources for all classes of the community." The Earl of Crewe announced at the end of the discussion that the Government requires time to consider the question, and that for the present a Commission will not be appointed. The Bishop of Birmingham unerringly exposed many of the weak points in the older universities as they are administered to-day. "The system of prize fellowships as it was established by the last Commission is," he remarked, "a mistake—post-graduate endowments should be used to subsidise either those who are to be teachers or those who are engaged in researches such as are worthy of advanced students." There were, of course, many champions to defend the present condition of things, but both sides expressed themselves as appreciative of the value to the community of higher learning in all departments of knowledge.

It was not sufficiently realised, however, that the existence of generously staffed and handsomely housed universities is ultimately a question of funds. In directing attention in these columns to the recent appeals made by both Oxford and Cambridge for funds, it was pointed out that, until as a nation we are prepared to make sacrifices comparable with those undertaken in Germany, the United States, and other countries, our older universities will continue to be a "playground for the sons of the wealthier classes" in order to secure money which is elsewhere provided by the State. There are many inquiries awaiting a Commission when it is appointed, and among them may well be a comparison of the amounts provided by the State for university work in the great countries of the world. The subjoined summary of the *Times* report of the debate in the House of Lords contains the substance of the Bishop of Birmingham's plea for a Royal Commission, the Bishop of Bristol's remarks relating to it, and the reply made by the Earl of Crewe on behalf of the Government.

The Bishop of Birmingham said, in the course of his remarks, that undoubtedly within the last thirty years immense changes had taken place in the higher education of the country—changes so immense that, unless the University was to fall out of the relation which it ought to hold to the whole education of the country, it was inevitable that reforms should be required. To an even greater extent, a fundamental change in the balance of power in the classes which formed the English nation had taken place. It had always been the honour and the pride of the old universities that they trained the governing classes of the country. The term "governing classes of the country" had, however, received a very wide extension. For example, it included now the working classes. There was a very real desire for the diffusion of higher education, and it was hardly possible to exaggerate the need for permeating those classes which were playing, and were destined to play, so increasingly an important part in the government of the country with the best education which we had to offer. Could not the university be brought into more immediate, direct, and effective relations to all those who really desired to be students and to profit by the best education the country could afford?

There could be no reasonable doubt that at present our ancient universities were allowed to become to an extent altogether beyond what ought to be tolerated a playground for the sons of the wealthier classes. As at present constituted, the universities were to a very large extent not in any serious sense places of study at all. There were a vast number of young men who never in any kind of way attained to the position of students—they never acquired the instinct or the power of getting knowledge out of books. The universities should have far more stringent and effective machinery for getting rid of those who had neither the ability nor the intention of becoming students. If those who had no real intention of becoming students were got rid of, the teachers would have more time for study and for the teaching which more properly belonged to a university; and a great deal more teaching power would be liberated for the system of university extension in the real sense—namely, for the purpose of teaching, not popular audiences, but trained and sifted students in different parts of the country, so that the influence of the university might be extended to those who were hungering and thirsting for that sort of knowledge and training which a university was able to supply.

He supposed it would not be denied that a very large part of the endowments of scholars and exhibitioners at the present time went to those who could in any case be at Oxford or Cambridge. It had been calculated recently that two in five of the scholars of the colleges did not, in fact, need the endowment in order to enable them to go there. He did not think it could be denied that the unlimited belief in open competitive examinations which characterised the last Commission had had effects which the reformers of those days never contemplated. Open competition had not really proved to be competition open to all classes; it had given an immense advantage to those whose parents were in a position to supply them with education of the more expensive kind. As a matter of fact, he expected it would be found that the universities did less now than they did generations ago to provide the crown of the educational ladder of the country. If the universities could get rid of the great body of those who had not the slightest intention of using the university as a place of study, there would be room for the employment of the endowments to do what they would all admit was the highest function of a university—namely, to provide a centre for the educational aspirations and desire for knowledge of the whole country. What they wanted was that the universities should be so re-organised and that their endowments should be so used as that, whatever there was of real intellectual aspiration and real desire for knowledge, should find its home and instruction in Oxford and Cambridge; and that, and nothing else, should be the real object which the universities manifestly existed to serve. As to the use of post-graduate endowments, there seemed to be wide agreement that the system of prize fellowships as it was established by the last Commission was a mistake—that post-graduate endowments should be used to subsidise either those who were to be teachers or those who were engaged in researches such as were worthy of advanced students. In order to redress the balance between the wealth of the colleges and the poverty of the university the principle had been established that the colleges should contribute to the needs of the university. But there was a widespread idea that certain colleges had in recent years grown very wealthy, and that the subsidies from the colleges to the university were in a number of cases very inadequate. If another Commission were appointed, it would be part of the duty of that Commission to inquire into the uses made of the college endowments, as well as the university endowments, and, perhaps, carry further the principle established by the last Commission of contribution from the colleges to the university.

The Bishop of Bristol spoke against the proposal, so far as Cambridge was concerned. He endeavoured to show that Cambridge had adapted itself to modern conditions, and he hoped that, as regarded Cambridge, the Government would not trouble the Commissioners with an inquiry. Last year the endowment of the University of Cambridge from its own property, which it could spend as it would, was half as much again as when he left the University, and it had now reached the large sum of 1965*l.* 6*s.* 4*d.* The quarterly payments from members were 14,500*l.*, fees for degrees 28,000*l.*, and oddments 1000*l.*, which, with 30,300*l.* received from the colleges, made a total receipt of 75,000*l.* or 76,000*l.* There were besides trust funds for various professorships, scholarships, studentships, and prizes. The estates of the colleges provided 220,000*l.*, while fees, rent of rooms, &c., amounted to 90,000*l.* The estate management of that 220,000*l.* cost only 7 per cent., but the management, rates, taxes, improvements, and cost of the national monuments came to 130,000*l.* This left a net amount for all purposes of 180,000*l.* Of this, scholarships absorbed 32,000*l.* It was difficult to imagine that Cambridge could have adapted itself more completely to modern conditions. But if a Commission were issued, it would be received, not only respectfully, but willingly; for a Commission could cut some knots which the University could not, or would not, cut for itself. One of these was the question of Greek. Science students ought to be allowed to pass their examinations without a knowledge of Greek. He suggested a small statutory Commission which would be able to make statutes having the force of law. It should be composed of experts who were not faddists and who had full sympathy for the new as well as full respect for the old. The Government might, perhaps, issue two Commissions, one for Oxford and one for Cambridge. Let them give the Bishop of Birmingham all he asked for; but not one-tenth part was necessary for Cambridge. The Government might well, in grateful recognition of the wonderful manner in which Cambridge had adapted itself, in spite of restricted means, to modern conditions, declare that they would secure to the University an additional 75,000*l.* a year.

In replying on behalf of the Government, the Earl of Crewe said:—There is no doubt that for some time what may be called university reform has been in the air. That is due to a variety of causes. The fields of study have been widely expanded in the manner so fully described by the Bishop of Bristol. Then there has been the upspringing of the new provincial universities with all their consequences; and there has within the last few years been impressed upon the public mind the whole question of university extension and the methods by which the endowments of the universities can in some way be applied for the benefit of those poorer citizens of this country for whom, as has been so truly said, they were originally intended.

The appointment of a Commission is urged upon various grounds. We are told that it is important to deal with the problems of the government and constitution of the universities, and to deal with the problems of study, both as regards the nature of the different studies carried on and what I may call the financial side of the question—such matters as scholarships and prize fellowships. Then, again, it is urged that the relations between each university and its colleges, and between college and college—with special relation, of course, to endowments—demand a close inquiry. We are reminded, too, that it is almost thirty years since the last Commission sat, and that even if the universities desired to reform themselves from within, yet it would not be possible for them to do so without the intervention of a Royal Commission. And it is further pointed out that the very work of the last Commission has in some cases proved to be of an actually hampering nature, and that the errors into which as human beings the commissioners in some cases naturally fell could only be set right by legislation founded on the report of a further Commission. Those are the reasons for which we are told that a Commission ought to be appointed. On the other hand, certain objections have been made, both in the course of the debate and outside. Lord Burghclere specially alluded to the requests which have been made by the Chancellors of both universities publicly for those who have been educated at each respectively to come to their aid. They no doubt bear in mind the fact that if such a movement is to succeed it must be to some extent of a national character, because the old universities cannot make those appeals to local patriotism which have been responded to so freely in the case of the newer universities. I have no doubt, also, that they compare the state of things somewhat sadly with what obtains in the United States, where it is estimated that during the last thirty years 48 millions sterling have been privately subscribed for the benefit of the universities of America. And my noble friend argued that, if we were now to accede to the request for the appointment of a Royal Commission, the flow of money which has come in to some extent, and which, it is hoped, will come in to a greater extent, would be, if not stopped altogether, seriously checked. Then, further, it is urged against the appointment of a Royal Commission that, although it is true that there are certain things in the direction of allowing greater flexibility to colleges and universities which the new Commission might do by undoing what has been done by the last one, still you cannot have any guarantee that the Royal Commission would undertake that duty, and that it might not imitate its predecessor in making very distinct and positive suggestions which would have to be carried out, and some of which might prove, as former ones have proved, to be erroneous and unfortunate. And, again, we have been told that really more time is wanted to watch the effect upon our national life and our education generally of the foundation of the new universities. It is urged that it is only after some experience of their work that we can decide what place Oxford and Cambridge really ought to take in our national life. Everyone will, I think, agree that we do not wish these universities to plunge into a competition of science and technology with such universities as those of Leeds and Birmingham, and consequently we are asked to wait in order to see what the next few years at any rate may bring.

Those are the various opposing views which are set before His Majesty's Government. I may remind the House that the Government, as such, has only had the opportunity of considering this matter at all for about ten days, and we certainly do feel that the appointment of a Royal Commission, like other important events in life, is one which is not to be undertaken lightly or inadvisedly. We have, as a matter of fact, only what I may call casual evidence of the feeling which actually exists either at Oxford or Cambridge, such intimations as people have been kind enough to send before this debate began, and we have learned very much from what the various speakers in the course of the discussion itself have said. But it is important for us, before arriving at a final conclusion, to know what the most thoughtful and the most competent opinion at both universities really demands, and we also must either inform ourselves or be informed exactly what the universities cannot do of their own motion and for what purposes legislation would be required on the recommendation of a Commission, and we should also desire to be informed as to whether there does exist at the universities anything like a deadweight of obstruction against reforms which is of the character which could only be removed by statute. Consequently, therefore, we desire time to consider this matter in the light of the best information which we can receive, and we look with confidence for help and suggestions as to the best methods of proceeding from those of both universities who are most competent to give it. In the meantime, I am quite confident that this discussion will of itself have done good and have been useful. This is one of the subjects on which, in Carlyle's famous phrase, "if we differ we differ only in opinion." It is merely a question of honest differences of opinion as to what the best way to proceed is in order to do what we all wish to be done; and certainly it does seem to me that the best minds of those who are either at the universities or who are interested in the universities cannot possibly be applied to a higher object than that of putting these ancient homes of learning, which many of us so deeply venerate, with all their splendid traditions, to the fullest possible use, and, where necessary, of bringing them into closer conformity with the needs of the country and with what, in the opinion of those best qualified to judge, is the truest conception of learning as it should exist to-day.

ARCHÆOLOGICAL EXPLORATIONS IN CHINESE TURKESTAN.

FURTHER news of Dr. M. A. Stein's archæological explorations in Chinese Turkestan has now been received. After leaving Keriya at the beginning of the winter, he proceeded eastwards 1200 miles along the borders of the Taklamakan desert to the Lop-nor region, where he intended to excavate. On the way he made further investigations at the Rawak Stupa, in the Hanguya Tati, and at the Domoko desert site, where he found remains of the Dandan-Uiliq period, the eighth century A.D. At the desert-site north of Niya, where in 1901 he had discovered the remains of a settlement buried in the third century A.D., renewed excavations brought to light more interesting and important antiquities of the same kind as those discovered in 1901, especially noticeable being the wooden tablets inscribed in Kharoshthi. Among the clay seals of these tablets, impressions from Græco-Roman intagli are the commonest.

Dr. Stein passed the scene of his former work at Endere on his way eastwards, and also made further investigations there. Evidence was now found that this site also was originally occupied in the time of the Indian "Kharoshthi"-using kingdom, and had been abandoned and re-occupied by the Chinese in the seventh century, only to be abandoned again after the Tibetan conquest a century later. During the period of their first abandonment, the Endere settlements were seen as ruins by the great Chinese pilgrim Hiuen-Tsang.

Similarly, the oasis of Cherchen, which Dr. Stein reached after leaving Endere, has undergone various vicissitudes of settlement and desolation, having come into being again only a few years ago, when, after the re-conquest of Turkestan, the Chinese made it a penal station for refractory Turkis and Tibetans. Since Marco Polo's day it had been abandoned, but then it was a flourishing province, which had grown up since the time of Hiuen-Tsang, who had seen but the desolate and uninhabited ruins of what had once been a town, where in 519 A.D. a previous Chinese pilgrim had found a hundred families living. The Taklamakan desert now encroaches, now recedes; now there is plenty of water, now little, and so the southern oases wax and wane and wax and wane again.

Dr. Stein's objective being the Lop-nor region, he passed on beyond Cherchen to Charkhalik, in the Tarim basin, finding various Mohammedan remains on the way. From Charkhalik he marched to Abdal, and thence more than a hundred miles northward into the salt desert, to an ancient site discovered by Dr. Sven Hedin in 1900. As it is only in winter that explorations in these deserts can be conveniently carried on, the rigours of the Central Asian winter had to be faced by Dr. Stein now as in the Taklamakan six years before, and 48° F. of frost, coupled with an icy boreal wind, were the usual weather.

On December 17 Dr. Stein reached the site, and pitched his camp at the base of the ruined stupa of the ancient town. This turned out to be very like Niya, and is of the same date (third century A.D.). Not only were masses of Chinese correspondence of that period found, but also, what was really unexpected, large numbers of Kharoshthi documents, which show that the Indian kingdom of Khotan included, not merely Cherchen, but the distant Lop-nor district in its dominion. The whole, then, of the Tarim basin must have been ruled by the Indian maharajas of Khotan in the third century A.D. This is a new contribution to history.

This eastern extension of the Buddhist kingdom of Khotan, which took its origin from that of Gandhara, explains more and more the close original connection between the hellenised art of India and that of China, and shows how the sculpture and painting styles of Gandhara passed, with their Greek character, which they derived from the influence of the Seleuoid kingdom, easily by way of Turkestan to northern Tibet and so to China and Japan.

The Lop-nor settlement was occupied by the Chinese in order to control the road from Turkestan to Kansu; Sha-chau, the nearest Chinese town, lies 300 miles east of the Lop-nor district.

Among the most important and interesting of Dr. Stein's discoveries have been those made at Miran, an ancient site in the Charkhalik district, which throw light on the connection between Græco-Indian and Chinese art. In the débris mounds of a fort and stupa-shrines he has found this time frescoes in which the influence of classical art is reflected with surprising directness.

"The main paintings, which illustrate scenes of Buddhist legend or worship, are remarkable for clever adaptation of classical forms to Indian subjects and ideas. But even more curious are the figures represented in the elaborate fresco dados. They are so thoroughly Western in conception and treatment that one would expect them rather on the walls of some Roman villa than in Buddhist sanctuaries on the very confines of China. One cycle of youthful figures, in a gracefully-designed decorative setting, represents the varied joys of life—a strange contrast to the desolation which now reigns in the desert around the ruins and, in fact, through almost the whole of this region. Kharoshthi inscriptions, painted by the side of the frescoes, and pieces of silk bearing legends in the same script, indicate the third century A.D. as the approximate period when these shrines were deserted."

From this account the importance of Dr. Stein's further archæological discoveries is evident, and both he and his German imitators in the Turfan district, 200 miles north of the Lop-nor, have added by their work a new chapter to history. We cannot doubt that Dr. Stein has added more to our knowledge by his fortunate expeditions to Turkestan than had he, as he tells us his dearest wish was to do, devoted himself to the exploration of Iranian antiquities in northern Persia. We knew much about Persia, nothing about the ancient Indian kingdom in Chinese Turkestan which Dr. Stein has discovered.

Dr. Stein's minor object, the control of a trigonometrical survey of the northern slopes of the Kuen-lun for the Indian Government, has also been carried out with success by Surveyor Rai Ram Singh. The net of the Indian trigonometrical system has been extended from the headwaters of the Keriya River along the mountain slopes above Surghak and along the chain which Continental geographers call the "Russian," with its peak dubbed "Tsar Liberator," right through to the mountains between Cherchen and Charkhalik. This is a great achievement.

Why, by the way, our Continental friends call this range "the Russian chain" is not quite apparent. Russia is still a long way off, and Japan has rendered it improbable that Russian earth-hunger will ever be able to extend the dominion of the White Tsar, as was once hoped by his subjects, to the borders of Tibet. The "Yellow Tsar," the "Bogdo-khan" in Peking, still rules the lands which his ancestors held two thousand years before St. Petersburg was built, and that his subjects are worthy to administer this dominion is evident from what Dr. Stein tells us of the civilised rule of the Chinese, and of the constant friendliness of the Imperial authorities to his mission and their keen interest in his archæological discoveries. The thanks of Western science are due to the Chinese for their ever-ready help to Dr. Stein, without which his discoveries would have been impossible to achieve.

NEW HIGH VACUUM PUMP.

NO laboratory, either chemical or physical, can be carried on to-day without a vacuum pump of some form or other, and in many laboratories it is essential that the pump shall be capable of producing the very

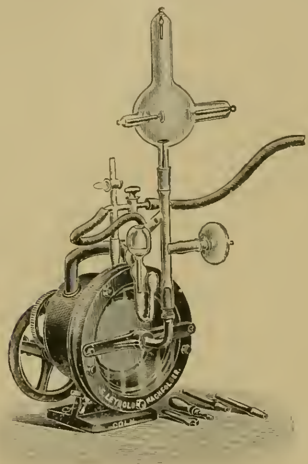

FIG. 1.

highest degree of evacuation. Not only is it necessary to be able to produce a high vacuum, but it is also eminently desirable that it should be possible to produce the state of evacuation as rapidly as possible.

The new high vacuum pump of Dr. Graede, manufactured by E. Leybold's Nachfolger, Cologne, would appear to meet these desiderata. It is claimed that with this pump the highest vacua yet obtainable are secured in a minimum of time. The pump is also simple and compact, and may either be mechanically or hand driven.

The pump which is illustrated in Fig. 1 consists of an iron vessel, half filled with mercury, in which a porcelain drum divided into three chambers rotates. When the drum is rotated the chambers into which it is subdivided are filled alternately with air and mercury. In the first place the chambers suck the air from the receiver, and during further rotation the air is expelled and its place taken by mercury. Fig. 2 shows a section of the pump, one-fourth the actual size. G is the cast-iron casing, which is glazed inside and is cast on to a strong base. The front of the pump consists of a thick plate of glass cemented into the frame P. It is then screwed tightly on to the frame against rubber rings, in order to make an air-tight joint. Three holes are bored into the glass plate, by means of which the two tubes R and R′ and the tap at the bottom are attached. The tube R is connected by means of the glass apparatus, Fig. 3, with the receiver, and R′ with a second pump which serves for preliminary exhaustion. The tap is for introducing mercury into the pump and also for emptying it. The auxiliary pump may be a water injector or any other suitable form of pump which is

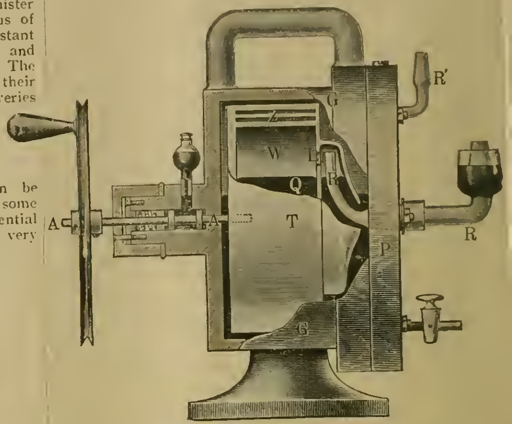

FIG. 2.

capable of giving a vacuum of from 15 to 20 mm. T is the porcelain drum which is attached to the axle A, passing through the casing by means of an air-tight joint, to which is attached the driving wheel.

In using the pump, exhaustion up to 15 to 20 mm.

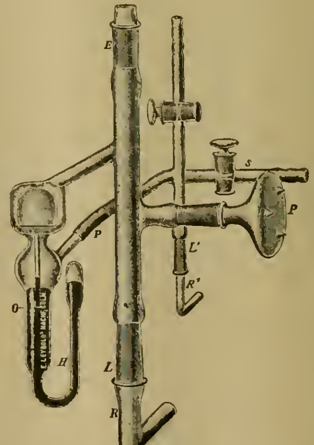

FIG. 3.

is first produced by means of the auxiliary pump; the drum is then slowly rotated in a direction contrary to the hands of a clock. The space W thus increases in size and air is sucked through the opening L. As rotation is continued the opening L passes below the level of the mercury, and the air in the chamber is no longer in connection with the receiver. But as the drum contains three chambers, one of them is always above the mercury; hence the action is continuous. As the chamber revolves W becomes more and more immersed in the mercury, and the air is forced out through the channels Z into the space between the drum and casing, from whence it is removed by the auxiliary pump.

Fig. 3 illustrates the glass attachment, which can be fitted on to the tubes R and R′, Fig. 2, by means of the ground pieces L and L_1. The receiver to be exhausted is attached at E. A manometer H, with a drying chamber P filled with phosphorus pentoxide, is employed to measure the pressure. It also serves as an automatic valve; at atmospheric pressure the orifice O is open; therefore the auxiliary pump connected at S exhausts the receiver fitted at E, directly through the opening O and the connecting tube P. On a vacuum of 20 mm. being attained, the mercury sinks in the right-hand limb, and, rising on the left, closes the opening O as illustrated in the figure; the mercury pump is then started.

Figures are supplied showing the extreme vacuum which can be obtained in a few minutes. Thus in five minutes the MacLeod gauge registered only 0·027 mm., and after fifteen minutes 0·000003 mm. This shows that the pump works extremely rapidly and very efficiently. If it is capable of doing all that is claimed for it, the Gaede pump should prove of great value either for research work or for showing lecture experiments with high vacua.

THE CAUSE OF EARTHQUAKES.

Among the results produced by the San Francisco earthquake of April 18, 1906, must be reckoned a memoir, by Prof. T. J. J. See, covering 140 pages of the Proceedings of the American Philosophical Society (vol. xlv., October–December, 1906), on the cause of earthquakes, mountain formation, and kindred phenomena. The explanation adopted is a development of an old-fashioned idea, and is supported by quotations from the writings of natural philosophers from Aristotle down to Charles Darwin. Earthquakes, with volcanoes and mountain ranges, are all ascribed to the explosive power of steam formed within or just beneath the heated rocks of the earth's crust, chiefly by the leakage of sea water through the ocean beds; the pressure of this steam forces the lava in a lateral direction, and its subsequent condensation leads to the subsidence of the sea bottom often observed after great earthquakes; the lava forced aside may either break out through volcanic vents or may lift the overlying rocks into mountain ranges, and, when the movement is sudden, give rise to faults and fractures which are the result, not the cause, of earthquakes.

It is round these last words, italicised by Prof. See, that criticism naturally centres, and the first consideration which arises is the verbal one of what is an earthquake and what is a cause. An earthquake, as ordinarily understood, is a shaking of the earth, and this shaking is due, wholly in the great majority of cases, and very largely in the remainder, to the molecular movements involved in the transmission of elastic wave motion. In the case of great earthquakes, fractures of the solid rock, accompanied by more or less displacement of the opposite sides of the fissure, are often found, and as the shaking of the earth is greatest near these, and the disturbance is propagated outwards from them, they have been regarded as the cause of earthquakes. In other cases, where no actual fissure is observed at the surface, there is good reason to suppose that the earthquake was caused by an underground fracture, which did not reach the surface, and there can be no doubt that this explanation is adequate in almost, if not quite, every case; but even if the fracture is the immediate cause of the disturbance which is commonly known as an earthquake, the explanation is still incomplete, for we have not reached the cause of the fracture.

It is to this ultimate cause that Prof. See appears to apply the term earthquake, and he is probably right in rejecting the tectonic hypothesis either in the form in which it presents itself to him or in the more ordinary one which regards the fractures as the result of compressional strains, largely due to the secular contraction of the earth, but his explanation fails to account for the remarkable connection between the irregular shifting of the earth's axis and the occurrence of great earthquakes. That these irregular movements of the axis are greatest when large earthquakes are most frequent is a certain, but as yet unexplained, fact; it seems to necessitate displacements of matter in the earth on a far larger scale than is indicated by the differential measurements which alone are open to us. Prof. See's explanation, though it provides for lateral and vertical displacements of matter, necessitates the elevations and depressions being so closely contiguous as practically to neutralise each other's effects, and, therefore, fails as an explanation of the ultimate cause of earthquakes, while it in no way affects the current acceptance of fracture as their immediate cause.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Leeds.—The retirement of Prof. Miall, F.R.S., from the chair of biology, which he has occupied in the Yorkshire College, and subsequently in the University of Leeds, since the year 1876, was recently made the occasion for expressing in a tangible way the esteem and regard in which he is held by his colleagues and friends. A testimonial committee, of which the Vice-Chancellor (Dr. Bodington) was chairman, was formed, and a ready response was obtained to the circular inviting subscriptions for this purpose. Among the testimonials to Prof. Miall which have been thus provided is a portrait by Mr. Frederick Yates, intended to be hung in the hall of the University. The presentation of this portrait was made at a recent meeting in the University library, when a large number of his colleagues and friends were present. The Vice-Chancellor, who presided and made the presentation, spoke in warm and feeling terms of the eminent services which Prof. Miall had rendered to the college and University, as well as to the cause of science, and described him as having been original as a teacher, eminent as a scientific worker, and active as a business colleague. Subsequent speakers included Mr. S. P. Unwin, Dr. Eddison (emeritus professor of the University), and Prof. Smithells. Prof. Miall, in acknowledging the presentation, gave a short historical sketch of the foundation of the Yorkshire College of Science and its development into the Yorkshire College and subsequently into the University of Leeds.

The chair of biology will in future be divided into the professorships of zoology and of botany. To the former has been appointed Dr. Walter Garstang. Prof. Garstang has held research fellowships in zoology at Owens College, Manchester, and subsequently at Lincoln College, Oxford, where he has filled various appointments as lecturer and examiner. He is at present chief naturalist to the Marine Biological Association in charge of the Lowestoft Laboratory.

To the chair of botany Mr. V. H. Blackman has been appointed. Prof. Blackman was sometime fellow of St. John's College; he has held an assistantship in the British Museum, having charge of the collection of fungi, and he is at present engaged in botanical teaching, being a recognised teacher of that subject in the University of London.

In connection with the new department of fuel and metallurgy under Prof. Bone, F.R.S., the Institute of Gas Engineers has established a research fellowship of the value of 100*l.* a year.

The extensions of the University buildings upon which the council is at present engaged comprise:—(1) an extension of the main building in College Road for the better accommodation of biology and of arts teaching; (2) an extension of the civil and mechanical engineering department; (3) the erection of a detached block for the department of electrical engineering; (4) an extension of the cloth finishing department; (5) the completion of the block of buildings for the mining and metallurgical departments. The last-mentioned block will be ready for occupation by the students at the beginning of next session, in October. In addition to these buildings, the University is erecting a new boiler house and lavatories; is proposing to extend the refectory; is adapting a large dwelling house for the purposes of an extension of the geological department, and is uniting the house by means of a bridge at the first-story level with the present geological department of the University; and is adapting other dwelling houses for the use of women students and for seminar work.

THE second International Congress on School Hygiene will be opened on August 5, at the request of the King, by Lord Crewe. The complete success of the meetings seems to be assured. The German Government has not only decided to send delegates to the congress, but, by permission of the Kaiser, Prince Eitel Friedrich has accepted the office of a vice-patron of the congress. While still adhering to its resolution not to issue official invitations to foreign Governments to send delegates, the Board of Education has arranged with the Foreign Office to take such steps as are likely to remove any misunderstanding which might have prevented some foreign delegates from accepting the invitations issued. The meetings will be held at the University of London, and will last until August 10. Sir Lauder Brunton, F.R.S., the president, will deliver the inaugural address on August 5. The sectional meetings will commence on the following day. There are eleven sections in all; their subjects and the name of the president in each case are as follows:—(1) The physiology and psychology of educational methods and work, Sir James Crichton Browne, F.R.S.; (2) medical and hygienic inspection in school, Prof. W. Osler, F.R.S.; (3) the hygiene of the teaching profession, Dr. T. J. Macnamara, M.P.; (4) instruction in hygiene for teachers and scholars, Sir William J. Collins, M.P.; (5) physical education and training in personal hygiene, Sir John W. Byers; (6) out-of-school hygiene, holiday camps and schools: the relation of home and the school, Lord Kinnaird; (7) contagious diseases, ill-health, and other conditions affecting attendance, Sir Shirley F. Murphy; (8) special schools for feeble-minded and exceptional children, Mr. W. H. Dickinson, M.P.; (9) special schools for blind, deaf and dumb children, Lord Crewe; (10) hygiene of residential schools, Dr. Clement Dukes; (11) the school building and its equipment, Mr. T. E. Colcutt. An exhibition of school building and furnishing appliances has been arranged in connection with the congress.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 6.—"On the Two Modes of Condensation of Water Vapour on Glass Surfaces, and on their Analogy with James Thomson's Curve of Transition from Gas to Liquid." By Prof. Fred. T. **Trouton**, F.R.S.

Experiments made with glass wool to determine the amount of water condensed on the surface of glass when in equilibrium with various vapour pressures showed that below a critical pressure, which is about 50 per cent. saturation, there are two distinct modes in which the condensed water can exist.

Thus for the same vapour pressure, if the condensation is in one of these forms, called for convenience the α type, there is much less condensed material present on the surface than in the other form, called the β type; or, to put it in another way, for the same amount of condensed vapour the pressure is greater when the condensation is of the α form than when it is of the β form.

Condensation will take place of the α type if the surface has been thoroughly dried at high temperatures, while of the β type if the drying has only been effected at ordinary temperatures, though in that case also the vapour pressure may be zero.

When the condensation is of the β type the curve, connecting pressure with the amount of condensed water, is found to be very similar to that for wool or cotton, but when the condensation is of the α type the curve is quite different. Thus, starting with the surface very dry, the pressure runs up quickly for relatively little condensation until a critical pressure is reached; after that, on further additions to the surface condensation, the pressure diminishes. This is attributed to a transformation into the β state supervening at this point, when consequently the vapour pressure is in excess of equilibrium, and thus a depletion of the vapour in the surrounding space results, with a corresponding fall in vapour pressure. If moisture be continuously supplied the pressure will, after reaching a maximum, begin to rise, and ultimately pass to saturation.

The analogy with James Thomson's curve of transition from gas to liquid is pointed out. In the one case there is attraction between water-vapour particle and water-vapour particle, in the other between glass and water vapour. The condensation of the α type corresponds to the supersaturated vapour stage in the transition curve, while the β corresponds to its liquid stage.

Where the surface is not completely dry, the fact that the condensation is in the β form, on vapour coming in contact with the surface, is attributed to there being an example of that type already on the surface; but if this is not present, that is, if the surface is desiccated, the condensation is of a type allied to supersaturated vapour rather than to the liquid.

A paradoxical consequence of there being these two modes of condensation is pointed out, namely, that a relatively wet surface is capable of drying one wetter than itself.

As an illustration of the phenomenon a simple experiment is given, in which two dishes of phosphorus pentoxide are placed under a bell jar, with only this difference, that one of the dishes is first made dry by heating. It is then found that the pentoxide which can initially obtain some moisture from contact with the damp dish absorbs the moisture in the bell jar, and ultimately runs liquid, while the other remains dry.

"On the Velocity of Rotation of the Electric Discharge in Gases at Low Pressures in a Radial Magnetic Field." By Prof. H. A. **Wilson**, F.R.S., and G. H. **Martyn**.

The apparatus used in this investigation was a small vacuum tube consisting of two concentric glass tubes cemented into aluminium discs. The discs served as electrodes, and the discharge was passed between them through the annular space between the glass tubes.

An iron bar was fixed along the axis of the vacuum tube, and could be magnetised so as to produce a radial field in the space between the glass tubes.

The discharge was produced by a large secondary battery, and its velocity of rotation round the annular space was measured. The variation of the velocity with the strength of the magnetic field, with the pressure of the gas, and with the current carried by the discharge, was investigated in air, nitrogen, and hydrogen.

The velocity was found to be nearly proportional to the strength of the magnetic field and inversely proportional to the gas pressure. The velocity in hydrogen was about thirteen times the velocity in air or nitrogen.

It is shown that theoretically the velocity should be proportional to the product of the two ionic velocities, and the results obtained, together with previous measurements of the Hall effect, enable the velocities of both the positive and negative ions to be calculated. The negative ions are found to have much higher velocities than the positive ions.

June 13.—"*Miadesmia membranacea*, Bertrand; a New Palæozoic Lycopod with a Seed-like Structure." By Dr. M. **Benson**. Communicated by Dr. D. H. Scott, F.R.S.

The vegetative organs of this interesting new type were discovered by Bertrand in 1894. He found them in sections of a calcite nodule from the Gannister beds of Hough Hill, England. A large quantity of new material has become available, and now not only are more details known as to the vegetative organs, but a fairly complete knowledge of the reproductive organs is possible.

Miadesmia was exceedingly minute, its stem slender and without any trace of skeletal tissue. It is the first Palæozoic Lycopod of herbaceous character known structurally. The megasporophylls, which were identified by Dr. D. H. Scott, F.R.S., in 1901, show a more advanced type of seed habit than has hitherto been met with in Cryptogams. The megasporange gives rise to but one thin-walled spore, which in development and structure resembles an embryo sac and germinates *in situ*. An integument surrounds the sporange, leaving but a small orifice as micropyle. This is surrounded by numerous long processes of the integument, which formed a collecting and incubating apparatus for the microspores. There is no trace of an envelope about the microsporange. The carpellary leaf was shed at maturity, and resembles a winged seed.

Disregarding the structural modifications of the megasporophyll, the nearest affinity of Miadesmia among forms so far known seems to be with the non-specialised species of Selaginella, such as *Selaginella selaginoides*, but the foliage leaves show the archaic leaf-base comparable with that of Lepidodendreæ.

"The Inhibitory Action upon Subsequent Phagocytosis, exerted on Active Normal Serum by Inactive Normal Serum through which Bacilli have been passed." By J. C. G. **Ledingham.** Communicated by Dr. C. J. Martin, F.R.S.

When inactivated normal serum is digested with tubercle bacilli, and finally freed therefrom by the centrifuge, it is found that the supernatant fluid has the property of inhibiting to a great extent the opsonic action of fresh normal serum, not only towards the tubercle bacillus, but also towards the *Staphylococcus pyogenes aureus*. The author interprets the phenomenon thus:—The amboceptors of heated normal serum combine with the tubercle bacilli and also with their free receptors, which remain in the supernatant fluid after removal of the bacilli. When this supernatant fluid containing the "free receptor amboceptor" combination, is added to fresh normal serum, the latter's complement becomes fixed, and consequently in the presence of fresh bacilli, opsonic action is inhibited. The experimental results obtained lend support to the view that the opsonic action of normal serum depends on the cooperation of complement with normal amboceptor.

June 20.—"Preliminary Note on a New Method of Measuring directly the Double Refraction in Strained Glass." By Dr. L. N. G. **Filon.**

If a plane wave of light be passed horizontally through a rectangular slab of glass under flexure in a vertical plane, it is broken up into two components polarised horizontally and vertically.

The light of either component suffers, owing to the stress, an additional retardation proportional to its distance from the "neutral axis," *i.e.* the mid-level of the slab. Thus the wave-front on emergence is no longer vertical, but has suffered a deviation proportional to the bending moment applied. The two components, however, are deviated by different amounts.

If the light be then analysed by a grating, the lines of the spectrum formed will be shifted, in consequence of the change in the angle of incidence. In addition, owing to the different shifts of the two components, each line appears doubled.

Experiment shows that the effect is quite measurable, and provides a new method for measuring directly the doubly refracting effect of stress, giving, not only the difference between the retardations of the two components, but the absolute amounts of each.

With a grating of 14,000 lines to the inch, the maximum separation of the components, for lines in the yellow, was about the distance between the two D-lines.

"On the Origin of the Gases evolved by Mineral Springs." By the Hon. R. J. **Strutt,** F.R.S.

It has long been known that thermal springs, such as those at Bath, give off considerable quantities of gas, which bubbles up with the water, and consists, for the most part, of nitrogen. Of recent years, interest in this subject has been revived by Lord Rayleigh's observation that helium and argon are present along with nitrogen.

It has been found that such gases, when fresh, are rich in radium emanation, and that the deposit thrown down by the water on standing contains a notable quantity of radium. It is natural to connect this observation with the discharge of helium by the springs. The author was formerly inclined to think that the facts were most easily explained by supposing that the supplies of helium and radium were derived from the disintegration of uranium lodes at a great depth by the water, but this view scarcely seems compatible with the universal presence of helium and radium in mineral springs, which has since been brought to light; for uranium lodes are very rare near the earth's surface, and there are fatal objections to supposing that metal to be generally more abundant at greater depths.

The unexpectedly large quantities of radium found in common rocks led the author to suspect that perhaps they might after all be able to supply the helium and radium products, as well as the ordinary gases and saline constituents of the spring. With the view of deciding this question, he has examined the inert portion of the gases given off by several varieties of rock on heating. The subject has attracted some attention from previous experimenters.

The results for two normal rocks were as follows:—

Matopo Granite. Quantity taken, 850 *grams*.

The inert residue consisted of

Nitrogen	11 c.c.
Argon	0·14 c.c.
Helium	0·04 c.c.
Neon	traces

Syenite Rock, Mt. Sorrel, Leicestershire. Quantity taken, 900 *grams*.

Inert residue—

Nitrogen	9 c.c.
Argon	0·026 c.c.
Helium	0·010 c.c.
Neon	traces

In both these cases, the vacuum tube, after removal of argon, gave a brilliant yellow helium glow.

We may compare these analyses with the composition of the Bath gas, as a type of the gases evolved by mineral springs. The total volume of inert gas (mainly nitrogen) is taken as 100.

Gas	Argon Per cent.	Helium Per cent.	Neon
Bath spring	1·5	0·12	traces
Matopo granite	1·27	0·36	traces
Syenite, Mt. Sorrel ...	0·29	0·11	traces

These figures make it fairly clear that there is a general resemblance between the gases of mineral springs and the gases of rocks, so far as nitrogen and the other inert constituents are concerned.

In addition to these constituents, rocks give off hydrogen, carbonic oxide, carbonic acid, and a little methane. The two former are probably secondary products, produced by chemical actions set up on heating. Carbonic acid is represented at the spring by the dissolved carbonates of the mineral water, while methane is present in the evolved gases. The author thinks, therefore, that we may consider that the disintegration and partial solution of ordinary rocks by water at a high temperature accounts for the gaseous, as well as the solid, products, delivered by springs such as those at Bath.

With regard to the primary origin of the argon and neon contained in rocks, the author has no theory to offer. It is natural, however, to associate the helium of rocks with the radium they contain. The relative quantities are quite in accordance with such a view, for the ratio is of the same order as in the strongly radio-active minerals. The author hopes to discuss this subject in detail in a future paper. He has found at least traces of helium in almost all of a considerable collection of ores and other minerals, but hitherto only one case has been found—in certain beryls—where there seems to be sufficient reason to look for any other cause than traces of the radio-active elements to explain its presence. The evidence so far obtained is not favourable to the view that the ionising radiation from ordinary substances is accompanied by production of helium.

June 27.—"On a Standard of Mutual Inductance." By Albert **Campbell.** Communicated by Dr. R. T. Glazebrook, F.R.S.

The author has designed a standard of mutual inductance of such a nature that its value is accurately calculable from the dimensions, and large enough to give good sensitivity in actual use. A high enough value (say 0·01 henry) can be got by having one of the associated circuits a coil of many layers. The objections to such a coil are overcome as follows:—

The primary circuit is a pair of single-layer coils wound on a single marble cylinder; their dimensions can be accurately determined. The secondary is a coil of many layers co-axial with, and midway between, the two primary coils, and of such radius that the mutual inductance is a maximum for change of radius. A series of curves is given from which the proper dimensions were chosen. All round the mean circumference of the secondary coil the magnetic field due to the current in the primary coils is zero, and is very nearly so over the section of the winding, thus allowing accurate calculation. The principle is applicable to other problems involving mutual inductance.

PARIS.

Academy of Sciences, July 22.—M. A. Chauveau in the chair.—A phenomenon resembling the spheroidal state: G. **Lippmann.** A strip of plaster of Paris adhering to a plane surface of glass becomes detached on raising the temperature above 100°, sliding over the surface with the greatest ease.—The effect of oxygen, osmotic pressure, acids, and alkalis in experiments on parthenogenesis: Yves **Delage.** The presence of oxygen is not necessary for the determining of parthenogenesis in starfish—it is even harmful; the presence of divalent ions is not at all essential, a solution of sodium chloride being often sufficient among sea-urchins. The requisite condition of parthenogenesis among certain of the latter consists in the treatment of the eggs by an acid solution, afterwards an alkaline, the first coagulating, the second liquefying certain constituents of the egg protoplasm.—The dielectric cohesion of helium: E. **Bouty.** By repeated purifications, the value of the dielectric constant was found to be reduced from 61·8 to 18·3.—The effect indicated by the electrolytic detector: M. **Tissot.**—A new optical property of magnetic bi-refraction belonging to certain non-colloidal organic liquids: A. **Cotton** and H. **Mouton.** Nitrobenzene shows a magnetic bi-refraction of positive sign, increasing proportionally to the square of the field and the thickness traversed. This property is more or less marked throughout the aromatic series, but not among aliphatic compounds.—The spectrophotography of minerals in different regions of the spectrum; galena and argyrite: A. **de Gramont.**—The coagulation of albumins by the actions of ultra-violet light and radium: Georges **Dreyer** and Olav **Hanssen.** Both serous and egg albumin are coagulated under the action of a prolonged intense light. The serum of the horse is only slightly coagulated by light; a solution of peptone remains clear, though becoming yellow, the same effect being also noticeable with casein. These results are all due to the ultra-violet portion of the light. Radium coagulates vitellin, but apparently no others.—The heats of formation of alkaline protoxides: E. **Rengade.**—A mixed anhydride of sulphuric and nitric acids: Amé **Pictet** and Georges **Karl.** Nitric anhydride dissolves with evolution of heat in freshly distilled liquid sulphuric anhydride. The product distils entirely at 218°–220°, and analysis shows it to have the composition $(SO_3)_4N_2O_5$.—The combination of nickel and cobalt with boron: Binet **du Jassonneix.** Compounds have been obtained of the composition NiBo and CoBo (already described by M. Moissan), Ni_2Bo, Co_2Bo, $NiBo_2$, and $CoBo_2$.—A new silicide of platinum: P. **Lebeau** and A. **Novitzky.** This compound, of the formula SiPt, can be obtained by direct union, is crystallisable, and chemically resembles platinum.—A general method of preparation of anhydrous metallic bromides, with oxides as a starting point: F. **Bourion.** The simultaneous use of sulphur chloride and hydrogen bromide gas provides a convenient means to this end.—The alloys of nickel and tin: Em. **Vigouroux.**—The effect of electric sparking upon a mixture of nitrogen and oxygen at low temperatures: E. **Briner** and E. **Durand.**—Discontinuities observed in the molecular conductivity of dissolved chromium sulphates: Albert **Colson.**—The rotatory power of the proteids extracted from the flour of cereals by aqueous alcohol: M. **Lindet** and L. **Ammann.**—Menthane 1:8-dicarboxylic acid and a new dicyclic ketone: Ph. **Barbier** and V. **Grignard.**—The origin of the deposits of colouring matter in red wine: V. **Martinand.**—Malic acid in wine must, and its destruction in fermentation: W. **Mestrezat.**—The liquefaction by diastase of fecula starch: A. **Fernbach** and J. **Wolff.**—Living reagents and diffusion: Michel **Yégounow.**—A new genus of Sapotaceæ in West Africa, with seeds containing an edible fatty matter: Aug. **Chevalier.** This tree provides a fine red well-veined wood, of density almost equal to unity.—The Pachypodium of Madagascar: MM. **Costantin** and **Bois.**—New researches on the cytology of the seeds of Graminaceæ: A. **Guilliermond.**—The morphological value of the caruncle of *Notopygos labiatus*: A. **Malaquin** and A. **Dehorne.**—The destructive function of the spleen towards trypanosomes: A. **Rodet** and G. **Vallet.** In the case of infection by *Trypanosoma brucei*, the spleen actively destroys the parasites.—The injection of artificial serums: C. **Fleig.** Those containing iron have been used with success in many cases of chlorosis.—The activity of Etna: A. **Riccò.**

CALCUTTA.

Asiatic Society of Bengal, July 3.—Notes on the Pollination of flowers in India. Note No. 4. On cotton in Behar: I. H. **Burkill.** The flowers of *Gossypium neglectum* and *G. intermedium* in Behar are a little visited by insects, chiefly small Hymenoptera of the genera Ceratina and Halictus, which seek honey in vain, and may collect pollen. Longer tongued insects, such as Xylocopa, Anthophora, and a few Lepidoptera only rarely go to the flowers. Plants intermediate between the two species, which are grown mixed, testify to the occurrence of cross-fertilisation; but they are rare, and the very early self-pollination in the flowers shows how much more the cotton crop depends on spontaneous self-fertilisation than on pollination by insects or other external agency.

CONTENTS.

THURSDAY, AUGUST 8, 1907.

RESEARCH IN CHINA.

Research in China. In three volumes and Atlas: vol. i. in 2 parts. Part i. *Descriptive Topography and Geology.* By Bailey Willis, Eliot Blackwelder, and R. H. Sargent. Pp. xiv. + 354 + xvi. (Washington, D.C.; Published by the Carnegie Institution, 1907.)

THE title of this volume recalls the great pioneer work of the illustrious Baron von Richthofen, to whom science is indebted for the first broad and masterly sketch of the physiography and geology of the Celestial Empire. His volumes, unfortunately left still incomplete at the time of his lamented death, form the basis on which all later explorers will build. He indicated some of the great problems which remain to be solved by a more prolonged and minute survey than it was in his own power to achieve. But even where he left questions in doubt, his trained powers of observation sometimes enabled him to see so far into them, and to leave so many pregnant suggestions concerning them, that the paths for subsequent exploration have been indicated by him to his successors.

One of these paths lay in the further investigation of the great series of ancient sedimentary deposits, to which Richthofen gave the name of "Sinisches" (Sinesian or Sinian) system. He collected from what he regarded as the higher parts of this system a number of fossils, which proved the strata containing them to be of Cambrian age. As these sedimentary accumulations appeared to be thousands of feet in thickness, they seemed to offer at least a possibility that, in their lower members, traces might be found of a still older or pre-Cambrian fauna. The great interest which would attach to the discovery of any recognisable remains of that primæval biological period had long drawn the attention of geologists to the desirability of following up the suggestive observations of the German explorer. The opportunity of undertaking this investigation came at last when the Carnegie Institution of Washington was founded in 1902, with ample funds for the purposes of scientific research of every kind in all quarters of the globe. Mr. C. D. Walcott, then the energetic Director of the United States Geological Survey, whose contributions to Cambrian palæontology have given him a worldwide reputation, suggested the sending out of an expedition to China, one of the objects of which should be the further elucidation of the fossil contents of the oldest Palæozoic rocks of the country. He succeeded in planning and organising a scientific mission for the purpose of investigating the stratigraphy, palæontology, structure, and physiography of the regions to be visited. The first grant was made by the Carnegie Institution in the autumn of the year 1902, but it was not until July of the following year that the mission sailed for Europe. The party consisted of two geologists, Mr. Bailey Willis, an active member of the staff of the United States Geological Survey, to whom the chief charge of the expedition was assigned, and Mr. Eliot Blackwelder, of the University of Chicago. They were subsequently joined in China by Mr. R. Harvey Sargent, of the United States Geological Survey, who acted as topographer, and produced the series of maps which forms the Atlas.

The observers reached Pekin late in September, 1903, and spent about two months of the autumn of that year in the geological investigation of certain parts of the province of Shan-tung. The first five and a half months of 1904 were devoted to the exploration of Central China, and the journey of investigation came to an end at I-chang, on the Yangtzi-kiang, on June 9. The time occupied by the research was thus little more than seven months in all. During this brief period the party must have worked hard. Their topographical surveys by graphic plane-table triangulation went on at an average rate of nearly fifty square miles a day, and an area of 2,900 square miles was mapped in fifty-eight days and a half. While the topographer was thus active, the geologists were simultaneously busy with their observations and collections. The results of this combined labour are intended to fill three massive volumes and an atlas of maps. The first part of the first volume which, with the Atlas, has just been issued, forms a bulky quarto of more than 350 pages, with upwards of fifty plates, consisting of photographic views of landscapes, maps, and geological sections. The second part is to include systematic petrography, zoological notes, and a syllabary of Chinese sounds. The second volume is intended "to summarize the detailed presentation of our results, and to combine them with the work of others in a systematic discussion of the geology of south-eastern Asia." The third volume is to be devoted to Palæontology. The Atlas contains some forty sheets of maps, sections, and photographic views, most of the maps being on the scale of 1/125,000, or two miles to the inch, engraved and coloured in the excellent style to which the United States Geological Survey has now accustomed us.

We willingly record our appreciation of the energy, skill, and success with which this expedition has been conducted. But we feel sure that the question will be asked by many not unsympathetic onlookers—were the few months of rapid and necessarily imperfect and incomplete observation sufficient to justify the addition of all these volumes to the ever-growing mass of geological literature? It has long been a characteristic of American geological explorers that they cannot simply describe what they have seen, but must launch out into theoretical disquisitions and systematic discussions, for which there has often been but slender basis in their own work. The various pioneering and other surveys have thus built up a pile of huge quartos, in which the really valuable original observations are often practically buried out of sight. The books are heavy alike for the hand and the head. They take up a large amount of space on library shelves, where they are now, we fear, comparatively seldom consulted.

The volume now before us is a conspicuous illustration of the American habit here referred to. We venture to think that all that was new and important among the results of the expedition might easily have been comprised within the limits of this first single volume. Not content, however, with the space the observers have contrived to fill with the amplification of their notes and discussions of the physiography of the regions which they rapidly traversed, and of which they can have acquired only the most superficial knowledge, Mr. Bailey Willis is yet to inflict upon us another volume of his "detailed presentation of results," besides the other reports that are promised.

If it is asked what have been the chief fruits of this skilfully-planned foray into the Chinese empire, two conspicuous features may be pointed to, on which the explorers deserve to be congratulated. They have materially increased our knowledge of the earliest Palæozoic fauna of China, and they have brought to light a remarkable band of boulder-clay, full of striated stones, lying apparently at the base of the Cambrian system.

The large increase which has thus been made to the known Cambrian fossils of China has been provisionally discussed by Mr. Walcott in a paper published in 1905, in the Proceedings of the United States National Museum, and will be more fully treated in the third volume of the Reports of the Expedition. It appears that at least forty-eight genera and 172 species of organisms are now known to occur in Chinese Cambrian formations, the greater number being assigned by Mr. Walcott to the middle division of the system. The lower division has yielded comparatively few forms, and it does not appear that any trace has been recovered of a fauna older than Cambrian. The trilobitic representation is especially abundant, comprising 118 species, belonging to twenty-five genera. The full details respecting this primæval fauna will be awaited with much interest.

It would appear from the observations of Messrs. Bailey Willis, and Blackwelder that Richthofen perhaps over-estimated the thickness of his "Sinisches System," and that the chances of the recovery of a pre-Cambrian fauna were less than had been hoped for. In Shan-tung the total thickness seems to be little more than 4000 feet, of which only some 1500 or 1600 feet are relegated to the Cambrian system, the overlying strata being referred to the next member of the Geological Record. The lower Cambrian division, consisting of 500 or 600 feet of shales and thin limestones, rests unconformably on a set of gneisses, schists, and granite, with other eruptive rocks. Mr. Blackwelder made a reconnaissance, in the Liau-tung peninsula, nearly along Richthofen's route; but he was unable to add anything of importance to what was noted by the German explorer regarding the Cambrian rocks of that district.

In threading the gorges of the Yang-tzi, the expedition at Nan-t'ou found at the base of the Palæozoic series a remarkable group of sediments resting unconformably on granite-gneiss, and having a total thickness of about 370 feet. Above a conglomerate and a series of red and white sandstones lies a mass of hard green boulder-clay or till, some 200 feet thick, which can be seen to dip under the Ki-sin-ling limestone. No fossils were obtained by the travellers from this boulder-clay, nor after a search for two hours were any found by them in the overlying bands of limestone. But as they disinterred Lower and Middle Cambrian organisms from what they regarded as the same limestone within less than 100 miles from Nan-t'ou, they regard it as highly probable that this ancient boulder-clay is of early Cambrian age.

The stones are subangular, with rounded edges and well-polished and well-striated surfaces. They are of various kinds of rock, and of all sizes up to two feet and a half in length, and they are huddled together without order, as in ordinary boulder-clay. The specimens represented in plate xxxviii. might have been selected as typical examples from any Pleistocene boulder-clay of Europe or America. It is hardly possible to resist the evidence that here is a true glacial deposit which, whether or not intercalated at the very base of the Cambrian system of China, must almost certainly be of early Palæozoic date.

The physiographical discussions in the volume are most unsatisfactory. When one reflects how difficult are the problems of physiographical development, how much patient research is needed into the geological history of a region, how much detailed local topographical knowledge is absolutely essential, and how little, after all, dogmatism on the subject is permissible, one is amazed at the confidence with which the physiography of vast territories is here disposed of. It is not by surveys of fifty square miles a day that these problems are to be solved, and it is matter for regret that such jejune attempts should be made, and should find a place in what ought to be a serious contribution to science.

THE EXPLORATION OF TIBET.

Tibet, the Mysterious. By Sir Thomas Holdich, K.C.M.G., K.C.I.E. Pp. ix+356; illustrated. (London: Alston Rivers, Ltd., 1906.) Price 7s. 6d. net.

"THE public which concerns itself about Tibet is a very small public indeed," says Sir Thomas Holdich in the volume he has compiled for "The Story of Exploration" series, and to this we may add that public interest in that country is not likely to be increased by such unsympathetic treatment as the subject receives in this book. The story of geographical achievement in Tibet, and especially of the attempts to reach the jealously guarded capital of the then closed land, was for many years one of the most fascinating interest, and now in the light of the more precise information that has recently been made available it could well afford re-telling as an instructive record of great daring and tenacity of purpose. In professing to supply such a summary, however, the present account is disappointing in that its information is neither very trustworthy nor up-to-date. The author does not appear to have any personal knowledge of the country, nor has he made himself sufficiently acquainted with what has been written on the subject, with the result that his book betrays frequent inaccuracies, and a lack of clear perspective that is rather bewildering to the reader. The narrative is made up for the most part of quotations from the reports of the more or less illiterate native surveyors, whose accounts, we are here told, although "the best and most important of all the stirring records of that remarkable country, have never yet seen the light"; whereas, as is well known, all those reports which were possessed of sufficient interest, including the best of them, namely, that by A-K, were published many years ago.

The geographical theme is frequently lost sight of altogether under the heaps of irrelevant topics that are dragged in. Indeed, fully one-fifth of the whole book is made up of generous extracts from the pages of Huc, the Lazarist missionary (not "Jesuit"), notwithstanding that our author admits "we do not gain much in the way of geographical information from it"! Relying on such antiquated sources of information, without being careful to check the stories by comparison with the more precise facts of later scientific research, Sir Thomas repeats many of the erroneous statements of the native surveyors as well as the mistaken notions of the older European writers. Thus, to take some instances at random, one would imagine that the author had never heard of the trustworthy work achieved by the British Survey officers of the Lhasa Mission, so generally is it neglected in preference to the less accurate data of the pioneer native surveyors. In this way we have here repeated the gross mistakes of U. G. and Sarat Das in respect to the route from Gyantse onwards to Lhasa. Amongst others, the Yamdok Lake is stated (p. 114) to be 13,900 feet above the sea-level, and at p. 252 to be 13,800 feet instead of the 14,350 feet as given by Major Ryder, while the adjoining Dumo Lake is made to be 500 feet higher than the Yamdok, whereas it is only some three feet higher. Even the elevation of Lhasa is given at 11,600 feet instead of 11,830 feet. So, too, with the map of Lhasa; we are told that A-K's old sketch-map is still "the best map we possess of it"—this is very hard on Major Ryder, who spent several days in the streets of Lhasa surveying and measuring, and plotting out the city in a large detailed map which was published more than two years ago.

The province of Nari, which stands in the extreme north-western corner of Tibet, is strangely enough stated to be in the "*southern* zone" of that country. Darchendo, the great mart for Chinese tea on the eastern border of Tibet, is, he says, "more correctly called 'Ta-chien-lu' in the newer" maps—the fact, however, is rather the other way, as the latter is merely a Chinese corruption of the former, which is the original and current Tibetan name of this important place. In alluding to the Chinese invasion of Nepal, our author goes beyond his authority when he credits Sir Clements Markham with the statement that the Chinese general "Sand Fo" (properly Sund Fô) sacked Kathmandu (which he spells Khatmandu); for Markham does not say that the victorious Chinese even entered the Nepalese capital, from which the battle was fought a day's march distant. So, too, we are informed that Moorcroft (who was really a veterinary surgeon temporarily employed by the East India Company on mule-breeding questions) was "a civilian of the Indian Civil Service."

Elementary facts even as to the position of Lamaism have not been grasped. We read (p. 51) that "Lhasa is the holy of holies, the ark of the covenant to over one-third of the human race." This amusing statement perhaps Sir Thomas did not mean to be taken seriously. For, as pointed out years ago, the Lhasa hierarchy has never been acknowledged by Buddhists outside Tibet, beyond Mongolia and a few of the sparsely populated Himalayan districts. The Buddhists of China, Japan and Corea, Siam, Burma and Ceylon would be astonished were they told that Lhasa, of which few of them have ever heard, was their "holy of holies." That place is sacred only to some five or six million votaries, and not the "400 millions" as here asserted. There are no distinctive page headings, and misspelling is frequent.

It would be pleasant to be able to congratulate the author on the illustrations, but nearly all of these we have seen elsewhere before. They are not very closely connected with the letterpress, nor are the landscapes very characteristic, whilst some of them are not what they profess to be; for out of the ten, at least two are from the Sikkim side of the Himalayas, and not in Tibet at all.

OUR BOOK SHELF.

An Outline of the Natural History of our Shores. By J. Sinel. Pp. xvi+347; illustrated. (London: Swan Sonnenschein and Co., Ltd., 1906.) Price 7*s.* 6*d.*

THIS book has been written "to help to open some of the volumes of this part of Nature's library" by one who, having spent nearly forty years by the sea-shore, has had excellent opportunities of gaining the necessary knowledge at first hand.

Chapters i.–xiii. are devoted to descriptions, more or less short, of the animals which are to be found between tidemarks and in the maritime zone of Jersey, their habits and where to look for them; some account is also given of the chief characters of the various groups, together with descriptions of the anatomy of a few species, and something about the development of others. The author then deals with the various reasons for colour in marine animals, of which he gives instances, together with examples of "mimetic artifices" among the crabs (others are given in the chapter on Crustacea). In the following chapters we are given lists of apparatus, &c., necessary for shore collecting and tow-netting, with the method of use. A number of useful hints are also given on anæsthetising, preserving, and mounting specimens for the museum and other purposes, and also for imbedding, cutting, and staining sections for the microscope. In the last chapter, dealing with the marine aquarium, the beginner is initiated into the, to most inland people at least, difficult art of keeping and feeding the various marine animals which flourish in captivity, and also of hatching and rearing marine larvæ.

Although on the whole good, the book is marred by several inaccurate statements; among others we may mention the following:—Echinoderms have a heart; *Loligo media* is the young of *L. forbesii*; *Galeomma* is the only bivalve which crawls, whilst the author's explanation of the way in which starfish open oysters is certainly not the correct one. Moreover, we cannot agree that the author has followed the nomenclature most generally in use, especially in Pisces and Echinoderms.

In the outfit of the shore collector, the absence of a crowbar is rather surprising, especially on a rocky coast; whilst half an hour for tow netting, in view of the fact that two or three collections are apparently put into the same bottle, is certainly too long.

The illustrations, 123 in number, are mainly derived from photographs, the majority of which show a considerable lack of skill on the part of the photographer. One or two appear to be out of focus, many are too much of the soot and sawdust type; while in others the background chosen is not calculated to show up the "sitter" to the best advantage. Typographical errors, of which there are a fair number, are almost invariably confined to scientific names, such as *Nephtys* for *Nephthys*, Maidæ for Maiadæ, Spangus for *Spatangus*.

In spite of the above faults, we can, however, recommend the book to all beginners in the fascinating art of shore collecting, although, of course, it does not obviate the necessity of access to monographs on the various groups. R. A. T.

Field Operations of the Bureau of Soils, 1904. (Sixth Report.) Pp. 1151 + a case of 53 maps. (Washington: United States Department of Agriculture, 1905.)

THE United States Survey of Soils continues from year to year its enormous task, under the direction of its chief, Mr. Milton Whitney, and the present sixth report differs in no essential respect from its predecessors. The soil divisions are mapped upon a basis of physical texture, the same name being used right across the continent for soils which are judged to be of the same type, however different the origin or however remote the locality from that of the type originally credited with the name. It is just this classification which has been called in question by the critics of the survey in the United States, who discredit both the methods of identification and analysis which are adopted, and also the rapidity with which the work is pushed along. Certainly when the cost of the survey amounts to less than 10*s.* per square mile, as in the present case, the distribution of soils in the United States must be very different from what we are familiar with in the Old World, or else the maps can be little more than very sketchy first approximations. However, we are too far away to have any means of forming a judgment in this domestic discussion, but what the English reader will always find of value in this survey are the preliminary general accounts of the physiography and agricultural development of each area. There we get sketches of the style of farming and the local conditions which compare, though in a more scientific fashion, with the reports on the counties of England initiated by Arthur Young a little more than a hundred years ago. Doubtless in time these reports will have the same permanent value for America as a detailed picture of the state of the country and the position of its chief industry.

Hypnotism and Spiritism—A Critical and Medical Study. By Dr. Joseph Lapponi; translated by Mrs. Philip Gibbs. Pp. xiv + 268. (London: Chapman and Hall, Ltd., 1906.) Price 5*s.* net.

THE opening chapter deals with the historical data connected with hypnotism and spiritism, and the author points out how spiritism passed through the various stages of spirit rapping up to definite materialisation. Dr. Lapponi then describes what is understood by hypnosis, and it is clear that his views are not in accord with those held by most authorities at the present time. When the reader reaches the chapter on "Details about Spiritism," he will find a most vivid description of a *séance*, as given by "some of the best and most esteemed mediums." The author honestly states that he has not had personal experience of the "truth and reality of the marvellous phenomena" which he describes; nevertheless, he is evidently convinced of its actual existence. Dr. Lapponi gives some interesting accounts of the mystic performances of the Indian fakirs, and also records some instances of telepathy.

In discussing the relationship of hypnotism and spiritism, he endeavours to prove that there is little or no relationship between them, a fact which few would dispute; on the other hand, we do not think that the arguments which he adduces would go far towards convincing the sceptic. The author admits that "illusions and hallucinations explain some isolated cases of spiritism"; he also allows that mediums may have largely had recourse to frauds in order to enhance their reputations, and he is generous enough further to concede that "to the spiritistic frauds done voluntarily may be added others, not only involuntary but unconscious"; but even after allowing all these, he considers that there are phenomena which are well authenticated, and for which neither deception, art, nor science can render an account. This may be true, but because a matter is too subtle to unravel does not justify us in assuming that it is the result of spiritism. The author's attempt to account for the valuelessness of spirit revelation is very feeble, but it is left to the closing chapter to reveal the worthlessness of spiritism, for here we read that "spiritism is always dangerous, harmful, immoral, reprehensive, to be condemned and most severely prohibited without reserve, in all its grades, forms, and possible manifestations," except, maybe, in some rare exceptions. Surely, if there are spirits with whom we can confer, some of them should be able to raise us to higher planes of thought, for the spirit world should belong to a hierarchy which is nearer to the perfect.

LETTERS TO THE EDITOR.

Festival of St. Alban.

WITH regard to what is said concerning the date of this festival in the review of the "Life of St. Patrick" in NATURE of July 25 (p. 296), it is to be noted that there is really only one date for the festival. In the time of Bede (H. E., i., 7), as in the pre-Reformation calendars of the English Church, as well as in the Latin Prayer Book of Queen Elizabeth, 1560, the date is June 22. But when the festival reappeared in the English Prayer Book of 1662 it was placed on June 17, an obvious error which is supposed to have arisen from wrongly writing xvii. for xxii. In the Roman calendar the date is, of course, June 22. C. S. TAYLOR.

Banwell Vicarage, July 26.

THE information supplied by the Rev. C. S. Taylor is most welcome. The evidence for regarding the 22nd as an arrested solstitial day, in connection with St. Alban, is now fairly conclusive.

(1) The 22nd was one of the three solstitial days about 303 A.D., the supposed date of Alban's martyrdom.

(2) If closely studied with that fact in view, the legend of his martyrdom, like those of the death of Patrick and Dewi, may reveal a clear midsummer festival setting. That much may be gathered from the statement that Alban was summoned to do sacrifice to the pagan gods. We know from other sources that people were penalised for non-attendance at the great pagan festivals.

(3) There is evidence that St. Alban's festival covered the three solstitial days.

(*a*) One old Welsh calendar fixes the festival on the 23rd.

(b) Though our modern bards call each of the solstitial quarter days an Alban, there is very little authority for such a use of the name. What appears likely is that Alban became a name of the midsummer festival, and that a bardic scribe at first wrongly applied the name to the other quarter days. The Alban of the bards covered three days, and each day is specially named. The first is the Vigil of the Alban, the second is the Alban itself, and the third is the Banquet of the Alban.

(4) Why have the Welsh made so much of the name Alban? The reason may be found in the association of the name with Caerleon-upon-Usk.

(a) There are some ruins near that ancient city still called Mount St. Alban's.

(b) Mr. Wade-Evans has made out a good case for localising Alban's martyrdom at that spot (in "Archæologia Cambrensis," about two years ago).

(c) Geoffrey of Monmouth tells us of a great observatory or school of astronomers in or near that city.

St. Alban's Day being the chief day of the year, and an observatory bearing his name, probably, at Caerleon being apparently the Greenwich of Wales at one time, it is no wonder that the Welsh bards have adopted the name as a solstitial epithet without ever a mention of Alban's martyrdom.

We have in Wales a very modern instance of the same process. In some districts June 22 is observed as Gwyl Barna, the Vigil of Barnabas. St. Barnabas's Day is the 11th, and in the seventeenth century it coincided with the solstice; but since 1752 it has been in those parts associated with the 22nd, and Gwyl Barna is now a name of the solstice. In the neighbourhood of Llandeilo Talybont, Glam., it is the custom of the farm labourers to get together the hay-making implements on the morning of Gwyl Barna, before going to a solstitial fair in the neighbourhood. John Griffith.

Llangynwyd, Glam.

The Sun's Motion with respect to the Æther.

So far as I know, it has not been pointed out that the velocity of light, as deduced from the observed times of occultation of Jupiter's satellites, is affected to the first order by the motion of the earth and Jupiter with respect to the æther. Taking the times best suited to such observations, when the distance between the two planets is very nearly a maximum or a minimum, there will be no appreciable relative velocity in the line of centres, and, to a first approximation, the velocity with which light from Jupiter approaches us is then made up of the true propagation-velocity increased by the common velocity-component of the two planets in the direction earth to Jupiter.

In order to determine the sun's motion with respect to the æther, the values for the apparent velocity of light deducible from the observed times of occultation might be analysed, so as to discover any systematic differences depending on the direction of the line of centres. Only very small corrections would be needed on account of the motion of the planets in their line of centres relatively to the sun. The probable absolute error in the finally deduced velocity of the sun (relatively to the æther) would be of the same order as that affecting the finally deduced velocity of light. The quantity to be determined might perhaps be swamped by the errors of observation, but even so a superior limit could be assigned to the sun's velocity through the æther. Two of the three rectangular components of that velocity being measured in the plane of the ecliptic, the determination of the third component would unfortunately be very badly conditioned. It may be some consolation, however, to reflect that a knowledge of our motion with respect to the æther is not theoretically unattainable.

Again, if the mean æthereal density is either less or greater where atomic matter is present than in free æther, it appears from some results which I have lately obtained in connection with a modified theory of gravitation that motional forces would be experienced (for example) by two bodies moving with uniform translational velocity through the æther. These forces would be proportional to the product of the masses of the two bodies, to the square of the velocity of translation, and inversely to the fourth power of the distance between the bodies. They would be equal in magnitude and opposite in direction, but would not in general act in the same line, so that an elongated body, partaking of the earth's diurnal and orbital motion, would in general be acted on by a couple. This couple would vary as the diurnal motion changed the orientation of the body, and if the variations were measurably great, we should have the means of determining, save for a constant factor and an ambiguity of sign, the velocity of the earth with respect to the æther at any point of its orbit. Observations at three or more points of the orbit would enable us to evaluate the constant factor and to remove the ambiguity of sign, thus determining the velocity of the sun with respect to the æther.

The effects referred to might or might not be detectable, but by means of quite simple apparatus they could be tested for with great delicacy. I hope shortly to publish a fuller account of the analysis on which the above conclusions are based. C. V. Burton.

Cambridge, July 29.

The Dog's Sense of Direction of Sound.

Our dog, Spot, of the intelligence of which an instance has been recorded in Nature, is peculiarly sensitive to sound. The following instance may be worth recording. On Sunday, July 21, a heavy storm of thunder and lightning with rain broke over Wick. I sat in the porch of our house watching—Spot with me. The lightning was frequent, and the thunder played round in all directions—over Bath six miles to the east and Bristol six miles to the south-west.

Spot barked at each clap or rumble and rushed forward, always *towards the direction* from which the thunder appeared to come; the lightning affected him in no way. It was laughable when the thunder appeared to come from no definite direction, but to play round us. For then he ran, barking, over the lawn and round the trees as if angered by a sound he could not locate. I observed carefully what he did for perhaps half an hour, and I think Spot located the directions of sound at least as quickly as I did myself. F. C. Constable.

THE INTERNATIONAL CONGRESS ON SCHOOL HYGIENE.

THE second International Congress on School Hygiene was opened on Monday last at the University of London by Lord Crewe, in the presence of a large gathering, which included delegates from all the countries of Europe, the Colonies, and North and South America, in addition to representatives of administrative bodies in Great Britain. We shall publish at a later date an account of the proceedings of the Congress, but are pleased meanwhile to direct attention to the warm interest taken by the King in the objects for the consideration of which the congress was convened; indeed, but for the King's intervention, the congress would probably have been anything but a success, as will be seen by the opening remarks of the president, Sir Lauder Brunton, F.R.S.

Lord Crewe, Lord President of the Council, in opening the congress, said the first duty he had to perform in connection with the opening ceremony was a very agreeable one. He had a gracious command from the King to express to them the interest with which His Majesty regarded the subjects with which that congress was concerned and his hopes that its discussions might be a great success. His Majesty had further commanded him to express his regret that, owing to his enforced absence from London, he was unable to receive those who were to attend the congress. He was also privileged as a member of the Government to express the same desire on their part that the proceedings of the congress might be crowned with success, and on behalf of the Government to offer them all a hearty welcome. It was not in a strict sense an official conference. It was not subject to official control, it was not run on official lines, and it was not subsidised by official money. That, from many points of view, he took to be a distinct advantage. It lent freedom to the discussions which would take place; but, on the other hand, it must not be supposed that the Government of this country did anything else but take a keen interest in the proceedings of the congress, and they were well aware that the public departments concerned with the subjects for discussion hoped to learn much in the course of the next few days. He hoped that the result of their meeting might have the best possible effects. It must be a good thing for those belonging to different nations and used to different systems to interchange ideas and to engage in a most honourable and friendly rivalry as to which nation and which system could best carry out the objects they all had in view. He hoped, therefore, that their meetings might leave some permanent mark on the subjects, and that their deliberations would do much to advance the knowledge of school hygiene, and to remove what they must all regard as having been a serious blot on the civilisation of the world.

After speeches by Lord Londonderry and Lord Fitzmaurice, Sir Lauder Brunton delivered his presidential address, from which we print the following extracts:—

After welcoming the delegates, he said that he was sure that the first duty which they would wish him to perform as their president was to voice their thanks to the King, patron of the congress, for the gracious welcome which they had received from him through his representative, Lord Crewe. But it was not for words of welcome alone that the congress owed a debt of gratitude to His Majesty. It had also to thank him for most substantial help at a critical time. A fortnight ago things seemed to be going all wrong with the congress; it threatened to be more or less of a failure. At this juncture, through the kind intervention of Mr. Alfred de Rothschild, His Majesty graciously granted him (Sir Lauder Brunton) a personal interview, and asked him to explain the circumstances. He did so, and in a few minutes the King had put everything right, and things, which had been going all wrong before, from that moment went right, and the congress which threatened to be more or less of a fiasco now bid fair to be a brilliant success. Its success would not be due only to the numbers attending it nor to the enthusiasm of its members, but to the work which they trusted it would accomplish, not only during the time of its sitting, but after it was over, for they hoped that arrangements would be made by which its work would become permanent, and would be carried on in the intervals between successive congresses. For his services to the congress the King not only deserved the gratitude of the congress itself, but also of all school children, born and yet unborn, who might owe to its labours health, strength, and happiness.

They were met from every part of the civilised world, throwing aside every subject of disagreement, and were intent only on one common object—the health of the children. Parental affection was one of the strongest and most fundamental instincts, not only in man, but even in the lower animals. They all desired that their children should grow up healthy, strong, and happy; and they were all anxious to take the best means at their disposal to obtain such a desirable end. Amongst these, one of the chief was education. In savage communities, where the chief objects of life were war and hunting, education was comparatively simple, and was thoroughly well adapted to the end in view. But in civilised communities the complexity of conditions sometimes led, and indeed had led, to mistakes in education, and the very meaning of the word had been forgotten, so that, instead of drawing out and developing in every child all its possible powers of body and of mind—so that in its life it should do the very best of which its nature was capable—education had degenerated into a system of cramming and cultivating one or two faculties of the mind, and especially that of memory, to the injury of others, while the condition of the body as the servant of the mind had, to a certain extent, been lost sight of in this country. They were now awakening to the necessity of attending to the body if the mind was to be developed, and many efforts were being made in various countries to secure a system of mental and physical training which would ensure the best development of children. The great advantage of a congress like this was that the systems employed in various places were brought together and compared, so that each country might learn from the others the useful plans they ought to adopt and the errors they ought to avoid.

One of the most important subjects of all in this respect was that of medical inspection in schools, because this was the keystone of physical education. Without it, the defects of eyes, ears, nose, and teeth which affected individual scholars could not be ascertained, and so those children remained backward in their learning, suffering in their bodies and so much damaged in physique that they were unfitted for many occupations, could not enter the Army, and went to swell the numbers of the criminal classes.

The physical training of children during the period of growth was one of the best means of ensuring proper development. In some countries this was carried out more especially by systematic exercise, which developed the muscles, while in this country we depended more upon games. Both of these systems left something to be desired, and the ideal system was to be looked for in a proper combination of both. One of the most difficult, and yet one of the most important, questions of school hygiene was how to combine educational work with physical training, so that both should be productive of benefit, and not of injury, to the child. Proper alternation of mental and physical exercise was one means of preventing this, but attention must also be paid to the nature of the physical exercise.

But all attempts to develop a healthy race would be ineffectual if they took care only of the children who were at school now. They must look a generation ahead, and consider that the children who were at school now fifteen or twenty years hence would be the fathers and mothers of a fresh set of school children whose physique would depend very much upon the way they had been treated and fed in their infancy and childhood. It was, therefore, of the utmost importance that boys and girls should be instructed in the laws of health, the need of cleanliness, the dangers of impure food or water, and the evils of alcoholic abuse. Such instruction should not be given by lectures, which were likely to be misunderstood or forgotten, but by actual demonstration.

In conclusion, the president said that he felt sure that by cooperation they would obtain the object they had in view—namely, the health of the children.

At the conclusion of the meeting the following telegram was sent to the King:—

To His Majesty the King, Royal yacht *Victoria and Albert*, Cowes.—Your Majesty's most gracious message at the opening of the International Congress of School Hygiene by Lord Crewe this afternoon was received with the most humble and most respectful thanks of the delegates from foreign Governments and public authorities and the members of the meeting assembled. Signed, Lauder Brunton, president, James Kerr and E. White Wallis, honorary general secretaries.

And in the evening, at the first general meeting and reception of delegates and members, the following reply from His Majesty was read:—

To Sir Lauder Brunton, 10 Stratford Place, London, W. The King desires me to thank you and the honorary general secretaries for the telegram he has received from you and to express his hope that the ceremony to-day went off well. (Signed) Knollys. Cowes.

THE BRITISH ASSOCIATION AT LEICESTER.

As anticipated, the British Association has been fortunate in its choice of Leicester for this year's annual meeting, and we congratulate the association because of the high character of its proceedings, initiated by the presidential address, and maintained in the special discourses of Mr. Duddell, Prof. Miers, and Dr. Dixey, and the sectional papers, and the town itself because of its genuine and hearty welcome to its many visitors, and the carefully considered arrangements made for the convenience and comfort of all. Many important papers have received consideration at the sectional meetings, and the attendances have shown the interest taken in the subjects covered.

Visitors on arrival found quite artistic street direction cards attached to the lamp-posts and tramway standards, and these, with the capital maps provided on the official ticket and bound with the local programme, gave clear and definite directions for all.

The social side of the meeting has not by any means been neglected, but this has been kept quite subordinate to the real work—the advancement of science. The Mayor's reception and evening *fête*, held at the Abbey Park on the Thursday evening, and attended by nearly 3000 persons, was followed by the garden-party given by Sir Samuel and Lady Faire at Glenfield Frith on the Friday afternoon; both were largely attended and complete successes. Bands have played each afternoon and evening in the pretty loggia erected adjoining the Town Museum, and this central spot has formed a most pleasant rendezvous. A reception by the Leicester Literary and Philosophical Society was held here on Tuesday last.

Saturday, as usual, was given up to excursions. The weather in the morning was anything but propitious, and no doubt deterred many from attending; the day, however, proved bright and clear. Charnwood Forest, Belvoir Castle, Chatsworth, Peterborough, and a trip over the old Swannington Railway proved happy hunting-grounds for scientific pleasure.

The local executive and its chairman, Mr. Colson, must be congratulated on the efforts made by them for the comfort of the members of the association, and the success which attended their endeavours.

The report of the council for the year 1906–7 was adopted at the meeting of the general committee on July 31. The following matters are referred to in the report:—

The council has acted upon the resolution from Section A:—"That, in the opinion of the committee of Section A, it is highly desirable that Sir William Hamilton's memoirs on dynamics, on systems of rays, and other memoirs on pure and applied mathematics, should be republished in accessible form; and that this resolution, if approved by the council, be communicated to the Royal Irish Academy." A subcommittee of Section A is making inquiries for the purpose of promoting the object in view. A resolution from Section H in regard to the appointment of an inspector of ancient monuments has been considered by the council:—"That the council of the British Association be asked to impress upon His Majesty's Government the desirability of appointing an inspector of ancient monuments, fully qualified to perform the duties of his office, with full powers under the Act, and with instructions to report periodically on his work with a view to publication." The council appointed a committee, consisting of Sir John Evans, K.C.B., Sir Edward Brabrook, Mr. Sidney Hartland, Sir Norman Lockyer, K.C.B., and Lord Balcarres, to report on the proposal; and the report of the committee, having been approved by the council, was sent with a covering letter to the Prime Minister on December 10, 1906. Furthermore, the president attached his signature to a memorial upon the same subject drawn up by the council of the Society of Antiquaries. It is understood that, whilst no immediate action will be taken by His Majesty's Government, the matter is receiving careful consideration by the Prime Minister, with the object of placing all ancient monuments in the United Kingdom under adequate protection and more effective supervision.

At the second meeting of the general committee on Friday, August 2, Mr. Francis Darwin, F.R.S., who was nominated by the council to fill the office of president for the year 1907–8, was elected. The Lord Lieutenant, as His Majesty's representative in Ireland, was elected to fill the office of vice-patron for the Dublin meeting next year. The following were elected vice-presidents of the association for the same meeting:—The Lord Mayor of Dublin; the Lord Chancellor of Ireland; H.M. Lieutenant for the County of Dublin (Earl of Meath); Chancellor of the University of Dublin (Earl of Rosse); Chancellor of the Royal University of Ireland (Lord Castletown); Provost of Trinity College, Dublin (Dr. Anthony Traill); president of University College, Dublin (Rev. W. Delany); Viscount Iveagh; president of the Royal Dublin Society; president of the Royal Irish Academy (Mr. F. A. Tarleton); Vice-Chancellor of the University of Dublin (Mr. Justice Madden); Vice-Chancellor of the Royal University of Ireland (Sir Christopher Nixon, Bart.); vice-president of the Department of Agriculture, &c. (Mr. T. W. Russell, M.P.).

The meeting will be held in the first week in September next year, that is, from Wednesday, September 2, to Wednesday, September 9, 1908.

The new members of council elected by the general committee are Dr. Tempest Anderson, Prof. A. R. Forsyth, F.R.S., Mr. D. G. Hogarth, Lieut.-Colonel Prain, F.R.S., and Prof. C. S. Sherrington, F.R.S.

Subjoined is a synopsis of grants of money appropriated for scientific purposes by the general committee at the Leicester meeting:—

Section A.—Mathematical and Physical Science.

	£	s.	d.
Seismological Observations	40	0	0
Further Tabulation of Bessel Functions	15	0	0
Kites Committee	25	0	0
Geodetic Arc in Africa	200	0	0
Meteorological Observations on Ben Nevis	25	0	0

Section B.—Chemistry.

	£	s.	d.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. A. SMITHELLS, B.Sc., F.R.S., PRESIDENT OF THE SECTION.

THE year which has elapsed since the meeting of our Section at York has been eventful in the most melancholy of ways; the losses sustained by our science have been unparalleled. The passing bell seems to have tolled almost without intermission as one after another of our masters has been taken from us: in Russia, Mendeléeff, Menschutkin, and Beilstein; in France, Berthelot and Moissan; in Holland, Bakhuis-Roozeboom. Whilst in some of these cases we may find consolation in contemplating a length of life and sustained activity beyond what we might have dared to expect, in others our regret is increased by the sense of untimeliness and of vanished hopes. I am tempted to speak of the work of such mighty men as Berthelot and Mendeléeff, to dwell upon the discoveries by which they transformed the whole fabric of chemical science; but this is not the occasion on which to offer an estimate of the labours of those who have passed away. I can only say that in the bond of brotherhood which the pursuit of science establishes among the different nations of the earth we who are Englishmen feel and deplore these losses as our own.

I must not omit to allude also, as I do with deep regret, to the death in our own country of two such ardent and fruitful workers as Cornelius O'Sullivan and Robert Warington.

These words were already in print when again we were called to mourn the loss of one of our greatest men, one who but a year ago was the subject of our special rejoicings, and whose vigour of body and youthfulness of spirit seemed to promise the long continuance of a noble and an extraordinarily fruitful life. We can at least feel thankful that William Henry Perkin lived long enough to learn in what honour and esteem his name was held, not only among his countrymen, but by all the chemists of the world, and by the leaders of those great industries of which he was justly acclaimed the founder. For more than a generation Sir William Perkin had been one of the most familiar figures at the meetings of this Section, and greatly shall we miss his gentle presence, his wise counsel, and his valued contributions.

I can, perhaps, best occupy your time to-day by attempting to give some account of the present state of the scientific subject to which I have paid most attention. The topic of flame, after a long period of repose, has aroused much interest during late years, and I think we may say that some considerable progress has been made in its elucidation, although in this, as in all other subjects of scientific inquiry, the more closely we scrutinise it the more impressed must we be with what still remains unknown.

One of the first questions that meet us in the study of flame is that of the temperature at which in any given case the phenomenon becomes evident. Here, I think, a great clarification of view has taken place. The old idea that there existed a fixed temperature at which inflammation suddenly took place cannot now be maintained, and the term "ignition temperature" has acquired a different meaning. It is now known that in a very great number of cases a mixture of two flame-forming gases, when gradually raised in temperature, will develop luminosity quite gradually, *pari passu*, with the chemical combination that is being induced. This phenomenon is, of course, known universally in connection with phosphorus, but it is not so widely known in connection with other combustible substances. There are some simple facts that seem as if they never could gain admission to text-books, and I do not think I have known more than a single chemical book that is not likely to leave a student under the impression that the phosphorescence of phosphorus is an almost unique phenomenon. I do not know how many times the independent discovery has been made that sulphur, arsenic, carbon disulphide, alcohol, ether, paraffin, and a whole host of other compounds, inorganic and organic, will phosphoresce as truly as phosphorus itself; that, in fact, phosphorescent combustion is the normal phenomenon antecedent to what we ordinarily call flame.

This is, after all, only in harmony with the general truth that chemical combination between two gases does not set in suddenly, but comes into evidence quite gradually as the temperature is raised from a point at which the action, if it occurs at all, is so slow as to be negligible. The increase in the rate of combination is, of course, very rapid as compared with the increase of temperature, a difference of about 10° C. serving to double it. The interval between the beginning of phosphorescence and the production of vigorous flames may therefore be very short. In the case of phosphorus this interval, being from 7° to 60° C., includes ordinary atmospheric temperatures; hence the phosphorescence of phosphorus is a phenomenon that could not well be overlooked. If the prevailing terrestrial temperature were below 7° C., at which, under normal air-pressure, the phosphorescence of phosphorus ceases, it is possible that this element might never have acquired its peculiar reputation; it would not have shone in the dark, and in lighting it with a taper the phosphorescent interval would have been passed over as quickly as is ordinarily the case in the ignition of sulphur, paraffin, and other common combustibles. To make phosphorescence apparent in these last cases it is necessary to take special care to heat up a mixture of the combustible gas and air gently, and to maintain it at a temperature approaching, but not quite reaching, that of ignition. There is no simpler way than that used by Sir William Perkin, who brought the combustible substance near to, or in contact with, a massive metal ball previously heated to the suitable temperature.

The change from phosphorescence to ordinary flame is not sudden, but the appearance of ordinary flame is the end point of a continuous, though rapid, development. This end point is the temperature of ignition. What, then, determines the temperature of ignition? The answer to this question has been given with characteristic conciseness by van 't Hoff as "the temperature at which the initial loss of heat due to conduction, &c., is equal to the heat evolved in the same time by the chemical reaction."

We may obtain a clear idea of the meaning of temperature of ignition by supposing a combustible mixture of gases such as that of air and the vapour of carbon disulphide to issue through an orifice into an indifferent atmosphere. If we surround the orifice by a ring of platinum wire, which is gradually heated up by a current of electricity, a flame will gradually make its appearance. If, as soon as this is observed, the heating of the wire by the current be discontinued, the flame will disappear; it is, in fact, not self-supporting, but depends on the accessory supply of heat through the electrically heated wire. If now we raise the ring to a higher temperature we shall get a brighter flame, owing to an increased rate of chemical action, and at last we shall reach a point where it is possible to cut off the electric current without causing at the same time the extinction of the flame. This is the true temperature of ignition, the temperature at which the reaction proceeds at a rate just sufficient to overbalance the loss of heat by radiation, conduction, and convection from the burning layer of gases, so that the next layer is put in the same state, and steady combustion proceeds.

Phosphorescence has been spoken of as degraded combustion, and, though literally the appellation is correct, I think it is liable to be misunderstood. Again, it is often supposed that phosphorescence is necessarily associated with the formation of incompletely oxidised products. This may be the case in a chemical system which is capable of affording different products at different temperatures, but it is not an essential feature; the phosphorescent combustion of sulphur, for example, affords nothing but sulphur dioxide.

Temperature of ignition is, then, neither a temperature at which combination suddenly begins nor one dependent solely on the nature of the combining gases. It will vary with the proportion in which the gases are mixed and with their pressure and other circumstances. Notwithstanding the simplicity of this conception, it must be admitted that there are many obscure facts connected with the ignition of gases. The inflammability of gaseous mixtures is not necessarily greatest when they are mixed in the proportions theoretically required for complete combination; the influence of foreign gases does not appear to follow any simple law; the presence of a very small quantity of a foreign gas may exercise a profound influence on the ignition temperature as in the case of the addition of ethylene to hydrogen. When a mixture of methane and air is raised to its ignition temperature, a sensible interval (about ten seconds) elapses before inflammation occurs. These facts are cognate to others which have increased upon us so abundantly in connection with the influence of moisture on chemical change. The study of the oxidation of phosphorus in particular brings us among rocks and shoals. Apart from the influence of moisture on the combination we have the limitation of the process by a certain tension of oxygen and by minute quantities of a vast number of chemical substances, among which, in spite of much labour, no other common bond can be found. We do not know what oxide is initially formed in the oxidation, and the existence of the oxides P_4O and P_2O is as confidently disputed as it is affirmed. There is some reason for believing that the phosphorescence connected with phosphorus succeeds the formation of one oxide and accompanies the formation of another. The state of the oxygen, whether atomic, ionic, or molecular, which acts on phosphorus, the induced oxidation of other substances, the ionisation of air accompanying the oxidation—these are all matters concerning which there exists a bewildering literature that hangs over us like a cloud. The whole of my Address would, in fact, not suffice for a summary of the state of our ignorance about the oxidation of phosphorus. The subject, simple as it appears at first sight, is really involved with a vast number of unsolved chemical problems the elucidation of which would throw much light on chemical action in general. I may, perhaps, bequeath the topic to some successor in this Chair as one which may serve to illustrate the advance of knowledge since these present days of darkness.

The structure of flames has always been regarded as dependent upon the chemical changes taking place in the differentiated regions, but until recent times little attention has been given to any question beyond the cause of the bright luminosity of hydrocarbon flames. In a flame such as that of hydrogen or carbon monoxide, where we have some reason to suppose that the same kind of chemical transaction is taking place throughout the region of combustion we should not expect to find a differentiation of structure, and, as a matter of fact, we do not find any. Erroneous ideas have gained currency from the use of impure gases, and hydrogen is still described as burning with a pale blue flame, although Stas long ago stated that if the gas is highly purified, and the air freed from dust, the flame even in a dark-room can only be discovered by feeling for it; a fact consistent with the line spectrum of water lying wholly in the ultra-violet. The presence of a very small quantity of free oxygen in carbon monoxide destroys the perfect simplicity of the single shell of blue flame with which the purified gas burns, and in other flames small quantities of gaseous impurities or of atmospheric dust give rise to features of structure and halos which have been frequently supposed to pertain to the flame of the combining gases. The fringe of a flame in air may be often tinged by the presence of oxides of nitrogen.

No flame better illustrates the relation of structure to chemical processes than that of cyanogen, where the two steps in the oxidation of the carbon are clearly marked out in colour. Apart from hydrocarbon flames, very few others have been carefully explored from this point of view. There is, unfortunately, no gas composed of two combustible gaseous elements; and, though such gases as the hydrides of phosphorus and sulphur do not fall far short of this, the experimental difficulties of an exact exploration of their flames are very great. We are thus prevented from studying the flame of a composite combustible in its simplest form.

The flames of hydrocarbons have naturally been the subject of most frequent investigation. The use of single hydrocarbons instead of the mixtures present in coal-gas and other common combustibles has simplified the study considerably. Two problems stand out prominently: one is to trace the steps in the oxidation of the hydrocarbon, the other to account for the bright patch of yellow luminosity. With regard to the question of the luminosity, I do not think there is any longer doubt about its being due essentially to the separation within the flame of minute solid particles of what is practically carbon. The separation seems to be adequately explained by the high temperature of the blue burning walls of the flame, which decomposes the unburned hydrocarbon within. In a similar way arsenic and sulphur and phosphorus are liberated within flames of their hydrides; but these elements, being volatile, do not appear as solids unless a cold object be placed within the flame. In the case of the hydride of silicon the liberated element at once oxidises to form the solid non-volatile oxide, which gives a bright glow.

The mode in which a hydrocarbon yields carbon by the application of a high temperature has been the subject of experiment and of hypothesis; but neither the view of Berthelot, that the carbon results from a continuous coalescence of hydrocarbon molecules with elimination of hydrogen, nor that of Lewes, according to which the formation and sudden decomposition of acetylene is the essence of the phenomenon, appears to me to be in harmony with the experimental facts; and I am not aware that either view has secured any support from other workers in this field. It is certainly not easy to ascertain experimentally the changes undergone by a single hydrocarbon as its temperature is raised, and at the last it may be objected that the course of events in contact with the solid walls of a containing vessel is not necessarily the same as that within the gaseous envelope of a flame. I am glad to think that there is promise of further light on this subject from the work of Prof. Bone.

The course of oxidation of hydrocarbons has been the subject of very careful and fruitful study. The old view that a selective or preferential oxidation of the hydrogen always took place, that with a restricted supply of oxygen the hydrogen was oxidised and the carbon set free, is, I think, no longer maintained by anyone who has studied the question. The explosion of ethylene with its own volume of oxygen, which leaves us with practically all the carbon oxidised and all the hydrogen free, is fatal to this view. Again, when hydrocarbons are burned in a flame with a restricted supply of air, as is the case in the inner cone of the flame of a well-aërated Bunsen burner, there is clearly no separation of solid carbon, and the products of combustion when withdrawn and analysed disclose the presence of much free hydrogen and no unoxidised carbon. In describing this experimental fact I have spoken of it as the preferential oxidation of carbon. I have always thought it pedantic to quarrel with that expression; for, in speaking of a chemical transaction, we usually include only a description of the initial and final states of combination. I should be sorry, however, to detach the expression from the facts it describes and to exalt it into a general doctrine. That would be quite inadmissible, and, if there is any danger of misunderstanding, it would be better to avoid using the expression.

The admirable researches carried out in the University of Manchester by Prof. Bone and his collaborators have afforded most valuable information as to the oxidation of hydrocarbons at temperatures extending from those of incipient oxidation up to the highest ones that prevail in a flame. According to Prof. Bone, the oxidation of a hydrocarbon involves nothing in the nature of a selective or preferential oxidation of the carbon or the hydrogen: but it occurs in several well-defined stages, during which oxygen enters into and is incorporated with the hydrocarbon molecule, forming oxygenated intermediate products, among which are alcohols and aldehydes. The reaction, just referred to, between ethylene and an equal volume of oxygen is, according to Prof. Bone, to be represented by the scheme:

$$\begin{array}{c} CH_2 \\ \vdots \\ CH_2 \end{array} \rightarrow \begin{array}{c} CH.OH \\ \vdots \\ CH_2 \end{array} \rightarrow \begin{array}{c} CH.OH \\ \vdots \\ CH.OH \end{array} \rightarrow \begin{array}{c} H_2C:O \\ \\ H_2C:O \end{array} \rightarrow \begin{array}{c} H_2+CO \\ \\ H_2+CO \end{array}.$$

There can be no question about the facts on which this scheme is based, and they are a new and important addition to knowledge.

It is a great aid to the study of chemical changes, when we can resolve them into stages, whether or not these stages be realisable under certain experimental conditions. In this way we can get a clear view of the relationship between the action in one set of circumstances to the action in another set; and in this way also we can often establish rational links between reactions which at first sight seem quite disconnected. Intermediate reactions are much used to elucidate cases of contact action, and in the processes of organic chemistry they are almost universally assumed.

I am far from wishing to disparage these practices, but I think it important that we should realise how far we are dealing with convenient devices and how far with ascertained facts. The isolation of an intermediate product in one set of circumstances is in itself no proof that this product is transitorily formed when the reaction is proceeding in another set of circumstances; and if we were to assume generally that because we can represent a chemical transaction as if it were due to a successive construction and destruction of a series of molecular edifices it actually does take such a course, we should, I think, be making the same kind of mistake as to suppose that in the application of two differently directed forces to a body at rest, the body will move successively in the direction of each force instead of moving immediately in the direction of their resultant. I know that I may be considered hypercritical, and perhaps obstinate, in this matter; but I wished to state the reasons that prevent me from accepting entirely the interpretation which Prof. Bone has given to his experimental results, and to direct attention to a question of general importance that has not, I think, received the attention it deserves.

The mode of burning of carbon, whether in the free state or as a constituent of a compound, is not at all easy to determine; and notwithstanding many investigations, among which must be specially mentioned those of Prof. H. B. Dixon and his collaborators, so simple-looking a question as whether carbon forms carbon monoxide by directly uniting with oxygen, or only by reducing carbon dioxide, is still a matter of uncertainty.

Our knowledge concerning the question of flame temperatures has been much improved in recent times, thanks mainly to the admirable work of M. Le Chatelier. The well-known memoir of Mallard and Le Chatelier on the explosion of gases supplied the data which first permitted of a moderately exact calculation of flame temperatures, and the perfection of the thermo-couple by M. Le Chatelier gave us the first instrument that could be used directly for making a satisfactory measurement. The uncertainty connected with this subject may be well illustrated by quoting the temperatures that have at different times been ascribed to the flame of coal-gas when burnt in a Bunsen burner, where we have had values varying from 1230° to 2350° C.

The question of calculating the temperature attained during combustion by reference to calorimetric values, specific heat, dissociation, and other considerations is to form the subject of a joint discussion with Section G during the present meeting, so that I shall not here enlarge upon it.

With regard to the use of thermo-couples, I may remark that the practical difficulties have been successfully met. The chief difficulty is, of course, to secure that the thermo-junction attains as nearly as possible the temperature of the region in which it is immersed. As ordinary flames consist of thin shells of burning gases, on either side of which there is a very rapid fall of temperature, it is necessary to use thin wires, and to dispose them so that there is no appreciable drain of heat from the junction. By using wires of different gauge for the couples it is possible by extrapolation to arrive at a temperature for a couple of infinitely small cross-section, and it is also possible to make a correction for the superior radiating power of the couple as compared with the flame-gases. Without this last correction a maximum temperature of 1770° was obtained for the Bunsen flame by Waggener in Germany, and 1780° by White and Traver in America. Correcting for radiation, Berkenbusch found 1830° as the maximum temperature.

M. Féry, by an ingenious application of his beautiful optical pyrometer to a flame containing sodium, gives 1871° as the highest temperature of the flame of a Bunsen burner burning coal-gas.

The consideration of flame-temperatures has become of increasing importance in the arts owing to the use of the Welsbach mantle as a means of deriving light from coal-gas. The great improvements which have been made in the efficiency of atmospheric burners depend primarily on the fact that the smaller the external surface we can give to a flame consuming gas at a fixed rate the higher must be the average temperature; and since the emission of light from a mantle is proportional to a high power of the absolute temperature, a small increase of temperature is of great effect on luminosity.

The acetylene-oxygen flame in which a temperature of about 3500° prevails, not very different from that of the electric arc, is the hottest of the hydrocarbon flames, and finds some important practical uses.

I have already said something about the luminosity of flames so far as relates to the separation and glow of solid carbon. But there remains the more general question of the luminosity of flames containing nothing but gases. The older explanation of the emission of light from combining gases said no more than that the energy liberated during the reaction and appearing as heat raised the product to incandescence—that is to say, so increased the velocity of its molecules and the violence of their collisions that vibrations were set up the wave-lengths of which lay within the limits of visible radiation. This explanation has long been questioned, and there is now, I think, a very general agreement that it will not suffice. The average temperature, in fact, prevailing in a flame, if attained in the product of combustion by the supply of heat from outside, does not suffice to make that substance luminous. We are therefore thrown back upon the conclusion that the generation of light in a flame is not a consequence, though it is an accompaniment, of the elevation of temperature. The question now is, Can we go any further? To do this we are led to consider individual molecular transactions instead of statistical averages, and the view presents itself that the combining atoms may, in losing their chemical energy, form directly systems of independent vibration where the radiation is such as to fall within the limits of visibility. If we picture such vibrating systems momentarily formed, it is easy to see that by their collision one with another they may acquire in a secondary way increased translational motion, and so lead to a state of things where the greater part of their energy is degraded in the form of heat. The high temperature of a flame would then be a consequence rather than a cause of its light.

This subject of the mechanism of luminosity, however, like so many others, has now become involved with the theory of electrons, and a chemist may be excused if he hesitates to pursue the subject further. Some years ago I called attention to the scantiness of our knowledge of the chemical changes that take place when metallic salts are used in flames for the production of spectra. Though there was general agreement that, for example, the yellow flame produced by common salt was due to the liberation and glow of metallic sodium, there was no agreement as to how the sodium was set free.

Arrhenius, pursuing the analogy which exists between the laws governing matter in the gaseous state and in the state of dilute solution, had previously been led to the view that the electrical conductivity of flames containing salt-vapours was due to ionisation of the salt throughout the volume of the flame. It appeared possible therefore that the luminosity might be ascribed likewise to the metal separated in the ionic state. Experimental investigation undertaken with a view to elicit information on this subject seemed to favour the view that the metal was reduced by chemical processes, and that it glowed in the un-ionised condition. Evidence seemed to point to the conclusion that, for example, when common salt is introduced into the flame of coal-gas the sodium chloride yields sodium by the conjoint action of steam and reducing gases; when liberation of the metal was prevented by adding a large quantity of hydrochloric acid to the flame the glow disappeared, but the conductivity was not always diminished. The fact that sodium salts, including the chloride, impart their characteristic glow to the flame of cyanogen and to other flames in which water is absent leads to some difficulty in finding a chemical explanation, and it must be admitted that a direct thermal dissociation of an alkaline halide or oxide is not out of the question. The interval of detachment of the metallic atom may be exceedingly brief, but it must be remembered that even so short a time as the interval between the molecular encounters in a gas at a high temperature is still sufficient for the emission of thousands of undisturbed characteristic vibrations. The experiments to which I have alluded have been followed up with great industry and success by Prof. H. A. Wilson, who has added much to our knowledge of the electrical condition of the flames containing vaporised salts; but the question of the condition of the luminous gas is still far from being settled. Very interesting and important investigations have been carried out by Lenard, who has shown that the stream of luminous vapour produced from a sodium salt in a Bunsen flame is deflected in an electric field in such a way as to indicate that the vapour is positively charged; but he gives reason for believing that the charged condition is intermittent with the neutral condition. The lines in the spectrum of an alkali metal are divisible, as is well known, into distinct groups or series, in each of which the oscillation frequencies corresponding with the lines are in a definite mathematical relationship. The principal series, which include the lines seen individually as such in ordinary flame spectra, are, according to Lenard, due to the electrically neutral atoms. In a salted spirit flame, and in other flames of low temperature where only lines of the principal series are represented, the stream of luminous gas does not behave in an electric field as if it were charged. In the flame of coal-gas burnt in a Bunsen burner the salt-vapour gives, in addition to the distinct lines of the principal series, diffuse bands of luminosity on the dark background, which, according to Lenard, represent the undeveloped subordinate series; and it is the atoms emitting these series that are deflected in the electric field. It is inferred, therefore, that the light in a salted Bunsen flame comes from different groups of centres of emission—the principal series from the neutral atom, and the lines of the first, second, and third subordinate series from atoms which have lost respectively one, two, and three electrons. Lenard goes further, and shows that the salt-vapour in a Bunsen flame, as in the flame of the electric arc, emits these different kinds of radiation from different structural regions; thus the vapour at the edge of the flame is electrically neutral and gives only the lines of a principal series.

The negative electricity in a salted flame would, according to Lenard, be disembodied, and recent experiments by Gold confirm the view that the negative carrier in flames is a free electron. In connection with this subject I ought to allude to an investigation by Tufts, which seems to throw some doubt on the conclusions which were drawn from the experiments made by Prof. Wilson, Dr. Dawson, and myself; and I must also mention an important contribution to the subject recently made by Prof. Hartley, in which considerable light is thrown upon the chemical changes undergone by compounds of the alkaline earth metals when they are introduced into flames, and upon the relation of these changes to the various spectral features. I am afraid, however, that it would be wearisome if I were to prolong this summary, and I must be content to leave it without doing justice to those who are engaged upon the work. The subject is obviously one of fundamental importance in relation to spectrum analysis, and my own slight connection with it has only strengthened my opinion that there is still a great deal connected with the genesis of spectra that requires the attention of the chemist even more than that of the physicist. Spectrum analysis arose under the joint influence of Bunsen and Kirchhoff, and I think its problems still call for more combined work on the part of chemist and physicist than has latterly been the custom.

Having given a short summary of the present state of knowledge on one particular chemical topic, I may perhaps be permitted to conclude my Address with a few general observations relating to the science as a whole.

The contemplation of such a life as that of Berthelot makes us realise in a vivid way the progress of chemical science. He was a chemist without limitation, his activity extending over the whole range of the science, physical, inorganic, and organic. Whilst we must not forget his exceptional powers, we cannot help feeling how different in its extent was our science when he entered upon his labours from what it was when they ceased, and we cannot help feeling how vain it now is for anyone to hope for so imperial a sway.

Yet it is difficult to believe that the state of chemistry can ever have been more interesting than it is at the present moment, or that anyone who sighs for the good old times can do so from anything but the love of a quieter life. We need not go back more than twenty years to find a sharp contrast. At that time there was indeed no want of activity, but it was that of a band of travellers who had left their frontier adventures far behind, and were marching steadily over a wide and almost uninterrupted plain. To-day we are among the mountains, with new peaks and prospects appearing on every side. Truly a steady head is required; and well may we ask, Whither are we going and where is the path of progress and of safety? I rejoice to live in such times; but I feel no competence to describe them, still less can I pretend to have vision keen and comprehensive enough to let me figure as a guide.

One of the penalties of devotion to a progressive science is the constant feeling of being left behind, and the knowledge that, while we are attending to our personal task, things are happening, near or far, that may, for all we know, be affecting the simplest facts and the most elementary principles on which we have been accustomed to rely. This is a feeling that may well prevail at the present day. At the same time I do not think there is any occasion for panic, and I cannot help regretting the somewhat sensational language that has been used, even within our own circles, in regard to recent discoveries. The revelations attendant upon the investigation of radioactivity do indeed mark a distinct epoch in the history of chemical discovery, but that they entail anything like an unsettlement of our scientific articles of faith is not to be admitted for a moment. They make us realise in perhaps a not unprofitable way that scientific knowledge and scientific theories are necessarily proximate, never ultimate, and that ideas which may have been entertained for a long time without modification, and so have begun to seem perpetual, are, after all, only provisional.

There is certainly some embarrassment on finding that a substance like radium, which according to the conventions would be called a chemical element, breaks up so as to give substances which, according to the same conventions, are likewise called elements. But the confusion is one of terminology and not of ideas. I think it likely that few chemists of my own generation have been in the habit of regarding the conventional elements as the ultimate compositional units of matter. We know that in our own country distinguished men of science like Sir William Crookes and Sir Norman Lockyer have always insisted on the complex nature of the elements, and I suspect there are many among us who might own to having made sober, if unsuccessful, attempts at the resolution of elements before the days of radium.

The perplexities of chemists at the present day do not come, I think, from the novelty of the ideas that are being presented to them, but from the great rapidity with which the whole science is growing, from the invasion of chemistry by mathematics and, in particular, from the sudden appearance of the subject of radio-activity with its new methods, new instruments, and especially with its accompaniment of speculative philosophy. There is an uneasy feeling that developments of great importance to the chemist are being made by experiments on quantities of matter of almost inconceivable minuteness. Spectrum analysis of course took chemistry beyond the limits of the balance, but the new materials which it disclosed could at least be accumulated in palpable quantity. With radio-activity we seem, in relation to the ponderable, almost to be creating a chemistry of phantoms, and this reduction in the amount of experimental materials, associated as it is with an exuberance of mathematical speculation of the most bewildering kind concerning the nature, or perhaps I should say the want of nature, of matter, is calculated to perturb a stolid and earthy philosopher whose business has been hitherto confined to comparatively gross quantities of materials and to a restricted number of crude mechanical ideas. He is tempted to think of Falstaff's reckoning and to exclaim with Prince Henry, "Oh, monstrous! but one halfpennyworth of bread to this intolerable deal of sack!" Experimental science has latterly been spun to greater and greater fineness, until in the region of the *n* rays the objective element seems to have disappeared altogether.

I should, however, gravely abuse the position in which I am allowed to speak for the moment as a representative of chemists if I failed to express profound admiration for the masterly work which has been accomplished by the pioneers of the science of radio-activity. All that I wish to say beyond that, is in explanation of a certain awe or trepidation which chemists of the older school may feel in the presence of such bold explorers; and I am the more tempted to say something on the subject, because in recent times, before the advent of radium, a good deal has happened which has given chemists occasion to ask themselves whether chemistry was not beginning, as it were, to drift away from them.

The most conspicuous development of the science during the past twenty years has been, of course, on the physical side, and abundant have been its fruits; but it has seemed to demand from chemists habits and endowments which they did not normally possess, and which they could not easily acquire. I was much struck by a remark made to me a few years ago by a distinguished chemist, who is, I think, the most perfect manipulator I have ever seen at work, to the effect that he felt himself submerged and perishing in the great tide of physical chemistry which was rolling up into our laboratories. Now, it is precisely such men that must be preserved to chemistry. Though chemistry and physics meet and blend, there is, I believe, an essential difference between the genius of the chemist and the genius of the physicist, and I venture to think that some insistence on the primary functions of a chemist is not untimely. The chemist's first qualification is that he shall be master of a peculiar craft; his greatest merit that he is a consummate workman; his distinctive power a nicety of discrimination in questions affecting the composition and quantity of materials. He is not given to elaborate theories and is usually averse to speculation; nor has he usually an aptitude for mathematics. Such the normal chemist is, or was, and such I hope he always may be—naked perhaps in some respects, but unashamed.

There seems to be a solicitude in some quarters to make a chemist something more than a chemist, a solicitude which, if gratified, will, I believe, make him something less than one. We are told, for example, that a chemist should be a mathematician. I do not admit it for a moment. Some mathematics he must of necessity have—that has always been admitted—but in proportion as chemistry develops on the mathematical side does it become important, not that our chemists should be trained in mathematics, but that they should be more than ever carefully trained in the art of exact experiment: that their methods of work, their powers of observation, and, if possible, their experimental conscience, if I may use the expression, should acquire a finer edge. There is never more cause for anxiety than when we see a mathematical theory awaiting the delivery of the confirmatory facts, and there is nothing more important for chemistry than the continual recruiting of that old guard which will be ever ready to stand to arms on the appearance of an eager theorist.

I do not for a moment wish to disparage the adventurous spirits within or outside our science, still less do I wish to range myself with those who meet new ideas with mere objurgation or raillery. We must be content to see new alliances and new activities on the frontiers that separate us from other sciences; content to see many new kinds of chemistry arise in which we cannot all effectually participate. Chemistry is becoming bewildering in its extent, and it would be a great misfortune if this led to the notion that every chemist must try to enlarge his ambit to its confines and fit himself for every variety of work. Those of us who have responsibilities as teachers cannot, I think, be too careful, lest in the attempt to secure breadth we may encourage shallowness and fail to give our students that peculiar and time-honoured discipline in exactitude of work in chemistry proper, which has characterised the chemists of the past, and which is infinitely more important than superficial dealings with a great variety of processes and appliances. I confess that I have frequent misgivings as to whether our modern courses of instruction may not tend to turn out chemists more learned in the science and less perfect in the art than was the case under the ancient *régime*. There was, after all, great virtue in the system which often detained a student day after day, or perhaps week after week, on a single problem of chemical composition such as is involved in the exact analysis of fahl-ore. It is not easy to meet all requirements, but I think we shall all agree that, whatever is left undone, we must make a chemist a good craftsman. It is of the utmost importance that those whom we send out to work in the newer fields shall take with them the resources that have proved most serviceable in the old, and I think it is by supplying such men for special service, rather than by attempting to shift the centre of gravity of the whole system of chemical education, that we can best serve the newer interests.

Another perturbation within the chemical camp in recent times has come from the region of philosophy. Even before the days of radium we have been accused of clinging too fondly to our atomic theory and of stating our knowledge too exclusively in terms of that theory. We are said to have drifted into a dogmatism as real as any we ourselves have had to attack, and to shut our eyes to the light which will enable us to orient ourselves truly in the wide realm of thought. The answer that most of us would give would be, that we value our hypotheses according to their productiveness in new knowledge, and that it is, on the whole, perhaps better to over-exalt an hypothesis that is fertile than from high considerations of philosophy to allow our ideas to become so fluid that they can afford no rigid framework for thought. I think that the attempts to view chemical phenomena apart from the atomic hypothesis, interesting as they undoubtedly are, have not made us feel that this hypothesis has either misled us in any matter of fact or obscured any pathway that we might have followed with greater profit. The value of the thermo-dynamical treatment of chemical problems is attested by its fruitfulness in promoting fresh discoveries; and here we may welcome a valuable adjunct to the atomic hypothesis. But I do not think we are called upon to acclaim a new method of treating old questions unless it promises some more tangible result than an alleged improvement of our intellectual morals.

If, as I have ventured to hint, mathematics brings with it an element of danger into chemistry, I think that the intrusion of metaphysics would give far greater cause for apprehension. Philosophy always stands with open arms desiring a closer embrace of all the sciences, of which she declares herself to be the fond mother, whilst Science, as we understand the term, has stood reluctant, suggesting, as someone has wittily remarked, that she regards Philosophy rather as a mother-in-law. It may perhaps be desirable, especially in the present state of things, that scientific men should allow themselves to become a little more interested in deep questions affecting all knowledge, and should at least examine with some care the gifts that Philosophy is so anxious to bestow upon us. I have a fear that otherwise in the elaboration of scientific theory we may find ourselves embroiled in an unequal contest with what I cannot but regard as the traditional enemy—I mean the unmitigated metaphysician—and the suggestion that I make is, to tell the truth, not so much from the hope of gain as from the desire for self-defence and the safe preservation of the methods that have served us so well in the past.

I think the accusation that we delude ourselves into the belief that our hypotheses are final truth is not true of any thoughtful chemist; the great men of science have surely possessed that quality of mind which philosophy would most approve. If, as has often been remarked, Faraday was mathematically-minded, though untrained in mathematics, it seems not less true that he stood in the same relation to philosophy. When, for example, he was asked to express his opinions on the atomic theory, he wrote as follows:—

"I do not know that I am unorthodox as respects the atomic hypothesis. I believe in matter and its atoms as freely as most people—at least I think so. As to the little solid particles, which are by some supposed to exist independent of the forces of matter, and which in different substances are imagined to have different amounts of these forces associated with, or conferred upon, them (and which even in the same substance, when in the solid, liquid, and gaseous state, are supposed to have like different proportions of these powers), as I cannot form any idea of them apart from the forces, so I neither admit nor deny them. They do not afford me the least help in my endeavour to form an idea of a particle of matter. On the contrary, they greatly embarrass me; for after taking account of all the properties of matter, and allowing in my consideration for them, then these nuclei remain on the mind, and I cannot tell what to do with them. The notion of a solid nucleus without properties is a natural figure or stepping-stone to the mind at its first entrance on the consideration of natural phenomena; but when it has become instructed, the like notion of a solid nucleus, apart from the repulsion, which gives our only notion of solidity, or the gravity, which gives our notion of weight, is to me too difficult for comprehension; and so the notion becomes to me hypothetical, and, what is more, a very clumsy hypothesis. At that point, then, I reserve my mind as I feel bound to do in hundreds of other cases in natural knowledge."

This is the attitude of mind, I think, of all thoughtful chemists; if they do not exhibit it ostentatiously it is only because it is as disturbing to the proper work of a chemist for him to be constantly dwelling on the inward nature of his hypotheses as it is distracting in ordinary life to have men always talking about their emotions.

Few, I think, will deny that the atomic theory stands to-day as an indispensable instrument for productive chemical work; it has neither had its day nor ceased to be. Physicists have never been quite satisfied with the hard indivisible ball of specific substance and definite mass which has served chemistry so well. They have given it bells, have made a vortex ring of it, and have indeed done much that few chemists can understand to make it meet the exacting requirements of their science. But to us it has always been the same; what we have done to it has been external; we have given it, vaguely perhaps, a charge of electricity, a store of energy; we have attached the hooks or rods of valency, but we have not meddled with its interior. We are now called upon by chemical considerations of change of composition, as well as by other considerations more recondite, to subdivide our atom, to credit it with an unsuspected store of energy, to consider it a congeries of unsubstantial electrons. We should wish, of course, to know that the evidence is good enough, but otherwise there can be no possible objection from our side; it will undo nothing that has been done, and we may have good hopes that it will lead to the doing of many new things in chemistry. The newer theories are in consonance with the old in one most vital point: they afford those mental pictures of phenomena which most of us find indispensable for fruitful work. They do not belong to what Prof. Schuster has characterised as "the evasive school of philosophy." "Those," he says, "who believe in the possibility of a mechanical conception of the universe, and are not willing to abandon the methods which from the time of Galileo and Newton have uniformly and exclusively led to success, must look with the gravest concern on a growing school of scientific thought which rests content with equations correctly representing numerical relationships between different phenomena, even though no precise meaning can be attached to the symbols used." Most of us, I think, will take comfort in this pronouncement and rejoice that if our conception of the atom is to be transformed, it may still be represented as having some kinship with what Sir Henry Roscoe's famous examinee described as the "square blocks of wood invented by Dr. Dalton."

SECTION C.

GEOLOGY.

Opening Address by Prof. J. W. Gregory, D.Sc., F.R.S., President of the Section.

I. *The Geological Society of London.*

1907! This is the centenary year of the Geological Society of London; next month the British geologists will celebrate the event, and their pleasure will be enhanced by the sympathetic presence of a distinguished company of foreign geologists.

With a just feeling of satisfaction may we celebrate this event; for to the Geological Society of London is due the conversion of Geology from a fanciful speculation to an ordered science. Yet so quietly has this society done its work that the debt due to it is inadequately realised. When we consider what the world owes to Geology in respect of its economic guidance—the intellectual stimulus of its conceptions—the reverence it inspires for the venerable and majestic universe—its liberating influence from dogma—we may rightly regard the work of the Geological Society as one of the most valuable British contributions to intellectual progress during the nineteenth century.

A hundred years ago the spirit of the eighteenth century still controlled much of the then orthodox Geology. Jameson's "Elements of Geognosy," of which the preface is dated January 15, 1808, taught, as the certain conclusions of Geology, doctrines that had been reached by applying prejudiced speculation to imaginary facts. It was a manual of pure, *a priori*, Wernerian Geology. The author claimed that to Werner "we owe almost everything that is truly valuable in this important branch of knowledge"; and that it was Werner "who had discovered the general structure of the crust of the globe and pointed out the true mode of examining and ascertaining those great relations which it is one of the principal objects of geognosy to investigate."

But Jameson's book was the death-song of Wernerian Geology in British science. A new Geology was developing; and the Geological Society of London ushered in its birth. No more should observations be made through the distorting medium of preconceived fancies! No more should Geology be inspired by that heedless spirit, which cares not to distinguish between fancy and fact! With youthful vigour the new Geology would have nothing to do with the search for cosmogonies and such like fancy foods; and the Geological Society of London should be nourished on unadulterated facts.

The time was ripe for the change. No less a person than Goethe, once an enthusiastic votary of Geology, was now, in his play of "Faust," holding up its teachers to ridicule. The theories "evolved from the inner consciousness" of Continental Neptunists and Plutonists were to Goethe excellent subjects for caricature. It was then the Englishman, Greenough, founded a society to turn Geology from the pursuit of fleeting fancies and lead her to the study of sober but enduring facts. The members of this society were to abandon the quest of scientific chimæras; they were to leave to later generations the attempt to solve the universe as a whole.

The Geological Society has owed its influence to its bold, original purpose. It was not founded as a drifting social union of men, with a common interest in a single science. Its object was to apply to Geology one particular mode of research. It adopted as its motto this fine passage from Bacon:—

"If any man makes it his delight and care—not so much to cling to and use past discoveries, as to penetrate to what is beyond them—not to conquer Nature by talk, but by toil—in short, not to have elegant and plausible theories, but to gain sure and demonstrable knowledge; let such men (if it shall seem to them right), as true children of knowledge, unite themselves with us."

The methods of the society were as practical as its ideals. London, with characteristic unconventionality and originality, has used its scientific societies as its university for post-graduate teaching. Informally the Geological Society enrolled every British master of Geology on its staff of unpaid professors, then set each of them to teach the branch of Geology which he knew best. And these professors were no carpet knights; they were knights errant who derived their knowledge, not from books alone, but from their wanderings over hills and dales, in mines and quarries, by ice-polished rocks and water-worn valleys. At its meetings the leaders of the society announced what they had discovered, gave sure and demonstrable proofs of their discoveries, and showed in what direction the geological forces should be directed for the conquest of Nature. The goodly fellowship of the Geological Society has always encamped on the ever-advancing frontier of geological knowledge, where the well-surveyed tracks pass out into the bright, alluring realms of the unknown.

The actual founders of the Geological Society were apparently men of less showy intellect than the great Werner, whose teaching had intoxicated many of the most gifted of his enthusiastic pupils. They were men, like Horner and Greenough, who had a practical insight that enabled them to give a permanent help to the progress of science. They had that supreme gift, the power to see things as they are. It would not be fair to claim for them that they were the originators of accurate methods in Geology; such methods had been used before their day—by William Smith in England, by Lehman in Germany, and by Desmarest in France. But these men, acting singly, had not been able to save Geology from the eighteenth-century spirit of adventurous speculation, nor had they lifted from Geology the burden of those quaint theories, that made this science the butt of Voltaire's luminous ridicule.

The great achievement of the Geological Society has been this: as a corporate body it has been able to spread its influence very widely; its clear-sighted pursuit of a practical ideal has been adopted in other countries; its resolute rejection of the temptation to wander in dreamland has affected geological students all over the world. In this way has been laid a broad foundation of positive knowledge upon which modern Geology has been built.

The fine self-restraint, which induced the founders of the Geological Society to restrict its work for a while to observing the surface of the earth, has had its reward. The methods this society was founded to employ have been so widely used, that we now have geological maps of a wider area than was known to geographers of a century ago. The general distribution of all the rocks on the earth's surface has been discovered; most settled countries have been surveyed in some detail; the main outlines of the history of life on the earth have been written and carried back almost as far as palæontologists are likely to go. There are doubtless fossiliferous areas still undiscovered in the "back blocks" of the world; but, though negative predictions are proverbially reckless, it seems probable that Palæontology will not carry geological history materially farther back. Fossils have been discovered in the præ-Cambrian rocks; the best known is the fauna described by Walcot from Montana; but his Beltina, the oldest well-characterised fossil, is still of Palæozoic type. It may be that the poverty of carbonate of lime, which is so characteristic a feature of most Cambrian and præ-Cambrian sediments, indicates that the bulk of the contemporary organisms had chitinous shells or were soft-bodied. Palæontology begins with the appearance of hard-bodied organisms; it can only reveal to us the dawn of skeletons, not the dawn of life. We are dependent for knowledge of the climate and geography of Eozoic time to the evidence of the sediments, of which there are great thicknesses beneath the fossiliferous rocks in most parts of the world.[1]

II. *The Geology of the Inner Earth.*

Now that this geological survey of the earth is in rapid progress; while the history of life has been written at least in outline; the chief fossils, minerals, and rocks have been described and generously endowed with names; and the manifold activity of water and air in moulding the surface is duly appreciated, it is not surprising to find that the centre of geological interest is shifting to the deeper regions of the earth's crust and to the problems of applied Geology. The secrets of these deeper regions are both of scientific and economic interest. They are of scientific importance, for it is now generally recognised that the main plan of the earth's geography and the essential characters of the successive geological systems are the result of internal movements. The relative importance of those restless external agents that we can watch, denuding here and depositing there, has been exaggerated; probably they do little more than soften the outlines due to the silent heavings produced by the colossal energies of the inner earth.

The study of the deeper layers of the crust is of economic interest, for, with keener competition between increasing populations and with the exhaustion of the most easily used resources of field and mine, there is growing need for the better utilisation of soils and waters, and for the pursuit of deeper deposits of ore.

If a shaft be sunk at any point on the earth's surface, a formation of Archæan schists and gneisses would probably always be reached; and, working backward, geological methods always fail at last—in primæval, Archæan darkness. The Archæan rocks still hide from us the earlier period of the earth's history, including that of all rocks which now lie beneath them. But already there are indications that the mystery of the "beyond" is not so impenetrable as it seemed.

(1) *The Nebular and Meteoritic Hypotheses.*—The eighteenth century explained the history of the earth by the nebular hypothesis of Laplace. Geologists respectfully adopted this idea from the astronomers; they accepted it as one of those essential facts of the universe with which geological philosophy must harmonise. The resulting theory represented the earth as originally a glowing cloud of incandescent gas, which slowly cooled, until an irregular crust of rock formed around a gaseous or molten core; as the surface grew cooler, the depressions in the crust were filled with water from the condensing vapour, forming oceans which became habitable as the temperature further fell. The whole earth was thought to have had a long period with a universal tropical climate, under which coral reefs grew where flow our polar seas, and palms flourished on what are now the Arctic shores. Still further cooling had established our climatic zones; and it was predicted that in time the polar cold would creep outward, driving all living beings toward the equator, until at length the whole earth, like the moon, would become lifeless through cold, as it had once been uninhabitable through heat. This theory has permanently impressed itself on geological terminology; and its corollaries, secular refrigeration and the contortion of the shrinking crust, once dominated discussions concerning climatic history and the formation of mountain chains. This nebular hypothesis, however, we are now told, is mathematically improbable, or even impossible; and it is only consistent with the facts of Geology on the assumption that, in proportion to the age of the world, the whole of geological time is so insignificant that the secular refrigeration during it is quite inappreciable; hence Geology can no more confirm or correct the theory than a stockbreeder could refute evolution by failing to breed kangaroos into cows in a single lifetime.

The theory of the gaseous nebula has been probably of

[1] Such are the Algonkian sediments represented by the Huronian and Algonkians of America, the Algonkians of Scandinavia, the Karelian of Finland, the Briovarian of North-West France, the Heathcotian of Australia, the Transvaal and Swaziland systems of South Africa, the Dharwar and Bijawar systems of India, the Itacolumnite series of Brazil, &c.

more hindrance than help to geologists; its successors, the meteoritic hypothesis of Lockyer and the planetismal theory of Chamberlin, are of far more practical use to us, and they give a history of the world consistent with the actual records of Geology. According to Sir Norman Lockyer's meteoritic hypothesis, nebulæ, comets, and many so-called stars consist of swarms of meteorites which, though normally cold and dark, are heated by repeated collisions, and so become luminous. They may even be volatilised into glowing meteoric vapour; but in time this heat is dissipated, and the force of gravity condenses a meteoritic swarm into a single globe. Some of the swarms are, says Lockyer, "truly members of the solar system," and some of them travel around the sun in nearly circular orbits, like planets. They may be regarded as infinitesimal planets, and so Chamberlin calls them planetismals.

The planetismal theory is a development of the meteoritic theory, and presents it in an especially attractive guise. It regards meteorites as very sparsely distributed through space, and gravity as powerless to collect them into dense groups. So it assigns the parentage of the solar system to a spiral nebula composed of planetismals, and the planets as formed from knots in the nebula, where many planetismals had been concentrated near the intersections of their orbits. These groups of meteorites, already as solid as a swarm of bees, were then packed closer by the influence of gravity, and the contracting mass was heated by the pressure, even above the normal melting-point of the material, which was kept rigid by the weight of the overlying layers.

This theory has the recommendation of being consistent with the history of the earth as interpreted by Geology. For whereas the nebular hypothesis represents the earth as having been originally intensely hot, and having persistently cooled, yet geological records show that an extensive low-level glaciation occurred in Cambrian times in low latitudes in South Australia;[1] indeed, it seems probable that, in spite of many great local variations, the average climate of the whole world has remained fairly constant throughout geological time. Whereas it has often been represented, in accordance with the nebular theory, that volcanic action has steadily waned, owing to the lowering of the earth's internal fires and the constant thickening of its crust, yet epochs of intense volcanic action have recurred throughout the world's history, separated by periods of comparative quiescence. Whereas it has been assumed, as a corollary to the nebular theory, that the force which uplifted mountain chains was the crumpling of the crust owing to the contraction of the internal mass, yet observation reveals that the crust has been corrugated, and fold mountains formed by contraction to an extent far greater than secular cooling can explain.

(2) *The Materials of the Inner Earth.*—This planetismal hypothesis is not only consistent with geological records, but also with the known facts as to the internal composition of the earth and the structure of extra-terrestrial bodies as revealed by meteorites. Meteorites are of two main kinds—the meteoric irons, which consist of nickel iron, and stony meteorites, which are composed of basic minerals. Some of the stony meteorites have been shattered into fault breccias, showing that they are fragments of larger bodies which were subject to internal movements, like those that have formed crush conglomerates in the crust of the earth. Those stony meteorites, therefore, both in composition and structure resemble the rocks in the comparatively shallow fracture zone of the earth's crust. The nickel-iron meteorites, on the other hand, represent the barysphere beneath the crust.

The earth appears to consist of material similar to that of the two types of meteorites; but whether the proportions of the two materials in the earth represent their proportions in other bodies and in meteoric swarms is problematical. There appear to be no satisfactory data for an estimate of the relative abundance in space of the iron and stony meteoric material. Stony meteorites have been seen to fall far more frequently than iron meteorites; but the largest known meteorites are of the nickel-iron group, although this material, in moist climates, very soon decays. The most trustworthy indication as to the relative amounts of the stony and nickel-iron meteorites is given by a comparison of the weight of the two types of material in meteorites of which the fall was seen. According to Mr. Fletcher's list of the meteorites in the British Museum up to 1904, the collection included 319 specimens of which the fall is recorded: of them 305 specimens were stony meteorites of an average weight of 2·63 lb., 9 were iron meteorites of an average weight of 2·31 lb., and 5 were siderolites (or meteorites containing a large proportion of both silicates and nickel iron) of an average weight of 54 lb.[1] Therefore, according to this test, the stony materials would appear to be the more abundant. But if all known meteorites are considered, the iron group far outweighs the other; for the iron meteorites in the British Museum collection weighed 11,873 lb., as against a total weight of only 865 lb. of stony meteorites. The available evidence suggests that the stony meteorites fall the more frequently on the earth, but the meteoric irons come in such large masses that they outbalance the showers of the smaller stones.

We might have expected help from another source in examining what lies below the Archæan rocks. Cannot the relative proportions of the stony and metallic constituents in the earth help us? Unfortunately, this proportion is as uncertain as that of stony and iron meteoritic material. The best-established fact about the interior of the earth is that its materials are much heavier than those of its crust. The specific gravity of the earth as a whole is about 5·67; the specific gravity of the materials of the crust may be taken as about 2·5, while that of the heavier basic rocks is only about 3·0. Hence the earth as a whole weighs about twice as much as it would do, if it were built of materials having the same density as those which form the crust.

Two explanations of the greater internal weight of the earth have been given. According to one, the earth is composed throughout of the same material, and the internal mass is only heavier because it is compressed by the weight of the overlying crust. Laplace estimated that the material would gradually increase in density from the surface to the centre, where its specific gravity would be 10·74, and the calculations of Schlichter show that condensation due to compression may be adequate to account for the greater internal weight.

According to the alternative or segregation theory, the difference in density is explained as due to a difference in composition; the interior of the earth is thought to be heavier owing to the concentration of metals within it. The probability of this metallic interior has been advanced from several lines of evidence; and the assumed metallic mass has received from Posepny the name of the "barysphere," or heavy sphere. According to this view the earth is essentially a huge ball of iron, which, like modern projectiles, is hardened with nickel; and it is covered by a stony crust, the materials of which were primarily separated from the metallic mass, like the slag formed on a ball of solidifying iron in a puddling furnace.

It has been objected that the weight of the earth is not great enough for much of it to be composed of metallic iron or of meteoritic material. The specific gravity of iron under the pressure at the earth's surface is about 7·7, and it would be even greater when compressed in the interior. But the barysphere is doubtless impregnated with much stony material that would lessen its weight. An estimate by Farrington (1897) of the average specific gravity of the meteorites of which the fall had been recorded is only 3·69. According to the Rev. E. Hill (1885) the mean specific gravity of all the meteorites in the British Museum was 4·5; and, though Mr. Hill duly considered the effect of compression, he concluded that "the density of the earth is perfectly consistent with its being an aggregation of meteoric materials." Moreover, within the metallic barysphere there may be a core of lighter material; for earthquake waves travel more slowly in the central core of the earth than in the intermediate zone, or are even suppressed altogether there; hence the centre of the earth may be occupied by matter less compact than that of the shell around it; and, according

[1] As shown by the work of Prof. Howchin, of Adelaide.

[1] The weights are given in pounds avoirdupois. For the calculation I am indebted to Mr. W. R. Wiseman, of the Geological Department of Glasgow University.

to Oldham's calculations, the light central core occupies two-fifths of the diameter of the earth.

The evidence of density alone, therefore, gives no convincing evidence of the nature of the earth's interior; and geologists have been left with no conclusive reason for choosing between the condensation and segregation theories. Radio-activity has, however, unexpectedly come to our aid, and has disclosed a further striking resemblance between the internal mass of the earth and the iron meteorites. It has supplied direct evidence about the constituents of the earth at depths which have hitherto been far beyond the range of observation. Mr. Strutt has shown that radium is probably limited within the earth to the depth of 45 miles; that the deeper-lying material is free from radium; and that this substance is not found in iron meteorites.

The agreement in radio-active properties between the iron meteorites and the interior of the earth is an additional and weighty argument in favour of the view that the earth is largely composed of nickel iron.

(3) *Physical Conditions and Temperatures.*—The physical condition in which the material exists is now of secondary interest. The old controversy as to whether the earth has a molten interior inclosed within a solid shell has lost its importance, because it has become a mere matter of definition of terms. The facts which led geologists to believe that the interior of the earth is fluid are consistent with those which prove that the earth is more rigid than a globe of steel. For under the immense pressure within the earth the materials can transmit vibrations and resist compression like a solid; but they can change their shape as easily as a fluid. They are fluid just as lead is when it is forced to flow from a hydraulic press. Not only are geologists now justified in their belief that the deeper layers of the earth's crust are in a state of fluxion, but, according to Arrhenius (1900), the earth is solid only to the depth of 25 miles, below which is a liquid zone extending to the depth of 190 miles; and below that level, he tells us, "the temperature must, without doubt, exceed the critical temperature of all known substances, and at this depth the liquid magma passes gradually to a gaseous magma." This distinguished physicist gives a description of the earth's interior which reminds us of the views of the early geologists. Arrhenius's theory rests, however, on the existence within the earth of exalted temperatures; and this assumption a geologist may now hesitate to accept with less risk of getting into disgrace than he would have run a few years ago. It is improbable that the rapid increase of heat with depth which is observed near the surface should continue below the lithosphere; for, if the earth consists in the main of iron, even although it be arranged as a mesh containing silicates in the interspaces, the heat conductivity might be sufficient to keep the whole metallic sphere at a nearly equal temperature. Here, again, Mr. Strutt's work on radio-activity is in full agreement with the requirements of geologists, for he estimates that below a crust 45 miles thick the earth has a uniform temperature of only 1500° C. Whether the further conclusion, that this heat is due to the action of the radium in the crust, be established or not, it is gratifying to hear a physicist arguing in favour of a moderate and uniform internal temperature.

All that the actual observations prove and that geological theories require is that the material within the earth be intensely hot, and that it lie under such overwhelming pressure that it would as readily change its form and as quickly fill up an accessible cavity as any liquid would do. Whether such a condition is to be described as solid, liquid, or gaseous is of little concern to geologists.

III. *The Deep-seated Control over the Earth's Surface.*

The modern view of the structure of the earth adds greatly to the interest of its study, for it recognises the world as an individual entity of which both the geological structure and the history have to be considered as a whole. Once the earth was regarded as a mere lifeless, inert mass which has been spun by the force of gravity, that hurls it on its course into the shape of a simple oblate spheroid. Corresponding with this astronomical teaching as to the shape of the world was the geological doctrine, that all its topography is the work of local geographical agents, the control of which over the surface of the earth is as absolute as that of the sculptor's chisel over a block of marble.

Both these conceptions are now only of historic interest. The irregular individual shape of the earth is expressed by its description as a geoid. The processes which have produced its varying shape have also controlled its geological history and evolution, for they cause disturbances of the crust, which affect the whole earth simultaneously; and so the geographical agents are given similar work and powers at the same time in different places.

Hence there is a remarkable world-wide uniformity in the general characters of the sedimentary deposits of each of the geological systems. The last pre-Cambrian system includes thick masses of felspathic sandstones alike in the Torridonian of Scotland, the sparagmite of Scandinavia, the Keweenawan Sandstones of the United States, and perhaps also the quartzites of the Rand. The Cambrian has its greywackes and coarse slates and its numerous phosphatic limestones; the Ordovician its prevalent shales and slates; the Silurian its episodal limestones and shales. The Devonian has its wide areas of Old Red Sandstones as a continental type, while its marine representatives show the prevalence of coarse grits and sandstones in the lower series, of limestones and slates in the middle series, and the recurrence of sandstones in the upper series; and this sequence occurs alike in North-Western Europe, in America, and Australia. The Carboniferous contains the first regional beds of thick limestone and the first important Coal Measures. The Trias is as characterised by rocks indicating arid continental conditions in America and Australia and South Africa, as Prof. Watts has shown then prevailed in the neighbourhood of Leicester. In the Mesozoic era we owe to Suess the demonstration of the world-wide influence of those marine encroachments or "transgressions" whereby the great continents of the Trias were gradually submerged by the rising sea.

Speaking generally, there is a remarkable lithological resemblance between contemporary formations in all parts of the world. This fact had been often remarked, but was usually dismissed as due to a number of local isolated coincidences of no special significance. But the coincidences are too numerous and too striking to be thus lightly dismissed. They are among the indications that the main earth-changes have been due to world-wide causes, which led to the predominance of the same types of sedimentary rocks during the same period in many regions of the world.

The conditions that govern the geological evolution and general geography of the earth are probably due to the interaction between the earth's crust and the contracting interior; they may take place as slow changes in the form of the earth, causing the slow rising or lowering of the sea surface, or the slow uplift or depression of regions of the earth's crust; or they may give rise to periods of violent volcanic action in many parts of the earth, between which may be long periods of quiescence. The geographical effects of changes in the earth's quivering mass affect distant regions at the same time. Therefore the landmarks of physical geology will probably be found to give more precise evidence as to geological synchronism than those of Palæontology, on which we have hitherto had to rely.

IV. *Plutonists and Ore-formation.*

Belief in the earth's internal fires was most faithfully held amongst geologists by the Plutonists of the eighteenth century, and repudiated with equal thoroughness by the Neptunists, who refused to concede that volcanic action was due to deep-seated cosmic causes. Thus Jameson in 1807 stoutly maintained that volcanoes were superficial phenomena due to the combustion of beds of coal beneath fusible rocks, such as basalt, and that the explosions were due to the sudden expansion of sea-water into steam by contact with the burning coal. Volcanoes, according to this view, were correctly described as burning mountains, giving forth fire, flame, and smoke. The extreme Neptunist and Plutonist schools have long since been extinct, but the controversy is not quite closed. The battlefield is now practically restricted to economic geology, and the issue is the origin of some important ores.

Ore deposits present so many perplexing features that deep-seated igneous agencies were naturally invoked to explain them, and some of the most thorough-going champions of the igneous origin of ores make claims that remind us of the eighteenth-century Plutonists. The question is to some extent a matter of terms. Many of the ores which Vogt, for example, describes as of igneous origin he attributes, not to the direct consolidation of material from a molten state, but to eruptive after-actions due to the hot solutions and heated gases given off from cooling igneous rocks. Igneous rocks probably play a notable part in the genesis of most primary ore deposits; for the entrance of the hot ore-bearing solutions is rendered possible by the heat of the igneous intrusions, as Prof. Kemp has well shown in his paper on "The *Rôle* of Igneous Rocks in the Formation of Metallic Veins." Prof. Kemp limits the term "igneous" to materials formed by the direct consolidation of molten material; and this decision seems to me to be most convenient. For example, the quartzite that is so often found beneath a bed of basalt is due to hot alkaline water from the lava cementing the loose grains of sand; the process is an eruptive after-action, but it would be unusual to call such a quartzite an igneous rock.

(1) *Igneous Ores.*—That there are ores which are the products of direct igneous origin is now almost universally admitted. The mineral magnetite is a most valuable source of iron, and it is a constituent of most basic igneous rocks. If iron were a high-priced metal, such as tin or copper, of which ores containing one or three per cent. are profitably worked, then basalt would be an ore of igneous origin. Under present commercial conditions, however, basalt cannot be regarded as an iron ore. But if the magnetite in a basic rock had been segregated into clots or masses large enough and pure enough to pay for mining, then they would be iron ores formed by igneous action. There are cases of such segregations large enough to be mined. The most famous is Taberg, a mountain in Småland, near the southern end of Lake Wetter, in Sweden. It is a locality of historic interest; a view of it, as a mountain of iron, was published by Peter Ascanius[1] in the Philosophical Transactions in 1755, and Sefström discovered the element vanadium in its ore in 1830.

Taberg consists of an intrusive mass of rock composed of magnetite, olivine, labradorite, and pyroxene. Many theories of its formation have been advanced. The view generally adopted is that of Törnebohm, who described the rock as a variety of hyperite in which there has been a central segregation of magnetite to such an extent that some of it contains 31 per cent. of iron. Törnebohm claims to have traced a gradual passage from normal hyperite to a variety poor in felspar, then to one without felspar, and finally to a granular intergrowth of magnetite and olivine. This Taberg ore was mined and smelted for iron in the eighteenth century, when transport was more costly and commercial competition less keen than it is to-day. The ore has been worked at intervals as late as 1870; and as the hill is estimated to contain 100 million tons of ore above the level of the adjacent railway, it is not surprising that efforts are being again made to utilise the deposit, in spite of its low grade and high percentage of titanium. The Taberg rock has almost reached the line which divides magnetite-bearing rocks from useful iron ores. Its igneous origin, however, has not been universally accepted. The theory has been rejected by so eminent an authority as Posepny, according to whom the ore occurs in solid veins as well as in grains; and he holds that, like other Scandinavian iron ores, it was due to secondary deposition. During a visit to the mountain, I failed to see any secondary veins, except of insignificant value. The microscopic sections of the ore show that it is a granular aggregate of olivine, generally with labradorite and pyroxene. Hence I have no hesitation in accepting the view of the Swedish geologists and regard Taberg as a magmatic segregation. Posepny[2] has in this case carried his Neptunist theory of the genesis of ores too far.

[1] vol. xlix. pp. 30–34, pl. ii.
[2] F. Posepny. "The Genesis of Ore Deposits," Trans. Amer. Inst. Min. Eng., 1893, p. 323.

At Routivaara, in Swedish Lapland, there is a still larger mass of magnetite, which is claimed, in accordance with the descriptions of Petersson and Sjögren, to be due to segregation from the magma of the surrounding gabbro. This mass of magnetite is of colossal size, but it is of no present economic value, owing to its high percentage of titanium and its remote position.

An igneous origin is claimed by Prof. Högbom for some small masses of titaniferous magnetite in the island of Alnö, opposite Sundsvall, on the eastern coast of Sweden. This case is of interest, as the surrounding rock is not basic: it is a nepheline syenite, containing only 2 per cent. of magnetite, which, however, has been concentrated in places, until some specimens (according to an analysis quoted by Prof. Högbom) contain as much as 64 per cent. of magnetite, 9 per cent. of ferrous oxide, and 12 per cent. of titanic oxide.

The Alnö magnetites, again, are of no practical value, as they are too low in grade and too refractory in nature. I understand that about 500 tons of the material have been smelted, but with unprofitable results, and the rest of the material quarried has been left on the shore. We may therefore accept the iron-bearing masses of Alnö and Routivaara, as well as that at Taberg, as due to magmatic segregation, without having conceded much as to the igneous formation of ores. The process in this case has formed rocks, rich in titaniferous magnetite, from which iron could be obtained, but rocks which no ironmaster is at present willing to buy as iron ore. Whether a basic igneous rock is to be regarded as an iron ore, or as only useful for road metal, depends on cost of treatment. The definition of the term "ore" is very elastic. Petrographers speak of the minute grains of magnetite or chromite in a rock as its ores; but that is a special use of the term "ore." Usually ore means a material which can be profitably worked as a source of metals under existing or practicable industrial conditions.[1] According to this definition, the Swedish deposits of titaniferous magnetite are at present doubtfully within the category of iron ores.

The famous iron mines of Middle Sweden at Dannemorra, Norrberg, Grängesberg, and Persberg occur under different geological conditions; they work lenticles or bands of ores in metamorphic rocks, of which some are altered sediments; and the view has therefore been held by de Launay and Vogt that the ores also are altered sediments.

That ores are formed by igneous segregation of sufficient size and purity to be of economic importance is a theory which rests on two chief cases—the nickel ores of Sudbury in Canada and the iron ores of Swedish Lapland.

(2) *The Sudbury Nickel Ores.*—The nickel ores of Sudbury are the most important historically. They have been repeatedly claimed as of direct igneous origin by Bell (1891), von Foullon (1892), Vogt (1893), Barlow (1903), and by other geologists; and his view was advocated before the Association at the Johannesburg meeting by Prof. Coleman. The theory was stoutly opposed by Posepny in 1893, and Prof. Beck in 1901 described some of the brecciated ore, and showed that its metallic minerals are sharply separated from the barren rock. He held that such ore must have been formed, not only after the consolidation of the rock, but even after or during its subsequent metamorphism. The views of Posepny and Beck seem to have been established by additional microscopic study of the ores by C. W. Dickson (1903). He has shown that the sulphides are separated from the barren rock by sharp boundaries, and without any indication of a passage between them; that the fragments of ore in the rock have short corners, whereas, had they grown in a molten magma, the angles would have been rounded, and the faces corroded. Most of the ore, moreover, occurs as a cement filling interspaces between broken fragments of barren rock and along planes of shearing. The Sudbury ores, therefore, appear to have been deposited from solution during or after the brecciation of the rocks in which they occur, and long after their first consolidation.

[1] The Oxford Dictionary adopts a still more restricted definition: according to it an ore is "a native mineral containing a precious or useful metal in such quantity and in such chemical combination as to make its extraction profitable."

If Dickson's facts be right, the Sudbury ores are necessarily aqueous and not igneous in origin.

(3) *Scandinavian Iron Ores.*—The other important mining field of which the ores are claimed as of igneous origin is Swedish Lapland. Its ores are rich and the ore bodies colossal. One mine, Kirunavaara, yielded more than one and a half million tons of ore in 1906, and according to a recent agreement with the Swedish Government the annual output of ore from that mine may be raised to three million tons by 1913.

The chief mining fields of Lapland, although situated to the north of the Arctic Circle, have long been known; for some of them contain veins of copper which were worked, for example, at Svappavaara in the seventeenth century. The iron ores, however, could not be used until a railway had been laid through the swamps of Lapland to carry the ores cheaply to the coast. In 1862 an ill-fated English company began a railway to the Gellivara mines, and thirty years later this was completed across Scandinavia, from the head of the Gulf of Bothnia at Lulea to an ice-free port at Narvik, on the Norwegian coast.

This railway, the most northern in the world, passes the two great mining fields of Gellivara and Kiruna. The mining field of Kiruna is the larger and at present of the greater geological interest, as its structure is simpler and its rocks less altered.

The ore body at Kiruna outcrops along the crest of a ridge two miles long, and it is continued beneath Lake Luossajarvi to the smaller but still immense ore body of Luossavaara. At Kiruna the ore rises to the height of 816 feet above the surface of the lake, and it varies in thickness from 30 to 500 feet, with an average thickness of about 230 feet. According to the report by Prof. Walfrid Petersson,[1] submitted this year to the Swedish Parliament, Kirunavaara contains 200 million tons of ore above lake-level, and Luossavaara another 22½ million tons. The ore is high-grade. According to Lundbohm 60 per cent. of the trial pits showed a yield varying from 67 to 71 per cent. of iron, and 21 per cent. of them showed a yield of from 60 to 67 per cent. of iron. The average of nineteen analyses published in Prof. Petersson's recent report gives the contents of iron as 64·15 per cent. Unlike the Taberg and Routivaara ores, the percentage of titanium is very low; thus in nineteen analyses given by Petersson the average of titanic acid is only 0·23 per cent., and it varies in the specimens from 0·04 to 0·8 per cent.

The ore lies between two series of acid rocks, which have been very differently interpreted, but will no doubt be fully explained by the researches now in progress under the direction of Mr. Lundbohm. The rocks were first called halleflinta, as by Fredholm, and regarded as of sedimentary origin. They are now accepted as an igneous series, associated with some conglomerates, slates, and quartzites. The ore body itself is bounded on both sides by porphyrites, of which that on the lower or western side is more basic than that overlying the ore to the east. The basic western porphyrite is in contact with a soda-augite syenite of which the relations are still uncertain. Interbedded with the overlying eastern porphyrite are rocks that appear to be volcanic tuffs, and both in the tuffs and in the upper porphyrite are fragments of the Kiruna ore.

Three main theories of the genesis of the Kiruna ores have been proposed. Their sedimentary origin was urged on the ground that they occur regularly interstratified in a series of altered sediments, and that the ores, therefore, are also sedimentary. This view may be promptly dismissed, since the adjacent rocks are igneous.

The second theory has been advanced independently by Prof. de Launay and Dr. Helge Bäckström: according to them the porphyrites above and below the iron ores are lava flows, and the ore was a superficial formation deposited in an interval between the volcanic eruptions. According to de Launay the iron was raised to the surface as emanations of iron chloride and iron sulphide; the iron was deposited as oxide, and most of it subsequently reduced to magnetite during the metamorphism of the district.

The third theory—that the ores are of direct igneous origin—has been maintained by Löfstrand, Högbom, and Stutzer; according to them the ores are segregations of magnetite from the acid igneous rocks in which they occur. The segregation theory has been opposed, amongst others, by de Launay and Vogt. Thus, de Launay maintains that the segregation would have been impossible in such fluid lavas as the Kiruna porphyrites, and is improbable, since there is no transition between the ore and the barren rock.

The segregation theory has serious difficulties, and is faced by several obvious improbabilities. The ore occurs as a band nearly forty times as long as it is broad. It has the aspect, therefore, of a bed or a lode. The ore has not the granular, crystalline structure of an igneous rock like the hyperite of Taberg, but the aspect of a material deposited from solution or formed metasomatically. It is almost free from titanium, the undesirable constituent so abundant in the ores of Taberg and Routivaara.

The igneous theory cannot, however, be lightly dismissed, as it is supported by the high authority of Prof. Högbom, and therefore demands careful consideration.

It has been advanced in two main forms, the one considering the ore to have been deposited at the time when the igneous rocks are consolidating, the other considering it was deposited at a later period. According to Prof. Högbom, the ore was syngenetic, being a true magmatic segregation from a syenite. But, according to Dr. Stutzer (1906), the segregation was later than the consolidation of the syenite. He describes the lode as an intrusive banded dyke, of which the chief constituents are magnetite and apatite; and the injection of this dyke pneumatolytically affected the rocks beside it, producing an intermediate zone, impregnated with ore, which he compares to contact deposits.[1]

In spite of the high authority of Prof. Högbom, I am bound to confess that the Kiruna ores do not impress me as of igneous formation. Their bed-like form, microscopic structure, and poverty in titanium are features in which they differ from those admittedly due to direct magmatic segregation. The microscopic sections that I have examined suggest that both the magnetite and apatite were deposited from solution and later than the consolidation of the underlying porphyrite, which the ore in part replaces. An examination of the field evidence supports the conclusions of de Launay and Bäckström as to the ore being a bedded deposit overlying a lava flow, but enlarged by secondary deposition.

V. *Future Supply of Iron Ores.*

This conclusion is perhaps economically disappointing. The possible existence of such vast segregations of iron in the acid igneous rocks has an important economic bearing. There is only too good reason to fear that the chief iron ores are comparatively limited in depth; for most of them have been formed by water containing oxygen and carbonic acid in solution, which has percolated downward from the surface. Ores thus formed are therefore restricted to the comparatively limited depths to which water can carry down these gases. On the theory, however, that these ores are primary segregations from deep-seated igneous rocks there need be no limit to their depth. They would rather tend to increase in size downward, while maintaining, or even improving, in the richness of their metallic contents. For these bodies may be regarded as fragments of the metallic barysphere which have broken away from it and revolve around it like satellites floating in the rocky crust. On this conception these ore bodies would be of as great interest to the student of the earth's structure, as their existence would be reassuring to the ironmaster, haunted as he is by constant predictions of an iron famine at no distant date. It is no doubt true that many of the richest, most accessible, most cheaply mined, and most easily smelted iron ores have been exhausted.

[1] *Bihang till Rikd. Prot.*, 1907, 1 Saml., 1 Afd., 84 Häft, No. 107, pp. 213, 217.

[1] In a later paper, of which only a short abstract has been issued, Dr. Stutzer, however, explains that "the intrusion of the ore dyke was at relatively the same time as the formation of the syenite, and that the ores were formed by magmatic separations *in situ*, or as peregrinating magmatic separations (magmatic veins and bedded streams)." He adds that "pneumatolysis plays no inconsiderable *rôle* in the formation of these veins." Dr. Stutzer's position may be summarised as regarding the ores as collected by segregation, but deposited in their present position by eruptive after-actions.

The black-band ironstone and the clay iron ores of the coalfields, which gave the British iron industry its early supremacy, now yield but a small proportion of the ores smelted in our furnaces. The Mesozoic beds of the English Midlands and of Yorkshire still supply large quantities of ore. Nevertheless the British iron industry is becoming increasingly dependent on foreign ores. So it would be pleasant to find that the Scandinavian iron mines are not subject to the usual limits in depth. I fear the typical iron deposits of Middle Sweden and of Gellivara will follow the general rule; but Kiruna may be an exception, and its ores may continue far downward along the surface of its sheet of porphyrite. The uncertainty in this case lies in the extent of the subsequent enrichment and enlargement of the bed; if most of the ore is due to secondary deposition, then it may be restricted to the comparatively shallow depths at which this process can act; and though that limit will be of no practical effect for a century or more to come, the ore deposit may be shallow as compared with gold mines.

The geological evidence may convince us that all the economically important iron ores are limited to shallower depths than lodes of gold, copper, and tin; but this conclusion shall not enroll me among the pessimists as to the future of the iron supply. Twenty years ago a paper on the gold supplies of the world was read to the Association at the request of the Section of Economics. About the time that the report was issued, there were sixty-eight mining companies with a nominal capital of 73,000,000*l.* at work upon the Rand. Nevertheless, the author, accepting the view that "the future of South African gold-mining depends upon quartz veins," concluded: "There is as yet no evidence that the yield will be sufficient in amount to materially influence the world's production. As regards India, the prospect is still less hopeful."

That quotation may be excused, as it is not only a warning of the danger of negative predictions, but of the unfortunate consequences that happen when geologists are unduly influenced in geological questions by the opinions of those who are not geologists. In economic Geology, as in theoretical Geology, we should have greater confidence in the value of geological evidence. Negative predictions are especially rash in regard to iron, it being the most abundant and widely distributed of all the metals. The geologist who knows the amount of iron in most basic rocks finds it difficult to realise the possibility of an iron famine; he can hardly picture to himself some future ironmaster complaining of "iron, iron everywhere, and not a ton to smelt." There are reserves of low grade and refractory materials which the fastidious ironmaster cannot now use, since competition restricts him to ores of exceptional richness and purity. When the latter fail, an unlimited quantity could be made available by concentration processes. The vast quantities of iron ores suitable for present methods of smelting in Australia, Africa, and India show that the practical question is that of supplies to existing iron-working localities, and not of the universal failure of iron ores.

VI. *Mining Geology and Education.*

The genesis of ores and the extent of future ore supplies are intimately connected questions, and the recognition of this fact has led to the remarkable growth of interest in economic Geology. This wider appreciation of the practical value of academic Geology should, I venture to urge, be recognised among teachers by giving a more honoured place to economic Geology.

It was inevitable that until the principles of Geology had been firmly established, the detailed study of their application should have been postponed. Now, however, last century's work on academic Geology enables the difficult problems connected with the genesis of metalliferous ores to be investigated with illuminating and practically useful results.

British interest in mining education has therefore been revived. Its history has been sadly fitful. Lyell,[1] in 1832, deplored the superiority of the Continent in this respect, as "the art of mining has long been taught in France, Germany, and Hungary in scientific institutions established for that purpose," whereas, he continues (quoting from the prospectus of a School of Mines in Cornwall, issued in 1825), "our miners have been left to themselves, almost without the assistance of scientific works in the English language, and without any 'School of Mines,' to blunder their own way into a certain degree of practical skill. The inconvenience of this want of system in a country where so much capital is expended, and often wasted, in mining adventures, has been well exposed by an eminent practical miner."

[1] C. Lyell, "Principles of Geology," vol. i., ed. 2 (1832), p. 63.

Though the chief British School of Mines made a late start, the brilliant originality of its professors soon carried it into the front rank; but in an evil day for the Mining School it was united with a Normal School for the Training of Teachers, now the Royal College of Science, and that school by its great success overwhelmed its older ally. Those interested in economic Geology therefore welcome the recent decision to separate the technical from the educational and other courses, while leaving the Schools of Mines and Science sufficiently connected for successful cooperation. This policy should give such opportunities for the teaching of mining research that we may not always have to confess, as at present, that British contributions to mining Geology do not rank as high as those made to other branches of our science.

Regrets are sometimes expressed, and perhaps still more often felt, at the tendency in scientific teaching to become more technical; but I, for one, do not fear evil from any such change. It is possible that the educational conflict of the future will be between academic science and technical science, on grounds in some respects analogous to those between classics and science during the last century. The advocates of the educational value of technical science are not inspired by mere impatience with the apparently useless, for they accept the principle that the essence of education is method, not matter. Therefore they claim that the methods and principles of science can be better taught by subjects which are being used on a large scale in modern industries than by subjects of which the interest is still purely theoretical. Those who fear that academic science will be neglected if technical science be used in education may be encouraged by the brilliant revival of classical research since classics lost its educational monopoly. Academic science is even less likely to be neglected. It will always have its fascination for those intellectual hermits—shall I not say those saints of science?—who prefer to work for love of knowledge, free from the worrying intrusion of the mixed problems and fickle conditions of the industrial world; and the greater the progress of applied science the more urgent will be its demands for help from pure science, and, as a necessary consequence, the wider will be the appreciation and the more generous the endowment of scientific research.

Technical education must be as rigorous as that in academic education, and its connection with the fundamental principles must be as intimate. When so taught, economic problems provide at least as good a mental training as those branches of science which are purely theoretical. If the new Imperial College of Science and Technology carry on the mission for which the Geological Society was founded a century ago, if it inspire its students to have their delight in using past discoveries on the open surface of the earth, so that they may penetrate to what is within, then they will gain that sure knowledge of the formation and distribution of ores, which is of ever-growing national importance.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY GEORGE G. CHISHOLM, M.A., B.SC., PRESIDENT OF THE SECTION.

Geography and Commerce.

THE subject which I have chosen for this Address is one that is very apt to raise questions that might lead to keen and even warm controversy. For the raising of such questions no occasion could be less suitable, and it will therefore be my endeavour to handle the subject in such a manner that burning questions may be altogether avoided. For that reason I propose to consider the relations of geography and commerce from an historical point of view, which at least gives one the opportunity of confining oneself to less debatable ground than is entered on when one ventures on prophecy, that "most gratuitous form of error," as it is styled by George Eliot. That I shall be able to keep wholly free from debatable matter is more than I can hope, but it is my intention to try to avoid it as much as possible by illustrating my subject chiefly by reference to the broad, familiar facts of commerce considered in the light of geographical and other implications that may be described as obvious—obvious, and yet perhaps not unimportant and not unworthy of having attention specially called to them; for, after all, the obvious is obvious only to those who are looking in the right direction and with the proper focus, not to those who are looking another way or far beyond what is immediately before them.

As the first of these obvious considerations I may point out that unquestionably the foundation of commerce is the mutual advantage to be derived from the exchange of commodities produced in different places. Geographical relations are therefore of necessity implied in commerce. But those who carry on commerce have always aimed at the greatest possible advantage to themselves, and the commerce that has always attracted the greatest attention is that which has resulted in the greatest additions to their wealth. Peculiar importance therefore belongs to the geographical relations between regions which in any given circumstances lead to the most profitable exchanges.

But before applying this consideration there is another point which must detain us a little. In speaking of wealth as I have just done I am aware that I have made use of a term which economists recognise as one requiring a great deal of exposition to prevent misunderstanding, and there is not the slightest doubt that in the history of commerce it has led to great misunderstanding, and therefore it is necessary, without entering upon an economic disquisition on the subject, to consider the meaning of the term "wealth" sufficiently to indicate the way in which that misunderstanding has arisen. For this purpose it will be most convenient not to give one of the highly abstract definitions of wealth which a modern political economist will give us, but to go back to the more concrete considerations set forth by Adam Smith, who tells us that "the wealth of a country consists not in its gold and silver only, but in its lands, houses, and consumable goods of all different kinds."[1] Now no definition of wealth is given by economists which excludes this last form of wealth, but the misunderstanding to which I refer arises from the fact that this form of wealth is apt to be overlooked. It may happen that a country or region produces a great abundance of consumable goods in proportion to its population, and hence from this point of view be entitled to be regarded as wealthy, and yet may not be a country or region that attracts much attention by its wealth. What has always attracted attention to wealth, and what has caused wealth to have an important effect in directing the main streams of commerce, and commerce to have an important effect, direct or indirect, on history, has been the accumulation of much wealth in few hands, so that a comparatively small number of people in a community have enjoyed, directly or indirectly, the command of a great deal of labour, have had the means of providing themselves with commodious and luxurious houses, with a variety of other comforts, luxuries, and splendours, and over and above that the means of so directing labour as to add still further to their wealth. Such conditions may exist where the great bulk of the population are extremely poor.

Now, it happens that wherever a great abundance of consumable commodities is produced on a relatively small area there is always in that area a greater or smaller number of individuals in whose hands much wealth is concentrated. It is for economists to explain how this comes about, or has come about, but it is a fact of the utmost importance for geographers to bear in mind in considering the relations of commerce and geography.

The existence of a relatively dense population may be due to different causes, such as a great abundance of agricultural products, the carrying on of mining or manufacturing industries, the concentration of the administration of a great dominion, or the pursuit of commerce itself. Where it is due to any cause but the production of great quantities of the necessaries of life foodstuffs must be imported in large quantities, and where the pursuit of manufactures is the cause, or one of the chief causes, then the importing of raw materials is entailed. Where these are most advantageously found there also much wealth is likely to be accumulated in few hands.

Further it is to be noted that where a comparatively small number have the command of much wealth there is sure to be a demand for things of such value that they can be bought only by the wealthy, things that are more or less rare, such as precious metals, jewels, gems, ivory, fine woods, ornamental skins and feathers, manufactured goods of rare materials or of fine quality, as well as, in many places and in most periods of history, slaves. Such trade is necessarily limited in amount, but puts great profits in the hands of those who carry it on with success, and for that reason attracts attention.

With this class of goods may be associated certain others that may be regarded as intermediate in position between those which are bought only by the wealthy and those which are not merely generally consumed but also very widely produced. Amongst these may be mentioned salt, the consumption of which is universal, but the production of which, away from the seaboards of the warmer latitudes, though in a sense widespread, is strictly confined to scattered spots. A more interesting example is that of spices, one of which, pepper, has from a remote period been very generally consumed, but in still smaller quantity than salt, and for that reason has been able to bear still higher transport costs. For ages these costs were very high, for various reasons, amongst which were risks both numerous and great, but the profits of those who were successful in the trade were proportionately high.

Peculiar importance in commercial geography is thereby given to the relations between the regions that yield or yielded spices and those in which they were consumed at a great distance from the place of origin, and one of the most important facts in human history is that for many hundreds of years an extremely valuable trade in these commodities was carried on between India and the Mediterranean. Spices no doubt were less talked about, less prominent as symbols of wealth, than gems and jewels, fine woods and ivory, but they formed the basis of a larger trade, which was in the aggregate probably more profitable than that in the still more costly wares.

The geographical relations between India and the Mediterranean necessarily determined the routes followed by this traffic. These routes were singularly few. They were practically confined for the most part to minor variations in two main routes, one by way of the Red Sea, the other by the Persian Gulf. At more than one period of history, in very early times in the days of the splendour of Assyria and Babylonia, and again in the flourishing days of the Caliphs of Baghdad, the Persian Gulf route had a peculiar advantage in the existence of the large and rich populations that afforded an intermediate market; and another important fact in the relations of geography and commerce, one that has had vast effects on human history, is that the physical conditions of the area between the head of the Persian Gulf and the Mediterranean are and throughout human history have been such as to make the most convenient outlet of that route some point or points on that seaboard which in ancient times was known as Phœnicia. Between that seaboard and the Euphrates the desert is sufficiently narrowed to be most easily crossed. The most favoured outlets on this seaboard were not always the same. They varied in different circumstances, which gave a different geographical value now to one point, now to another. But on these variations, interesting and instructive as they are from a geographical point of view, there is no time to enter on this occasion, and it will be enough to call attention to a very interesting paper by the late Elisée Reclus entitled "La Phénicie et les Phéniciens," dealing with this and other matters connected with the geographical basis of Phœnician commerce and industry, a paper too that is apt to be overlooked, inasmuch as it was con-

[1] "Wealth of Nations," book iv., ch. i.

tributed by him with a generosity characteristic of one of the least self-seeking natures with which the world was ever blessed to a rather out-of-the-way publication, the *Bull. de la Soc. Neuchâteloise de Géol.* (vol. xii., 1900). But while I do not desire to enter into details regarding the Phœnicians it is necessary to point out how naturally and indeed inevitably this position of the Phœnician cities between the Mediterranean on the one hand and Mesopotamia and the Persian Gulf route to India on the other hand brought other sources of wealth in its train. Conveniences for the distribution of manufactured goods have always been one of the most important advantages for the development of manufacturing industry, and the wealthier the community forming the market for the products of such industry the more valuable are the manufactures likely to be. Hence the Phœnician manufactures of fine linens and woollens richly dyed, glass and metal wares, for which other parts of the Mediterranean and its seaboard furnished the raw materials, slaves to do the manual labour, and food for that population which the narrow strip of Phœnicia could not adequately supply. Food is indeed a bulky commodity, but even bulky commodities could be transported by sea at a relatively small cost, and in connection with this traffic we must note the indirect effect which the wealth of Phœnicia must have had in promoting the settlement of districts favourably situated for supplying food, and especially of such districts where the opportunities for producing food were great, but not fully turned to account, where the supply therefore could easily be made superabundant in proportion to the wants of the population. This shows that from the very nature of commerce its benefits are not confined to one side. Although the geographical conditions for a long period of time led to a special accumulation of the wealth due to commerce on Phœnicia, Phœnician trade promoted the growth of wealth and civilisation elsewhere. The Greeks of the Ægean distinctly recognised what they owed to the Phœnicians, and they in their turn derived much wealth from Eastern trade, even though not so directly as the Phœnicians, and they in their turn derived some of the food for a commercial population from the far west —from Syracuse, Sybaris, and even the distant Kume. But the far east had a peculiar fascination. As the articles from which much of the wealth of commerce was derived originally came from India, it was natural that the idea should arise that India was a wealthy country, a country well worth possessing. I am not aware whether India ever was in historical times a wealthy country in the sense of producing a great abundance of the necessaries and ordinary conveniences and comforts of life in proportion to the population, but if it was not rich itself it was at least the means of making others rich. There can hardly be a doubt that the desire of possessing this country of real or imagined wealth was prominent among the motives that led Alexander the Great to embark on that enterprise which had such surprisingly—one might almost say miraculously—widespread, profound, and lasting effects on the history of the Near East. If we may accept as historical the speech in which Quintus Curtius represents Alexander as having addressed his troops after his victory over Porus, in order to encourage them to advance further into India, that speech affords fairly strong evidence of what has just been stated. "What now remained for them," said Alexander, "was a noble spoil. The much-rumoured riches of the East abounded in those very regions to which their steps were now bent. The spoils accordingly which they had taken from the Persians had now become cheap and common. They were going to fill with pearls, precious stones, gold, and ivory not only their private abodes, but all Macedonia and Greece." Alexander was no merchant. Pepper was beneath his notice. His symbols of wealth are those which have always most powerfully affected the imagination. Later on, however, we shall meet with a king who was a merchant, and who understood perhaps better than Alexander wherein consisted the value of Indian trade.

At the outset of his career Alexander had destroyed Tyre, thinking, no doubt, that he had thereby wiped away the claims of one rival for a share of the wealth of the East; but it is a noteworthy fact that he did not thereby destroy the value of the site of Tyre under the conditions which then subsisted. Tyre revived and again obtained wealth from its trade with the East, as it did again and again in subsequent history. A heavier blow to Tyre than its mere destruction was the ultimate accomplishment of Alexander's idea for founding a great seat of commerce on the harbour which he saw could be created in the neighbourhood of the Nile delta. The foundation of Alexandria and the successful efforts of the successors of Alexander in Egypt to divert a large part of the trade in spices and other Oriental goods to the Red Sea route for the Mediterranean did more than a single act of war to deprive Tyre and other Phœnician cities of the peculiar preeminence which they had long enjoyed in the trade in those wealth-bringing commodities.

But perhaps the history of Venice shows even more clearly than that of Tyre the importance of this eastern trade in connection with certain inevitable geographical relations. The foundation of the future commercial glory of Venice may be said to have been laid when Rome planted her colonies north of the Po. The gradual clearing of forests gained for agriculture to a greater and greater extent one of the most favoured agricultural areas in Europe. There resulted a superfluity of agricultural products, which begot a trade by sea. The great outlet of this plain in Roman times was Aquileia, which in the beginning of the fifth century, when no one of discernment could imagine that there would ever be other than Roman times, was described by a Roman man of affairs and minor poet as one of the nine great cities of the world. But before that century was out Aquileia was destroyed, never to recover. The value of its site was replaced, and that in a strange way, which no man of discernment could ever have foreseen. The time that saw the destruction of Aquileia and the times that immediately followed were such as made safety a prime consideration, and especially for all who possessed or desired to possess wealth. Refugees from Aquileia, and afterwards from other Italian cities, thought at first of nothing but safety. Many of them found it on a few muddy and sandy islands near the muddy shores of the lagoon in which Venice now lies. But here they found the means of trade. The sea could be made to furnish both fish and salt, and the rivers that flowed into the lagoon enabled them to exchange these commodities for provisions of other kinds which the adjoining land could supply. Gradually this commerce grew, until in the eighth century we find the Venetians trading with Syria and Africa, Constantinople, and the ports of the Black Sea.

Throughout the period of growth the policy of this trading republic, both by land and sea, is very significant. Venice early realised the force of Bacon's maxim "that he that commands the sea is at great liberty, and may take as much and as little of war as he will." Power at sea was necessary to provide security for her commerce. In early times she generally owned allegiance to the Eastern Roman Empire, a suzerainty which could do her little harm and could and did do her much good. To that allegiance she adhered until she was strong enough to turn against and reap advantage from the overthrow of her suzerain. At an earlier date, before the close of the tenth century, she had conquered Dalmatia, and thereby destroyed the hordes of pirates who had found refuge in the innumerable harbours of that coast and constantly harassed the commerce of the Adriatic. At every opportunity she secured establishments and acquired possessions in the Levant.

On the land side, however, dominion would have added more to her risks than her advantages, and that dominion was not sought. For more than eight hundred years after the first flight to the islands of the lagoon, more than six hundred after the election of the first Doge (697), Venice possessed no territory on the mainland beyond a mere narrow ribbon on the edge of the lagoon. The nature of the situation made her indispensable to the trade of the land immediately behind. An incident belonging to the close of the ninth century illustrates the force of this observation. A keen dispute had arisen between the Patriarch of Aquileia and the Patriarch of Grado. Venice supported the Patriarch of Grado, and war seemed to be threatened. But so necessary had the commerce of Venice become to the inhabitants of the territory acknowledging the authority of Aquileia that in order to bring about the submission of the Patriarch of Aquileia it was enough to close or blockade the port of Pilo, on the mainland opposite the *lidi*. The subjects of Aquileia then forced the patriarch to sue for peace.[1] On another occasion, in a dispute with the Bishops of Belluno and Treviso, the matter was again partly settled through the efficacy of the measures taken by the Doge Orseolo II., with the consent of the people, to stop commerce with the territory of the bishops, by which the inhabitants found themselves without supplies of salt, and without the means of exchanging their leather and meat for Venetian wares or selling the abundant timber of their forests for the building of Venetian ships.[2] In holding the outlets for maritime commerce Venice felt herself to be in the possession of "the keys of trade," to use the expression employed by Sir William Petty in speaking of the analogous position of Holland in later times at the mouths of the Rhine, Meuse, and Scheldt.

But while possession on the mainland was not necessary to Venice she always recognised and sought the advantage of good relations with the occupants of the plains behind her, whoever these occupants might be, and on every occasion endeavoured to turn to her own benefit the vicissitudes of those plains. In her early days she is found now in alliance with the Greeks, now with the Pope, now with the archbishops of Ravenna, and now with the Lombards, just as it happened to suit her interests, and in any case taking every opportunity of obtaining direct and indirect advantages from trade with the most profitable customers in the plains. When famine pursued the steps of the Lombard invaders of Italy in the sixth century "the Venetians in their pacific retreat," says Mutinelli,[3] "could send their ships to the ports of Apulia and elsewhere to obtain victuals and corn for the famished barbarians," and in consequence the Lombards took them under their protection and granted them security and favours throughout the Lombard kingdom. When Charlemagne, at the invitation of the Pope, invaded Italy to deliver the Church from its subjection to the Lombards, Venetian traders promptly appeared in the camp of the Franks at Pavia and sold to the Frankish chiefs all the riches of the East—Tyrian purples, the plumage of gay birds, silks, and other ornaments, pranked in which the purchasers stalked about in their pride, feeling, no doubt, that now at last they had conquered a land the wealth of which would reward all their labours and hardships.[4] Charlemagne, it is true, was inclined to look with little favour on the Venetians, whom he regarded as supporters of the Greeks, but an attack by his son Pepin in 809 on the islands of the lagoon only served to establish the strength and security of their position, at least on the inner islands of the lagoon. By closing the passages of the canals, removing the navigation beacons, and fortifying and barring the chief entrances to the land they succeeded in holding out during a siege of six months, until the heats of summer began to decimate the troops of Pepin, who, on hearing also of the approach of a Greek fleet, came to terms with the Venetians on conditions similar to those which had been maintained with the Lombards. The Venetians agreed to a tribute, but solely for the narrow strip of territory held on the mainland and in return for commercial privileges in the Frankish dominion, not for any recognition of the existence of the State. The tribute was afterwards paid or withheld according to the power which the Emperors showed of enforcing it; but one permanent result of this incident was that the Venetians, perceiving the smaller security belonging to the islands nearer the mainland, of their own choice made the Rialto the capital of their little State[5] (810).

As a last illustration of the nature of the relations of Venice to the North Italian plains we may refer to some of the points mentioned in a celebrated and often quoted address delivered to the principal senators of Venice by the Doge Mocenigo just before his death (1423), at the time at which Venetian trade was at the very height of its prosperity. At that time Venice was in possession of a considerable tract of adjacent territory on the mainland, and there was a party favourable to further action on the part of Venice against the growing power of Milan. The aged and sagacious Doge feared that this party was going to gain the upper hand and elect as his successor Francesco Foscari, who, he thought, would involve them in dangerous and disastrous as well as useless enterprises. The immediate occasion of the conflict of views in the Venetian Senate was a request of the Florentines for support against alleged designs of the Duke of Milan. Mocenigo, however, not only warned the senators in the most earnest and urgent language against Foscari personally, but also advised them against the particular enterprise, maintaining that it was of no consequence even if the Duke of Milan made himself master of Florence, since the artisans of Milan would continue to send their manufactures to Venice, and the Venetians would be enriched to the loss of the Florentines. He then went on to give particulars of the trade of Venice at that time, dwelling specially on the value of that with Lombardy. To Lombardy alone, it appears, Venice sold every year cloths to the value of 400,000 ducats, *tele* (? linens) to the value of 10,000 ducats: wools of France and Spain to the value of 240,000 ducats, cotton to the value of 250,000 ducats, wine to the value of 30,000 ducats, cloth of gold and silk to the value of 250,000 ducats, soap to the same value, spices and sugar to the value of 539,000 ducats, dye-woods to the value of 120,000 ducats, other articles 110,000 ducats: in all, goods to the value of more than 2,500,000 ducats, the profit amounting to quite half a million ducats. With the exaggeration that comes natural to a lover of his country Mocenigo goes on to say rather grandiloquently that to the Venetians alone land and sea were equally open; to them only belonged the carriage of all riches, they were the providers of the entire world.

All this trade, as well as that of Genoa and other Italian ports which shared with others in the spice trade must have had a remarkably fructifying effect in North Italy generally. Agriculture and manufactures would be alike promoted, and in consequence of that the growth of population; and when war, with its attendant scourges, led to a diminution both of industry and population, this commerce could not fail to assist in bringing about a speedy recovery. It has already been hinted that in manufactures both Milan and Florence took a prominent place in the time of Mocenigo. In truth, manufactures in both cities are of much older date, and it may be interesting to mention here that even in the thirteenth century English wool was a commodity sufficiently valuable to bear the cost of transport to Florence. A letter has come down to us,[1] dated London, January 6, 1284, from the representative of a Florentine house, giving particulars as to purchases that he had made, in many cases for several years in advance, of all or a portion of the wool of many English monasteries from Netley and Titchfield, in Hants. and Robertsbridge, in Sussex, to Grimsby, in Lincolnshire, and Sawley, on the Ribble, in the county of York (one of these monasteries, you may be interested to learn, as near Leicester as Monks Kirby, about midway between Rugby and Nuneaton); and from the work in which this letter is published we also get particulars[2] as to the cost of conveying wool from London by way of Libourne to the Mediterranean port of Aigues Mortes in the same or

[1] Published (1765) in a work having no author's name, but stated in the British Museum Catalogue to be by G. F. Pagnini della Ventura, and bearing the title "Della Decima e delle altre Gravezze della Moneta, e della Mercatura de' Fiorentini fino al secolo XVI.," the third volume of which contains "La Pratica della Mercatura" of Balducci Pegolotti (ascribed to the first half of the fourteenth century), under whose name the work is entered in the British Museum Catalogue. The date of the letter is given on p. 94 of vol. ii., and the letter itself on pp. 324–7 of the same volume. For the identification of the names of monasteries in their much disguised Italian forms and spelling I am indebted to my friend Mr. A. B. Hinds, M.A., editor of the last issued volume of the "Calendar of State Papers (Venice)." Most of them, however, are entered and identified in the list given from Pegolotti on pp. 629–41 of Cunningham's "Growth of English Industry and Commerce, Early and Middle Ages," 4th edition (1905).
[2] *Ibid.*, vol. iii., pp. 261–3.

the following century. Florence, indeed, depended on England, Spain, and Portugal for wools of fine quality, its own and other wools of Italy being of very inferior value, so that when four bales of English wool were worth in Florence 240 gold florins the same quantity of wool of Garfagna dell' Aquila was worth only 40 florins.[1] The author of this work adds that he has found no indication of the prices of the wools of Spain and Portugal in Florence. Besides manufacturing cloths from the raw material "Florence carried on a large trade in dressing and finishing woollens manufactured in Flanders and Brabant, and brought to Florence either by way of Paris and the Saône-Rhône valley or by way of Germany and across the Alps. In the time of Mocenigo many of these products of Florentine industry came to Venice for export. In the address already referred to Florence is said to have sent to Venice every year 16,000 pieces of cloth, which were sold to Aquila, Sicily, Syria, Candia, the Morea, and Istria.

It will be noticed that in the address above quoted Mocenigo lays no special stress on the spice trade, but there is not the slightest doubt that spices were amongst the most important commodities with which the Venetians provided a large part of the western world. Just as nowadays the large trade of Britain in bulky goods makes of this country a great entrepôt for the more valuable and less bulky, so in Venetian times the exceptionally large population behind Venice receiving and supplying the bulky goods thus fed the shipping which brought to Venice a much larger proportion of the more valuable goods of the East than was brought to other ports. But there is plenty of direct evidence of the importance of Indian trade to Italy in the Middle Ages. It is to be remembered that of necessity this trade enriched other countries before it reached Venice, and in proof of its importance in the Mediterranean generally one may call attention to the investigations of the Venetian Marin Sanuto Torcello about the end of the thirteenth century, who, we are told, saw with indignation that the defeats of the Christians in Palestine were specially due to the power of the Soldans of Egypt, and perceiving that their great power derived its nourishment from the commerce with the Indies, based on that observation the projects which he urged on Christendom for the overthrow of that power. It is further significant that a sea way to India should have been sought by Genoese as early as 1291,[2] and even more significant that a century later Venice should have found it worth while to maintain a consul in Siam.[3]

But the clearest evidence of the supreme importance of the Indian trade to the Italian cities is to be found in the results of the discovery which finally diverted from Venice and the Mediterranean the great bulk of the Indian trade until that trade had lost all the special significance which it had retained for thousands of years. It need hardly be said that I refer to the discovery of the sea way to India by the Portuguese in 1497–9. Of the feeling aroused in Venice by this discovery Romanin has reproduced,[4] from the "Diarii" of Priuli, an interesting contemporary record, written with reference to a despatch to the Doge probably from Pietro Pasqualigo, a Venetian envoy at Lisbon at the time of the return of the second Portuguese voyage to India under Cabral. The letter is stated to have reached Venice on July 24, 1501. After giving the letter, in which we are told, among other things, how the Portuguese had charged their ships at Cochin with spices at a price which the writer feared to mention, Priuli adds: "On the arrival of this news at Venice all the city was deeply moved and remained stupefied, and the wisest held it for the worst news that could reach them. For, it being recognised that Venice had risen to so high a degree of renown and wealth solely by the commerce of the sea and by navigation, by means of which every year a great quantity of spices was brought thither, which foreigners then flocked together to acquire, and that by their presence and the traffic they obtained immense advantages, now by this new voyage the spices would be brought from the Indies to Lisbon, where Hungarians, Germans, Flemings, and French[1] would seek to acquire them, being able to get them there cheaply; and that because the spices that came to Venice passed through the whole of Syria and the countries of the Soldan, paying in every place exorbitant duties, so that at their arrival at Venice they were so weighted that what at first was of the value of a single ducat was raised in the end to sixty and even a hundred ducats; from which vexations, the voyage by sea being exempt, it resulted that Portugal could give them at a much lower price." So said the wisest, but it is interesting also to note what was said by the less wise. Priuli goes on: "And while the wisest saw that, others refused to believe the story [these, I presume, were the least wise], and others again said that the King of Portugal would not be able to continue this navigation to Calicut, since of thirteen caravels only six had returned safe, the loss would be greater than the advantage, and that it would not be so easy to find men who would consent to risk their lives in so long and perilous a navigation; that the Sultan of Alexandria, seeing the loss of so fine a profit as that obtained by the passage of the spices through his lands, would see to that."

But in this case it happened that the wisest were right. The effects of this discovery were not long in making themselves felt in the notable diminution in the sales of spices at Venice. Under the date February, 1504, Priuli enters in his diary, "The galleys of Alexandria have entered into harbour empty: a thing never before seen." In the following month the same thing happened in the case of the galleys from Beirut.[2] Under August, 1506, it is stated that the Germans at the fair of the preceding month had bought very little. Various remedies for these evils were thought of, and among these it is interesting to note that in 1504 the Council of Ten seriously discussed a proposal to empower an envoy to the Sultan of Egypt to come to an agreement with him, if possible, for the cutting of a canal through the Isthmus of Suez.[3] But the proposal was not adopted. Other efforts to avert the results of the great achievement of the Portuguese were vain. Other disasters befell the republic about the same time. Not only was commerce taking another direction, but, says Romanin, "the wars of Italy were emptying the treasury, the Turkish power was despoiling the republic step by step of its possessions beyond the sea, and Venice was beginning to descend that incline which was to reduce it to a subordinate position among the powers of Europe."[4] North Italy generally suffered at the same time. The withdrawal of the greater part of the spice trade, by diminishing the growth of wealth among the inhabitants, made that part of the world a less important market for manufactured goods. Countries outside of Italy, where rival manufactures had already started, were increasing their wealth more rapidly, and thus imparting an increasing stimulus to their manufactures, and these increased while those of Italy declined. In 1338 the number of woollen factories in Florence is given at 200, making in all 70,000 to 80,000 pieces of cloth in the year; in 1472 the number of shops or factories had risen to 270, but no estimate is given of the quantity of the product; in 1529, however, the number of shops is said to have sunk to 150, and the quantity of cloth manufactured to 23,000 pieces per annum, and in the time of the editor of Balducci Pegolotti the quantity was only about 3000 pieces annually.[5]

Before going further, however, there is one point in the comments on the discovery of the sea way to India quoted above from the "Diarii" of Priuli which calls for notice. Hungarians, Germans, Flemings, and French, he observes, will in future go to Lisbon to get the spices of India more cheaply than at Venice. This remark illustrates the difficulty of shifting the geographical point of view according to circumstances, a difficulty of which at all times abundant illustrations can be offered. The

purchasers of spices who come first into the mind of Priuli are Hungarians and Germans. It was inevitable that they should be among the leading customers of Venice. The Hungarians were supplied from the Dalmatian ports which belonged to Venice. The Germans came by way of the Rhine and the Elbe, and then across the Alps, to get supplies for central, north-western, and northern Europe. But it was neither Hungarians nor Germans who came in greatest numbers to Lisbon to buy the spices which Portuguese ships brought from the East. In any case Lisbon had no advantages like those of Venice for supplying by land a large and rich population immediately behind it. The valley of the Tagus was small and poor, and had not the capacity for expansion in wealth and population which the Lombard plains had when the commerce of Venice began to grow. The bulk of the spices brought to Lisbon had therefore to reach their final markets by routes that did not pass through Lisbon into the interior. To supply the most important of those markets it was the Dutch, the people who held "the keys of trade" for the important valleys of the Rhine, Meuse, and Scheldt, who came to Lisbon in greatest numbers to buy spices of the Portuguese. And here it has to be added that, in spite of the discovery of the sea way to India, the Venetians continued to retain great advantages in the spice trade with Hungary and parts of Germany, as well as, of course, the northern plains of Italy. Things did not remain always as bad as recorded in the years 1504 and 1506. The Portuguese, while maintaining successfully for a hundred years the monopoly of the trade in spices at the place of origin in the East, found their advantage in dividing the trade with Europe between the sea way and the Persian Gulf route, of which latter route they held the key since the final capture of Ormuz in 1515. The trade by way of the Tigris through Baghdad (the so-called Babylon of those days) and the Euphrates to the old Phœnician seaboard was again revived, and was maintained as long as Portugal held command of the trade. It was by this route that the first English commercial expedition to India, that of Newberie, Leedes, Story, and Fitch, went out in 1583, and by which Ralph Fitch, the sole survivor of that expedition, returned in 1591. By this route Venice got back some of her spice trade; not perhaps with the same profit to herself as formerly, but still a trade of no slight importance not only to Venice, but also to Augsburg, Nuremberg, and some of the other cities of South Germany.

But beyond doubt the bulk of the trade was now carried on by the sea route, and we are thereby enabled to get a better idea both of the amount and the nature of the trade. On both points we get information from the "Narrative" of the above-named Ralph Fitch, who tells us that "the Fleete which commeth every yeere from Portugal, which be foure, five, or sixe great shippes, commeth first hither [to Goa]. And they come for the most part in September, and remaine there fortie or fiftie dayes; and then go to Cochin, where they lade their Pepper for Portugall."[1] Now in 1583 a ship of 500 tons would certainly be called a great ship. In 1572 the largest vessel sailing from the port of London was of 240 tons,[2] and the largest of the first fleet of the East India Company was one of 600 tons. I could give more definite information as to the capacity of these fleets at that time if I knew exactly what a *salma* was, for in a report on Portuguese trade sent to the Grand Duke Ferdinand I. of Tuscany (1587–1608) we are told that the fleet consisted of four or five carracks of the capacity of 5000 or 6000 *salme*.[3] But a *salma* is a term for which one sometimes gets a very indefinite meaning, at other times definite but very diverse meanings, sometimes a weight of 25 lb., which is obviously too little, and again a weight of 1000 lb., which is probably too much. The large dictionary of Tommaseo gives this latter weight with an example stating the capacity of a ship; but if that were the meaning then the carracks would be of a burden of from 2250 to 2700 tons, a much heavier tonnage than is elsewhere indicated, so far as I am aware, for vessels of the period. Probably 3000 tons would be the outside limit of the aggregate cargoes annually brought to Portugal, for in any case much room in the ships was required for the large crews of those days with their armaments, for then the idea of carrying on commerce by sea without being in a position to defend your ship was out of the question.

Of the commodities sent home from India, Fitch mentions in this place only pepper, and the correspondence of Albuquerque with the King of Portugal soon after the discovery of the sea way to India clearly reveals how all-important the pepper trade was; but it may be worth while to give the complete list of the commodities which Ralph Fitch enumerates at the end of his "Narrative" as coming from India and the country further eastward. The list is not a long one. It comprises pepper, ginger, cloves, nutmegs and maces, camphora ("a precious thing among the Indians . . . solde dearer then golde"), lignum aloes, long pepper, muske, amber, rubies, saphires, and spinels, diamants, pearles, spodium, and many other kindes of drugs from Cambaia—all of them, it will be observed, having the character of being of high value in proportion to their bulk, so that a very great value of such goods might be carried in ships of small capacity.

Fitch does not tell us what was sent in return, but information as to that is to be had from other sources and presents one or two points of interest. In 1513 Albuquerque, after a long course of fighting, concluded a peace with the Zamorin of Calicut, in which it was agreed, among other things, that the Zamorin should supply the Portuguese with all the "spices and drugs" his land produced, and that "coral, silk stuffs, quicksilver, vermilion, copper, lead, saffron, alum, and all other merchandise from Portugal" should be sold at Calicut as heretofore.[1] Coral comes first in this enumeration. To us at the present day this does not seem a very important article of commerce, but it was otherwise then. One Mafio di Priuli, writing from India in 1537 to the Magnifico M. Constantino di Priuli, says, "At a great fair which is called that of Tremel I have seen buttons of coral sold for their weight in silver."[2] That is the point of view of a European in India, but a native of the East Indies in Europe at the same date would no doubt have spoken with astonishment of the amount of silver that could be got in Europe for a few grains of pepper. Our letter-writer says in his cheerful, hopeful, gossiping way, "The gains of these parts are other than those of Damascus, Aleppo, and Alexandria: for if one does not gain cent. per cent. from Portugal here, and from here back again, one thinks that one gains nothing. And three or four years would be quite enough."[3] But, while he indicates how these immense gains are made, he also indicates clearly enough how they continue to be made—that is, how they are so counterbalanced by losses that if these great gains were not made on occasion commerce would cease. It was all very well to exchange your coral for spices, but the great matter was to get your coral out and your spices home in safety. The writer of this letter had entrusted to a friend who had left on a ship for Ormuz jewels of the value of 4000 Venetian ducats, but the jewels were lost. He believed that his friend was murdered. "But such losses," he adds, "will occur." Another time he lost more than 6000 ducats gold in Portuguese vessels going to Ormuz, and on another occasion he suffered great loss when Pegu was sacked by the King of Burma.

These notes may serve to illustrate the conditions of trade in the glorious days for Portugal when fine fortunes were heaped up in Lisbon through trade, but the great bulk of humanity got very little at least directly through that trade; but we have not exhausted the interest connected with the nature of the outgoing commodities for India, and to that it will be well to return. Another of the stipulations of the treaty of 1513 above referred to was that while duties were to be paid in coin "the Portuguese were to pay for all the pepper and other

merchandise they might purchase in kind," and, as the peace led among other things to a dearth of prizes, Albuquerque "was constrained to send an urgent request home for large quantities of merchandise to be sent out to make up for this deficiency."[1] How long this stipulation remained in force I cannot say, but things were certainly different a hundred years later. In the report to the Grand Duke of Florence above cited we are told that what the Portuguese carry to India for exchange is above all "silver in reals, and besides silver wine, oil, and some other sort of merchandise, such as coral, glass, and the like, of little importance"; and as to the silver he adds that "the reals bring a gain of more than 50 per cent. as soon as they have reached India, for the real of eight, which in Lisbon is worth 320 reis, in India is sold and spent at the rate of 480 to 484 reis of that money, and with it one buys all sorts of spices and drugs which are sold there, except pepper, which is the monopoly of the King of Portugal and those to whom he gives a lease of that trade." The importance of silver among the outgoing commodities for India has continued from that time down to the present day, latterly, however, in diminishing proportion. For a long time after the date at which we have now arrived it was as predominant as a means of exchange with India as it was in the first century of the Christian era, when the drain of silver from the Roman Empire to the East was bewailed by the writers of that time. In the voyages of the English East India Company of the four years 1620–3 inclusive the value of the bullion (chiefly silver) sent out to India was 205,710*l.*, as against only 58,806*l.* worth of merchandise.[2]

Now, what is the meaning of the change in the position of silver in Indian trade which seems to have taken place between 1513 and the end of the sixteenth century? No doubt we may see there the result of another change in geographical relations brought about by a discovery nearly contemporaneous with that of the sea way to India—namely, that of the New World. The first result of that discovery of importance to commerce was the pouring into Europe of large quantities of the precious metals, and the quantity was enormously enhanced after the silver mines of Potosi, in Upper Peru (as it was then called), were discovered in 1545. It was probably this discovery that brought it about that of all commodities of such small bulk in proportion to their value as to stand the costs of transport to the East this was the one which could be sent out for the most part with the greatest advantage. And this discovery no doubt also helps to explain why that of the sea way to India had so little effect for a very long time in lowering the prices of spices in Europe, why prices even rose. At the time of the return of Vasco da Gama from the first voyage to India the price of pepper at Lisbon is estimated by Danvers[3] to have been about 1*s.* 5*d.* per lb., and we all know that the immediate occasion of the foundation of the English East India Company about a hundred years later was that the Dutch suddenly raised the price of pepper against the English from 3*s.* to 6*s.* and 8*s.* per lb.

But the particular commodity which made up the principal portion of the outward trade to India is, after all, a matter of detail, though not unimportant detail. The main point on which I want to insist is that, whatever the commodities were, whether carried out or home, the nature of the trade with the East was little if at all altered by the discovery of the direct route to India by sea. The trade still continued to be one concerned in a moderate number of articles of small bulk but high value. It was merely a change of route that the Portuguese effected, and for more than a hundred years they remained in sole command of this route. After that, however, they were ousted from the greater part of this trade, and that the more valuable part, chiefly by the Dutch, and from a geographical point of view it is very interesting to note how the Dutch did it. They did not trouble themselves much about India proper. They left the Portuguese alone at Goa, and from that port as a base allowed them to pick up as much trade as they could at Calicut and Cochin, which, said Albuquerque, "were capable of supplying the Portuguese fleets until the Day of Judgment." But Malacca, on the straits of that name, gave command of the route to the further East, whence came in the end even larger quantities of pepper than could be got from India, whence came too ginger, cloves, and nutmegs, as well as the products of China. The importance of this place Albuquerque had accordingly recognised, and in 1511, the year after he took Goa, he took it also by the right that always belongs to the lion as against the jackal. This place was taken by the Dutch (1641), who had previously established themselves on Java and the Spice Islands, where they maintained an absolute monopoly. Ceylon, again, was (and is) almost the only place from which the true cinnamon was to be obtained, so the Dutch took that island also from the Portuguese (1656). As long as the Portuguese were the sole Europeans in the East, Calicut and Cochin not merely furnished the Portuguese with Indian wares, but were important entrepôts for the spices, perfumes, drugs, and jewels of the Further East as well as of Chinese silks and porcelains; but the trade in these commodities could be wholly or largely diverted to places in the possession of the Dutch. Even before the capture of Malacca and Ceylon a Portuguese viceroy had reported (1638) that the Dutch had a monopoly of trade from the Bay of Cochin China to the point of Sunda.

But this change also was little more than a change of route. The general character of the Eastern trade remained the same. The English East India Company, the operations of which, through the hostility of the Dutch, came to be restricted to India proper, there founded a trade that gave much more opportunity for expansion under modern conditions than that of the Dutch, but for a long time it retained the same character. All the commodities enumerated by Colquhoun as brought back by the voyages of 1620–3 in exchange for the bullion and merchandise sent out were pepper, cloves, mace, nutmegs, Chinese and Persian raw silk, besides calicoes, the sole manufactured article, and one of course that had relatively a much higher value than now, when the direction of the trade in that commodity is reversed.

A similar character for a long time belonged to the trans-Atlantic trade, even though the costs of transport in that case were less, and favoured the development of a trade in somewhat bulkier commodities. Furs from the Far North, tobacco from Virginia, sugar and afterwards coffee and cotton from the West Indies, were by far the most prominent imports. It was the tobacco trade of Virginia that first enabled Glasgow, which at the time of the union of the English and Scottish Parliaments was an insignificant town with less than 13,000 inhabitants, to convert itself into a seaport, and thus lay the foundations of its subsequent prosperity. Now tobacco makes up less than 1 per cent. of the value of the goods imported at Glasgow, and, though that may be partly due to a diminution in the actual quantity of tobacco imported at Glasgow, this result has chiefly been brought about by changes in relative values. A hundred years ago the value of the imports into Great Britain and Ireland from the British West Indies was about one-fourth of the total value of the imports from all parts; now it is less than 1 per cent. of that value.

What has brought about such changes, what makes the essential difference between recent and all previous commerce, is the series of enormous improvements in the means of communication which followed so closely on the invention of textile machinery and the improvement of the steam-engine in this country. These improvements have had two important effects on commerce. First, they have facilitated the maintenance of order and security both by land and sea, and thus enormously reduced the risks of commerce. Secondly, they have directly lowered the cost of transport for different goods in different degrees. Bulky goods of little value could now for the first time be profitably conveyed many hundreds of miles by land to a seaport, and there load ever larger ships for distant shores, thus opening up markets with vast undeveloped resources in the heart of great continents. Along with these bulkier goods the more valuable goods are carried at a cost far

[1] Danvers, vol. i., pp. 284, 286.

[2] I take these figures from p. 6 of the appendix to P. Colquhoun's "Treatise on the Wealth, Power, and Resources of the British Empire," 2nd ed., London, 1815.

[3] As above, vol. i., p. 64.

below that of former times, so that for such commodities as pepper the mere freight is almost a negligible item.

At the present day there can be no doubt that in point of quantity the spice trade is much larger than it ever was. If Venice could get the whole of that trade into her hands, a thing which she never had, notwithstanding the patriotic boast of Doge Mocenigo, the trade would not now bring her a tithe of the wealth which it brought in the days of her grandeur. Much has been said of the sudden "fall" of the Portuguese and Dutch in turn, and that fall has often been explained by mistakes in method. "The fall of the Dutch colonial empire resulted," says Sir William Hunter, "from its short-sighted commercial policy. It was deliberately based upon a monopoly of the trade in spices, and remained from first to last destitute of sound economical principles."[1] But one may well ask, Did the Dutch ever fail in a manner for which they were in any way responsible? It is true that the Dutch East India Company did not supply as many people as they could with the spices of which they held the monopoly. But that was not their aim. It is true that they did not build up a great empire like that of the English East India Company. But neither was that their aim. Their aim was to declare dividends, and dividends they declared. The profits of the company down to 1720 averaged 20 per cent. per annum, never sinking below 15 per cent., and sometimes rising to 50 per cent. If spices ceased to enable them to declare such dividends that was not their fault. It was James Watt, George Stephenson, William Symington, and Robert Fulton, who, without intending it, and without being able to foresee what in this respect they were destined to do, sucked the value out of pepper, and that in a manner which neither the strength of armies nor the subtlety of statesmen could have done anything to prevent.

Now the countries that offer the most attractive markets for the greatest quantities of goods of all kinds are no longer those which look to the spice trade or to trade in any specially valuable commodities for their enrichment, but those which abound in coal so placed as to develop a great amount of manufacturing industry, an industry engaged for the most part in working for the million, not merely in producing the luxuries of the rich. The commodities of very small bulk in proportion to their value now have a comparatively insignificant place in commerce. The precious metals and precious stones still indeed retain a good deal of their former importance. But very few vegetable or animal products can be put in the same category. Rubber, indeed, may be reckoned as one, and very handsome profits are reaped from some rubber estates. But everyone knows that such exceptional profits can be reaped only for a short time. Of animal products ornamental feathers are the most valuable in proportion to their bulk. Egrets' feathers, I believe, are seldom worth less and often worth a good deal more than twice their weight in gold, but ornamental feathers altogether make up less than a third of 1 per cent. of the total value of British imports.

Perhaps the greatest feature of modern commerce is the unparalleled manner in which it has promoted the increase of population nearly all the world over. Rendering it possible for manufacturing and commercial peoples to depend in a very large measure for their very means of subsistence on supplies brought from the ends of the earth, it is rapidly pushing the settlement of vacant land to the base of the mountains and the edge of the desert. Fifteen years ago Prof. Bryce said, "We may conjecture that within the lifetime of persons now living the outflow from Europe to North America will have practically stopped."[2] We are at least nearing the time when the "new lands" of this earth in the temperate zone will all have been allotted. The results of such a check to expansion after a long period of stimulation to expansion must be momentous, but what the nature of these results will be I for one confess that I am unable to foresee. I am, however, convinced that, if we are to be enabled to make any probable forecast as to the course of future development, one of the most important aids to that result must consist in the study of the relations of geography and history from the point of view which I have endeavoured to indicate. To study these relations merely with reference to the immediate causes and effects of wars and treaties gives little real insight into the working of geographical influences in history. As in the study of the human body medical men have recognised the necessity of ascertaining with the aid of the microscope the normal functions of the cells of which the body is composed, the pathological states that interfere with their normal working, and the effects on one part of the body of minute disturbances of function in another part, so in tracing the course of history it is becoming more and more recognised that the minute gradual silent changes must be inquired into and taken into account, not merely in relation to the regions in which they take place, but in relation, it may be, to regions far distant. Such studies, it is true, are not confined to the geographer. In them, indeed, the geographer must seek the aid of workers in other fields: but there can hardly be a doubt that it must help greatly towards arriving at a sound solution of the problems presented to keep steadily before one the geographical point of view. The field for such studies is of course immense, the material perhaps not all that could be wished; but I can imagine no task more delightful for those who have the opportunity to engage in it than that of seeking out and examining from that point of view such material as actually exists.

NOTES.

THE death is announced, at the age of fifty-one years, of Prof. Emil Petersen, professor of chemistry in the University of Copenhagen. Prof. Petersen was a pupil of and collaborator with Prof. Jörgensen, and was well known for his researches in physical and analytical chemistry.

WE regret to see by the *Scientific American* that Prof. Angelo Heilprin died on July 17 at the age of fifty-four years.

THE sum of 900*l*. has been given by Mr. W. H. Crocker, of San Francisco, to the University of California for the purpose of defraying the expenses of an expedition to observe the total solar eclipse of January 3 next, which will be visible on the Pacific coast.

THE Board of Trade is about to constitute a special temporary branch (under the direction of Colonel Sir Herbert Jekyll, K.C.M.G.) for the purpose of dealing with matters relating to London traffic so far as they come within the scope of the Board.

MR. H. C. PLUMMER, assistant in the Oxford University Observatory, has been appointed to a fellowship at the University of California in connection with the Lick Observatory on Mount Hamilton.

IN reply to a question put to him in the House of Commons on Thursday last by Mr. McCrae, the member for Edinburgh, East, as to whether he was in a position to say if he was able to accede to the request of the Scottish members of Parliament for a grant to the Scottish Meteorological Society for the purpose of reopening and maintaining the Ben Nevis observatories, the Chancellor of the Exchequer said the only scheme which had up to the present been placed before him was one under which the whole cost of the re-equipment and maintenance of the observatories would be thrown upon public funds, and to this he did not feel justified in assenting. He was, however, quite prepared to consider the question of renewing the Government grant, which was for many years given to these institutions through the Meteorological Council, provided that an adequate contribution towards their re-establishment and maintenance were forthcoming from other sources.

A party of observers, consisting of Dr. T. A. Jaggar, jun., head of the department of geology, Massachusetts Institute of Technology; Dr. H. S. Eakle, University of California; Prof. H. V. Gummery, professor of mathematics, Drexel Institute, Philadelphia, who will have charge of the magnetic observations; Dr. Van Dyke, who will study the botany and entomology of the islands; and Prof. F. T. Colby, who will investigate the natural history of the region, recently sailed from Seattle, Washington, to study the geological formation of the Aleutian group of islands and other scientific features of the archipelago. The investigators will, according to the *Scientific American*, pay particular attention to Perry Island, which suddenly rose from the sea more than a year ago. The party will begin working westward from Attu Island, and will devote several months to their researches.

Dr. Charcot has furnished the *Geographical Journal* with further particulars of the plans for his new Antarctic expedition. The choice of the same field of exploration as on the former expedition was made, after due consideration of the plans of other expeditions now being organised or projected, for the following reasons:—(1) the importance of gaining further knowledge of the almost unknown Alexander I. Land; (2) the possibility of the existence in that region of an ice-barrier similar to that of Ross, over the surface of which an advance could be made; (3) the advantages of continuing the scientific work begun by the former expedition, and utilising the experience gained by it; (4) the support to be expected from the Argentine Republic in view of the excellent relations entered upon on the former occasion. The building of a special ship will, it is hoped, soon be begun. While large enough to permit the carrying out of scientific work under suitable conditions, the vessel will be small enough to enable it to navigate in safety along the coasts and to seek shelter in small coves. In addition to ordinary sledges, it is proposed to take motor-sledges for possible use on the surface of an ice barrier. Wandel Island is to be the final base of operations, and from this the coast of Alexander I. Land will be explored as far as possible, also the unknown area, scientific work being at the same time carried on at the base. During the second summer an attempt will be made to navigate westward as far as possible in the direction of King Edward VII. Land.

Information is given in the August number of the *Geographical Journal* respecting a new scientific expedition to the extreme south of South America which is being organised by Mr. Carl Skottsberg, one of the members of the recent Swedish Antarctic Expedition. The expedition, which will leave Gottenberg next month, will consist of Messrs. Skottsberg, P. Quesnel, and T. Halle. It will not sail in a ship of its own, but will make use of the ordinary mail steamers and coasting vessels for transport to the scene of operations, and will be equipped for botanical, geological, zoological, and meteorological work. Proceeding *via* Buenos Aires and Montevideo to the Falklands, the leader and Mr. Halle will there spend the summer of 1907–8 for the purpose of continuing the researches begun by the Swedish Antarctic Expedition, Quesnel meanwhile going to Punta Arenas, where he hopes to make an excursion to the Cerro Payne region. On re-uniting at Punta Arenas, the party will, if time permits, make an expedition to the northwards along the Cordillera and round Otway and Skyring waters, before winter sets in. This will be spent in the rainy region of the western channels, and in the spring an attempt will be made to reach Lago Fagnano, the party then moving its headquarters to the region of Beagle channel. It is proposed to conclude the summer's work with a trip to Tekeenika Bay, returning to Sweden in April or May, 1909.

Mr. Charles Hawksley has commemorated the centenary of the birth of his late father by offering the sum of 1000*l*. to the council of the Institution of Mechanical Engineers for the foundation of a scholarship or premium. The offer has been accepted by the institution, and the terms on which the gift is to be held are under consideration.

Two sums, each of 250*l*., have been received by the Institution of Mechanical Engineers from the Metropolitan Water Board and the chairman of the Court of Arbitration (under the Metropolitan Water Act, 1902), which the donors desire to be used for some engineering purpose connected with the institution. The council have invested the amount—500*l*.—in a trustee security, the income from which they have decided, after consultation with Sir Edward Fry, shall be offered biennially for a paper submitted in accordance with prescribed conditions. It has been further decided that the prize shall be known as the "Water Arbitration Prize," and shall be offered for a paper on an engineering subject to be announced by the council one year before the time for sending in the papers. The prize, which will have a value of approximately 30*l*., will take any form which the council may from time to time decide upon, and will be accompanied by a certificate bearing the seal of the institution. If, in the opinion of the council, no paper of sufficient merit be received in reply to any particular offer of the prize, the amount available for that award will be added to the capital of the fund. The conditions for the first award, to be made in 1908, are that:—(1) The award will be made to the author of the selected paper dealing with the filtration and purification of water for public supply. (2) Members, associate members, associates, and graduates of the institution may compete. (3) Papers must be sent in to the secretary of the Institution of Mechanical Engineers, and must reach him not later than January 3, 1908. (4) Each paper must be clearly written, or typewritten, on one side only of foolscap paper, with a margin, and must be accompanied by an outline or synopsis of its contents of not more than six hundred words; any illustrations submitted with the paper must be properly drawn to scale. (5) Papers submitted for competition will become the property of the institution, and, at the discretion of the council, may be either read and discussed at a general meeting or printed in the Proceedings without having been so read and discussed. Each paper must consist of original matter written by the competitor himself, and the council will require a written statement to that effect. Any paper not accepted for printing in the Proceedings will be returned to the author. No paper which has been previously published will be accepted for competition.

A special committee, with M. V. V. Podvysotsk, director of the Institute of Experimental Medicine, as president, has been appointed by the Medical Council of the Russian Ministry of the Interior to study the question of establishing a committee for the investigation of cancer.

According to the *Lancet*, the late Prof. Grancher, of Paris, has left to the society founded by himself, the object of which is the protection of children from tuberculosis, a sum sufficient to provide an annual income of 20,000 francs. Dr. Roux, director of the Pasteur Institute, has accepted the position of president of the society.

At the first meeting of the medical section of the Royal Society of Medicine, which is to take place on October 22, Dr. Hector Mackenzie will open a discussion on the complications and sequelæ of pneumonia and the treatment of pneumococcal infections by serum or vaccine. The section is now fully constituted, and is open to receive papers for reading and discussion during the winter session.

The fourteenth International Congress of Hygiene and Demography will meet in Berlin from September 23 to September 29. A strong international committee has been constituted for the organisation of the meeting, which promises to be a very successful and interesting one. Of the British section, Sir Shirley Murphy is the chairman, Prof. Nuttall, F.R.S., and Mr. Paul Moline are the secretaries, and Mr. Cutler is the treasurer. The congress is divided into eight sections, and a number of interesting subjects have been selected for discussion. Anyone engaged scientifically or practically in hygiene or demography is eligible as a member, the subscription being 1*l.*, which entitles him to a copy of the transactions. Those not eligible for membership (*e.g.* the relatives of members) will be admitted to the sectional meetings, &c., on payment of a subscription of 10*s.* Some of the subjects selected for discussion are the ætiology of tuberculosis, pathogenic protozoa, alcoholism, care of infants, overwork in schools, caisson disease, uniform methods of testing disinfectants, preventive inoculation, housing of the working classes, artificial ventilation, sleeping sickness, and control of milk.

The eighth session of the Australasian Medical Congress is to take place in Melbourne in October of next year. The president will be Prof. H. B. Allen, of the University of Melbourne. The eleven sections into which the congress is to be divided will be presided over respectively by Dr. G. E. Rennie, medicine; Dr. B. Poulton, surgery; Mr. E. T. Thring, obstetrics and gynæcology; Dr. J. T. Wilson, anatomy and physiology; Dr. F. Tidswell, pathology; Dr. J. M. Mason, public health and State medicine; Dr. J. Lockhart Gibson, diseases of the eye, ear, and throat; Dr. F. Truby King, neurology and psychiatry; Dr. A. Jefferis Turner, diseases of children; Surgeon-General W. D. C. Williams, naval and military surgery and medicine; Dr. W. McMurray, skin diseases, &c.

An electrical exhibition lasting a fortnight is to be held in Montreal, commencing on September 2, and from September 11 to 13 the Canadian Electrical Association is also to meet in the same city, when the following papers, among others, will be read:—How to increase the load factor; some of the difficulties encountered in operating alternating current systems; new and old type incandescent lamps; the Nernst lamp; and electric heating and cooking appliances.

In the Scottish National Exhibition to be held in Edinburgh in 1908 there will be sections devoted to fine arts, education and history, arts and crafts, mining, engineering and metallurgy, transportation and motive power, shipbuilding and waterways construction, chemistry and scientific appliances, lighting, heating and ventilation, agriculture, horticulture and sylviculture, domestic economy, sports and pastimes, botany and zoology, artisans' work, women's section, urban and rural improvements.

A recently issued report from the British Consul at Copenhagen states that the Danish Government has allocated the sum of 4276*l.*, to be used during the next three years, for the purpose of the extermination of rats, on the understanding, however, that the sum of 1666*l.* be expended over a like period by an organisation which is in existence for the destruction of rats. It is stated that a Danish patent rat destroyer has been invented, which, when eaten by rats, causes disease of the bladder, which kills them; whereas it may be swallowed by human beings, dogs, and poultry without danger.

In connection with the international investigations of the upper air, conducted from July 22 to 27, several kite ascents have been made under the auspices of the Meteorological Office. A number of registering balloons (*ballons sondes*) have also been sent up, six at Manchester and three at Ross (Herefordshire), for the joint committee of the Royal Meteorological Society and the British Association; six at Petersfield by Mr. C. J. P. Cave; five at Crinan and four at Pyrton Hill, Oxon, for the Meteorological Office. The recording instruments for nearly all the ascents have been supplied by the Meteorological Office. Up to Monday, July 29, nine had been recovered, and one has been reported since. One balloon sent up at Ross, Herefordshire, on July 23, is reported to have reached the height of probably 60,000 feet, or about eleven miles. It is too early yet for any detailed results to be given.

As the annual presidential address to the Philosophical Society of Washington on December 8, 1906, Prof. C. Abbe read a most interesting and instructive paper on the progress of science as illustrated by the development of meteorology. The author pointed out that while some portions of this subject are already as exact as our knowledge of other sciences can make them, the path of progress is strewn with the wrecks of popular errors. Since the establishment of the Meteorological Society of the Palatinate at Mannheim in 1780, the advance made has been entirely in the direction of the line of work that it laid out, viz. to collect data from all parts of the globe for the purpose of compiling synoptic daily weather maps for the study of the atmosphere as a whole. At the present time the investigation of the upper air is being made throughout the world, and each national weather bureau is extending its field of observation horizontally, while each is now alive to the fact that satisfactory advance in practical meteorology requires corresponding progress in our knowledge of the sciences involved in the motions of the atmosphere. Another step in advance is due to the investigation of the interaction of the continental and oceanic hemispheres, to our knowledge of which subject the researches of Sir Norman and Dr. Lockyer, among others, have greatly contributed. This principle is already recognised by the directors of the Indian Meteorological Service in their forecasts of the approaching monsoons.

At the annual meeting of the National Association of Colliery Managers at Chesterfield on July 25, Mr. J. P. Houfton delivered the presidential address. He dwelt upon the increasing difficulty and complexity of the problems connected with mining as the shallower seams were exhausted, and urged the necessity for the colliery manager to be a man of scientific training and education. He considered that it was of national importance that a university of mining should be established in order to furnish the colliery managers of the future with the technical knowledge and scientific training required to enable them to work the deeper coal seams.

For the summer meeting of the Institution of Mechanical Engineers, which opened on July 30 at Aberdeen under the presidency of Mr. T. Hurry Riches, an interesting programme of papers was arranged. Mr. William Simpson's paper on granite quarrying in Aberdeenshire was specially noteworthy in that it furnished information on a subject regarding which the technical literature is remarkably sparse. Nowhere in the whole of Great Britain is there such a large exposure of granite as in north-east Scotland, and the supply of granite of the highest durability and beauty is practically inexhaustible. The quarrying presents many features of difficulty. The overburden is costly to remove, and the top rock unremunerative. As a rule the quality of the rock improves with the depth, and there is a temptation to deepen without a proportionate surface area. Where this has been done the quarry has assumed the form of a conical pit with a small floor, difficult and costly to work. Mr. Herbert Bing submitted a paper on portable pneumatic tools. Of recent years there has been great progress made in these tools, and in the range of work to which they are applicable. At the present time they will be found in use in practically all engineering works, shipyards, and mines. Mr. C. E. Larard described an electrically controlled single-lever testing machine at the Northampton Polytechnic Institute, London. The machine constitutes quite a new departure in many of its arrangements, and has given very satisfactory results in testing, due primarily to the good control over the rates of loading and straining. Papers were also contributed by Mr. J. M. Henderson, on cableways used on shipbuilding berths, and by Mr. D. J. Macdonald, on jute preparing and spinning.

In October, 1905, a committee was appointed by the council of the Royal Institute of British Architects to draw up rules for guidance in the use of reinforced concrete. The report of this committee has recently been published, and in the *Engineer* of July 26 the rules drawn up are compared with the French Government instructions. In the more important matters there is uniformity in treatment, and the rules proposed by the committee are by no means revolutionary.

The fuels committee of the Motor Union of Great Britain and Ireland has issued a valuable report on motor-car fuels, of which a summary is published in the *Engineer* of July 26. Readers of the report will find cause for a despondent view of the petrol supply, and will probably agree that a famine in petrol appears to be inevitable in the near future, owing to the fact that the demand is increasing at a rate much greater than the rate of increase of the supply. In 1904 the consumption of petrol in the United Kingdom was 12,000,000 gallons; in 1907 it had risen to 27,000,000 gallons. In November, 1904, the trade price was 7*d*. per gallon; in December, 1906, it was 13*d*. Having recognised that the time is not far distant when a substitute for petrol must be sought, the committee discusses in the report other possible fuels. The supply is divided into two parts. The first includes all fuels limited in quantity; they are the spirits of a specific gravity between petrol and paraffin, paraffin itself, coal dust, gas, and benzol. The second group contains one item only—alcohol—and it is evident from the whole tone of the report that the committee expects to find in denatured vegetable spirits the fuel of the future.

An article on the natural regeneration of the "dhowra" tree, *Anogeissus latifolia*, in the Panch Mahal division of Bombay, is communicated by Mr. R. F. Pearson to the May number of the *Indian Forester*. Owing to the occurrence of a large number of trees of an even age, the author was led to examine the conditions under which such extensive seedling growth was developed. Whilst the rainfall in the year of germination was distinctly favourable, the opinion is expressed that, in addition, the seed must have been unusually fertile. The fertility of seeds from trees is a question deserving the attention of foresters. Mr. Pearson attributes the fertility of the seed in this instance to the stimulus or shock caused by the drought of the previous year. A note on the Kashmir trout fisheries refers to the attempts, finally successful, made by Mr. F. Mitchell whereby the Harwan stream and the Dhal Lake have been stocked with brown trout.

With reference to afforestation, in a paper printed in the Transactions of the Royal Scottish Arboricultural Society, vol. xx., part ii., Mr. A. C. Forbes discusses the problem of planting up waste land, and places on record certain data, obtained by the measurement of sample plots of Scots pine, larch, and spruce on plantations in Northumberland and Cumberland, showing an annual increment varying from 50 cubic feet to 80 cubic feet per acre. Figures are also presented, on the authority of Lieut.-Colonel F. N. Innes, for plantations in Aberdeenshire. Other papers in the volume include a summary of a paper by Mr. M. Henry on the interrelation between forests and rainfall, arboricultural notes from Portuguese East Africa contributed by Mr. J. A. Alexander, and an account of the work at Eberswalde Forest Academy by Mr. A. F. Wilson.

A dissertation on the physiological significance of caffein and theobromin, by Dr. Th. Weevers, is published in *Annales du Jardin botanique de Buitenzorg*, ser. ii., vol. vi. These xanthin derivatives were found in all parts except the roots of *Thea assamica* and *Coffea arabica*, but only in the early vegetative stages of *Coffea stenophylla* and *Cola acuminata*. From a comparison of the quantities obtained in young and maturing leaves, also in leaves placed in air devoid of carbon dioxide, the author concludes that these substances are formed as secondary products in the breaking down of proteins, and are subsequently absorbed in protein synthesis; in the seeds they are plentiful, forming a nitrogenous reserve.

A bulletin, No. 187, issued by the United States Department of Agriculture, deals with the digestibility and nutritive value of legumes, recording the results of experiments conducted by Dr. C. E. Wait at the University of Tennessee. Although these tend to prove that legumes are not so thoroughly digested as many other foods, the author recommends their inclusion as a source of protein in the diet, and directs attention to the value of cow-peas, the product of *Vigna Catiang*.

We have received copies of two issues, No. 68, part i., and No. 69, of the Bulletin of the U.S. Bureau of Entomology, the former, by Mr. Dudley Moulton, dealing with the pear-thrips (*Euthrips pyri*), while in the latter Mr. F. M. Webster discusses the ravages of the chinch-bug (*Blissus leucopterus*). The pear-thrips flourishes in the districts around San Francisco Bay and the Sierra Nevada foot-hills, but whether it is an indigenous species which has become unusually numerous owing to the development of orchards, or whether it is introduced, has not yet been ascertained. In 1905, when this insect was exceedingly numerous, the pear-crops were hopelessly blighted, but how much of the injury was due to the thrips and how much to wet weather is uncertain. Owing to the long period spent by the thrips underground, remedial measures are difficult to apply. Practically the whole of the eastern half of the United States is infested by the chinch-bug, which is represented by a short-winged maritime phase and a long-winged inland form. It is a migratory, two-brooded species, which originally fed upon the native grasses, but has now turned its attention to wheat and other cereals. On reaching a suitable food-supply, the insects congregate on the plants until these are literally covered with individuals of various ages, ranging in colour from the vermilion of the older larvæ to the black and white of the adults. When the plant is drained of its juices, the larvæ move on to the next one, the adults alone making long migrations.

THE African honey-guides (Indicatoridæ), which have acquired parasitic habits parallel to those of cuckoos, are wiser in their generation than the latter, for (as we are told by Mr. A. K. Haagner in the Journal of the South African Ornithologists' Union for June) they are in the habit of breaking the eggs of the birds they select as foster-parents for their offspring. This is illustrated by a plate in the same issue, where two of the fractured eggs are shown. In some cases, however—probably when they are attacked by the future foster-parents—they do not succeed in breaking the rival eggs, in which event it is probable that the strong hooks on the tip of the beak of the young honey-guides come into play for the purpose of aiding in the ejectment of the other occupants of the nest. A nestling of one species of honey-guide is represented in a second plate. It may be added that most of the plates in this issue are lettered vol. iii., whereas the cover is lettered second series, vol. i., No. 1. The idea of commencing a second series with the third volume of this serial thus seems to have been an afterthought—and a by no means happy one.

SLUGS, according to Mr. B. B. Woodward's presidential address to the Malacological Society for 1907, are more specialised creatures than snails, for among molluscs of all classes there appears to be a general tendency, more especially in the carnivorous types, to discard the shell as the result of the assumption of more active habits than ordinary. Other instances of adaptive modifications in the group are mentioned in the same address.

IN *Science Progress* for July (ii., No. 5), Dr. Bashford discusses the application of experiment to the study of cancer, and summarises the results obtained by a study of the development of transplanted cancer in mice.

WE are asked by the author, Mr. Arthur Trewby, to state that the little volume entitled "Healthy Boyhood," which was reviewed in our issue of July 25, may be obtained post free for 1*s.* 6*d.* from the author, Fenton House, The Grove, Hampstead Heath, N.W.

OUR ASTRONOMICAL COLUMN.

ASTROGRAPHIC CATALOGUE WORK AT THE PERTH OBSERVATORY (W.A.).—Mr. W. Ernest Cooke, Government astronomer of Western Australia, informs us that the prospects for the astrographic catalogue work are not now so hopeless as they appeared from the report referred to in NATURE of May 23 (p. 89). He says that the present Government recognises the importance of the work, and a start has been lately made to measure the plates. It is feared, however, that the images will deteriorate before the completion of the work. Upon comparing a plate taken a few years ago with a recent one of the same region, the image of a ninth-magnitude star on the former was found to be about equal to that of a 9·5 magnitude on the latter. With reference to the 10,000 standard stars which have to be observed by means of the transit circle, Mr. Cooke hopes to obtain good positions of all these stars (three observations of each) in ten or twelve years, and certain zones have been completed already. It is proposed to make this list of stars the standard work at the Perth Observatory, observing and re-observing exactly the same list, in order to obtain good determinations of the position of each star every ten years or so.

DANIEL'S COMET (1907*d*).—This comet is now approaching the naked-eye stage, and may be found quite readily with small opera glasses. On August 9 it will rise at about 12h. 45m., some $3\frac{3}{4}$ hours before the sun. On August 14 the comet will be about 46′ north of γ Geminorum. An observation made on August 1 showed no indication of a tail, but the comet has a well-defined nucleus.

MARS.—Telegrams received from the Lowell expedition to the Andes announce that on July 2 Mr. Slipher photographed several of the canals, and that on July 6 canals were seen double and oases were photographed (*Astronomische Nachrichten*, No. 4193, p. 291, July 26).

In vol. xxvi., No. 1 (p. 1, July), of the *Astrophysical Journal*, Prof. Newcomb discusses the optical and psychological principles involved in the interpretation of the so-called canals of Mars. From the optical point of view he shows that in the best refracting telescopes the effects of aberration, diffraction, and atmospheric softening will materially increase the breadth of any linear marking. As a rough estimate he submits that a perfectly black line on Mars three miles in breadth might be visible if the surface of the planet were perfectly uniform, but, as it is not, the actual breadth would have to be increased to eight or ten miles in order that the feature might be differentiated from those surrounding it. Aberration, &c., would spread a marking of this width for some twenty miles on each side, so that the apparent breadth in the telescope would be fifty miles or upward. Allowing this width to each of the 400 canals mapped by Lowell, the total area covered would be 33,000,000 square miles, the actual surface of Mars extending over some 55,000,000 square miles. Although this large relative area does not disprove the objective reality of the canal system, it shows how wide the interpretation of the results must of necessity be, when the whole network is crowded on to a disc only 20″ in diameter. Concerning the interpretation of such features by different observers, Prof. Newcomb gives some illustrated results of a number of interesting experiments he has carried out in this direction.

SOME NEW APPLICATIONS OF THE SPECTROHELIOGRAPH.—Using a temporary spectroheliograph of 30 feet focal length, Prof. Hale has obtained spectroheliograms with the primary slit set on some of the dark lines which are found strengthened in the sun-spot spectrum. The lines employed in this preliminary work were those which appear to be strengthened in the umbra and penumbra and on the photosphere for some distance from the spots, and the resulting photographs show the umbra and penumbra much darker than they appear on plates taken with the light of the continuous spectrum; the diameter of the spot also appears to be considerably increased. Lines weakened in sun-spots were also tried and gave definite results, which are, however, less marked than in the case of the strengthened lines. For work with the numerous faint lines of the spot spectrum a large dispersion is absolutely essential, and a suitable instrument is being constructed for use with the new vertical telescope.

Prof. Hale has also obtained some spectroheliograms for stereoscopic examination, which, when viewed with a stereoscope, show the masses of flocculi standing boldly above the general level of the hemisphere. A pair of these, taken at an interval of 2h. 5m., are reproduced in the *Astrophysical Journal* (vol. xxv., p. 314, June). It is hoped that by examining such pairs of spectroheliograms in the stereocomparator changes may be detected in the appearance of the flocculi, &c., which might otherwise escape detection.

THE "ANNUARIO" OF THE RIO DE JANEIRO OBSERVATORY.—The twenty-third annual publication of the Rio de Janeiro Observatory, for 1907, which we have just received, is very much like its predecessors, and contains an exposition of various calendars, numerous tables and data useful to astronomers, and a compilation of various physical data which will be found of general use.

PERSEIDS—COMET DANIEL.

On the night of August 4 several bright Perseids were observed, and this marked return of the shower at so early a date presages a display exceeding the ordinary richness this year. There is evidence that the shower is pretty strong every ten years, for there were considerable numbers of Perseids seen in 1877, 1887, and 1897. It will be desirable to watch the phenomenon during its ensuing apparition, with special regard to the fact alluded to, and to ascertain the hourly number of Perseids visible throughout the nights of Sunday and Monday, August 11 and 12. The latter date will probably be found to represent the time of maximum. St. Lawrence's Day, August 10, is no longer contemporary with the Perseid display at its best.

The diurnal motion of the radiant, amounting to one degree in a direction to E.N.E., was first definitely observed by the writer in 1877 and announced in NATURE at the time. Every year supplies fresh evidence of the displacement and corroborates the facts described in Monthly Notices, vol. lxii., pp. 161–9.

Daniel's comet has been visible to the naked eye since the first few days of July, and is now sufficiently conspicuous to arrest the immediate attention of anyone who will look towards the eastern sky before the morning twilight becomes too strong. On August 5, at 3 a.m., the nucleus of the comet appeared like a blurred star of $2\frac{1}{2}$ magnitude, and the tail extended westwards over nearly 3°, but it was difficult to assign limits, as it faded gradually away into the tone of the sky. Ephemeris by Dybeck (*Ast. Nach.*, 4194):—

W. F. DENNING.

THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

The seventy-fifth annual meeting of the British Medical Association was held last week at Exeter under the presidency of Dr. Henry Davy, physician to the Royal Devon and Exeter Hospital.

The subject of the presidential address was "Science in its Application to National Health." After giving some particulars concerning Exeter and the Royal Devon Hospital, Dr. Davy proceeded to point out that every organ, muscle, and structure in the body required a proper amount of work to keep it healthy. Exercise was therefore very important, and he deplored the present tendency to watch games rather than to participate in them. Physical culture was one of the most pressing questions of the day, and it should not be left to professors of Swedish exercises to lecture on physical culture and to direct the kind of exercise to be employed; in such questions the medical man should be consulted. Schools should have proper playgrounds and gymnasiums, and trainers in physical exercises were as necessary as school teachers. The question of food was another important one, and the "man in the street" should be able to obtain from his medical attendant precise details of the quantity required and of its nature. As regards infective diseases, pyæmia was now almost unknown, thanks to the labours of Lord Lister, typhoid fever was diminishing, and it was now tuberculosis that required to be attacked. Something, it was true, had been done in this direction, but much more remained; are no precautions to be insisted on with regard to disinfection? Are we for ever to allow consumptives to disseminate their infectious expectoration? Are consumptives alone to be allowed to stay in hotels and lodgings without taking precautions?

The address in medicine was delivered by Dr. Hale White, whose subject was "A Plea for Accuracy of Thought in Medicine." He instanced such terms as "irregular" or "suppressed gout" and "liver out of order" as really being only a cloak for ignorance, which it would be much better to confess. "Selective action" was another mystery, *e.g.* why does alcohol pick out the anterior tibial nerve and lead the musculo-spiral? Why do beer drinkers get "beer-drinkers' heart" in Munich but not in London? Unreflecting adhesion to authority has a particularly serious effect in keeping back the advent of correct knowledge.

Mr. Butlin discussed the "Contagion of Cancer in Human Beings: Autoinoculation" in his address in surgery. He brought forward a number of cases in which cancer in a part was followed by cancer of the same type in another part in contact with the first, *e.g.* cancer in one lip followed by cancer in the other lip.

In the section of medicine there was a discussion on the indications for operation in cases of intra-cranial tumour introduced by Dr. Risien Russell, Dr. Gardner Robb read a paper on the recent outbreak of cerebro-spinal fever in Belfast, and Dr. Rivière one on the tuberculin treatment of tuberculosis in children.

In the section of pathology there were important discussions on pernicious anæmia and on phagocytosis. In the section of tropical diseases, Prof. Simpson read a paper on anti-malarial sanitation, in which he discussed how recent discoveries have rendered anti-malarial sanitation more precise and less costly than formerly.

In the section of State medicine, Dr. Newsholme delivered an address on the need for coordination of the public medical services. Voluntary effort, as illustrated in the hospitals, and State-aided treatment under the Poor Law, failed entirely to produce an adequate result for the vast sums expended. A coordinated system of State-paid and State-directed medical service would speedily justify itself from an economical standpoint, and must of necessity ally itself with preventive medicine.

Dr. Gilchrist read a paper on the necessity of increasing the degree of immunity against small-pox, and Mr. Garrett Horder one on the new vaccination order. A resolution was passed by the meeting recommending the council of the association to approach the Local Government Board on the subject of the new vaccination order.

The association was received by the civic authorities at the Guildhall, and numerous garden-parties and excursions helped to pass an instructive and pleasant week in the delightful old city.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MANCHESTER.—Harling fellowships in physics have been awarded to Mr. J. N. Pring and Dr. Hans Geiger.

The University has made arrangements for a number of public lectures in the autumn which are to be given by leading men of science and others.

Dr. Graham Steell has been appointed by the council of the University of Manchester professor of medicine in the university.

OXFORD.—The Romanes lecture will be delivered by Lord Curzon, Chancellor of the University, in the Sheldonian Theatre, on Saturday, November 2. The subject of the lecture will be "Frontiers."

SHEFFIELD.—Mr. D. H. de Souza has been appointed demonstrator in physiology, and Mr. W. F. G. Swann assistant lecturer and demonstrator in physics.

PROF. VON LEYDEN has resigned the professorship of clinical medicine at the University of Berlin, and Prof. His, of Göttingen, has been appointed to succeed him in the chair.

DR. GEOFFREY MARTIN, a former student of the Merchant Venturers' Technical College, Bristol, has been appointed lecturer and demonstrator in chemistry at University College, Nottingham.

A "PROF. TAIT'S MEMORIAL FUND" of the value of 200*l.* per annum, for the encouragement of physical research in the University of Edinburgh, has been endowed by Sir John Jackson.

Two research studentships in science of the value of 60*l.* and 40*l.* respectively have been founded at University College, London, by an anonymous donor; they will be awarded for the first time next session.

A MOVEMENT is on foot in Glasgow to recognise in a suitable manner the scientific services of Prof. J. G. McKendrick, F.R.S., and a committee of former pupils and friends has been formed to raise a memorial to the late Prof. Pirie, Aberdeen.

MR. W. E. CURNOCK has been appointed head of the department of mechanical engineering and building trades at the Battersea Polytechnic. Mr. Curnock has for the past three years been head of the engineering department of the Technical College, Huddersfield.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 29.—M. A. Chauveau in the chair.—New contribution to the study of the trypanosomiasis of the Upper Niger: A. **Laveran.** An account of a new trypanosome to which the name *T. soudanense* has been given. This parasite, from a morphological point of view, resembles *T. evansi*, but differs from it in its pathogenic action on animals, especially mice. Experimental evidence is given that the trypanosome of Mal de la Zousfana and El Dabab is probably *T. soudanense*.—The function of the spleen in trypanosomiasis: A. **Laveran** and M. **Thiroux.** A criticism of a paper on the same subject by MM. Rodet and Vallet. The latter regard the spleen as possessing trypanolytic properties, but this view is disputed by the authors of the present note.—The early diagnosis of tuberculosis by the ophthalmo-reaction with tuberculin: A. **Calmette.** This reaction, as applied by the author, consists in the application to the eye of a 1 per cent. solution of dry tuberculin precipitated by alcohol. In healthy subjects no reaction is produced, but in tuberculous subjects a characteristic conjunctival redness is produced within twenty-four hours. This reaction has been utilised in nearly a thousand cases with very satisfactory results, and in many instances, especially of children, has revealed tuberculous lesions the presence of which had not been suspected.—Mr. E. C. Pickering was elected a correspondant for the section of astronomy, in the place of the late M. Rayet.—A point in the theory of the sun of M. Julius: Henri **Bourget.**—Linear homogeneous representations of finite groups: M. **de Séguier.**—Differential equations of the third order with fixed critical points: M. **Chazy.**—Differential equations of the third order the integral of which is uniform: René **Garnier.**—The representation of integral equations of any degree: J. **Massau.**—The determination of the altitude of the summit of Aconcagua: Fr. **Schrader.** The mean of two observations was 6953 metres. Full details are given of the method used.—Ionisation by bubbling through liquids: L. **Bloch.** A question of priority regarding a recent note by M. de Broglie.—The compressibility of gases in the neighbourhood of atmospheric pressure: Daniel **Berthelot.** The variation of pv with the pressure has been studied for carbon dioxide, nitrous oxide, and sulphur dioxide for pressures between 0·25 and 2·0 atmospheres. Between these limits of pressure the variation of pv is not, as has been assumed by M. Guye, a linear function of the pressure, but is a linear function of the density.—Nitrate of silver: calorimetry at high temperatures: M. **Guinchant.** The calorimeter is isolated by a vacuum jacket, and heated electrically. It has been applied to measure directly the latent heats of fusion of tin, mercuric iodide, and silver nitrate.—Ortho- and pyro-arsenic acids: E. **Baud.** Pure pyro-arsenic acid can be obtained by keeping $As_2O_5.4H_2O$ over strong sulphuric acid at a temperature of 15° C. to 20° C. From thermochemical experiments the author concludes that orthoarsenic acid exists only in solution. The crystals which separate from this solution are the hydrate of pyroarsenic acid.—The direct oxidation of phosphorus: E. **Jungfleisch.** A detailed study of the combustion of phosphorus in oxygen at low pressures, phosphorus anhydride being formed. Under special conditions as much as 95 per cent. of the phosphorus can be converted into P_4O_6.—The properties and constitution of tantalum steels: Léon **Guillet.** Four samples of steel were prepared containing about 0·17 per cent. of carbon, 0·2 per cent. of manganese, 0·2 per cent. of silica, and proportions of tantalum varying from 0·09 per cent. to 1·05 per cent. These steels were studied micrographically and as regards their mechanical properties. Contrary to what has been claimed for these steels, they show no property of any importance.—Some derivatives of menthone: Eyvind **Bœdtker.**—Two new glucosides, linarine and pectolinarine: T. **Klobb.** These are obtained from the flowers and leaves of *Linaria vulgaris*.—The production of high temperatures in laboratory researches: Léon **Guillet.** Reclamation of priority against M. Chabrié.—The mode of distribution of the muscular glycogen in well fed and in starved subjects. The influence of the seasons on the proportion of glycogen in the muscles: F. **Maignon.**—The relative toxicity of the salts of chromium, aluminium, and magnesium; comparison with the analogous properties of the rare earths: Alexandre **Hébert.**—The influence of acids on the action of laccase: Gabriel **Bertrand.**—The influence of manganese salts on alcoholic yeasts: E. **Kayser** and H. **Marchand.**—The urinary chromogen resulting from the administration of indol-carboxylic acid: Ch. **Porcher** and Ch. **Hervieux.**—The dwarf coffee plant of Sassandra, *Coffea humilis*: Aug. **Chevalier.**—The buccal incubation in *Arius fissus*: Jacques **Pellegrin.**—*Coccus anomalus* and the disease causing the blueing of champagnes: E. **Manceau.**—The pharmacodynamical action of kolatine: J. **Chevalier** and A. **Goris.**—Some ophthalmological experiments made with the aid of a mercury vapour lamp: P. **Fortin.** Certain details of structure very difficult to observe with ordinary light are readily perceived by the light of a Cooper-Hewitt lamp. This light is also very useful in the study of colour blindness.—The discovery of the sulpho-gypsum formation in the basin of Seybouse: J. Dareste **de la Chavanne.**—The fishes of the family of Cichlideæ found in the Tertiary strata at Guelma: H. E. **Sauvage.**

THURSDAY, AUGUST 15, 1907.

CORNISH GEOLOGY.

The Geology of Falmouth and Truro, and of the Mining District of Camborne and Redruth. By J. B. Hill and D. A. MacAlister, with Petrographical Notes by J. S. Flett. Memoirs of the Geological Survey. Pp. x+335; with 65 illustrations and 24 plates. (London: Wyman and Sons, Ltd., 1906.) Price 7*s*. 6*d*.

OF the new series one-inch map of England and Wales, few sheets are of greater interest than No. 352 (colour-printed, price 1*s*. 6*d*.), which represents that portion of western Cornwall that contains the oldest and richest mines in the county; and the value of the map is greatly enhanced by the admirable explanatory memoir, which contains a description of the older slaty rocks, the granites, elvans, and greenstones of this area, together with particulars of the metalliferous veins. Attention is given to the genesis of the ores, and to their mode of occurrence, to the methods of dressing the tin ore, and to the mineral output. In short, the description is much more detailed than is usual in a Geological Survey sheet explanation.

The original geological survey was carried out by De la Beche, whose results were published in 1839. New editions of the maps were published in 1866, with additional lodes inserted by Sir Warington Smyth. A comparison of the new map with the older one shows that the additions that have been made are of great importance. The area formerly represented as Devonian has been subdivided into Lower Devonian and three subdivisions, based on lithological characters, designated by the terms Portscatho, Falmouth, and Mylor. These three subdivisions, together with the Veryan beds, formerly classed as Lower Silurian, are shown to be Lower Palæozoic. The grits of Grampound and Probus, representing the base of the Devonian rocks, are taken as the equivalents of the conglomerate on the Helford River (one-inch map, 359).

The igneous rocks are divided by Mr. Hill into four groups: (1) the greenstones, the oldest, which are epidiorites derived from dolerites and basalts; (2) the granite, the dominant representative, with which the mineral products of the area are intimately associated; (3) the elvans, which represent the dyke phase of granite, and were intruded after its consolidation; and (4) the mica traps, the age of which is uncertain. Chapters are devoted to a description of the contact metamorphism effected by the granite and of the faults. The fractures are the product of the later Carboniferous period, and have a trend of about E.N.E. Many of them occur in the mineral areas, where they form the home of the lodes. They are traversed by a second set of faults, of early Tertiary age, which are known to the miner as cross-courses. The Pliocene deposits receive careful attention, the Polcrebo gravels appearing to represent a patch of the Pliocene deposits which formerly spread over the killas platform of this area, and are represented at St. Erth, St. Agnes, and Crousa Downs in adjacent districts. With the exception of these gravels, this area affords no evidence of stratified deposits from the Palæozoic period until the Pleistocene, which is represented by the raised beaches underlying the Head, that is probably a product of the Glacial age.

The second part of the work, which is written by Mr. MacAlister, deals with the mining industry of the district. Modern theories of the genesis of ore deposits are applied to the Cornish tin and copper ores, and detailed descriptions of the mines are given, illustrated by more than fifty sketches. Statistics of production since 1845 are set forth in detail, and ten pages are devoted to a description of the tin-ore dressing processes employed in the Camborne area. Products from the various operations have been subjected to microscopic examination, the results showing that grains of cassiterite which are less than the average size of the grains in the concentrates tend to be lost in the tailings of subsequent operations. The dressing operations are elucidated by means of excellent reproductions of photographs.

On the whole, the work is a very creditable production. It forms an excellent introduction to the geology of Cornwall; and it is satisfactory to note that the price at which it is published is not such as to preclude its use by students of economic geology.

MODERN INTRODUCTIONS TO PHYSICAL THEORIES.

(1) *Elektromagnetische Schwingungen und Wellen.* By Dr. Josef Ritter von Geitler. Pp. viii+154. (Brunswick: Fried. Vieweg und Sohn, 1905.) Price 4.50 marks.

(2) *Theorie der Elektrizitat.* By Dr. A. Foppl and Dr. M. Abraham. Vol. i., pp. xviii+443; vol. ii., pp. x+404. (Leipzig: B. G. Teubner, 1904 and 1905.)

(3) *Ueber den gegenwärtigen Stand der Frage nach einer mechanischen Erklärung der elektrischen Erscheinungen.* By Dr. Hans Witte. Pp. xii+232. (Berlin: E. Ebering, 1906.) Price 7.50 marks.

(4) *Die Fortschritte der kinetischen Gastheorie.* By Dr. G. Jäger. Pp. ix+119. (Brunswick: F. Vieweg und Sohn, 1906.) Price 3.50 marks.

(5) *An Elementary Treatise on Theoretical Mechanics.* By J. H. Jeans, F.R.S. Pp. viii+364. (Boston and London: Ginn and Co., n.d.) Price 10*s*. 6*d*.

A COMPARISON of text-books of the last year or two with those published, say, a quarter of a century ago affords a clear and definite measure of the great changes which have occurred during the interval in our commonly accepted physical theories. All the books now before us reflect these changes in a greater or less degree, but we take Dr. von Geitler's manual as our first example because the author has closely followed the historic order of development in leading his readers from the simple early notions of action at a distance to the modern theories of electrical oscillations and their applications to wireless telegraphy.

Starting with Newton's discovery of the law of gravitation, the reader is led up to Faraday's researches on the electromagnetic field, and he first learns the dependence of this field on the nature of the medium filling it, and the interdependence of electrostatic and magnetic phenomena. While the author in his preface directs attention to the great difficulty of treating the subject in a popular way, it is noticeable that he has been remarkably successful in overcoming this difficulty, and the liberal use of diagrams illustrating lines of force, as shown both from plotting and by experiment, does much to impart a reality to the discussions. The second section is devoted to Clerk Maxwell's electromagnetic theory of light, and emphasis is rightly laid on the discovery of the coincidence between the "*v*" of the physicist and the velocity of light. The third section deals with Hertz's classical experiments, culminating in the realisation of electric waves; while the last section is devoted to those further developments which have established the identity in character of electric and optical phenomena and have resulted in wireless telegraphy. This section includes the study of polarisation, dispersion, optical resonance, and the determination of wave-lengths. The author is very clever in the way he keeps mathematical formulæ in the background, and at the same time leaves the reader perfectly conscious of their existence.

Drs. Foppl and Abraham's two volumes deal with the same phenomena treated from the point of view of the advanced student of physics instead of that of the popular reader. For this purpose the historic method of our older books is now quite unsuitable, and we are glad to see its place taken by a more powerful method of treatment. The present writer has clear reminiscences of the difficulties into which the text-books in use in the 'eighties of last century led the reader. We were taught that quantities of electricity and quantities of magnetism acted on each other according to the law of the inverse square, that the units could be so chosen as to give unit force at unit distance, and that the forces in every case were derivable from a potential. We believed these statements implicitly, and then we were introduced to statements inconsistent with the first under "specific inductive capacity," with the second under "electrostatic and electromagnetic units," and with the third under "electromagnetic induction."

Dr. Abraham's readers start by equipping themselves much better with the analytical methods required for arriving at a clear conception of electromagnetic phenomena. The first section, extending to 122 pages, written by Dr. A. Foppl, deals exclusively with vector analysis and vector fields, and the latter subject is introduced by means of hydrodynamical analogies. It may truly be said that if the study of the dynamics of perfect fluids has not led to many practical applications, it possesses great educational value in affording a simple and intelligible representation of the quantities and equations occurring in electromagnetism. By the time the student has grasped these introductory notions he is able easily to follow the sections on electrostatics and magnetostatics without falling into any misconceptions regarding their limitations, and he can then pass on directly to the study of electromagnetic induction and electric waves. Especially careful is the author in avoiding the old pitfalls in connection with the "Dimensions of Units." His equations are all written with the three constants, and he then shows how the electrostatic, electromagnetic, and Gauss's systems of units may be obtained by putting two out of these three constants equal to unity. We should, however, have liked to see the dimensions of the units tabulated in terms of force (or perhaps energy), length and time instead of mass, length and time. The formulæ are then much simpler, and better express the fact that electrical phenomena in general manifest themselves to our senses by the *forces* they produce on material bodies, though the existence of these phenomena is independent of the concept of mass as commonly understood.

So much for the first volume, which, as the author points out in his preface to the second volume, covers what may be described as the "first floor" of modern electrical theory. The second floor, which has now been built up as a superstructure on the first, consists of the modern electron theory discussed in this second volume.

The first chapter deals with the definition of an electron and its elementary properties, while the second deals with radiation from electrons. In chapter iii., which deals with the dynamics of a system of electrons, certain assumptions have to be made. In most cases Dr. Abraham follows Lorentz's theory. In the second section, in dealing with ponderable bodies in motion, comparisons are made showing the differences in the results obtained by Lorentz's and Hertz's assumptions.

In a book like the present, dealing with theories about which differences of opinion exist, the list of formulæ collected for reference at the end is particularly useful, as it enables the reader to see at a glance what hypotheses are made. While the book contains an excellent exposition of the electron theory, based on these hypotheses, we only have to turn to the table at the end of Dr. Witte's book to find that there are twelve different conceivable mechanical theories of electric phenomena of which the great majority are classed as recognised theories.

Of these theories, two are theories of action at a distance, and the third is Newton's emission theory, all of which are easily dismissed as insufficient to account for known phenomena. The remaining theories, which Dr. Witte describes as undulation theories, and their classification is a simple matter of permutations and combinations. We have two kinds of energy of the ether, electrostatic and electromagnetic, which have to be potential or kinetic, or partially potential and partially kinetic. These possibilities lead to six different combinations or nine different permutations. The cases where each part of the energies is wholly kinetic or wholly potential lead to three combinations, namely, Mie's group (both energies potential), Lord Kelvin's (one potential and one kinetic), and Hertz's (both energies kinetic). But another totally independent line of classification is also pointed out in the separation of theories of the ether into atomic hypotheses and hypotheses of a continuous medium, and this line of discussion brings us very close to the electron theory. What the author has really done is to apply the method of exhaustion to mechanical theories of the electromagnetic medium, and he finds that when atomic theories of the ether are taken into account the number of possible hypotheses is very large. Perhaps, as the author points out, no mechanical theory may be found to be capable of explaining satisfactorily all the phenomena of nature. The subject-matter of the present book is certainly only a very small fraction of all that might be written on mechanical theories of the ether, and probably no physicist would regard the arguments as conclusive except so far as they show that certain hypotheses are insufficient to account for the results of experience. But at the same time, if the book does nothing else, it shows that clearer and more definite ideas of existing electromagnetic theories may be obtained by an attempt to exhaust and classify the different possibilities which present themselves.

It is in connection with irreversible phenomena that mechanical theories present the greatest difficulties. As a consequence, the kinetic theory of gases has not received much attention from physicists very recently. But Dr. Jäger points out in the preface to his book that meanwhile an atomic theory of electricity has been built up, bringing us back to the fundamental notions of the kinetic theory of gases. The present book contains a good outline of those applications of the kinetic theory which are most easily understood. Under this heading we include the error law of distribution with special reference to spherical molecules; the virial theorem, a brief account of Boltzmann's minimum theorem without examination of its difficulties, and a discussion of applications to viscosity and other convection phenomena. This book is a very good introduction to place in the hands of the student of physics whose time is very limited, but he must remember that there is a great deal more to be said about the kinetic theory than meets the eye in these pages.

Whether "Theoretical Mechanics" is properly described as a branch of physics or of applied mathematics is a matter of opinion. But the ever-increasing part played by mechanical theories in the study of physical phenomena is sufficient justification for Prof. Jeans's book. It is becoming every year more and more difficult for the science student to keep pace with the demands made on his time by modern developments of physics, and a book which starts with the laws of motion and leads the reader up to Lagrange's equations, all in the compass of a single volume, is certain to prove a great boon to a large class of students. In his preface Prof. Jeans discusses the reasons for carrying the subject so far as the study of generalised coordinates, but in view of the fact that Lagrange's equations are freely used in treatises on electricity—for example, in discussing the effects of mutual and self-induction in electric circuits—no defence of their inclusion in the present volume seems to be needed. In the chapter on motion of rigid bodies we should like to have seen a little more about "uniplanar" motion. This would enable the student to obtain a much more tangible and definite conception of the meaning of a moment of inertia than is possible when he is rushed on at once to Euler's equations. Moreover, the proof of these equations is unnecessarily cumbersome and difficult for the beginner, and space could easily be saved by simplifying it. The equations of § 250 for moving axes, when generalised for any vector, such as angular momentum, immediately lead to Euler's equations. Instead of doing this, Prof. Jeans gives what is nothing more than an alternative proof of the vector differentiation formulæ, as applied to angular velocity in § 252, and after all this trouble the student has learnt nothing about the fundamental principle involved in both applications.

Returning to the earlier chapters, Prof. Jeans makes an attempt in chapter iii. to prove the parallelogram of forces by the now usually discarded dynamical method. He escapes the fallacies of the old books in connection with the parallelogram of velocities, but is led into the usual *non sequitur* in assuming that the acceleration which the forces produce when acting simultaneously must be compounded of the accelerations which they would produce if acting singly. In connection with his proof of the property that any motion of a rigid body is compounded of a motion of translation and one of rotation, he defines rotation as motion with one point fixed; the subsequent paragraph, headed "Axis of Rotation," is so extraordinary that it is best reproduced here in full. It runs as follows:—

"In a motion of rotation, let P be the point which remains fixed. Take any plane A through P and let B be the position of the plane A after the rotation has occurred. These two planes both pass through P, and must therefore intersect in some line PQ passing through P. This line is called the *axis of rotation*. The rotation can be imagined as a turning about an imaginary pivot running along the axis of rotation."

The absurdity of this statement is evident if we suppose that the chosen plane A does not contain the axis of rotation.

The book is freely illustrated by examples. Many of these are very useful, but others are calculated to inculcate very extraordinary ideas in the mind of the reader. For example, on p. 68 we have an impossible figure of a nut-cracker, neither the nut nor the cracker being in equilibrium. The ladder in the next example is free from this objection, but it contains a superfluity of trigonometry which is hardly justified by the preface. The question can be solved by geometry with half the work. On p. 194 is given a construction for placing a chute in such a position that the time of sliding from a ship's side on to a pier may be as short as possible. If any reader were to put the matter to a practical test, he would certainly not get the same result, even if he got the objects to slide at all. The correct construction is obtained by placing the chute along a chord of a certain circle touching the ship's side, but the tangent to this circle at the point where it meets the pier should be inclined at the angle of friction to the horizon instead of being horizontal.

Suppose next that the inquiring reader wishes to put the examples on the motion of pulleys of given mass on pp. 202, 203 to a practical test. He goes to a scientific instrument maker, and orders some expensive pulleys. However well he oils their bearings to make them smooth, it is pretty certain they will never move with the accelerations given by Prof. Jeans's formulæ. The tensions of a string may be equal on both sides of a pulley so long as that pulley remains at rest, but so soon as it begins to rotate differences of tension will be set up, and no amount of lubrication applied to the bearings will affect the result. Of course, if the inertia of the pulley is small, the tension differences will also be small, but the masses of the pulleys are "given" in the questions, and the proper lesson to be learnt is that a solution of the problems which does not take account of rotational as well as translational inertia is incorrect.

There are several good features, however, which well deserve mention. Among these are the treatment of strings, including the early references to Hooke's law, the example on p. 53, with its neat geometrical solution, the example on p. 360, in which accelerations in polar coordinates are deduced from Lagrange's equations, and finally the omission of all references to poundals, slugs, and other abominations of the same nature. It is a pity that some of the examples involve the usual tedious and uninteresting drudgery in the form of multiplication or division by 2240 or 5280 or 1728 or 33,000, or another of the same series of objectionable numbers. We do not blame Prof. Jeans for following the common practice in this respect, as most of us find ourselves forced to do the same, but surely the time has come when examples involving the metric system may figure more freely than they do in treatises on theoretical mechanics, especially when those treatises are particularly adapted for students of physics. G. H. B.

THEORETICAL ELECTROCHEMISTRY.

The Electrolytic Dissociation Theory. By Prof. R. Abegg; translated by Dr. Carl L. von Ende. Pp. ix+180. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd.) Price 5*s*. 6*d*. net.

Electrochemistry. Part I., Theoretical Electrochemistry and its Physico-chemical Foundations. By Dr. Heinrich Danneel; translated by Dr. Edmund S. Merriam. Pp. vii+181. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd.) Price 5*s*. 6*d*. net.

THE advent of the translation of these two little books into English shows that the subject of electrochemistry, or rather, we should say, physical chemistry, with an electrochemical bias is coming more and more to the front. But while we have had of late a large number of books upon the theoretical side of the subject, there is not very much literature dealing with the practice of electrochemistry and its applications to industrial problems.

Prof. Abegg's book is a translation of the author's "Die Theorie der elektrolytischen Dissociation," which appeared in 1903 in the "Sammlung chemischer und chemisch-technischer Vorträge." Prof. Abegg starts off in an elementary manner, and explains the dissociation theory so that the beginner may understand the subject. On several occasions he uses the term osmotic pressure, but throughout the book he does not explain what osmotic pressure is or how it is measured. Although the commencement of the book is quite simple, it is not long before Prof. Abegg revels in mathematics, which, combined with the slavish style of the translation, makes the reading rather uninteresting. The section upon equilibria among several electrolytes is very long, and includes subsections upon hydrolysis, avidity or affinity of acids and bases for each other. The style of the book may perhaps be shown by the following passage:—

"Since in the case of equal concentration the ionic concentrations of pure (unmixed) acids are to each other as the roots of their dissociation constants, we may with Arrhenius also express this equation thus, that both acids divide themselves between the base in the same ratio as their degrees of dissociation would be, if each were present alone in the volume considered."

A section is also devoted to "non-aqueous solutions," and in it the author explains some of the difficulties which occur when one tries to bring the behaviour of solvent and solute into line with a similar substance dissolved in water; for example, the complications arising by the phenomena of the association of the non-ionised portion of the electrolyte. The book is a useful review of the ionic theory written entirely with the view of supporting the theory.

Dr. Danneel's book, although it explains the ionic theory in considerable detail, is an exposition of general theoretical electrochemistry. The book begins with an explanation of the terms work, current, and voltage. The gas laws lead up to osmotic pressure, which is fully and lucidly presented. The theory of electrolytic dissociation and conductivity brings us up to p. 114. The average student who is called upon to study the ionic theory will obtain, we venture to think, a better grip of the subject by a study of Danneel's book than from that of Abegg. The latter book treats the subject more fully, but Danneel's style is more interesting, and he leaves none of the salient facts out. Chapter v. treats of electromotive force and the galvanic current, and chapter vi. of polarisation and electrolysis. The last chapter, which is very short, treats of the electron theory. We find it here stated that "The electron acts chemically like an element. It combines with other elements to form saturated compounds, which are the ions"; thus

$$Cl + \ominus = Cl\ominus = Cl'.$$

It would have been of special interest had Dr. Danneel enlarged upon this subject; he has, however, just given enough to make it suggestive.

OUR BOOK SHELF.

Christiaan Huygens, Traité: De iis quae liquido supernatant. Rédigé par D. J. Korteweg. Pp. lxxxiii+210. (Extrait des Oeuvres complètes de Christiaan Huygens. Tome xi., n.d.)

THIS treatise of about a hundred quarto pages, printed from a hitherto unpublished MS. of Huygens, forms part of the eleventh volume of the collected edition of his works which is now in progress. The accomplished editor, Prof. Korteweg, of Amsterdam, who has himself made valuable contributions to hydrodynamics and to mathematical history, has judged wisely in issuing it separately, and so rendering it accessible to a wider public.

The contents are certainly remarkable. Book i. begins by deriving the Archimedean conditions of equilibrium of floating bodies from the principle that the altitude of the centre of gravity of the whole system composed of solid and fluid must be a *minimum*, and the same principle is then applied to the question of stability for angular displacements. Owing to the manner in which the problem is stated, *stable* positions are alone the subject of investigation; the recognition of the fact that the conditions of equilibrium are equally satisfied by a *stationary* altitude of the centre of gravity, belongs to a later period. The special cases of the paraboloid of revolution, and the cone, floating with the axis vertical, are treated in some detail.

In Book ii. we find a somewhat elaborate, but not quite complete, treatment of the problem of the stability in different positions of a floating log of rectangular section; but the method followed is different, and is more closely related to Archimedean principles. Book iii. deals, on similar lines, with the problem of the floating cylinder.

This brief recital will show how great is the historical interest attaching to this tract. The interest is increased when we are told that it was a youthful essay, which the author himself condemned as fragmentary and incomplete. A note appended to the MS. reads: "Haec de corporibus solidis in liquido supernatantibus in prima adolescentia scripsi, cum nullum adhuc majoris momenti argumentum sese obtulisset . . . E primis Theorematis quaedam retineri possent, item de Cylindris. Reliqua vulcano tradenda." The student of mathematical history will be glad that this elegant, and in some respects significant, essay should have escaped the fate here threatened, and will be grateful to the editor for having now placed it beyond the reach of accident.

The volume, which is (by the way) most beautifully printed, contains a valuable introduction and commentary by Prof. Korteweg, who points out in detail the relation of Huygens's work to later developments of the theory. It includes also reprints of other MS. notes by Huygens on the same subject, with interesting facsimile reproductions of the original diagrams.

H. L.

A Health Reader. By Dr. C. E. Shelly and E. Stenhouse. Books i. and ii. Pp. vi+160 and viii+196. (London: Macmillan and Co., Ltd., 1907.) Price 1*s.* and 1*s.* 4*d.*

THE great importance of imparting to children, while at school, a knowledge of the broad principles of healthy living is generally recognised; and the past few years have witnessed the outcome, in response to a growing demand, of many handbooks upon elementary hygiene for school purposes. Some of these have erred on the side of attempting to explain too much, and the book, whether designed to meet the needs of the school-teacher or of the scholar, has dealt with non-essentials in an unnecessarily technical manner.

These two small works, both of which are fully illustrated, have been compiled with great discretion, for the subject-matter is that which every child should know, and it is treated in such a manner that the child, while acquiring useful information, will be interested.

The earlier book is designed for use among children of nine to ten years of age, and the later volume for pupils of from ten to twelve years of age. A noteworthy feature of both books is the omission of all technical terms. For instance, the cranium and sternum are called the brain-case and the breastbone, and the red blood corpuscles of the blood are described as "grains of red jelly"—"the oxygen-boats." Another noteworthy feature is the due appreciation shown of the importance of presenting the subject-matter in the simple manner which appeals to the child-reader. Those who are unfamiliar with the difficulty of appealing to the child of from ten to twelve years with a subject such as hygiene may judge Book ii. to be too elementary; but others will not share that view.

It is most desirable that a health reader, the information of which can (where necessary) be supplemented or explained by occasional conversational digressions, should be introduced into every school; for it is doubtless the easiest and the most effective way of teaching the subject. The works under review are exceedingly well designed to serve this purpose.

Ptolemäus oder Kopernikus? Eine Studie über die Bewegung der Erde und über den Begriff der Bewegung. By Dr. Karl Neisser. Pp. vi+154. (Leipzig: J. A. Barth, 1907.) Price 3 marks.

THE author of this little book aims at showing that all motion is relative, and that the people who three hundred years ago disputed as to whether the earth moved round the sun or the sun round the earth were all equally right, and were only fighting about words. In the first chapter it is set forth with needless prolixity how all apparent phenomena produced by the motion of an observer will be the same if he is at rest, and all the surrounding objects are in motion with the same velocity in the opposite direction. The author next deals with the system of Copernicus, and points out how it could only claim to represent the planetary motions in a somewhat simpler manner, but that the relative positions of the earth and a planet were exactly the same according to the old and the new system. But everything was changed by the discovery of the proper motions of the fixed stars, which made it theoretically impossible to refer the celestial motions to a fixed origin of coordinates, while the sun's own motion through space shows that the earth cannot describe a closed curve round it. As regards the rotation of the earth, the author maintains that the deviation of a falling body towards the east and Foucault's pendulum do not absolutely prove that it is the earth and not the whole rest of the universe which is turning. Whether we say that the earth or the heavens, or both, move is thus a mere matter of taste depending on the point of view; and the two first laws of motion are incapable of proof, since there is no such thing anywhere as motion in a straight line.

The most unsatisfactory part of the author's reasoning is the way in which he lightly skims over the aberration of light in a footnote only. One might grant him that everything else he brings forward is conceivable, but the human mind is hardly capable of imagining that all stars might move in the course of a year in circles, the planes of which are parallel to each other. If aberration is not an absolute proof of the earth's annual motion, we may give up the hope of proving anything.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

British Association; Section A.

As an old member interested in the welfare of Section A, and appreciative of the useful work it has long done in bringing physicists and mathematicians of various kinds together, I want to suggest that the comparatively recent practice of crowding all its multifarious work on to a few days, and getting through it by sitting in duplicate and by hurry, is unsatisfactory. This suggestion is not intended as a complaint, but as a warning that such a method of dealing with Section A must sooner or later result in its disintegration into two or more sections.

So long as it keeps together—and it is much to be desired that it should keep together, so that workers in different fields may hear something of each other's results—it is necessary that it should take all the time allowed to it, and sit as a rule both on Saturday and on Wednesday. The Saturday meeting is especially important. In the old days the mathematicians frequently had an excellent opportunity on that day, of which they took full advantage. So also the final meeting on Wednesday, for some of the papers on minor experimental points, and for such as had been postponed from other days, has also been often quite interesting.

If Saturday is not utilised, some of the senior members are apt to leave at the week end, and the discussions on future days then lack some of their interest and importance.

The only reason for not meeting on Saturday is on account of excursions. It is to be hoped that excursions will not be allowed to ruin the meeting. Saturday excursions are an innovation: they began as visits to works and the like, in the immediate neighbourhood, on the afternoon; and the full-day excursions were kept for the second Thursday.

An attempt was made to diminish the excursions by abolishing the second Thursday, with the unfortunate result that excursions have now encroached on and consumed the Saturday—which is much worse. There are sections perhaps, such as C, and no doubt others, of which excursions are an important feature; but it is not so with A. Let me urge the officers of that section to return to the older practice, and to aim at taking meteorology on Monday, general physics and astronomy on Thursday and Monday, pure physics on Friday and Tuesday, pure mathematics on Saturday, and an overflow, together with experimental papers, on Wednesday. Then allied sections, such as B and G, can take papers of more interest to physicists on the Monday, as indeed used to be, and perhaps is, their custom; and Section L might perhaps then assist Section A with some of the interesting and important papers on details connected with teaching.

Another minor matter is to express my belief that sectional committee meetings would be more convenient, and likely to be better attended, in the afternoon than in the early morning. But on that there may easily be differences of opinion.

Oliver Lodge.

Fecundity of the Leopard Moth.

A specimen of the above (*Zeuzera aesculi*) was sent to me by post in a tin box a few days ago from Felixstowe. The moth was dead when it reached me, but had laid eggs in the box. As there seemed to be such a large number I had the curiosity to have the eggs counted, and it was found that there were 725. It is, of course, impossible to say whether this represents the whole family or whether she may have laid some eggs previous to capture.

The relative fecundity of different species of insects in relation to their life-habits is an interesting subject from the selectionist's point of view. The caterpillar of this moth is a wood borer, and the conditions for favourable nutrition may be difficult to find, so that a high fecundity has been developed in order to meet precarious conditions of survival. Other wood borers seem also to lay large numbers of eggs, but I do not know whether the families have ever been counted. As a contribution to the subject this observation appeared worthy of record.

Nairn, N.B., August 10. R. Meldola.

THE SECOND INTERNATIONAL CONGRESS ON SCHOOL HYGIENE.

The Second International Congress on School Hygiene was opened on August 5, and closed on August 10. The papers were mainly practical. At the first congress (Nuremberg, 1904) there was a distinctly greater proportion of research work; but this was due to the fact that the medical examination of school children had been longer established in Germany, Austria, and other European countries than it has been in England. Such scientific investigation as the present congress has evoked is almost exclusively directed towards justifying immediate administrative measures, or developing existing organisations. For example, medical inspection has, in England and Scotland, now all but become a widespread reality, and the hygiene of school buildings and school work has rapidly grown into a speciality. We here indicate the main problems raised for discussion.

(1) *Methods of Medical Inspection.*—The desirability of medical inspection has been assumed at every section. The chief concern is to what extent it shall proceed. Dr. Méry (Paris) maintained that the first examination on entry to school should include (*a*) an anthropometric record of weight, height, chest measure, dynamometric observations; (*b*) physiological record of the primary educational senses—eye and ear; (*c*) a medical record of all the organs—throat, lymphatic system, skin, skeleton, lungs, heart, &c. He insisted on the extreme value of minute thoracic measurements, as shown by insurance results. Experiment has shown that spirometry as a test of lung conditions is not practicable with children. The minute measurements required to establish the "thoracic index" can be carried out only by skilled specialists.

The other papers on medical inspection recommend only a medical examination, conducted strictly in relation to the school-work required. Accounts were given of the methods of report and examination employed in Sweden, Breslau, Wiesbaden, Leipzig, Nice, and other places.

Dr. Clement Dukes (Rugby) gave the results of an elaborate physical examination of 1000 boys of ages thirteen to fifteen. The boys were taken as they entered the public school. This paper is of great practical value. It deals with boys whose home-nurture was of the best possible. As tested by Dr. Roberts's standard tables, 522 boys were above the normal height; 113 were average; 365 below normal. In weight, 472 were above normal; 57 average; 471 below normal. In chest measurement, 445 were above normal; 132 average; 423 below. Acquired deformities (such as spinal curvatures, pigeon-breast, bow legs, flat feet) were surprisingly numerous. *E.g.* there were 529 cases of knock-knee; of lateral curvature of spine, 445; of flat-feet, 329. There were 13 cases of eustachian deafness; 19 of aural deafness. Hypermetropia, 40; myopia, 128; astigmatism (considerable), 27. Heart disease, 10. Albuminuria, 157. This is a startling figure. As to puberty, 317 had attained the state between thirteen and fifteen years; in a few cases, not until fifteen. This research is the most elaborate yet published regarding English public school boys. It has an important bearing on the question of environmental *versus* germinal deterioration.

(2) *Effect of School on Health.*—Dr. Hüttel (Prague) records that the upper classes suffer more in nutrition than the lower from bad teeth. Myopia is admitted to be a result of school work. Girls suffer more than boys from spinal curvature. Nervous diseases, headaches, insomnia, night-terrors, are more frequent in the higher classes.

Tuberculosis.—Dr. Oldwright (Toronto) deals with the schoolroom as a factor in tuberculosis. As to teachers, he shows that, in the returns of six great cities (Baltimore, District of Columbia, New York, Brooklyn, Philadelphia, Boston), female teachers in schools rank next to highest in order of mortality from consumption, printers and pressmen being highest. This is confirmed by other returns. The ratio of consumption-deaths per 1000 deaths is found uniformly higher among teachers (male and female) than in all other occupations. Chalk dust is suggested as one factor in causing this exceptional incidence.

Dr. Arthur Newsholme (Brighton) states, as the result of a careful examination of 806 children (conducted by Dr. Lecky), and a comparative analysis of other figures from Dundee, Dunfermline, and Edinburgh, that he is inclined "to think that there is not, on the average, more than 1 in 300 children in schools showing revealed or diagnosable pulmonary tuberculosis." But "latent tuberculosis" is considerable. Naegeli "found in autopsies of children aged one to five 17 per cent., and of children aged five to thirteen that 33 per cent. had tuberculous lesions." But the origin of the tuberculous infection is almost certainly domestic, not scholastic; though school conditions and work may, and do, provoke latent tuberculosis into activity.

Measles.—The scientific grounds for school closure in measles epidemics were discussed by Dr. Thomas (London) on the basis of 5512 carefully investigated cases. Measles tends to spread when a class accumulates unprotected numbers to the extent of between 30 and 40 per cent., and when spread has begun it extends until the proportion is reduced to between 15 and 20 per cent. unprotected. School closure to be of any use must occur before the first "crop" falls. This conclusion is confirmed by Dr. Davies (Woolwich).

Diphtheria.—Dr. Niven (Manchester) states, as the result of numerous investigations, that the "year of maximum incidence precedes the years of school life," and that the "great drop at age six" is probably due to widespread establishment of immunity. The sanitary condition of the schools has probably less to do with outbreaks than the absence of playgrounds; but aggregation multiplies the chances of infection. The "slight or latent" cases far outnumber the discoverable cases. But many "latent" cases proceed so slowly that an antitoxin is naturally produced, and immunity thus established. In practice, it is well, as Newsholme suggests, "to exclude diphtheria convalescents from school for six weeks after discharge from school and recovery at home." Diphtheria "contacts" may, though not themselves showing any marked symptom, spread the disease.

(3) *School-work and Healthy-mindedness*.—Prof. James Sully, from the standpoint of general psychology, concludes that current educational ideals overemphasise Rousseau's half-truth that "education is essentially a process of following nature, of observing, understanding, and safeguarding a natural process of development." Healthy-mindedness means vigorous intellectual faculties strongly predisposed to exercise their proper functions. But many facts show that present-day school-work, by excess of book-learning and neglect of the actualities of life, tends to reduce mental vigour and to predispose the average person to accept opinions without examination or test. But there are signs that the schools are conscious of this. Prof. Sully does not seem to allow sufficiently for the large positive content of the reaction against books. This positive content is more obvious in American methods than here. But all agree with him that education ought to produce a "healthy, vigorous attitude of mind."

(4) *Age for School Attendance*.—The science of the English custom of sending to the day-school infants of three to five was examined by Dr. Newsholme. His main conclusion is against the custom, first, on the practical ground that the danger of fatal infection is vastly increased (though the facts are too few to be conclusive); second, because there is no educational advantage. On the opposite side, it was contended that the school, if properly adapted as a play-place, not a work-place, fulfils the functions of the home by giving scope and atmosphere for infantile play-energies and dispositions, which are the biological prelude to education proper. The problem is of profound importance; for it involves the whole theory of the *crèche*, the kindergarten, and the play-centre. But there is no body of scientific evidence to make even a provisional conclusion possible. It is certain, on the other hand, that many schools as they exist are quite unfit for the work of tending infants of three to five, and there is no general "play-curriculum" adapted to their needs. Biologically, it is a doubtful gain to leave the delicate organism of three absolutely to the chance environment of "home" or street, where an ineradicable bias to evil mental habits may readily be produced. Scientifically, the problem remains for future congresses.

A related topic is the vacation camp or holiday home. Many practical descriptions were given, but no criticised quantities. Captain Polvliet (Amsterdam) described in detail the practice of a holiday camp in Holland, and the conditions of healthy freedom combined with sport programmes seemed to be realised. The results to health were undoubted.

(5) *Physical Training*.—The tendency of the practical educationist is rather to rest in "systems" of muscular training than to make an effort to discover fundamental principles. Such an effort, however, was made by Dr. Hulbert (London), who showed how intimately the voice is affected by the stiffness or elasticity of the body, and so forms an indicator of physical conditions. Position in voice-using must be good, but absolutely free from rigidity. Control of breathing must be acquired by cultivating elasticity of the elastic parts of the chest. Respiration for voice-production should depend on the essential muscles of respiration, not on the external. When the right quality of muscular movement and of muscle is secured by training, good voice naturally results. The ordinary "systems" fail in this, because they rely on coarse muscular movements. For good tone, physical training of the right kind is essential. There are three main factors—position, control of breathing, and the abdominal press.

Dr. Gulick (New York) described the place and limitations of folk-dancing as an agency in physical training. School gymnastics fail to establish habits of exercise, especially in girls. Selected dances can be adapted to the feminine physiological, psychological, social and æsthetic needs. They involve large masses of muscle, and can be carried on two or three times as long as gymnastics without fatigue—a fact of cardinal importance. The instinct feelings are tied up with the neuro-muscular system in a fundamental way, and the dance evokes them in the individual. But dancing fails to correct the faulty postures due to school-desks. It is a useful adjunct to training, but not alone adequate. But the interest excited has led to its securing a high place in the New York elementary and high schools.

(6) *School Work—Duration, Sequence of Lessons, and Seasons*.—Dr. Leo Burgerstein (Vienna) opened a general discussion on this subject, commenting on the practical difficulties of obtaining trustworthy measurements of fatigue. But it is certain that work con-

tinued in a state of fatigue is of no value for obtaining skill. Lessons should never exceed forty-five minutes in high schools, and for pupils under age of puberty. The earlier lessons of the day should last longer than the later. Six-year-old children should not be kept sitting at work for more than half an hour without exercise and rest. For infants and junior pupils, writing should be interrupted every five or ten minutes by change to a comfortable position. Rests should never be used for the purpose of instruction or punishment. Lessons requiring mental effort or memory work should be taken early in the day. Lessons in drawing or needlework should not follow a lesson in bodily exercise. Two lessons requiring mental concentration or near-vision should not follow each other. Season has an effect on quality and quantity of work, school-work being harder in summer.

Prof. Chabot (Lyons) analysed carefully the same problems. In the French elementary school, a lesson does not last more than thirty or forty minutes, but the day's session lasts about an hour and a half, the only rest being change of subject. The official regulations, however, permit a margin of variation, and no lesson must exceed an hour. After discussing fatigue and the details of typical time-tables, Prof. Chabot suggests that from age seven to ten a lesson should run from fifteen to thirty minutes; from age ten to fourteen it should run from thirty to forty-five minutes; after age fourteen, the lessons may last for an hour or an hour and a half. The limit of daily work should be six hours from age seven to twelve; seven hours from age twelve to fifteen; eight hours after fifteen. The rhythm of mental effort—invention or assimilation, analysis or synthesis—depends more on the consecutive masters than on the distribution of subjects; but abstract lessons should be followed by concrete lessons and practical exercises. It is preferable to have two or three classes in forenoon and two in afternoon. There is a growing opinion in England that afternoon work is worth little.

(7) *School Suicides.*—Prof. Chlopin (St. Petersburg) gave a paper on suicide and attempted suicide among pupils of Russian middle schools. He had investigated 337 actual and 95 attempted cases. Among school children, the suicide rate is three times higher than among the general population. Shooting, hanging, and poisoning are the leading methods. The chief causes are mental and nervous derangements.

Prof. Eulenberg (Berlin) gave similar facts from Germany (as Prof. Gurlitz has already done in a book recently published in criticism of German school methods). He had traced during the last twelve years 1152 cases of actual suicide among school children. More than 50 per cent. of these were traceable to failure in examinations or overwork at school.

(8) *Economics of Neglected School Children.*—Dr. Cronin (New York) gave an estimate of the waste due to diseases and defects of school children. In 1902 (New York) there were 24,000 exclusions, which, at the known cost of 20 cents a day, represents a loss of 4800 dollars in three months. In a school population of 650,000, 30 per cent. were from one to two years behind their proper class—a loss of about 40 dollars per child, if only one lost year be counted. Thirty per cent. (or 195,000) lose one year in six—a loss of 1,666,666 dollars in each school year. Most of the diseases were preventable, and it is economic waste not to prevent them.

(9) *Anthropometry in School.* — Dr. Shrubsall (London) sketched what the British Association regard as essential in school anthropometry—stature, weight, hair-coloration, iris colours, maximum length and breadth of head, chest in deep inspiration and expiration, diameters of chest, breadth across shoulders and trochanters, height of head. (The report of the Physical Training Commission [Scotland] contained all these and some other measurements of 1200 school children.) The opinion is general that this work should form a special investigation, and should not be expected of the education authority at the ordinary medical inspection. It certainly takes more time than medical inspection; but the data wanted are of value for anthropology. No results were produced at the congress. Mr. Gray gave details of a uniform scheme of yearly measurements of school children as a basis for estimating deterioration of the race.

Dr. Schuyten (Antwerp) presented a summary of ten years of research in the pædological laboratories of Antwerp. It is difficult to overestimate the value of those researches. The chief general conclusions are, (1) that the child, on entering the ordinary school, undergoes physical and mental depression; (2) that growth in muscular power is not regular during the school year, there being a distinct depression in March; (3) that, as tested by the dynamometer, muscular power varies with the season; (4) that voluntary attention decreases from January to July, and increases from October to December; (5) that fatigue increases during the school year from one end to the other without perceptible recovery of energy due to holidays; (6) that the validity of æsthesiometric methods of determining fatigue is now demonstrated (a view contested by Dr. Altschul, of Prague, who criticises Prof. Griesbach's results, and maintains that his own are conclusive against Griesbach's method). The methods used by Dr. Schuyten are ingenious. For instance, in drawings of a "little man" on a uniform-sized white surface by children of different ages, it was found that there is a regular increase in the length and breadth of the figure from $3\frac{1}{2}$ to 6 years of age. At age six, on entrance to school, there is roughly a 40 per cent. reduction in the dimensions, which again increase with age. Schmidt Monnard noted actual slackening in the child's own development at this age.

It is important to have some confirmation of Prof. Griesbach's method of testing fatigue by the æsthesiometer. It has been subjected to much criticism; but its simplicity and ease of application are strong inducements to further definitive experiment. It is undoubtedly the simplest method yet suggested for school children, and research will probably centre round it for some time to come.

(10) *Relations of Medicine and Paedagogy.*—Prof. Griesbach (Muelhausen), who first suggested an international congress on school hygiene, and, as president, carried through the Nuremberg congress with untiring energy, wound up the London congress with an evening lecture on the "Relations between Medicine and Pædagogy." He gave a really encyclopædic view of the whole vast subject, and his printed lecture will remain one of the most important documents of the movement. In a series of elaborate tables he outlined the whole educational curriculum of elementary and higher schools in Germany, giving body to his comments by large masses of analysed observations and records. His table on the relations between circumference of head and mental capacity is a striking record of observations made by himself. The numbers examined were not stated, but they were large enough to justify averages. When the full lecture is published, this table will deserve careful criticism. It sustains the view that, on the average, the larger head goes with the greater mental capacity. The lecture was, in every respect, a worthy close to a great congress.

ELECTRICITY IN BULK.

HOWEVER far we may still be from a proper understanding of the actual nature of the phenomena connected with the production of electrical energy, the past twenty years has clearly shown that in its economic aspects it follows certain well established laws. Just as the great increase in the scale of wholesale production and the invention of new and more rapid means of distribution enables the big manufacturer and stores to compete with the local workshop, or shopkeeper, so the lower first cost of producing electricity on a large scale, and the higher electrical pressures used in its transmission, enable the central authority to compete with the smaller local source of production.

The economy of concentration and bulk production of electricity was recognised by Ferranti nearly twenty years ago, and that his attempt to carry it out at Deptford in 1889 was unsuccessful was solely due to the fact that there, as in the case of the "Great Eastern," the idea was in advance of the state of manufacturing knowledge.

The size of units proposed for the Deptford station in 1889, 10,000 h.p., and the pressure used, 10,000 volts, have since been exceeded, and the latest serious proposal for the supply of electricity wholesale to London, was based upon 20,000 h.p. units, and 20,000 volts pressure. But although the premature attempt to concentrate electricity production at Deptford did not meet with the success it deserved, the correctness of the principle was not lost sight of. Another company, the Metropolitan Electric Supply Company, in the succeeding ten years carried out a policy of partial concentration in its own area, abolishing a number of small stations in the West End, and replacing them by a larger station at Willesden. But nothing so radical has taken place in electricity as has been the case in gas supply. The Ordnance Maps of forty years ago recall the existence of some seventeen or eighteen gas works, scattered throughout the Metropolitan area, nearly all of which have now been dismantled. To-day, 90 per cent. of the gas used in London is produced at Beckton, on the Greenwich Marshes, or at Nine Elms.

There are still, however, more than seventy electric generating stations in Greater London, and at present little prospect of their number being reduced. For Parliament has now rejected the third and last possible alternative for solving this knotty but urgent problem. The freedom with which the process of concentration was carried out in the case of gas arose largely from the fact that the undertakings were entirely in private hands, and that no political questions were raised in connection with their abolition.

The need for improvement, and the technical soundness of the methods suggested for improving existing electrical conditions, have now been generally admitted, both by those who favour municipalisation and those who favour private enterprise under municipal control. The fact that the existing stations, which have cost 45*l.* to 50*l.* per kw., could now be built for 10*l.* per kw., that the present cost of production is more than 1*d.* per unit, and in a new station need only be 0·2*d.* per unit, that the consumption of electricity in London is only one-tenth of that in other great cities, are no longer questions of discussion.

During the past three years three serious attempts have been made to carry out a similar concentration, the first by private enterprise, and the second by the London County Council. Although the first only failed to become law by a few days, neither of these proposals succeeded in obtaining Parliamentary sanction. It was, therefore, hoped that the third and last alternative, that of co-operation between municipal and private enterprise, which was put before Parliament this year, would have been more successful. The fact that it also shared the fate of the previous proposals, and has been rejected, is therefore the more to be regretted, for it appears as though the scientific solution of London's electricity supply difficulties will now be indefinitely postponed. Private enterprise cannot be expected perpetually to provide the money for promoting schemes which are endorsed by Parliamentary Committees on their merits and rejected by the House of Commons on political grounds. The London County Council naturally does not feel justified in making further proposals for establishing a wholesale supply of electricity at the ratepayers' expense, in view of the recent elections. The supporters of complete municipalisation, however, have indicated that they are unwilling to agree to any proposal other than one for the complete municipalisation of electricity supply, and hence the present deadlock.

NOTES.

WE are glad to be able to notify that the honour of a knighthood of the Most Honourable Order of the Bath (Civil Division) has been conferred upon Sir Archibald Geikie.

THE *Times* announces the death of Dr. W. D. Miller, professor of odontology at Michigan University, the author of many treatises on the teeth, and until last year professor of odontology in the University of Berlin.

BY the death of Angelo Heilprin on July 17, at the age of fifty-four, science loses an enthusiastic naturalist, geologist, and explorer. He was born in Hungary, but at an early age emigrated with his parents to the United States. His education was completed in England at the Royal School of Mines during the years 1874–7, when he showed especial aptitude for natural history and gained the Edward Forbes medal. Returning to the United States, he was in 1879 appointed professor of invertebrate palæontology and curator in charge of the Academy of Natural Sciences at Philadelphia, and for a time he was professor of geology at the Wagner Free Institute of Science in the same city. He was author of a handbook on the local "town geology," of a memoir on the Tertiary geology of the United States (1884), as well as of works on the Bermuda Islands and west coast of Florida. For the International Scientific Series he wrote the "Geographical and Geological Distribution of Animals" (1887). He was author of an essay on the Arctic problem, and in 1892 he led the Peary relief expedition to the Polar regions. In later years he turned to volcanic phenomena. In 1902 he visited Mont Pelée while it was still in eruption, and wrote a work entitled "Mont Pelée and the Tragedy of Martinique" (ed. 2, 1903); while in a recent article, published in *Science* (New York, 1906), he discussed the "Concurrence and Interrelation of Volcanic and Seismic Phenomena."

THE first meeting of the Italian Association for the Advancement of Science will take place at Parma from September 23 to 29. According to the *Lancet*, the medical sciences will be strongly represented, particularly in anatomy, human and comparative; and the section devoted to anthropology, ethnography, and palæoethnology will have special attractions because of its programme. It is expected also that fresh light will be thrown at the meeting upon the subjects of forest growth, rainfall, and hygiene.

THE second International Congress on Physiotherapy will meet in Rome under the presidency of Senator Guido Baccelli in October next, and bids fair to be a great success, representatives from Great Britain, France, Germany, Austria, Denmark, Sweden, Norway, Belgium, Holland, Switzerland, and Japan having already intimated their intention of being present. The Italian Government is granting special travelling facilities to those attending the congress. The general secretary of the congress is Prof. Carlo Colombo, Via Plinio, Rome. The English secretary is Mr. W. Deane Butcher, Holyrood, Ealing.

A REUTER telegram from New York states that the main expedition of the Peary Arctic Club has been postponed for a year in consequence of the new boilers in the *Roosevelt* having been delayed; the vessel meanwhile is to be taken to Etah, Greenland, for the purpose of establishing a coal depôt, and will return by the end of September.

ACCORDING to the *Athenaeum*, a scientific expedition for the exploration of Central Asia has been organised by the Russian Geographical Society. It will be under the leadership of M. Kozlow, and will leave in October next. The expedition proposes to spend two years in the close examination of southern Mongolia and the western parts of the Chinese provinces of Kansuh and Szechuen. It is stated by our contemporary that the entire cost of the expedition will be borne by the Czar.

IT is stated in the *Western Electrician* that wireless telegraph stations have been erected on Spitsbergen and at Hammerfest and Trömso in order that wireless communication may be kept up with the Wellman Arctic Expedition.

ACCORDING to the *Electrical Review*, a committee of inquiry into the question of electric-railway working in the United States is about to leave Berlin for New York, in connection with the long-discussed scheme for the introduction of electric traction on German railways, and particularly on the Berlin city railways. The committee intends to inspect, among other lines, the Baltimore-Washington-Annapolis Railway, which is equipped on the Westinghouse single-phase system, together with the elevated and tunnel railways in the United States. It is stated that the Berlin State Railway Administration will soon prepare plans for the conversion of certain lines as a result of a recent order made by the Minister for Railways, although nothing of practical value can really be accomplished until the return of the committee and the presentation of its conclusions.

THE Mississippi Valley Laboratory of the United States Department of Agriculture has, according to *Science*, been abolished, and the work in forest pathology will in future be carried on at Washington, D.C.

THE Alvarenga prize of the College of Physicians of Philadelphia for the present year has been awarded to Dr. W. Louis Chapman for his investigations on "Post-operative Phlebitis, Thrombosis and Embolism."

THE council of the Selborne Society has for some time had under its consideration a suggestion that the work of the society could be done much more efficiently if sections were formed, consisting of members specially interested in any particular objects. It is thought, for example, that one group of members might deal with the protection of plants, another with the question of the wearing of feathers, a third with the preservation of ancient buildings, a fourth with that of places of natural beauty, a fifth with general amenities, and so on. The matter has now been referred to the general purposes committee, and members who are interested in any matter coming within the society's objects are invited to communicate with the honorary general secretary, that a report may be made to the council as to the possibility of carrying out the idea.

THE Gypsy Lore Society, which was founded in 1888 and met an untimely end four years later, has now been revived, with its headquarters at 6 Hope Place, Liverpool. The first number of the new Journal illustrates the difficulties which surround the problem of the origin of this mysterious people. The most important contribution is Mr. John Sampson's article on "Gypsy Language and Origin," which contains a useful summary of the literature of the subject. The linguistic evidence seems to connect the Gypsy speech of Europe with that of Kashmir or Dardistan, but the intervening links, particularly the dialects of Syria and Armenia, are still little known, and much work remains to be done before a comparative grammar and dictionary can be compiled. The society, however, must resist the tendency to confound the ethnological with the linguistic problem. It may perhaps be admitted that the basis of Gypsy speech is to be found in that of one of the vagrant tribes of India. But it is probable that this Dravidian race element has now largely disappeared in the European branch of the tribe, and anthropometry can throw little light on the varied elements from which it has been recruited. All students of anthropology, linguistics, and folk-lore offer a friendly welcome to the revived society, which will, it may be hoped, enjoy a longer lease of life than its predecessor. It has been suggested that, with the collaboration of members of the Gypsy Lore Society, an anthropological survey of the Gypsies should be undertaken, with the view of classifying them from that point of view and determining their ethnographical position among the races of India. Members of the society who are interested in this subject, and especially those who are in a position to take part in the work, are invited to communicate with Mr. J. W. Scott Macfie, Rowton Hall, Chester.

AN institute entitled the Istituto Therapeutico Italiano has been established at Milan under the directorship of Dr. Zanoni, the work of which will be the investigation of the action of new drugs, especially in regard to serum-therapy and hypodermic medication.

THE Vienna correspondent of the *Lancet* states that the new premises of the Vienna Serum Institute have been recently opened. The institute serves two distinct purposes, viz. scientific research and the preparation of sera against certain diseases for the supply of medical institutions and practitioners. It is stated that 71,506 bottles of anti-diphtheritic serum were made in the institute and sold in 1905, and 75,000 bottles in 1906, together with 7500 doses of anti-scarlatinal serum and 2000 doses of dysentery serum. Since 1906 the institute has been self-supporting, as the sale of the sera to private patients covers the cost of manufacture. The quantity of blood taken from each animal amounts to six litres (eleven pints) each time, and as this is repeated ten times a year, 110 pints of blood have to be reproduced by the organism within a year.

THE French Association for the Advancement of Science recently met at Rheims under the presidency of Dr. Henrot. In the presidential address, after remarking that with notification, isolation, and disinfection, with certain exceptions, we may hope to stamp out infectious diseases, Dr. Henrot proceeded to deal with the question of child-life protection. Various societies have been founded in France to care for the mother, both before and after the birth of the child, and to educate the parents in the proper feeding and care of their children. For this purpose, associations for the supply of proper milk, comparable to our infants' milk depôts, have been established. Crèches also have been organised to look after the children while the mothers are at work. Children abandoned or in immoral surroundings are cared for by the State, and in France there are no less than 178,000 of these, for whom schools are established where, as they become old enough, various trades are taught. The families which have the most numerous members should be the best housed, and at Nancy the "Bureau de Bienfaisance" has provided dwellings with gardens for those families where there are children.

An interesting report by Dr. Leslie Mackenzie and Captain A. Foster has been issued by the Scotch Education Department on a collection of statistics relative to the physical condition of children attending the public schools of the School Board for Glasgow. The figures show that the one-roomed child (*i.e.* the child of a family occupying one room only), whether boy or girl, is always on the average distinctly smaller and lighter than the two-roomed; the two-roomed than the three-roomed; and the three-roomed than the four-roomed. "The numbers examined are so large, and the results are so uniform that only one conclusion is possible, viz. that the poorest child suffers most in nutrition and in growth. It cannot be an accident that boys from two-roomed houses should be 11·7 lb. lighter on an average than boys from four-roomed houses and 4·7 inches smaller. Neither is it an accident that girls from one-roomed houses are, on the average, 14 lb. lighter and 5·3 inches shorter than the girls from four-roomed houses." The report contains a number of elaborate tables and diagrams.

The Bulletin of the Johns Hopkins Hospital for June-July contains a number of papers of interest to the pathologist and clinician, mostly from the laboratories of the medical clinic of the hospital. The August number of the same Bulletin is principally devoted to tuberculosis, and contains an article, by Dr. Pohlman, on "The Purple Island" by Phineas Fletcher, a seventeenth-century layman's poetical conception of the human body.

The Journal of the Royal Sanitary Institute for August (xxviii., No. 7) contains the inaugural address by Sir Charles Cameron at the Dublin conference, in which he demonstrated how sanitation has reduced the death-rate, and discussed the questions of tuberculosis, milk supply, and infant mortality.

After quoting a considerable portion of Sir H. H. Johnston's article on big-game protection which appeared in vol. lxxvi., p. 37 (1907), of Nature, a writer in the *American Naturalist* for July asks the question whether we cannot do without furs, remarking that the lack of "buffalo-robes" due to the extermination of the bison is not felt in America. He then goes on to raise a protest against collecting skins and eggs for museum purposes, observing that their scientific value is but slight, while it is a question whether oology has any right to rank as a science at all. In his opinion a museum with specimens of species as rare in collections as the great auk is of less value for educational purposes than a barn where swallows nest. "In these days of inexpensive and quite accurate pictures, collections are not necessary for identification, and science is advanced by detailed studies of common forms, rather than by collecting luna and imperial moths."

The July number of the *Emu* (forming the first part of vol. vii.) opens with an account by Mr. I. Batey of the changes which have taken place in the bird-life on an estate of fifteen thousand acres in Victoria during the last sixty years. In its early days the tract was a veritable bird paradise, but, largely owing to the felling of its timber, many of the species have now completely disappeared, some of them from an area of much wider extent than that occupied by the estate. Wedge-tailed eagles abounded in 1846, and but little effect was made on their numbers by the shot-guns then in use, although the introduction of strychnine soon led to their practical extermination.

The July issue of the *American Naturalist* opens with some interesting personal reminiscences of Louis Agassiz related by Mr. C. W. Eliot at a meeting of the "Saturday Club" in connection with the Agassiz centenary. Emphasis is laid on the great naturalist's eminence as a teacher and expositor, and the novel methods of education he adopted. The son of a distinguished surgeon was, for instance, set to study a few trilobites, upon which he was expected to work for several weeks without any aid from books or illustrations, and at the same time to be his own artist. His powers of organisation and of obtaining financial support were also very noteworthy in these early days of science teaching. Years ago it was remarked that "Agassiz will get more money out of the Commonwealth of Massachusetts for his subjects than any of you have dreamed of getting, than any of you could possibly get; but he will so equip his subject, he will set such a standard for collections in all subjects, that every department of learning in the University will profit by his achievements." These words have proved absolutely prophetic.

In the August issue (No. 3) of *British Birds*, Miss E. L. Turner announces that the ruff has made its re-appearance as a breeding species in Norfolk, where the last known nest was recorded so long ago as 1889. In June of the present year a keeper discovered a reeve's nest containing four eggs, which, together with the parent bird, was successfully photographed. It is probable that another pair of ruffs also nested in the county during the present summer, while as young birds were killed during the two previous seasons, there is reason to believe that the species has nested in Norfolk since 1904. Ruffs have been reported as breeding in Yorkshire in 1901 and the two succeeding years. In the same issue Mr. F. Smalley points out that the alleged occurrence of the Pacific eider-duck (*Somateria v-nigrum*) in the British Isles is due to ornithologists having failed to recognise that drakes of the ordinary eider-duck may show a faint dark chevron on the throat. A specimen of the Sardinian warbler (*Sylvia melanocephala*), killed near Hastings in June last, definitely adds another species to the British list.

We have received a memoir by Dr. Alvan A. Tenney on "Social Democracy and Population," issued in the series of "Studies in History, Economics and Public Law" of Columbia University. By "social democracy" the author means "that form of society . . . in which every man has a chance and knows that he has it," a form of society based primarily on the maintenance of a reasonable plane of living for all, and it is the object of the essay to discuss the influence of biological factors on such a form of society, assuming it possible of attainment. Thus the maintenance of a social democracy requires a rate of increase of population that is not too rapid as compared with the rate of progress in the arts; this probably implies that the democracy would be outstripped in population by nations of a lower standard of living, and hence might be only capable of survival in the case of a nation living in an easily defended situation. The low rate of increase postulated would not, the author considers, sensibly lessen the action of selection, as the latter acts in too many ways, nor would it be likely to lead to degeneration. But a recognition of the existence of hereditary individual differences and of the importance of selection is sufficient to warrant "conscious social interference in the biological process," interference which already takes place in such matters as the control of immigration. The question arises whether the principle should not be extended for the purpose of maintaining the level of natural ability in the population. As regards the United States, the author considers that the attainment of social democracy should be possible if they do not enter into the struggle for foreign markets in competition with peoples of a lower plane of living.

IN the Journal of the Society of Arts for July 26 Mr. T. E. Younge gives an account of the "sand-counter" (ψαμμίτης) of Archimedes, which may help to revive popular interest in this very remarkable tract. Practically, Archimedes uses a scale of notation the radix of which is a myriad (10,000), and shows that by means of this scale it is possible to estimate the number of grains of sand in a sphere of the size of the earth. His estimate, of course, is only approximate, and his data imperfect; but considering the state of Greek science at the time, it is a most interesting achievement, and it is quite clear that Archimedes could have used more exact data with equal facility. Mr. Younge has checked Archimedes' numerical calculations, and found them all correct.

IN the *Monthly Weather Review* for April, issued by the U.S. Department of Agriculture, Mr. H. Helm Clayton proposes a new method of weather forecasting by analysis of atmospheric conditions into waves of different lengths. Data in support of his theory were published by the author in the *American Meteorological Journal* of July, 1885, and June, 1891, and after further research into the laws underlying the drift of weather conditions he concludes that the meteorological elements at any place may be analysed into oscillations or waves differing in length, each having a distinct physical existence; further, that the waves drift generally from west to east, with a velocity inversely proportional to their length. Specimens of the movements of pressure and temperature waves over the United States illustrate the investigation, and the author considers that the results not only open the way to an improvement in forecasting weather from day to day, but furnish a scientific basis for long-range forecasts.

PROF. H. EBERT describes in the March number of *Terrestrial Magnetism* an extremely sensitive arrangement he has used for investigating the pulsations of short period in the strength of the earth's magnetic field. For observations of the vertical component, a wire 3000 metres in length is formed into a coil of fifteen turns, and is placed on the ground. In series with it is a sensitive "filament galvanometer" of the Einthoven type. Any change in the number of magnetic lines through the coil will produce a current through the galvanometer, and the arrangement will indicate a change in the vertical component of the earth's magnetic field equal to 1/400,000 of its mean value. Prof. Ebert finds that periodic changes of certain frequencies most often occur, and one of these has the period 1/6 to 1/7 second, which is that of the oscillation of an electrical charge on a sphere of the size of the earth. The observations are being continued, and will probably play an important part in the search for an explanation of the phenomena of terrestrial magnetism.

THE Carnegie research memoirs submitted at the meeting of the Iron and Steel Institute in May last, brief summaries of which were given in NATURE (this vol., p. 65), have now been published in full in a special volume of the Journal of the institute (vol. lxxiv.). The volume contains papers by Mr. P. Breuil (Paris), on copper steels; by Mr. W. H. Hatfield (Sheffield), on cast iron as cast and heat treated; by Mr. E. F. Law (London), on the non-metallic impurities in steel; and by Dr. O. Stutzer (Freiberg), on the geology and origin of the Lapland iron ores. There is also a paper on boron steels, by Dr. L. Guillet (Paris), received since the meeting. These steels have not hitherto been the subject of systematic investigation, and the researches described show the commercial interest attaching to these products when quenched. Boron steels will probably never prove of commercial use in the raw state, but they may prove useful after quenching. In that condition they possess high tensile strength and a remarkable degree of elasticity. The best results were obtained with a steel containing 0·50 per cent. of boron. The volume concludes with a reprint of considerable historical interest. It is an address on the effect of air and moisture on blast furnaces, delivered at Bradford in the year 1800 by Joseph Dawson, of Lowmoor.

IN summarising the work of the United States Geological Survey during 1906 in the investigation of ores, Mr. S. F. Emmons directs attention to the way in which science is handicapped. The increasing exodus of members of the economic staff of the survey in consequence of their employment by large mining organisations at salaries much greater than those they have been receiving from the Government seriously impairs the efficiency of the work of this branch of the survey. The loss of trained men in this work is, for a time, irreparable, as it is only by years of practical experience in the field that the geologist becomes competent to carry on independent work of this kind.

IN the Journal of the Franklin Institute (vol. clxiv., No. 1) Mr. Albert Obholzer describes the methods used to avoid piping in steel ingots at the Hungarian Government steel foundries at Diosgyör. With the addition of thermite to the charge of open-hearth steel, homogeneous ingots are obtained. The method presents considerable advantages over the very successful Harmet process, which necessitates the use of elaborate machinery.

THE number of the Bulletin of the College of Agriculture (vol. vi., No. 3), Tokio University, lately received, contains several short papers on the physiological action of various chemical substances on plants. Prof. O. Loew and Dr. K. Aso discuss the importance of culture solutions being physiologically balanced, and allude to the use of lime in averting the injurious action of an excess of magnesium salts. They also touch upon the beneficial action of treating the soil with bactericidal substances such as carbon disulphide, attributing the effect to the breaking down of living matter. Mr. T. Takeuchi refers to the use of shoots of *Aralia cordata*, called in Japan "udo," as a salad or a vegetable, comparable with celery or asparagus.

A SEMI-POPULAR article on the phylogeny of the various groups of the plant kingdom is contributed by Prof. M. Möbius to *Naturwissenschaftliche Wochenschrift* (June 30 and July 7). To the Flagellatæ is accorded the lowest position, from which arose the algæ, bacteria, diatoms, and other elementary groups. From the green algæ were derived the brown and red seaweeds, the connection of the latter being through Coleochæte or through an Ulva-Bangia link. With regard to the mosses, the author favours the view that they have been derived from an early type of the Jungermanniaceæ, and that the prototype of the ferns and fern-allies was probably a plant akin to Anthoceros. Finally, the origin of the monocotyledons is traced through the dicotyledons to the conifers, and thence back to the lycopods.

FOUR papers dealing with the identification of new plants chiefly from Mexico are published in the Proceedings of the American Academy of Arts and Sciences (July). Mr. J. M. Greenman is responsible for new species of the liliaceous genus Schoenocaulon; among the diagnoses prepared by Mr. M. L. Fernald are a group of Salvias. The collections brought by Mr. C. C. Deam from Guatemala and Mexico yielded, amongst others, *Streptochaeta sodoriana*, a grass already known from Ecuador, and a curious Euphorbia. The majority of the identifications by Mr. B. L. Robinson are additions to the Compositæ, and include two new genera, Cymophora and Loxothysanus, also a series of species of Eupatorium.

IN the account of the grasses of British Somaliland contributed to the *Kew Bulletin* (No. 6), Dr. O. Stapf establishes half a dozen new species, including the economically important "durr" grass, *Andropogon cyrtocladus*, and *Sporobolus fruticulosus*, another shrubby species. These shed their leaves and young shoots in the dry season, but produce large, feathery branches after the rains set in. The culms of *Panicum turgidum* and *Pennisetum dichotomum* are persistent, and form a tough fodder suited to the hard-mouthed camel. Phytogeographically the grasses of Somaliland have affinities with the grasses of Eritræa, eastern Nubia, and tropical Arabia. A considerable number of new fungi are recorded by Mr. Massee as additions to the wild fauna and flora of the gardens; a Hypholoma and several parasitic Melanconiaceæ and Hyphyomyceteæ provide the types of new species. Mr. Botting Hemsley has a note on a new species of Rhododendron from China described by Mr. E. H. Wilson.

THE Annual Report and Transactions of the Manchester Microscopical Society for the year 1906 has just reached us. The society is, we are pleased to see, in a satisfactory condition. The volume before us contains the address delivered in January last by the president, Prof. S. J. Hickson, F.R.S., on "The Differentiation of Species of Cœlenterata in the Shallow Water Seas," and many papers of interest to students of microscopical science.

As a member of the International Congress of Geologists meeting in Mexico in 1906, Prof. H. F. Cleland, of Williams College, took the opportunity of visiting, in the company of trained observers of the Mexican Geological Survey conversant with the regions investigated, several of the Mexican volcanoes, and describes in the August number of the *Popular Science Monthly*, under the title of "Some Little-known Mexican Volcanoes," the volcanoes known as the Volcano Colima and the Nevado de Toluca, and the cinder cones of Valle de Santiago. The article is well illustrated.

PROF. KARL PEARSON'S Robert Boyle lecture, entitled "The Scope and Importance to the State of the Science of National Eugenics," delivered at Oxford on May 17 last, has now been issued by Mr. H. Frowde at one shilling net.

OUR ASTRONOMICAL COLUMN.

HELIUM ABSORPTION IN THE SOLAR SPECTRUM.—In a letter to the *Observatory* (No. 386, p. 315, August) Mr. Nagaraja, of the Kodaikanal Observatory, records the results of some further observations of the helium line, D_3, as a dark line in the spectrum of the sun. Having already frequently observed this dark line in the regions of the photosphere adjacent to sun-spots, he suspected that he had also seen it as a faint line in the ordinary solar spectrum, but for several reasons found the observation difficult to confirm. He now states that, with a recently mounted large grating spectrograph, he obtained a photograph of the D_3 region on April 19, and on examination found that it shows both the darkening and the chromospheric (bright) line, where a spot was close to the limb, and, further, both the dark and the bright lines appear to be a continuation of a faint line in the normal solar spectrum. Further examination is necessary ere the identity of this faint line with the helium line can be definitely affirmed, and to this end Mr. Nagaraja proposes to carry on the research.

In the same journal Mr. A. A. Buss discusses at some length the appearance of dark and bright helium in various solar regions.

POSSIBLE CHANGES IN THE "OWL" NEBULA (M. 97).—In a paper communicated to the Royal Astronomical Society, Prof. Barnard compares the results of his recent observations of the "Owl" nebula, made with the 40-inch refractor of the Yerkes Observatory, with those made with Lord Rosse's large reflector in 1848. The latter were embodied in the well-known drawing of this object which shows a small star placed in each of the two holes, or "eyes," seen in the nebula, each star representing the pupil of the "eye" in which it was placed.

But according to Prof. Barnard's observations in recent years these stars are clear of the dark openings, and are seen on the nebulosity itself, although quite near to the dark spaces. It follows, then, that either the older drawing, which is corroborated by the observer's notes, did not correctly represent the relative positions of the stars, or that a change has occurred in the nebula, for the two stars have not changed their places in the sky. As a working hypothesis, Prof. Barnard suggests the possibility of the nebula having rotated from west to east on an axis having the position angle of 50°, and states that, if the velocity of rotation were great enough, the two stars in question would have occupied the positions in the holes as shown on Lord Rosse's drawing (Monthly Notices R.A.S., vol. lxvii., No. 8, p. 543, June).

A QUICKLY CHANGING VARIABLE STAR.—According to the results of observations made at the Yerkes Observatory by Mr. Naozo Ichinohe, the variable star 87.1906 Draconis has the very short period of only 10h. 37m. 35s. The light increases from minimum (mag. 11·6) to maximum (mag. 10·9) in about three hours, decreases to minimum in about five hours, and remains at minimum for the remainder of the period.

An ephemeris accompanies Mr. Ichinohe's note in No. 4194 of the *Astronomische Nachrichten* (p. 293, August 2), and the position of this object, for 1900, is given as 16h. 33m. 43·3s. + 58° 2′ 36″.

VENUS AS A LUMINOUS RING.—A brief note by Messrs. H. N. Russell and Z. Daniel, published in No. 1, vol. xxvi., of the *Astrophysical Journal* (p. 69, July), describes an observation of the ring-phase of Venus made at Princeton Observatory, with the 5-inch finder, at 5h. 7m. (G.M.T.) on November 29, 1906.

At that time Venus was about $1^\circ 40'$ from the sun's centre, and in moments of atmospheric steadiness the complete outline of the planet's disc was seen distinctly. The space within the circle always appeared a shade darker than that without, but this was probably a subjective effect. A bright spot was several times suspected in the bright part of the ring. If the atmospheric conditions are very favourable, the ring-phase of this planet may be seen again in 1914; after that there will be no further opportunity until 1972.

OBSERVATIONS OF JUPITER, 1906–7.—During the opposition of 1906–7, the Rev. T. E. R. Phillips observed Jupiter on 106 occasions, and records the results of his observations in a paper communicated to the Royal Astronomical Society (Monthly Notices, vol. lxvii., p. 522, June).

The most remarkable change, as compared with the previous opposition, was observed in the great development of the N. equatorial belt, which had become broader and darker, and, in August, was marked with numerous white rifts and dark reddish streaks along its S. edge.

Later in the apparition this belt was seen to be triple, the S. component being the darkest of the three. Changes of colour were also observed in this belt and on the whole of the disc lying between the N.N. temperate belt and the N. pole. Observations of the dark matter in the great S. tropical disturbance tend to confirm, in principle, Major Molesworth's hypothesis concerning the sudden transference of the dark matter from the following to the preceding end of the red spot, for this transference took place in about two weeks instead of taking nearly three months as it should do under normal conditions of transit.

AUGUST METEORS, 1907.

ENCOURAGED by the appearance of several bright Perseids on the nights of August 4 and 6 to expect a somewhat plentiful return of this shower, a careful watch was maintained of the sky on August 10, 11, and 12, but the results scarcely realised expectation. The display was by no means an abundant one, and the individual meteors were not so bright generally as in ordinary years.

The results of watches were as under:—

August 10.

10h. to 12h., twenty-five meteors per hour, of which half were Perseids; 13h. to 14h., forty-five meteors, of which two-thirds were Perseids; 14h. to 15h., twenty-five meteors seen, but there were many passing clouds from west. Two other observers at Bristol counted thirty-one meteors between 11h. and 12h.

August 11.

9h. to 10h., fifteen meteors; about half of them were Perseids; 13h. to 14h., thirty-six meteors, of which twenty-two were Perseids. Sky rather misty. The shower was regarded as very poor for August 11.

Miss Irene Warner, of Horfield Common, Bristol, obtained the following results:—

9h. 25m. to 10h. 5m., eleven meteors, including eight Perseids; 10h. 5m. to 11h. 5m., thirty-three meteors, including twenty-seven Perseids; 11h. 5m. to 11h. 40m., twelve Perseids.

The horary number was about twenty-eight meteors, of which about twenty-four were Perseids.

Two other observers at Bristol, watching from 9h. to 11h., counted thirty-five meteors.

August 12.

Miss Warner watched as follows:—

9h. 15m. to 9h. 40m., five meteors; 10h. 10m. to 11h. 20m., twenty-one meteors; 11h. 20m. to 12h. 20m., twenty-three meteors. Fine meteor seen at 10h. 55m. with train. The path was from δ to α Cygni. At 11h. 20m. one as bright as Venus from about $35^\circ + 58^\circ$ to $60^\circ + 47^\circ$.

11h. to 12h., about forty-five meteors, including thirty-three Perseids; 13h. to 14h., about fifty meteors, including thirty-five Perseids.

There were many passing clouds, rendering observation difficult, and the horary numbers were derived from the number of objects seen during clear intervals.

Radiant point on August $10 = 44^\circ + 56^\circ$.

Radiant point on August $12 = 47^\circ + 57^\circ$.

A brilliant flash was noticed on August 11, 13h. 17m., probably given by a large Perseid falling in the southern sky, but this quarter was hidden from the observer by a building.

I would be glad to hear of any duplicate observations of the following objects seen on August 10:—

	h. m.				
(1)	10 22	...	$1\frac{1}{2}$	..	$339° + 66$ to $306 + 57\frac{1}{2}$
(2)	10 30	...	1	..	$5 + 26$,, $8 + 22\frac{1}{2}$
(3)	11 6	...	$1\frac{1}{2}$		$2\frac{1}{2} + 65$,, $54 + 73$

No. 2 was a fine, bluish-white Cygnid, which flashed out suddenly in a short diving course. No. 3 was from the direction of the λ Aquilid radiant, and it moved very slowly, occupying $3\frac{1}{2}$ seconds in sailing along its path of 19°. The nucleus was yellow, and it threw off a trail of reddish sparks.

Other showers were seen on August 10–12 from $332^\circ + 50^\circ$ and $333^\circ + 28^\circ$.

W. F. DENNING.

TREASURY GRANTS TO UNIVERSITY COLLEGES.

THE report of the permanent advisory committee appointed on January 31, 1906, to advise the Treasury as to the distribution of the grant in aid of colleges furnishing education of a university standard, has now been published.[1] The report states that a study of the problem how education of a university standard may be most advantageously assisted by State grants shows that there is at the present time considerable complexity surrounding the question, not only by reason of the overlapping due to various educational bodies carrying on similar work in the same areas, but also by reason of public money derived from rate or tax being voted for higher education by different authorities with insufficient information as to one another's operations. For these reasons the committee has obtained permission to shorten from five years to two the period for which the present re-allocation shall hold good. It is hoped that it will be possible by April 1, 1909, to make recommendations for a permanent arrangement.

With regard to the question of standard, the committee finds that it is only in comparatively few of the university colleges that the majority even of the day students have passed a matriculation examination or equivalent test. A well-recognised standard once established would make it easier for the colleges to coordinate their curricula with those of secondary schools. For the present, the report continues, a step may be taken in this direction by excluding rigorously from the category of university work all classes which are preparing students for matriculation.

The committee appointed two inspectors to visit the colleges which already receive grants and certain other institutions which had applied for recognition. Sir Thomas Raleigh, K.C.S.I., and Dr. Alex. Hill undertook this task, and their reports on the various institutions visited are printed as an appendix to the report.

After summarising the financial assistance received by the colleges from Imperial funds and recapitulating the rules laid down for its guidance in various Treasury minutes, the committee recommended that a new maximum limit for all grants be set up, and 10,000*l*. has been decided upon. This maximum relates only to the annual grants for general purposes, and is exclusive of grants for special purposes which may be made from time to time.

The grants recommended for the intervening period of two years, pending a settlement of the general questions referred to in the report, are shown in the following table:—

[1] "University Colleges (Great Britain)." Grant in Aid. [267]. Price 1*s*. 6*d*.

College.	Grant, 1906–7. £	Proposed Grant. £
Victoria University of Manchester	12,000 ...	10,000
University of Liverpool	10,000 ...	10,000
University College, London	10,000 ...	10,000
University of Birmingham	9,000 ...	9,000
University of Leeds	8,000 ...	8,000
King's College, London	7,800 ...	7,800
Armstrong College, Newcastle-on-Tyne...	6,000 ...	6,000
University College, Nottingham	5,800 ...	5,000
University of Sheffield	4,600 ...	5,000
Bedford College for Women, London ...	4,000 ...	4,000
University College, Bristol	4,000 ...	4,000
University College, Reading	3,400 ...	3,400
Hartley University College, Southampton	3,400 ...	2,250
London School of Economics	— ...	500

The report gives the committee's reasons for the diminution of the grant in the case of Manchester, Nottingham, and Southampton, and for the grant to the London School of Economics.

After a consideration of the reports of the inspectors who visited the institutions and of the statistics provided by them, the committee decided not to recommend a grant in the case of the Birkbeck College, the East London College, and the Royal Albert Memorial College, Exeter.

The grants enumerated in the table above amount to 84,950*l.*, leaving, if the grant of 1000*l.* to Dundee University College is continued, a balance of 14,050*l.* available for grants for special purposes.

THE BRITISH ASSOCIATION.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY SILVANUS P. THOMPSON, D.Sc., F.R.S., PAST PRESIDENT OF THE INSTITUTION OF ELECTRICAL ENGINEERS, PRESIDENT OF THE SECTION.

It would be impossible for any assembly of engineers to meet in annual gathering at the present time without reference to the severe loss which the profession has so recently sustained by the death of Sir Benjamin Baker. Born in 1840, he had attained while still a comparatively young man to a position in the front rank of constructive engineers. His contributions to science cover a considerable range, but were chiefly concerned with the strength of materials, into which he made valuable investigations, and with engineering structures generally. His name will doubtless be chiefly associated with the building of great bridges, to the theory of which he contributed an important memoir entitled "A Theoretical Investigation into the Most Advantageous System of Constructing Bridges of Great Span." In this work he set forth the theory of the cantilever bridge. Upon the plan there laid down he built the Forth Bridge, besides many other large bridges in various parts of the world. With that memorable structure, completed in 1890, his name will ever be associated; but he will be remembered henceforth also as the engineer who was responsible for the great dam across the Nile at Assouan, a work which promises to have an influence for all time upon the fortunes of Egypt and upon the prosperity of its population. Sir Benjamin Baker was, moreover, closely associated with the internal railways of London, both in the early days of the Metropolitan Railway and in the later developments of the deep-level tubes. He was elected a Fellow of the Royal Society in 1890, became President of the Institution of Civil Engineers in 1895, and was a member of Council of the Institution of Mechanical Engineers, besides being an active member of the Royal Institution and of the British Association. He was also a member of the Council of the Royal Society at the time of his death.

He enjoyed many honorary distinctions, including degrees conferred by the Universities of Cambridge and Edinburgh. In 1890 there was conferred upon him the title of K.C.M.G., and in 1902 that of K.C.B.

He had but just returned from Egypt, whither he had gone in connection with the project for raising the height of the Assouan dam, so as to increase its storage to more than double the present volume, when he died very suddenly on May 19, in his sixty-seventh year.

The Development of Engineering and its Foundation on Science.

We live in an age when the development of the material resources of civilisation is progressing in a ratio without parallel. International commerce spreads apace. Ocean transport is demanding greater facilities. Steamships of vaster size and swifter speed than any heretofore in use are being built every year. Not only are railways extending in all outlying parts of the world, but at home, where the territory is already everywhere intersected with lines, larger and heavier locomotives are being used, and longer runs without stopping are being made by our express trains. The horsed cars on our tramways are now being mostly superseded by larger cars, electrically propelled and travelling with greatly increased speeds. For the handling of the ever-increasing passenger traffic in our great cities electric propulsion has shown itself a necessity of the time; witness the electric railways in Liverpool and the network of electrically worked tube railways throughout London. In ten years the manufacture of automobile carriages of all sorts has sprung up into a great industry. Every year sees a greater demand for the raw materials and products, out of which the manufacturer will in turn produce the articles demanded by our complex modern life. We live and work in larger buildings; we make more use of mechanical appliances; we travel more, and our travelling is more expeditious than formerly; and not we alone but all the progressive nations. The world uses more steel, more copper, more aluminium, more paper; therefore requires more coal, more petroleum, more timber, more ores, more machinery for the getting and working of them, more trains and steamships for their transport. It requires machines that will work faster or more cheaply than the old ones to meet the increasing demands of manufacture; new fabrics; new dyes; even new foods; new and more powerful means of illumination; new methods of speaking to the ends of the earth.

We must not delude ourselves with imagining that the happiness and welfare of mankind depend only on its material advancement; or that moral, intellectual, and spiritual forces are not in the ultimate resort of greater moment. But if the inquiry be propounded what it is that has made possible this amazing material progress, there is but one answer that can be given—science. Chemistry, physics, mechanics, mathematics, it is these that have given to man the possibility of organising this tremendous development. And the great profession which has been most potent in applying these branches of science to wield the energies of Nature and direct them to the service of man has been that of the engineer. Without the engineer how little of all this activity could there have been; and without mathematics, mechanics, physics, and chemistry, where was the engineer?

If looking over this England of Edward the Seventh we try to put ourselves back into the England of Edward the Sixth—or for that matter of any pre-Victorian monarch—we must admit that the differences to be found in the social and industrial conditions around us are due not in any appreciable degree to any changes in politics, philosophy, religion, or law, but to science and its applications. If we look abroad, and contrast the Germany of Wilhelm the Second with the Germany of Charles the Fifth, we shall come to the like conclusion. So also in Italy, in Switzerland, in every one indeed of the progressive nations. And it is precisely in the stagnant nations, such as Spain, or Servia, where the cultivation of science has scarcely begun, that the social conditions remain in the backward state of the Middle Ages.

Interaction of Abstract Science and its Applications.

In engineering, above all other branches of human effort, we are able to trace the close interaction between abstract science and its practical applications. Often as the connection between pure science and its applications has been emphasised in addresses upon engineering, the emphasis has almost always been laid upon the influence of the abstract upon the concrete. We are all familiar with the doctrine that the progress of science ought to be an end in itself, that scientific research ought to be pursued without regard to its immediate applications, that the importance of a discovery must not be measured by its apparent utility at the moment. We are assured that research in pure science is bound to work itself out in due time into technical applications of utility, and that the pioneer ought not to pause in his quest to work out potential industrial developments. We are invited to consider the example of the immortal Faraday, who deliberately abstained from busying himself with marketable inventions arising out of his discoveries, excusing himself on the ground that he had no time to spare for money-making. It is equally true, and equally to the point, that Faraday, when he had established a new fact or a new physical relation, ceased from busying himself with it and pronounced that it was now ready to be handed over to the mathematicians. But, admitting all these commonplaces as to the value of abstract science in itself and for its own sake, admitting also the proposition that sooner or later the practical applications are bound to follow on upon the discovery, it yet remains true that in this thing the temperament of the discoverer counts for something. There are scientific investigators who cannot pursue their work if troubled by the question of ulterior applications; there are others no less truly scientific who simply cannot work without the definiteness of aim that is given by a practical problem awaiting solution. There are Willanses as well as Regnaults; there are Whitworths as well as Poissons. The world needs both types of investigator; and it needs, too, yet another type of pioneer—namely, the man who, making no claim to original discovery, by patient application and intelligent skill turns to industrial fruitfulness the results already attained in abstract discovery.

There is, however, another aspect of the relation between pure and applied science, the significance of which has not been hitherto so much emphasised, but yet is none the less real—the reaction upon science and upon scientific discovery of the industrial applications. For while pure science breeds useful inventions, it is none the less true that the industrial development of useful inventions fosters the progress of pure science. No one who is conversant with the history, for example, of optics can doubt that the invention of the telescope and the desire to perfect it were the principal factors in the outburst of optical science which we associate with the names of Newton, Huygens, and Euler. The practical application, which we know was in the minds of each of these men, must surely have been the impelling motive that caused them to concentrate on abstract optics their great and exceptional powers of thought. It was in the quest—the hopeless quest—of the philosopher's stone and the elixir of life that the foundations of the science of chemistry were laid. The invention of the art of photography has given immense assistance to sciences as widely apart as meteorology, ethnology, astronomy, zoology, and spectroscopy. Of the laws of heat men were profoundly ignorant until the invention of the steam engine compelled scientific investigation; and the new science of thermodynamics was born. Had there been no industrial development of the steam engine, is it at all likely that the world would ever have been enriched with the scientific researches of Rankine, Joule, Regnault, Hirn, or James Thomson? The magnet had been known for centuries, yet the study of it was utterly neglected until the application of it in the mariners' compass gave the incentive for research.

The history of electric telegraphy furnishes a very striking example of this reflex influence of industrial applications. The discovery of the electric current by Volta and the investigation of its properties appear to have been stimulated by the medical properties attributed in the preceding fifty years to electric discharges. But, once the current had been discovered, a new incentive arose in the dim possibility it suggested of transmitting signals to a distance. This was certainly a possibility, even when only the chemical effects of the current had yet been found out. Not, however, until the magnetic effects of the current had been discovered and investigated did telegraphy assume commercial shape at the hands of Cooke and Wheatstone in England and of Morse and Vail in America. Let us admit freely that these men were inventors rather than discoverers: exploiters of research rather than pioneers. They built upon the foundations laid by Volta, Oersted, Sturgeon, Henry, and a host of less famous workers. But no sooner had the telegraph become of industrial importance, with telegraph lines erected on land and submarine cables laid in the sea, than fresh investigations were found necessary; new and delicate instruments must be devised; means of accurate measurement heretofore undreamed of must be found; standards for the comparison of electrical quantities must be created; and the laws governing the operations of electrical systems and apparatus must be investigated and formulated in appropriate mathematical expressions. And so, perforce, as the inevitable consequence of the growth of the telegraph industry, and mainly at the hands of those interested in submarine telegraphy, there came about the system of electrical and electromagnetic units, based on the early magnetic work of Gauss and Weber, developed further by Lord Kelvin, by Bright and Clark, and last but not least by Clerk Maxwell. Had there been no telegraph industry to force electrical measurement and electrical theory to the front, where would Clerk Maxwell's work have been? He would probably have given his unique powers to the study of optics or geometry; his electromagnetic theory of light would never have leapt into his brain; he would never have propounded the existence of electric waves in the ether. And then we should never have had the far-reaching investigations of Heinrich Hertz; nor would the British Association at Oxford in 1894 have witnessed the demonstration of wireless telegraphy by Sir Oliver Lodge. A remark of Lord Rayleigh's may here be recalled, that the invention of the telephone had probably done more than anything else to make electricians understand the principle of self-induction.

In considering this reflex influence of the industrial applications upon the progress of pure science it is of some significance to note that for the most part this influence is entirely helpful. There may be sporadic cases where industrial conditions tend temporarily to check progress by imposing persistence of a particular type of machine or appliance; but the general trend is always to help to new developments. The reaction aids the action; the law that is true enough in inorganic conservative systems, that reaction opposes the action, ceases here to be applicable, as indeed it ceases to be applicable in a vast number of organic phenomena. It is the very instability thereby introduced which is the essential of progress. The growing organism acts on its environment, and the change in the environment reacts on the organism—not in such a way as to oppose the growth, but so as to promote it. So is it with the development of pure science and its practical applications.

In further illustration of this principle one might refer to the immense effect which the engineering use of steel has had upon the study of the chemistry of the alloys. And the study of the alloys has in turn led to the recent development of metallography. It would even seem that through the study of the intimate structure of metals, prompted by the needs of engineers, we are within measurable distance of arriving at a knowledge of the secret of crystallogenesis. Everything points to the probability of a very great and rapid advance in that fascinating branch of pure science at no distant date.

History of the Development of Electric Motive Power.

There is, however, one last example of the interaction of science and industry which may claim closer attention. In the history of the development of the electric motor one finds abundant illustration of both aspects of that interaction.

We go back to the year 1821, when Faraday, after studying the phenomena of electromagnetic deflexion of a needle by an electric current (Oersted's discovery), first succeeded in producing continuous rotations by electromagnetic means. In his simple apparatus a piece of suspended copper wire, carrying a current from a small battery, and dipping at its lower end into a cup of mercury, rotated continuously around the pole of a short bar-magnet of steel placed upright in the cup. In another variety of this experiment the magnet rotated around the central wire, which was fixed. These pieces of apparatus were the merest toys, incapable of doing any useful work;

nevertheless they demonstrated the essential principle, and suggested further possibilities. Two years later, Barlow, using a star-wheel of copper, pivoted so that the lowest point of the star should make contact with a small pool of mercury, found that the star-wheel rotated if a current was sent through the arm of the star while the arm itself was situated between the poles of a steel horseshoe-magnet. Shortly afterwards Sturgeon improved the apparatus by substituting a copper disc for the star-wheel. The action was the same. A conductor, carrying an electric current, if placed in a magnetic field, is found to experience a mechanical drag, which is neither an attraction nor a repulsion, but a lateral force tending to move it at right angles to the direction of flow of the current and at right angles to the direction of the lines of the magnetic field in which it is situated. Still this was a toy. Two years later came the announcement by Sturgeon of the invention of the soft-iron electromagnet, one of the most momentous of all inventions, since upon it practically the whole of the constructive part of electrical engineering is based. For the first time mankind was furnished with a magnet the attractive power of which could be increased absolutely indefinitely by the mere expenditure of sufficient capital upon the iron core and its surrounding copper coils, and the provision of a sufficiently powerful source of electric current to excite the magnetisation. Furthermore the magnet was under control, and could be made to attract or to cease to attract at will by merely switching the current on or off; and, lastly, this could be accomplished from a distance, even from great distances away. How slowly the importance of this discovery was recognised is now a matter for astonishment. To state that Sturgeon died in poverty twenty-six years later is sufficient to indicate his place among the unrequited pioneers of whom the world is not worthy. Six years elapsed, and then there came a flood of suggestions of electric motors in which was applied the principle of intermittent attraction by an electromagnet. Henry in 1831 and Dal Negro in 1832 produced see-saw mechanisms so operated. Ritchie in 1833 and Jacobi in 1834 devised rotatory motors. Ritchie pivoted a rapidly commutated electromagnet between the poles of a permanent magnet—a true type of the modern motor—while Jacobi caused two multipolar electromagnets, one fixed, one movable, to put a shaft into rotation and propel a boat. A perplexing diminution of the current of the battery whenever the motor was running caused Jacobi to investigate mathematically the theory of its action. In a masterly memoir he laid down a few years later the theory of electric motive power. But in the intervening period, in 1831, Faraday had made the cardinal discovery of the mechanical generation of electric currents by magneto-electric induction, the fundamental principle of the dynamo. Down to that date the only known way—save for the feeble currents of thermopiles—to generate electric currents had been the pile of Volta, or one of the forms of battery which had been evolved from it. Now, by Faraday's discovery, the world had become possessed of a new source. And yet again, strange as it may seem, years elapsed before the world—that is, the world of engineers—discovered that an important discovery had been made. Not until some thirty years later were any magneto-electric machines made of a sufficient size to be of practical service even in telegraphy, and none were built of a sufficient power to furnish a single electric light until about the year 1857. In the meantime in America other electric motors, to be driven by batteries, had been devised by Davenport and by Page; the latter's machine had an iron plunger to be sucked by electromagnetic attraction into a hollow coil of copper wire, thereby driving a shaft and flywheel through the intermediate action of a connecting-rod and crank. Page's was, in fact, an electric engine, with 2-foot stroke, single-acting, of between 3 and 4 horse-power. The battery occupied about 3 cubic feet and consumed, according to Page, 3 lb. of zinc per horse-power per day. This must have been an under-estimate; for if Daniell's cells were used the minimum consumption for a motor of 100 per cent. efficiency is known to be about 2 lb. of zinc per horse-power per hour.

Electric Motive Power Impossible in 1857.

Upon the state of development of electric motors fifty years ago information may be gleaned from an exceedingly interesting debate at the Institution of Civil Engineers upon a paper read April 21, 1857, "On Electromagnetism as a Motive Power," by Mr. Robert Hunt, F.R.S. In this paper the author states that, though long-enduring thought has been brought to bear upon the subject, and large sums of money have been expended on the construction of machines, "yet there does not appear to be any nearer approach to a satisfactory result than there was thirty years ago." After explaining the elementary principles of electromagnetism, he describes the early motors of Dal Negro, Jacobi, Davenport, Davidson, Page, and others. Reviewing these and their non-success as commercial machines, he says: "Notwithstanding these numerous trials . . . it does not appear that any satisfactory explanation has ever been given of the causes which have led to the abandonment of the idea of employing electricity as a motive power. It is mainly with the view of directing attention to these causes that the present communication has been written." He admits that electromagnets may be constructed to give any desired lifting power; but he finds that the attractive force on the iron keeper of a magnet of his own, which held 220 lb. when in contact, fell to 36 lb. when the distance apart was only one-fiftieth of an inch. To this rapid falling off of force, and to the hardening action on the iron of the repeated vibrations due to the mechanical concussion of the keeper, he attributed the small power of the apparatus. Also he remarked upon the diminution of the current which is observed to flow from the battery when the motor was running (which Jacobi had, in his memoir on the theory, traced to a counter electromotive force generated in the motor itself), and which reduced the effort exerted by the electromagnets; this diminution he regarded as impairing the efficiency of the machine. "All electromagnetic arrangements," he says, "suffer from the cause named, a reduction of the mechanical value of the prime mover, in a manner which has no resemblance to any of the effects due to heat regarded as a motive power." Proceeding to discuss the batteries, he remarked that as animal power depends on food, and steam power on coal, so electric power depends on the amount of zinc consumed; in support of which proposition he cited the experiments of Joule. He gives as his own results that for every grain of zinc consumed in the battery his motor performed a duty equivalent to lifting 86 lb. 1 foot high. Joule and Scoresby, using Daniell's cells, had found the duty to be equivalent to raising 80 lb. 1 foot high, being about half the theoretical maximum duty for 1 grain of zinc. In the Cornish engine, doing its best duty, 1 grain of coal was equivalent to a duty of raising 143 lb. 1 foot high. He put the price of zinc at 35*l*. per ton as compared with coal at less than 1*l*. per ton, which makes the cost of power produced by an electric motor—if computed by the consumption of zinc in a battery—about sixty times as great as that of an equal power produced by a steam-engine consuming coal. He concludes that "it would be far more economical to burn zinc under a boiler and to use it for generating steam power than to consume zinc in a battery for generating electromagnetical power."

In the discussion which followed, several men of distinction took part. Prof. William Thomson, of Glasgow (Lord Kelvin), wrote, referring to the results of Joule and Scoresby: "These facts were of the highest importance in estimating the applicability of electromagnetism, as a motive power, in practice; and, indeed, the researches alluded to rendered the theory of the duty of electromagnetic engines as complete as that of the duty of water-wheels was generally admitted to be. Among other conclusions which might be drawn from these experiments was this: that, until some mode of producing electricity as many times cheaper than that of an ordinary galvanic battery as coal was cheaper than zinc, electromagnetic engines could not supersede the steam-engine." Mr. W. R. Grove (Lord Justice Sir William Grove) remarked that a practical application of the science appeared to be still distant. The great desideratum, in his opinion, was not so much improvement in the machine as in the prime mover, the battery, which was the source of power. At present the only available use for this power must be confined to special purposes where the danger of steam and the creation of vapour were sought to be avoided, or where economy of space was a great consideration. Prof. Tyndall agreed with the last speaker, but suggested that there might be some way of mitigating the apparent diminution of power due to the induction of opposing electromotive forces in the machine itself. Mr. C. Cowper spoke of some experiments, made by himself and Mr. E. A. Cowper, showing the advantage gained by properly laminating the iron cores used in the motor. He put the cost of electric power at 4*l.* per horse-power per hour. He deprecated building electric motors with reciprocating movements and cranks; described the use of silver commutators; and mentioned the need of adjusting the lead given to the contacts. There was, he said, no reason to suppose that electric motors could be made as light as steam-engines. Even in the case of small motors of one-tenth or one-hundredth of a horse-power, for light work, where the cost of power was of small consequence, a boy or a man turning a winch would probably furnish power at a cheaper rate. Mr. Alfred Smee agreed that the cost would be enormous for heavy work. Although motive power could not at present be produced at the same expense on a large scale by the battery as by coal, still they were enabled readily to apply the power at any distance from its source; the telegraph might be regarded as an application of motive power transmitted by electricity. Mr. G. P. Bidder considered that there had been a lamentable waste of ingenuity in attempting to bring electromagnetism into use on a large scale. Mr. Joule wrote to say that it was to be regretted that in France the delusion as to the possibility of electromagnetic engines superseding steam still prevailed. He pointed out, as a result of his calorimeter experiments, that if it were possible so to make the electric engine work as to reduce the amount to a small fraction of the strength which it had when the engine was standing still, nearly the whole of the heat (energy) due to the chemical action of the battery might be evolved as work. The less the heat evolved, as heat, in the battery, the more perfect the economy of the engine. It was the lower intensity of chemical action of zinc as compared with carbon, and the relative cost of zinc and coal, which decided so completely in favour of the steam-engine. Mr. Hunt, replying to the speakers in the discussion, said that his endeavour had been to show that the impossibility of employing electromagnetism as a motive power lay with the present voltaic battery. Before a steam-engine could be considered, the boiler and furnace must be considered. So likewise must the battery if electric power were to become economical. Then the President, Mr. Robert Stephenson, wound up the discussion by remarking that there could be no doubt that the application of voltaic electricity, in whatever shape it might be developed, was entirely out of the question, commercially speaking. The mechanical application seemed to involve almost insuperable difficulties. The force exhibited by electromagnetism, though very great, extended through so small a space as to be practically useless. A powerful magnet might be compared to a steam-engine with an enormous piston, but with exceedingly short stroke; an arrangement well known to be very undesirable.

In short, the most eminent engineers in 1857 one and all condemned the idea of electric motive power as unpractical and commercially impossible. Even Faraday, in his lecture on "Mental Education" in 1854, had set down the magneto-electric engine along with mesmerism, homœopathy, odylism, the caloric engine, the electric light, the sympathetic compass, and perpetual motion as coming in different degrees amongst "subjects uniting more or less of the most sure and valuable investigations of science with the most imaginary and unprofitable speculation, that are continually passing through their various phases of intellectual, experimental, or commercial development, some to be established, some to disappear, and some to recur again and again, like ill weeds that cannot be extirpated, yet can be cultivated to no result as wholesome food for the mind."

Fifty Years Later.

Fifty years have fled, and Hunt, Grove, Smee, Tyndall, Cowper, Joule, Bidder, and Stephenson have long passed away. Lord Kelvin remains the sole and honoured survivor of that remarkable symposium. But the electric motor is a gigantic practical success, and the electric motor industry has become a very large one, employing thousands of hands. Hundreds of factories have discarded their steam-engines to adopt electric-motor driving. All travelling cranes, nearly all tramcars, are driven by electric motors. In the Navy and in much of the merchant service the donkey-engines have been replaced by electric motors. Electric motors of all sizes and outputs, from one-twentieth of a horse-power to 8000 horse-power, are in commercial use. One may well ask: What has wrought this astonishing revolution in the face of the unanimous verdict of the engineers of 1857?

The answer may be given in terms of the action and reaction of pure and applied science. Pure science furnished a discovery; industrial applications forced its development; that development demanded further abstract investigation, which in turn brought about new applications. It was beyond all question the development of the dynamo for the purposes of electrotyping and electric light which brought about the commercial advent of the electric motor. For about that very time Holmes and Siemens and Wilde and Wheatstone were at work developing Faraday's magneto-electric apparatus into an apparatus of more practical shape; and the electric lighthouse lamp was becoming a reality which Faraday lived to see before his death in 1867. That eventful year witnessed the introduction of the more powerful type of generator which excited its own magnets. And even before that date a young Italian had made a pronouncement which, though it was lost sight of for a time, was none the less of importance. Antonio Pacinotti in 1864 described a machine of his own devising, having a specially wound revolving ring-magnet placed between the poles of a stationary magnet, which, while it would serve as an admirable generator of electric currents if mechanically driven, would also serve as an excellent electric motor if supplied with electric currents from a battery. He thereupon laid down the principle of reversibility of action, a principle more or less dimly foreseen by others, but never before so clearly enunciated as by him. And so it turned out in the years from 1860 to 1880, when the commercial dynamo was being perfected by Gramme, Wilde, Siemens, Crompton, and others, that the machines designed specially to be good and economical generators of currents proved themselves to be far better and more efficient motors than any of the earlier machines which had been devised specially to work as electromagnetic engines. Moreover, with the perfection of the dynamo came that cheap source of electric currents which was destined to supersede the battery. That a dynamo driven by a steam engine furnishing currents on a large scale should be a more economical source of current than a battery in which zinc was consumed, does not appear to have ever occurred to the engineers who, in 1857, discussed the feasibility of electric motive power. Indeed, had any of them thought of it, they would have condemned the suggestion as chimerical. There was a notion abroad—and it persisted into the 'eighties—that no electric motor could possibly have an efficiency higher than 50 per cent. This notion, based on an erroneous understanding of the theoretical investigations of Jacobi, certainly delayed the progress of events. Yet the clearest heads of the time understood the matter more truly. The true law of efficiency was succinctly stated by Lord Kelvin in 1851, and was recognised by Joule in a paper written about the same date. In 1877 Mascart pointed out how the efficiency of a given magneto-electric machine rises with its speed up to a limiting value. In 1879 Lord Kelvin and Sir William Siemens gave evidence before a Parliamentary Committee as to the possible high efficiency of an electric transmission of power; and in August of the same year, at the British Association meeting at Sheffield, the essential theory of the efficiency of electric motors was well and admirably put in a lecture by Prof. Ayrton. In 1882 the present author designed, in illustration of the theory, a graphic construction, which has been ever since in general use to make the principle plain. The counter-electromotive force generated by the motor when running, which Hunt and Tyndall deplored as a defect, is the very thing which enables the motor to appropriate and convert the energy of the battery. Its amount relatively to the battery's own electromotive force is the measure of the degree to which the energy which would otherwise be wasted as heat is utilised as power. Pure science stepped in, then, to confirm the possibility of a high efficiency in the electric motor *per se*. But pure science was also brought into service in another way. An old and erroneous notion, which even now is not quite dead, was abroad to the effect that the best way of arranging a battery was so to group its component cells that its internal resistance should be equal to the resistance of the rest of the circuit. If this were true, then no battery could ever have an efficiency of more than 50 per cent. It was supposed in many quarters that this misleading rule was applicable also to the dynamo. The dynamo makers discovered for themselves the fallacy of this idea, and strove to reduce the internal resistance of the armatures of their machines to a minimum. Then the genius of the lamented John Hopkinson led him to apply to the design of the magnetic structure of the dynamo abstract principles upon which a rational proportioning of the iron and copper could result. A similar investigation was independently made by Gisbert Kapp, and between these accomplished engineers the foundations of dynamo design were set upon a scientific basis. To the perfection of the design the magnetic studies of our ex-President, Prof. Ewing, contributed a notable part, since they furnished a basis for calculating out the inevitable losses of energy in armature cores by hysteresis and parasitic currents in the iron when subjected to recurring cycles of magnetisation. Able constructive engineers, Brown, Mordey, Crompton, and Kapp, perfected the structural development, and the dynamo within four or five years became, within its class, a far more highly efficient machine than any steam engine. And as by the principle of reversibility every dynamo is also capable of acting as a motor, the perfection of the dynamo implied the perfection, both scientific and commercial, of the motor also. The solution in the 'eighties of the problem how to make a dynamo to deliver current at a constant voltage when driven at a constant speed, found its counterpart in the solution by Ayrton and Perry of the corresponding problem how to make a motor which would run at constant speed when supplied with current at a constant voltage. Both solutions depend upon the adoption of a suitable compound winding of the field magnets.

A little later alternating currents claimed the attention of engineers; and the alternating current generator, or "alternator," was developed to a high degree of perfection. To perfect a motor for alternating currents was not so simple a matter. But again pure science stepped in, in the suggestion by Galileo Ferraris of the extremely beautiful theorem of the rotatory magnetic field, due to the combination of two alternating magnetic fields equal in amplitude, identical in frequency and in quadrature in space, but differing from each other by a quarter-period in phase. To develop on this principle a commercial motor required the ingenuity of Tesla and the engineering skill of Dobrowolsky and of Brown: and so the three-phase induction motor, that triumph of applied science, came to perfection. Ever since 1891, when at the Frankfort Exhibition there was shown the *tour de force* of transmitting 100 horse-power to a distance of 100 miles with an inclusive efficiency of 73 per cent., the commercial possibility of the electric transmission of power on a large scale was assured. The modern developments of this branch of engineering and the erection of great power-stations for the economic distribution of electric power generated by large steam plant or by water-turbines are known to all engineers. The history of the electric motor is probably without parallel in the lessons it affords of the commercial and industrial importance of science.

But the query naturally rises: If a steam-engine is still needed to drive the generator that furnishes the electric current to drive the motors, where does the economy come in? Why not use small steam-engines, and get rid of all intervening electric appliances? The answer, as every engineer knows, lies in the much higher efficiency of large steam-engines than of small ones. A single steam-engine of 1000 horse-power will use many times less steam and coal than a thousand little steam-engines of 1 horse-power each, particularly if each little steam-engine required its own little boiler. The little electric motor may be designed, on the other hand, to have almost as high an efficiency as the large motor. And while the loss of energy due to condensation in long steam-pipes is most serious, the loss of energy due to transmission of electric current in mains of equal length is practically negligible. This is the abundant justification of the electric distribution of power from single generating centres to numerous electric motors placed in the positions where they are wanted to work.

Education and Training of Engineers.

Interplay of action and reaction make for progress not only in the evolution of the scientific industries, but also in the development of the individual engineer. In him, if his training is on right lines, pure theory becomes an aid to sound practice; and practical applications are continually calling him to resort to those abstractions of thought, the underlying principles, which when known and formulated are called theories. Recent years have brought about a so much better understanding of education, in its bearing upon the professions and constructive industries, that we now seldom hear the practical man denouncing theory, or the theorist pooh-poohing practice. It is recognised that each is useful, and that the best uses of both are in conjunction, not in isolation. As a result of this better understanding distinct progress is being made in the training of engineers. Of this the growth of the engineering departments of the universities, and of the technical colleges and schools, affords striking evidence. The technical schools, moreover, are recognising that their students must have a sound preliminary education, and are advancing in the requirements they expect of candidates for admission. They are also finding out how their work may best supplement the practical training in the shops, and are improving their curricula accordingly. In the engineering industry, too, Great Britain is slowly following the lead taken in America, Germany, and Switzerland, in the recognition afforded to the value of a systematic college training for the young engineer, though there is still much apathy and even distrust shown in certain quarters. Yet there is no doubt that the stress of competition, particularly of competition against the industry and the enterprise of the trained men of other nations, is gradually forcing to the front the sentiment in favour of a rational and scientific training for the manufacturer and for the engineer. As William Watson, in his "Ode on the Coronation," wrote in a yet wider sense of England:—

> For now the day is unto them that know,
> And not henceforth she stumbles on the prize:
> And yonder march the nations full of eyes.
> Already is doom a-spinning. . . .

Truly the day is "unto them that know." Knowledge, perfected by study and training, must be infused into the experience gained by practice: else we compete at very unequal odds with the systematically trained workers of other nations. Nor must we make the mistake here in the organisation of our technical institutions of divorcing the theory from its useful applications. In no department is this more vital than in the teaching of mathematics to engineering students. For while no sane person would deny that the study of mathematics, for the sole sake of mathematics, even though it leads to nothing but abstract mathematics, is a high and ennobling pursuit, yet that is not the object of mathematical studies in an engineering school. The young engineer must learn mathematics not as an end in itself, but as a tool that is to be useful to him. And if it is afterwards to be of use to him, he must learn it by using it. Hence the teacher of mathematics in an engineering school ought himself to be an engineer. However clever he be as a mathematical person, his teaching is unreal if he is not incessantly showing his learners how to apply it to the problems that arise in practice; and this he is incapable of doing if these problems do not lie within his own range of experience and knowledge. Were he a heaven-born senior wrangler, he is the wrong man to teach mathematics if he either despises or is ignorant of the ways in which mathematics enter into engineering. The fact is that for the great majority of engineering students, the mental training they most need is that which will enable them to think in physics, in mechanics, in geometric space, not in abstract symbols. The abstract symbols, and the processes of dealing with their relations and combinations, are truly necessary to them: but they are wanted not for themselves, but to form convenient modes of expressing the physical facts and laws, and the interdependence of those physical facts and laws. When the student loses grip of the physical meaning of his equations, and regards them only as abstractions or groupings of symbols, woe betide him. His mathematics amount to a mere symbol-juggling. That is how paper engineers are made. The high and dry mathematical master who thinks it beneath him to show a student how to plot the equations $y=A \sin x$, or $r=b \sin \theta$, or who never culls an example or sets a problem from thermodynamics or electricity, must be left severely on one side as a fossil. Better a living Whitworth scholar than a dry-as-dust Cambridge wrangler. He at least knows that elasticity is something more real than the group of symbols $E=p \div \frac{\Delta x}{x}$, which any mathematician may "know," even though he be blissfully ignorant whether the force required to elongate a square-inch bar of steel by one one-millionth of its length is ten ounces or ten tons.

One evidence of the wholesome change of opinion that is springing up concerning the training of engineers is the abandonment of the system of taking premium pupils into works with no other test or qualification than that of the money-bag. Already many leading firms of engineers have been finding that the practice of taking sons of wealthy parents for a premium does not answer well, and is neither to their own advantage nor in many cases to that of the "pupil," whom it is nobody's particular business in the shops to train. Premium pupilage is absolutely unknown in the engineering firms of the United States or on the Continent of Europe. The firms who have abandoned it are finding themselves better served by taking the ablest young men from the technical schools and paying them small wages from the first, while they gain experience and prove themselves capable of good service. Messrs. Yarrow and Co. have led the way with a plan of their own, having three grades of apprenticeship, admission to which depends upon the educational abilities of the youths themselves. Messrs. Siemens have adopted a plan of requiring a high preliminary training. The Daimler Motor Company has likewise renounced all premiums, preferring to select young men of the highest intelligence and merit. Messrs. Clayton and Shuttleworth have quite recently reconstructed their system of pupil-apprenticeship on similar lines. The British Westinghouse Company and the British Thomson-Houston Company have each followed an excellent scheme for the admission of capable young men. Even the conservatism of the railway engineers shows signs of giving way; for already the Great Eastern Railway has modernised its regulations for the admission of apprentices. What the engineering staffs of the railway companies have lost by taking in pupils because of their fathers' purses rather than for the sake of their own brains it is impossible to gauge. But the community loses too, and has a right to expect reform.

To this question, affecting the whole future outlook of engineering generally, a most important contribution was made in 1906 by the publication by the Institution of Civil Engineers of the report of a committee (appointed in November, 1903) to consider and report to the Council upon the subject of the best methods of education and training for all classes of engineers. This Committee, a most influential and representative body consisting of leading men appointed by the several professional societies, the Institutions of Civil, Mechanical, and Electrical Engineers, the Institution of Naval Architects, the Iron and Steel Institute, the Institution of Gas Engineers, the Institution of Mining Engineers, and two northern societies, was ably and sympathetically presided over by Sir William H. White. Its inquiries lasted over two years and included the following sections: (1) Preparatory Training in Secondary Schools; (2) Training in Offices, Workshops, Factories, or on Works; (3) Training in Universities and Higher Technical Institutions; (4) Post-graduate Work. The findings of this Committee must be received as the most authoritative judgment of the most competent judges. So far as they relate to preparatory education they suggest a modernised secondary school curriculum in which there is no one specialised scientific study, but with emphasis on what may be called sensible mathematics. They also formulated one recommendation so vital that it must be quoted in full:—

"A leaving examination for secondary schools, similar in character to those already existing in Scotland and Wales, is desirable throughout the United Kingdom. It is desirable to have a standard such that it could be accepted by the Institution [of Civil Engineers] as equivalent to the Studentship Examination, and by the Universities and Colleges as equivalent to a Matriculation Examination."

One may well wonder why such a reasonable recommendation has not long ago been carried out by the Board of Education. Perhaps it has been too busy over the religious squabble to attend to the pressing needs of the nation.

The second set of recommendations relates to engineering training. It begins with the announcement that "long experience has led to general agreement among engineers as to the general lines on which practical training should proceed"; but goes into no recommendations on this head beyond favouring four years in workshops, on works, in mines, or in offices, expressing the pious desire that part of this practical training should be obtained in drawing-offices, and suggesting that during workshop-training the boys should keep regular hours, be subject to discipline, and be paid wages. It then lays down a dozen recommendations as to the "academic" training suitable for the average boy. He should leave school about seventeen; he should have a preliminary year, or introductory workshop course of a year, either between leaving school and entering college, or after the first year of college training. If the workshop course follows straight on leaving school there must be maintenance of studies either by private tuition or in evening classes, so that systematic study be not suspended. For the average student, if well prepared before entering College, the course should last three academic years (three sessions); in some cases this might be extended to four or shortened to two. A sound and extensive knowledge of mathematics is necessary in all branches of engineering, and those departments of mathematics which have no bearing upon engineering should not claim unnecessary time or attention. The Committee strongly recommends efficient instruction in engineering drawing. The college course should include instruction (necessarily given in the laboratory) in testing materials and structures, and in the principles underlying metallurgical processes. In the granting of degrees, diplomas, and certificates, importance should be attached to laboratory and experimental work performed by individual students, and such awards should not depend on the results of terminal or final examinations alone.

All this is most excellent. It will be seen that it is entirely incompatible with the premium-pupil system, which may therefore be regarded as having been weighed and found wanting. For two things clearly stand out; that the young engineer must be college-trained, and that when he goes to works he should be regularly paid. It would have been well if the Committee could have been more explicit as to the proper course of workshop training; for instance as to the systematic drafting of the young engineer through the shops—forge, foundry, pattern-shop, fitting-shop, &c., and as to the proper recognition of the duty of the shop-foreman to allocate work to the novice in suitable routine. These are doubtless among the matters in which "long experience has led engineers to general agreement." But this being so, it would have been well to state them authoritatively. A notable feature of this report is its healthy appreciation of the advantages of training, and an equally healthy distrust of the practice of cramming for examinations. So soon as any subject is crammed, it ceases to afford a real training. "Nature provides a very convenient safety-valve for knowledge too rapidly acquired." It is even whispered that a new species of crammer has arisen to "prepare" candidates in engineering for the graduate examinations of the Institution of Civil Engineers. The distinguished framers of this epoch-making report on the education and training of engineers at least give no countenance to any such parasitical development. For the scheme of education and training at which the Committee has aimed is genuinely scientific, a happy federation of the theoretical with the practical. It seeks to place the training on a broad basis, and to secure to every future engineer worthy of the name the advantage of learning his professional work in both its aspects. It seeks, in short, to take advantage of that reflex action between science and its applications in which lies the greatest stimulus to progress. Its adoption will utilise for the young engineer, and therefore for the engineering industry as a whole, the facilities for training now so widely afforded throughout the country. If the institutions, schools, and colleges where engineering training is offered are but rightly developed and co-ordinated, the engineers of Great Britain need have no fear as to holding their own against the trained engineers of other countries. It is for the employers to make use of these institutions, and to show that sympathetic interest in their efficiency which is essential to their full success.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY D. G. HOGARTH, M.A., PRESIDENT OF THE SECTION.

Religious Survivals.

THE science of Anthropology, from its very nature, seldom touches the beliefs or customs of the higher actual civilisations; but exceptions occur when it enters the field of comparative religion. In coming to the aid of this fascinating study it can hardly help offending, sooner or later, certain prejudices which are deeply rooted and widely distributed, and that not only when it really contravenes the beliefs of pious minds, but, often enough, when its exponents neither wish to impair these beliefs, nor, as a matter of fact, are taking any steps to do so; for the opposition which meets science when it concerns itself with religion is very frequently arrayed before the opponent has taken the time or the trouble to ascertain whether anything vital or essential is concerned in the investigation. At any rate it will be allowed that the majority of the treatises on this study written in the English tongue do not, by any lack of reverent treatment or by any obvious oblivion of the responsibility resting on those who inquire into the religious basis of our social order, display any desire to offend. But just because some offence must almost inevitably be given, even by the most reverent anthropologist, in pursuing investigations which involve examination of actual pious beliefs, it is especially incumbent on students of this particular subject to proceed only along the most strictly judicial lines, careful not to force a conclusion from evidence which is in any respect dubious or even incomplete; and, moreover, to be quite clear in their own minds and to make it clear to others how far their investigation really touches actual religion in vital and essential points of belief as distinguished from mere points of observance or ritual, *i.e.*, religious accidents, as they might be called. Obvious as this caution may seem, neglect of it is very general, and has led to much needless suspicion of Anthropology as a science with covert and far-reaching purpose, subversive of all religion.

It is in the interests of definition and clearness in a controversial topic among the religious inquiries of anthropologists that I have chosen my theme to-day. I have small claim to expound the science, as usually understood, to which this Section is devoted, whether on its physical or on its social side, so far as the latter is principally concerned with actual custom and folklore. But as one who has spent more than twenty years in studying the ancient life of that region of the world in which three of the greatest actual systems of religion were developed, and a good part of his time among the modern peasantry of the region itself, I have had my attention particularly directed to the evolution of religious beliefs and observances during long periods of time, which are unusually well illuminated for us from first to last by the light of both monuments and literature; and that attention has often been arrested by striking instances of *cultus* continuity under successive religious systems or dispensations. I enjoyed the advantage of beginning travel in the Nearer East in the company of the acute observer who is now Sir William Martin Ramsay, and to his comments on what we saw together in the Phrygian highlands as long ago as 1887 I owe much of my earliest interest in the question of religious survival and my direction towards the lines on which I have since tried to study it. Some day let us hope that, prompted by such a lectureship as the Gifford Foundation, or encouraged by some discerning publisher, Sir William Ramsay may collect from his many books the observations scattered here and there upon the religious elements which survived from Anatolian heathendom into both Christian and Moslem observance, and adding to them others from the storehouse of his memory and his notebooks, produce a volume parallel to that "Religion of the Semites" which is the abiding memorial of his dead friend and ally.

I have called "Religious Survivals" a controversial topic. That is to put it mildly. Indeed, few anthropological topics generate so much heat. In addition to a common distaste with which one may sympathise, even if one does not share it, manifested by many reverent minds for all objective discussion of things religious, this topic challenges a certain very widespread prejudice, as irrational as it is strong—namely, the prejudice against the inclusion of orthodox religious beliefs and observances under the general maxim, "There is nothing new under the sun." The more sacred a man holds anything the less will he believe that evolution has had anything to do with it—evolution with its inevitable implication of embryonic and imperfect stages. The Athenian loved to think that the great patron goddess of his city sprang fully grown and fully armed from the head of the King of heaven. The devotees of all creeds have wished to believe that when the first founders of systems proclaimed their missions the old things passed away like a burning scroll and a wholly new earth and heaven began. Nothing is more repugnant to the ordinary orthodox Moslem than the suggestion that the Prophet borrowed theology and doctrine from earlier Semitic systems, notably the Hebraic, and that much of the ceremonial and observance now followed by the faithful in their most religious moments, those of the Meccan pilgrimage, survive from the times of ignorance. Yet what contentions are less controvertible in fact than these? The devotee can believe that every detail of a new dispensation was known from all time in heaven, but will refuse to allow that anything can have been known on earth. With that direct revelation which he thinks to have been vouchsafed at a given moment from on high, the slate of time must have been wiped clean of all previous religious thought and practice. I do not, of course, speak for one moment of the enlightened and scholarly doctors of our own creed or any other. These have always seen and often stated that the religious systems by which they hold have assimilated much from systems of earlier date; nor in admitting that have they found their faith take any harm.

How natural and compelling, however, is the prejudice in question may be estimated by the fact that it is extended to dispensations in other fields than the religious. For example, that message to civilisation which it was given to the pagan Hellene to deliver does not admit in the view of certain devout Hellenists of the view that the Greek artistic sense had any pedigree in pre-classical times. They resent as an insolent innuendo the contention that what is essential in the Greek spirit can be detected in the work of peoples living in the Hellenic area long before the rise of classic Hellenic art, and that from these peoples and from others who possessed older civilisations the fabric of Hellenism was built up in strata, which can still be observed, and referred to their pre-Hellenic authors. So close akin is *odium archæologicum* to *odium theologicum*! Yet, perhaps, in this case they are really one and the same, for perfervid Hellenism is the last half-conscious protest of the Western peoples of Europe against the dominance of an Asiatic religion.

Irrational is this prejudice in the first degree of course, because not only have we the clearest historical evidence that in our own religious practice, as in that of other races, details of earlier ritual and observance have survived, often by conscious and intentional adoption, but also, as Robertson Smith well said, "experience shows that primitive religious beliefs are practically indestructible, except by the destruction of the race in which they are ingrained." All apostles of new creeds have had to preach to and gain the adherence of societies which they could not hope to lead to a perfect way all at once or even in centuries of time, and all have had to take account of the pre-existing habits of religious thought and actual expressions of religious feeling, and by accepting some compromise to modify these to their purpose. And if this be obviously true of those societies which such an apostle as Mohammed could influence directly and retain under some sort of personal control, what must we say of the societies to which the truth only came at second hand or by many more degrees removed from the original prophetic utterance? What of the remote or scattered folk to whom it came not at all till after a long interval, and then faint and confused as a reverberating echo? For these at least there was no possibility of such utter change as revelation working through the human agency of a magnetic personality may have effected elsewhere; and of their belief and their practice much, perhaps the most, has remained primæval and local, and as the physical conditions of their life have prompted it from all time to be, and prompt still.

All this stratification in religious belief and practice it is the function of Anthropology to investigate; and thereby it may render no small service to religion itself by distinguishing accidental elements in ritual and observance which have persisted from systems worn out and abandoned. But while proclaiming that this investigation is not only legitimate but necessary, I wish to-day to utter a note of warning against a certain confusion of thought which is often manifested by the investigators in this particular field, and is apt to occasion unfortunate ethical consequences or, at the best, unnecessary scandal. It finds expression in the grouping of all the elements in belief, observance, and ritual, which have persisted from earlier systems to later, under one head as religious survivals, without due account being taken of very vital differences, both in their essential nature and in the history and reason for their persistence. The word "survival" itself is *per accidens* not a very fortunate one. Though in the broad sense perfectly appropriate to all things that persist, it has acquired in our modern speech, largely from its use in medical science, a certain particular connotation of opprobrious import. It suggests something which has lost its useful purpose, and is effete or even dead, persisting among living organisms usually to their detriment. Such is the sense in which many anthropologists seem to use the word in speaking of religious persistences without discriminating between divers kinds of these; and such, still more often, is the connotation which their readers attach to the word in this connection. Yet all religious persistences are not survivals in this pathological sense—nay, the class to which this connotation is suitable includes but a small proportion of the whole. It is to distinguishing these classes of survivals that I propose to address myself in the remainder of the time which is allotted to me to-day.

In the first place there is a most numerous and important body of religious persistences which ought not to be called survivals at all, if that word be used, as it usually is, with a causative implication; that is to say, there are elements of belief and practice the existence of which in actual cult is not necessarily due at all to the fact that they, or something very closely akin, existed in a previous cult. If religion is the expression of the instinctive desire of man to find an intelligible relation between his own nature and a nature which transcends its limitations, he appears unable to establish that relation by other than a very small and definite number of conceptions; and among certain races, and indeed in certain geographical areas, those conceptions seem not to vary over immense spaces of time and under successive dispensations. The just way to regard them, therefore, is as falling within categories of thought inevitably imposed on the human mind by its humanity and necessary conditions of any religious sense whatever. Man does not form these conceptions because his predecessors formed them, nor indeed because his contemporaries hold them; but because, as an individual limited by race and environment, he cannot otherwise satisfy his religious instinct. How important this class is, and how much it includes which has often been discussed by anthropologists under the head of religious survival, may be judged if we recall that there falls under it such an article of belief as the Incarnation of God with all its consequences of expression—the immaculate conception, atoning death, and bodily resurrection. Neither this belief nor any of its expressions, I need hardly say, make their appearance for the first time in Christianity. They are to be recognised as forms—necessary categories of creed if you will—under which races of the Nearer East and of other regions of the world also have conceived the relation between the human and the divine as far back as we know anything of their history. But since anthropological knowledge concerning this delicate and difficult instance has been set forth lately in full detail by a distinguished student of religious persistences, Mr. J. G. Frazer, in his "Adonis, Attis, and Osiris," I feel no obligation to deal with it further than to remind you that, apart from all question whether Christian tradition states historical facts in this matter, nothing which Anthropology has collected in the way of comparative facts from other creeds serves to place either this belief or its form of expression among religious survivals in the narrower sense—that is to say, among religious elements which appear in Christianity merely because they existed in earlier religions. Much accidental circumstance has beyond doubt attached itself to this Christian tenet from the previous cult observances and ritual of the many races which it has convinced; and to certain of these I shall call attention presently when I come to deal with another class, more properly to be called religious survivals; but as for the essentials of the belief, they have as much right to be regarded as independent conceptions of Christianity, despite their earlier appearance in other religions, as history proclaims them to have been endued by Christianity with a wholly new ethical significance.

But in order to fortify my generalities with a particular example, I may be allowed to deal in brief detail with another, though related, religious conception of the same class, which has not been so exhaustively treated by anthropologists. As a student of Mediterranean races and a frequent observer of their actual representatives, I have often been struck by the persistent dominance of femininity in their conception of the Divine, and equally by the distinction which that fact makes between their instinctive creeds and those of other races domiciled contiguous to them, but round an outer radius. In fact, it would not be difficult to draw a broad frontier line at a certain distance inland round the Mediterranean area from the Atlantic to the African deserts, within which a Goddess has always reigned supreme in the hearts of the unsophisticated folk, with a God occupying only a subordinate, and often demonstrably a less primæval, throne; while without it the God has been dominant and feminine divinity secondary. Within the frontier lie the peninsular and other littoral districts with a broad *hinterland* of mountainous or hilly regions. With the great continental plains begins the outer and contrasted circle. The predominance of a great Nature Goddess among all the races of the East Mediterranean basin in the earliest historic time is well known; and to what had been ascertained of her among the Semites, under her many names, Tanith, Al-Lat, Baalit, Ishtar, Atta, Ashtaroth—these last but variants of one appellation; among the Nilotic peoples also under many names, e.g., Neith and Isis; among the Anatolian races as the Great Mother, Kybele, Ma, and the unknown "Hittite" title; among the historic inhabitants of Greece and the Ægean as Rhea, Artemis, Britomartis, and a score of other appellations; among the Italic tribes, as Diana or local variants, there has been added latterly the discovery that a Goddess of character and attributes, readily to be compared with those of the Nature deity in various parts of the surrounding area, was dominant in the religion of that important artistic race which occupied the Ægean in the prehistoric age, and had so much influence on the momentous civilisation of its later time—that race which has been rescued from long oblivion by Schliemann in Greece and Troy, and by Evans and others in the Isles. The more we learn of this great Nature- or Mother-Goddess, the more primæval and predominant is the position she is seen to hold. All round the Eastern Mediterranean she was before all created things: she became the mother of a son by spontaneous generation or some other process independent of the male—an idea, it may be remarked, which presents no impossiblity to the minds of very primitive races, some of whom even at this day do not connect fertilisation and conception as cause and effect. With her son she produced all life: she gave her son to the humanity so created, and humanity killed him that it might live; he revived and returned again to his mother, was again killed, and so the cycle of the seasons revolved. So far as concerns Him in all his *avatars* Mr. Frazer's book may be consulted. As for Her, a Woman still holds the same place in the religious belief of the old races of the same region, wherever they have escaped assimilation by conquering races and faiths from beyond the border. Hear any Greek or Italian peasant in a moment of excitement or danger. He calls on no Person of the Trinity, but on the Virgin. For him her power does not come from her Motherhood of her Son. Indeed, I have known Christian countrymen of a West Anatolian valley to whom that motherhood was evidently unknown, and when spoken of remained without interest or significance. She is a self-sufficient, independent embodiment of divinity, to whom the ruder folk of Mediterranean lands offer their prayers and pay their vows alone. She and no other is beseeched to grant increase and fertility; she and no other is credited with the highest direction of human affairs. But to say, as so often is said, that, for instance, in Greek lands the Panaghiá is simply a survival of Artemis or Aphrodite under another name, is to convey a false impression. She stands for the same principle of divinity as they; she has taken on, as I shall point out presently, even the feasts and the ritual of her predecessor; and she has often made peculiarly her own the spots especially sacred to the earlier Mother-Goddess. But, as I take it, she is not worshipped now in Ephesus or Cyprus merely because there was once a dominant cult of Artemis or Aphrodite in those places, but because to the peoples of a wide Mediterranean region it is still, as it always was, a religious necessity to embody their idea of divinity in the feminine; and I would state the relation of the Christian Virgin-Goddess to the pagan one rather in this way—that, coming from without, she gained acceptance at once for herself, and probably also, in a great measure, gained acceptance for the whole creed with which she was connected, because she offered a possible personification of the same principle which had always been dominant in the local religion.

Why that principle was so deeply rooted in the peoples of this particular region I cannot pretend precisely to say. To ascribe it, as has been suggested, to the original prevalence of *Mutterrecht* is probably to mistake effect for cause. The principle has its roots deeper down than even the matriarchal system. In a general way we may hold it the result of a peculiar mental concentration upon the idea of generation and reproduction of life, upon the increase of man, the brute creation, and the earth. In these processes the more obvious part played by the female in Nature inevitably tends among primitive peoples, who are comparatively peaceful and more of agriculturists and herdsmen than warriors or hunters, to make woman seem the sole condition of their being and the predominant arbiter of their destinies. More we can hardly say. We cannot determine whether there were peculiar geographical conditions in the dawn of time, which, either in some other home or in the Eastern Mediterranean region itself, predisposed the ancestors of the actual races of the latter to this cult of the reproductive force. One can but bear witness that at the present day this idea is an obsession of these inhabitants wherever they remain in a comparatively simple state of society. All their thoughts, their prayers, and their actions seem to be inspired by it, and of all their thoughts, their prayers, and their actions—so far as they have not been warped to the Father-God of the Southern Semites by the armed pressure of an alien folk from the warlike steppes of Northern Asia—Mary, the Panaghiá, is the focus.

In her essential identification with the religious sense of these peoples, therefore, the Virgin is no mere survival. But in an accidental or secondary sense her actual personality may, perhaps, be so regarded in the region in question if we are careful to exclude from the word all connotation of superfluity or decaying energy. Her cult may be brought under that body of beliefs, observances, and practices which have demonstrably passed from earlier religious system to later by processes of transference, usually unconscious, but often half-conscious, and undoubtedly in some cases wholly conscious. Where the process has been unconscious or half-conscious these beliefs, observances, and practices have survived in the new system because the religious sense of the masses felt instinctively that they were necessary to its expression. They cannot therefore be regarded as survivals with any implication of decay or death. They were necessities under the former system; they remained necessities under the later, and may be living forces and vital expressions of the human desire for relation with the divine under the new as much as under the old. Where the process has been conscious a popular demand for their survival as necessities has been appreciated by leaders of the system, and observances and forms of ritual have been consciously taken from the old system to express a principle still active under the new. Often we are in a position to know that the old beliefs, observances, and forms did not accord with the highest ideals of the most advanced professors of the new system, and that they came to be consciously adopted by compromise in the interests of the more rapid and permanent establishment of the latter among inferior intelligences. They were better than the worse, if not as good as the best. Of these Dr. Bigg is speaking in the preface to his book "The Church's Task under the Roman Empire" when he says, "The most significant changes in history were not imposed upon the Church by the bishops from above, but forced upon the bishops by the pressure of popular opinion from below." A well-known example is supplied by the early history of Islam, when the Prophet, having learned in exile at Medina, what many of his apostles have since had to learn, that the Semitic masses could not be weaned to a perfectly spiritual system, came to terms with the primæval worship of the Arabian Goddess in Mecca and displaced her personality by retaining many expressions of the popular cult of her; and, as so often has happened in similar cases of religious transference, those expressions remaining to this day the most strictly observed by Moslems, testify still to the vitality of the religious necessity which lay and lies behind them. And not only the early history of Islam, but the early history of Christianity offers instances of such conscious transference, some of which may be read of in Sir William Ramsay's works, *e.g.*, in "The Church in the Roman Empire," where he deals with that strange story of Glycerius the Cappadocian deacon, who broke out at a certain great gathering of Christians at Venasa, one of the holiest of the pagan high places of the land, and revived the former orgiastic form of cult by leading a band of enthusiastic maidens dancing and singing through the hills to the glory of Christ crucified. Condemned in haste by the stern Basil of Cæsarea, the recalcitrant deacon found an apologist and a protector in no less saintly a priest than Gregory of Nazianzos, who knew better than his Metropolitan how real and deep a local religious instinct lay beneath this scandalous manifestation, and how much better it were to bend to the service of the Church, than to break, the religious zealots who had expressed it. Another curious collection of such transferences may be found in a recent work of Mr. Rendel Harris, which he entitled "The Heavenly Twins." Here are set out an immense number of facts and suggestions tending to show how the early Church adapted to its ends the cult of th Dioscuri or of similar twin gods known by other names both in the West and East, a cult which expressed a certain conception of the relation between human and divine, salutary and indeed necessary to many pagan minds. The book needs to be read in a critical spirit, for the author has been led on by the fascination of myth-interpretation to find his twin nature-gods wherever he turns to look for them; and often his reading of the legends is less convincing than would be (if it is allowed to use a frivolous instance in such a connection) a similar explanation applied to the story of Box and Cox—those obvious twins of Dark and Light who occupied, turn and turn about, their chamber, the World, under the benign influence of the landlady of the tale, a manifest Earth-Mother of mythology.

Many of the undoubted transferences which took place under the Christian system cannot at this time of day be certainly distinguished into the conscious and the unconscious. We know that saints of the Church have entered often into the honour and the local habitations of pagan deities. Mr. Frazer has told us how St. Felicita has replaced Mephitis, the heathen personification of the poisonous gas of the pool of Frigento, and how Adonis in Sicily and Sardinia lives on as St. John. These instances might be multiplied to many hundreds. We know, too, that almost all our stated ecclesiastical festivals are continuations of heathen feasts, so far as their dates and the general nature of their commemorative significance are concerned. What had to be changed has been changed, but not more. Christmas has succeeded to the festival of the winter solstice which celebrated the new birth of the Sun; Easter to the spring festival at which in many parts of the Mediterranean world the Nature-Goddess, and especially the death and resurrection of her Son, were commemorated. The Assumption of the Virgin replaces the August feast of Artemis and Diana in Greece and Italy. The anniversary of St. George, so great a day in modern Greece, seems to be the old Parilia; St. John the Baptist has taken on the heathen rites of midsummer, and you may see the folk of Smyrna, Christian and Moslem alike, jumping through fire to his honour on any St. John's Eve. Very rarely, as in the case of the Feast of All Souls, the late Christian adoption of which in the tenth century happens to be known, can we ascribe these transferences to any definite action of a leader of the Church. Usually we know no more than that where and when there was once a pagan saint or a pagan feast there are now saints and feasts of Christianity. But no reasonable person feels that the latter are discredited or lose anything of their actual significance by the fact of their having a pre-Christian pedigree. St. John may have succeeded to Adonis, but he is not Adonis. Christmas may be the heir of the Saturnalia, but it is the Saturnalia no longer. To feel that the sanctity of either is impaired by these facts is as if one were to refuse reverence to the art-types of early Christianity, because most unquestionably these were not invented fresh and new for the new religion. Why should they have been? If there were ready to hand images in pagan art, fit to express the early Christian ideas, it would have needed a miracle for the nascent Church to have invented new ones. The human creative faculty in matters of art is strictly limited as to types. Presentations of Apollo or Orpheus were used naturally for the new Christ, and those of the Nature-Goddess of Asia with her Son for the new Mother and Child. How else should gracious maternity have been represented? Last year I showed in this Section certain terra-cotta images of the Ephesian Goddess with her child, dated to the fourth century before Christ, which might easily have been mistaken for Madonna figures of the Italian Renaissance; and last winter I saw in a newly excavated Coptic chapel of the sixth century at Memphis a fresco painting of the Virgin suckling her Son which was indistinguishable from late representations of Isis.

As a matter of fact there is little fear that anthropologists in demonstrating the fact of transference in such categories of religious expression as these with which I have just been dealing will impair their religious efficiency. For, after all, how much is there not in the everyday expression of the religious sense among ourselves which has suffered a transference in time and space so obvious that no reflective mind can be unconscious of it? Consider only the religious phraseology current among the simplest Christians all that mass of images and ideas proper to an alien race and to the latitude and climate of the Mediterranean in which, for example, the Presbyterian of Scotland expresses the most pious of his aspirations. He sighs for the shadows of great rocks in a weary land, for the plash of running waters, for the shade of the fig and the vine; and, the most restless of men to whom all inaction is hateful, he aspires to a heaven floored with the crystal of Oriental imagery, where he shall for ever sit still. These ideas one meets at every turn, not only in religious, but in the secular, thoughts of every Oriental or South European. Among us they appear in religion only, known for manifest exotics, but not the less full of religious significance, even to the lease congruous Christian.

Ere I leave this second class of Survivals let me revert again for a moment to the cult of the Virgin in the Nearer East. It is possible, even probable, that Mary, the mother of Jesus, also owes her divine, or at least semi-divine, position in the Christian system to such a conscious effort by leaders of the Church as those to which we have just alluded. It is a well-known fact that neither the primary nor the secondary authorities for the first two centuries of Christianity supply any warrant for the position which she was to hold later. They are, in fact, almost silent about her. Nor has Christian archæology discovered any better evidence of her glorification above other holy women during that time. It seems established that it was not till the third century that she began to assume semi-divinity. By the fourth her position was sufficiently exalted to cause the schism associated with the name of Nestorius, whatever the real views of that ecclesiastic may have been; but it was not till A.D. 431 that she was officially acknowledged by a General Council to be divine in virtue of her Theotokiá, her Motherhood of God. It is difficult not to believe that this is one of the examples of the general fact which I have just quoted from Dr. Bigg, and that the bishops assembled at Ephesus on that occasion were tardily conceding a demand for the recognition of the feminine principle in divinity made even more and more openly by the voice of the common people all round the Eastern Mediterranean. We are told indeed in a contemporary letter written by one present in Ephesus at the time that the populace of the city itself, that immemorial seat of a Virgin-Goddess, gathered about the church while the Council was sitting, and put pressure on the bishops when they showed signs of wavering in their decision to proclaim the Theotókos by condemning Nestorius; and that when the decree had at last gone forth the Ephesians went wild with joy. Their Great Mother had come again to her own.

Once established, or, more probably, little by little while she was gaining recognition, the Christian Virgin appropriated the festival dates, the holy places, and even the rites of her predecessors. Here we approach a third class of survivals. The great August feast of Artemis, as I have said, became that of the Assumption of Our Lady; temples, groves, sacred springs, and other holy spots of Nature-worship were transferred to the new patroness of all life and fertility. There are hundreds of places in Anatolia, Greece, and Syria which might be called to testify. One of singular interest I visited a few years ago, that wild spot in the Lycian mountains where the ever-burning gaseous flames of the Chimæra break out in a clearing of the forest. Here, on the foundations of a temple, stands the ruin of a church built over the largest vent of the fire. Islam has decreed that the goddess of the earth-flames be no longer openly adored, but all the bushes which grow about the ruin I found hung with mouldering rags of quite modern date, witnesses that her cult is not yet dead in the hearts of shepherds and woodmen. On the wall of a ruined convent hard by is a half-effaced fresco of Mary. And for persistent rites and ceremonies let me quote once more the anointing of the great corner-stones of the ruined shrine of Paphian Aphrodite—the "Queen," as she is called shortly in inscriptions in the old Cypriote character. This observance takes place on the Feast of the Assumption of the Virgin, to whose honour, under the name Panaghiá Chrysopolitissa—the Lady of the Golden City—a church stands hard by in the precinct of the Temple. Even Moslems in Cyprus at times of stress reveal the pre-Islamic secret of their souls and bow down before the holy icon of the Virgin, painted, it is believed, by St. Luke, wafted oversea to the same Paphian shore as Venus of old, and kept by the Monastery of Kykko, and carried in procession round fields to bring rain and bless their increase. So too do they in the remoter parts of Egypt. When I was being taken over the Church of the Convent of St. Gemiana, in the marshland of the Northern Delta, I saw a woman kneeling and muttering prayers before an icon of the Virgin. It struck me she was no Copt, and I put a question to the monk who acted as guide. He shrugged his shoulders apologetically: "She is of the Muslamin," he said. "Her son is very ill. Why should she not? Who knows?"

Finally, let me return to Ephesus, whose cult with its environment I have peculiar reason to know. A phenomenon has taken place there latterly which illustrates singularly well both kinds of religious transference, the conscious and the unconscious. About fifteen years ago a Catholic priest of Smyrna who had been reading Clement Brentano's "Life of the Virgin," which is based on visions of the German mystic Anne Catherine Emmerich, and contains the story that Mary accompanied St. John to Ephesus, lodged in a dwelling at some distance from the city, and there died—a belief which we know from the French traveller Tournefort to have been held locally two centuries ago—identified the holy house with a ruined building, standing above a spring in the southern hills, and dedicated by the Orthodox Church to Panaghiá Kapouli—Our Lady of the Gate. He succeeded in buying the site and much ground about it, fenced it in, found the gardens which the Virgin had tended, and the path with its stations by which she had climbed daily to Calvary on the hill-top, and when I was there was sanguine of finding also her tomb. He proclaimed his discoveries far and wide and instituted two pilgrimages which now draw thousands of Catholics every year on the Wednesday in Easter week and in the octave of the Assumption. So far we are considering a conscious revival, located by a coincidence at the great Asiatic seat of the pagan Virgin Goddess. But there is a stranger coincidence of which the good priest was not conscious. The holy house stands far from all villages or haunts of men at the head of that same glen of Ortygia where we know, from Strabo and Tacitus, stood the original shrine of the great Ephesian Mother. It stands too on obviously earlier foundations, and, as I have said, over an *Aghiasma*, as it is called, that is, a holy spring. Indeed, very possibly it occupies the actual site of the Ortygian temple. How did this coincidence come about? On this wise. When searching the Ephesian district the Smyrniote priest asked the Orthodox peasants for places sacred to the Virgin, and was directed to this in the glen as the most holy of all. It had been, in fact, a place of pilgrimages and of intercession for the sick, for rain and fertility, and for the easy delivery of women as far back as local tradition ran. This it had been because it was Ortygia, though the villagers of Kirkinji and Arvalia knew it not. In virtue of that fact the priest appropriated it, though he never suspected the identity; and thither the faithful flock twice a year, even less aware of, but none the less compelled by, the persistent sanctity of Ortygia.

Such, then, are the religious survivals which are not survivals at all in what may be called the pathological sense, not, that is to say, elements in actual religion which have survived their utility in this system; and such should not, I urge, be treated by anthropologists without explicit reference to the fact that they are as full of meaning, as vital, and as necessary in actual cult as ever they were. They offer not so much examples of the conservatism of religion—a much used phrase of slightly contemptuous implication—as of the identity of the religious sense throughout the life of particular races and within certain geographical areas, and of the necessary conditions and limitations of its expression. They claim all the respect and tenderness of treatment due to beliefs which still make part of the foundations of our social order, and cannot be impaired or cut away, like a pathological survival, without the provision of substitutes equally efficient. Even when the rudest beliefs of primitive and simple folk are dealt with, *maxima debetur pueris reverentia*; and much, be it remembered, in the content of these great classes of religious persistences is concerned with the belief of folk who are by no means simple or primitive.

There remains, of course, an immense body of religious persistences which are more or less rightly to be regarded as survivals in the ordinary pathological sense, beliefs, observances, and rites, that is, which have indeed survived from earlier religious systems, and have lost or are losing their meaning, because they express nothing necessary or vital to the religious sense. So far as this class includes beliefs at all, these are of the kind which are called superstitions, and I venture, despite the reluctance of some anthropologists to admit a definite distinction between religion and superstition, to maintain that there is such a distinction, and that it is just this, that superstition includes only those beliefs which are held wholly or chiefly because they have always been held; which are, in effect, results of earlier religious systems, or survivals in the narrower pathological sense of the word. Some religious beliefs may be survivals in the wider sense; all superstitious beliefs are survivals in the narrower sense.

The most numerous content of the class, however, is composed of observances and ceremonies. These may often persist as pathological survivals in connection with beliefs of the really religious kind. The object of cult may be a survival of the necessary and vital class, as, for example, the Virgin mother; but the particular place and manner of her worship may be conditioned by survivals of the pathologic sort. The persistence of local sanctity supplies the most obvious illustration of the latter kind of survival. For instance, while the consideration of many holy places to Christendom is due to events or traditions of Christian history itself, to connection with the Gospel story or with early preachers, teachers, or other saints, to reputed epiphanies, and so forth, a much greater number owe the fact that they are still frequented by the pious to reasons of which the pious have not the dimmest consciousness, often to features of pre-Christian Nature-worship—to rocks or springs, or even objects which may have perished long ago, like sacred trees. What Greek votary in the shrines of St. George or St. Elias could give a satisfactory account of either of those saints, demonstrate their place in the history of his Church, or say why their shrines stand in certain valleys or on certain peaks of the hills? We often know better than he; for we can say definitely that many of these saints of the Orthodox Church and of Islam, whose churches and tombs dot the Nearer East, have never died because they never lived, but are the unsubstantial shadows of old gods, clinging to the sites of shrines and groves whence their names perished long ago with the victory of the Galilean.

The particularism, which communities—village, tribal, urban, and even national—display all the world over, has had, of course, much to do with local persistence of sanctity. A small body, blessed with a private deity of its very own for uncounted centuries, who has been identified with its particular interests, and has favoured it in its multifarious local feuds, will not readily resign it for a deity of more general jurisdiction. If it accepts the Christian Virgin in place of a pagan goddess, she will be the Virgin of that particular community, unconnected with any other Virgin, and in full sympathy with the insults which Latin peasants, for example, will heap upon the Madonna of the rival village across the valley. Indeed, an indistinctive distrust of and disinclination to accept an impartial god is characteristic of all imperfect humanity, and lies beneath the sectarianism which has been promptly and continuously developed within the pale of all the great universal religions—for instance, in both Islam and Christianity. The omnipresent, omniscient Deity is too far removed, too catholic, too vague. Man ever desires to focus divine attention on a smaller area, to establish for himself some preference in the eyes of his God; and, even when most anxious to bring the rest of the world into the fold, he often most jealously reserves to his own community the distinction of a Chosen People.

This great and well-known class of observances and rites, which represent true pathologic religious survivals, supplies the bulk of the matter of all the great treatises written on cult by anthropologists, such as those, for example, of Mannhardt and Bötticher on Tree-worship, as well as others to which I have already referred, and many more. With this class the anthropologist can deal freely. In the others it seems reasonable that he should move with greater reserve; and I venture to think that he will best avoid offence if he keep clearly in his own mind, and as clearly before his readers, the main distinction between the classes of religious survivals, which, quite independently of my presentation of it, is real, vital, and of momentous significance.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY AUGUSTUS D. WALLER, M.D., LL.D., F.R.S., PRESIDENT OF THE SECTION.

On the Action of Anaesthetics.

THE duty laid upon me by the Chair which I have the honour to occupy to-day is in the first place to copy the example of my predecessors by submitting to the Section some distinct and definite contribution to the advancement of science.

And inasmuch as the subject has firmly held my attention during the last fifteen years, I am naturally led to name Anæsthesia as the title of my Presidential Address to the Section of Physiology.

With due regard paid to the fact that the audience to which the British Association addresses itself is not principally medical nor exclusively scientific, I shall deal with the subject in a manner that may, I hope, justify my opinion that it is a subject capable of being usefully considered by all educated minds.

And surely, quite apart from its value as an illustration of the method of physiological inquiry, the subject is one with which any educated man may well desire to possess some rational acquaintance, since every one of us may some day require the saving boon of anæsthesia.

Most people have some idea of what is meant by an anæsthetic, and will recognise by name at least one anæsthetic drug—chloroform. It is even probable that the first stranger whom you should meet in the street might also name ether and "gas" as being anæsthetics. And pretty surely he would also know that the use of an anæsthetic is to abolish pain. But if you were to tell him that a plant can be anæsthetised—that seeds can be chloroformed or etherised—he might very possibly express surprise.

The popular notion of an anæsthetic, in conformity with the literal meaning of the word, is that it is something that abolishes sensibility and takes away pain. But how, then, can a plant be chloroformed? Does that mean that a plant is sensitive and can feel pain as we do? Well, probably not; nevertheless it is very certain that a plant can be anæsthetised, and when you have properly appreciated what this means I think you will admit that our notions of vital processes and of their anæsthesia by ether, or by chloroform, or by a host of other reagents have been considerably widened. For we shall then have realised that the state of a person or of an animal rendered insensitive of pain by an anæsthetic is a particular instance of the general principle that all protoplasm—vegetable as well as animal—is liable to be immobilised—put to sleep—more or less completely—temporarily or permanently—by the action of substances which we therefore designate as anæsthetics or narcotics. A volatile narcotic, like ether or chloroform, gets to the living cells of a plant by direct diffusion; in the case of ourselves and of the higher animals it gets to the living cells by the channels of respiration and of circulation. The molecule of chloroform (or of ether) is drawn into the lungs with the inspired air, passes from the pulmonary air to the pulmonary blood, combines with its corpuscles, is thus carried first to the heart and then distributed with the blood to all parts of the body; in the capillaries the molecule of chloroform parts company from hæmoglobin, passes from the blood to the tissues and tissue fluids, and enters into combination with the living cells which it immobilises more or less profoundly, temporarily or permanently. The various kinds of living cells that constitute our organs are unequally susceptible as regards the immobilising effect of this general invasion of the system by the narcotising molecules.

Of all the cells of the body, the most labile, and therefore the first immobilised, are the master cells of the body—the cells of the grey matter of the brain, that is, the seat of sensation and the organ of voluntary motion. The most stable, and therefore the last immobilised, are the executive cells of the body that constitute muscle and nerve. The order of lability from greatest to least is as follows:—Brain; spinal bulb and cord; terminal nerve cells, cardiac muscle; skeletal muscle; nerve fibres. And while all living cells and tissues of the body are subject to the immobilising action of narcotic substances, their individual differences of susceptibility are such that, whereas one part of chloroform in 5000 of blood is sufficient to immobilise cortical nerve cells, a nerve fibre requires a more than tenfold effective mass of chloroform before exhibiting any falling-off of its normal excitability.

Let us now briefly consider what happens when a patient is anæsthetised by, say, chloroform in the usual manner by inhalation of an unknown mass of vapour. The inhaled vapour, more or less diluted in air, diffuses into, and is distributed to, the entire body by the circulating blood. The lymph bath that sorrounds and permeates all the tissues and cells of the body becomes a weak solution of chloroform in water, and gradually within that weak chloroform atmosphere the most labile parts fall under the immobilising effect of the anæsthetic, first the organ of conscious sensation and movement—the cortical grey matter of the brain—then the organ of unconscious reactions, the medullary grey matter of the spinal bulb and cord. So that the order in which the effects unfold themselves are (after a brief stage of excitement or mobilisation) first a suppression of sensation and voluntary movement, then a suppression of reflex and automatic movements, inclusive of the movements of respiration. Finally—and if this finally is reached the immobilisation can no longer be recovered from—the heart stops beating. The patient is dead.

From life to death by the way of anæsthesia there are three principal finger-posts dividing the journey into three stages. Of these three finger-posts two are to be carefully watched for; the third should never be sighted.

During the first stage of anæsthesia—commencing, it may be, by some amount of preliminary agitation—sensation and voluntary motion become suppressed, while reflex and automatic movements are preserved. The finger-post between this first stage and the next is quite clear: if when the conjunctiva is touched the eye winks the anæsthesia is "light"; if the eye does not wink the anæsthesia is "deep."

During the second stage of anæsthesia not only *voluntary* but also *reflex* movements (of which the conjunctival reflex is the most convenient indicator) are wholly suppressed, while the *automatic* movements of respiration persist. This is the degree of anæsthesia required for any major surgical operation, and is therefore frequently spoken of as surgical anæsthesia. The finger-posts to its boundaries are: on this side the conjunctival reflex, on that side the movements of respiration.

The third and last finger-post—arrest of the heart's beat—should not be passed. Arrest of the pulse signifies an almost hopeless state. The time of grace between arrest of respiration and arrest of the pulse from which recovery is almost hopeless is very brief indeed—hardly more than a minute. The doctrine of the Edinburgh school—watch the respiration, not the pulse—is sound doctrine. Stoppage of respiration means danger; stoppage of the pulse means death.

I think this sketch, rough as it is, will be sufficient to bring before our minds a clear picture of the process of anæsthesia and of its principal danger—cardiac syncope. I do not wish to blur it with details. I shall therefore not enter into the question of primary cardiac syncope, nor call off your attention to other symptoms, such as the state of the pupil and the character of the pulse and the colour of the face. Nor shall I at present lay any stress upon the fact that chloroform can be of variable quality, and that like alcohol it may act differently upon different people.

First and foremost, if we are to secure the safe administration of a powerful poison like chloroform, we require to know how much of the drug is required for the production of the desired physiological effects, how much is dangerous, how much is necessarily fatal. Considering the fact that chloroform has now been in common use for sixty years,[1] and that the uniform experience of physiologists is to the effect that it is a dangerous drug as ordinarily used, it is astonishing that its administration should not rest upon any definite scientific basis.

[1] The first major operation under chloroform was performed by Sir James Simpson on January 19, 1847.

Occasional attempts have been made in the past—by Snow[1] first of all, by the French school of physiologists, Paul Bert,[2] Grehant,[3] Dubois,[4] and others, more recently by committees of medical societies and of the British Medical Association[5]—to determine what may be designated as the physiological arithmetic of chloroform; but partly by reason of the difficulty in the way of measuring percentages of chloroform in the air and in the blood, partly by reason of the facility with which chloroform can be administered without any reference to percentages, the results obtained produced very little impression upon clinical practice, and deaths that could not have occurred if the principles laid down by Snow and by Bert had been properly appreciated and acted upon, were and still are regarded by the medical profession and by the public as the normal incidents of medical practice, and attributed to any but their true cause—an overdose of chloroform.

I shall not venture to guess at the number of avoidable deaths that have taken place from this cause, but I place before you a diagram constructed from the annual returns of Somerset House and giving the number of deaths officially classified under the heading "Anæsthetics" during the last fifty years. I do not wish to use the diagram in an alarmist sense, so I hasten to call your attention to the fact that the numbers are not percentages, but absolute figures, which may in your opinion be sufficiently accounted for by the fact that the absolute number of cases has augmented in which anæsthetics have been employed, and that official returns of fatal cases may have become more complete.

Indeed, I do not myself base my judgment of the matter so much upon statistics, which are notoriously apt to be imperfect and misleading, as upon the common experience of most members of the medical profession and of many persons outside that profession; I have rarely met a well-informed person who was not personally acquainted with at least one accidental death by chloroform. Nevertheless I have presented to you the above statistical diagram because I consider that with due reservation this outcome of unprejudiced observation gives a by no means exaggerated picture of an actual fact, and because I believe it is an avoidable fact and will be diminished in future years by the wider knowledge of the physiology of anæsthesia.

I hope I shall not tax your attention too severely if I ask you to follow me through a short arithmetical argument in order to convince you that accidental deaths by chloroform must of necessity be expected to occur in the ordinary way of administration if the administrator is not fully alive to the physical and physiological properties of chloroform, and to outline in your minds a definite picture of some very simple and important measurements.

By ordinary methods of administration the percentage of chloroform vapour in the mixture of chloroform and air inhaled may be anything between 1 and 10 per cent.: let us say that it is 4 per cent.—*i.e.*, that an inhalation of, say, 500 c.c. carries 20 c.c. of chloroform vapour into the lungs. Of this 20 c.c. it is no exaggerated estimate to take one-half, or 10 c.c., as absorbed by the pulmonary blood, the other half being expelled in the expired air. If the subject breathes twenty times per minute 500 c.c. at each inspiration, his blood absorbs 200 c.c. of chloroform vapour in one minute—*i.e.*, one gram of fluid chloroform. He may, of course, absorb less than one gram per minute; but he may also absorb more. Snow estimated that 17 minims of chloroform in the blood (*i.e.*, about one gram) was sufficient to produce anæsthesia, while double the amount was fatal.

Grehant found that after death by chloroform the blood contained half a gram of chloroform per litre of blood—*i.e.*, five litres of blood, which is the normal amount in an average man, would contain two and a half grams. Buckmaster and Gardner find from numerous experiments results that may be summarised as follows:—

Quantity of chloroform (in grams) contained in 100 grams of blood:

	Min.	Mean	Max.
Taken during deep anæsthesia	0·020	0·030	0·040
Taken after death by anæsthesia ...	0·040	0·050	0·060

[1] Snow, "On Chloroform and other Anæsthetics," 1858.
[2] Paul Bert. [3] Grehant. [4] R. Dubois. [5] B.M.A.

These results signify in five litres of blood between one and two grams as the anæsthetic amount, between two and three grams as the lethal amount.

Consider, then, what might happen if a patient were to absorb chloroform at anything like the rate of one gram per minute, and what might happen if by mischance he should absorb two or three grams in a fraction of a minute. This is a mischance that can occur in the ordinary method of inducing anæsthesia: a few deep gasps by a struggling patient, a few moments' inattention on the part of an administrator, and the blood almost at once be fatally overloaded with chloroform.

In the early days of chloroform anæsthesia it used to be considered admissible to administer chloroform vapour of 4 and 5 per cent. strength in air; but at that time the means of estimating percentage were very imperfect, and the figures quoted were little better than guesswork.

The dictum of the Edinburgh school was "plenty of chloroform with plenty of air by continuous administration."

Some ten years ago, at a meeting of the Society of Anæsthetists,[1] I pleaded for the continuous administration of chloroform vapour at a strength (in air) of not below 1 per cent. and not above 2 per cent., which amounted to a translation into figures of the Edinburgh dictum, with justification of the figures by quantitative observation. Perhaps I may briefly explain the method[2] by which the percentages of chloroform and air are obtained:—

	Grams
A litre, or 1000 c.c., of chloroform vapour weighs	5·333
A litre, or 1000 c.c., of air weighs	1·288
The litre weight difference is therefore	4·045

The weight difference of 1 c.c. is approximately 4 milligrams.

So that a 100 c.c. flask in which 1, 2, 3, &c., c.c. of air are replaced by 1, 2, 3, &c., c.c. of chloroform vapour is 4, 8, 12, &c., milligrams heavier than the same flask filled with air.

So that added weights of 4, 8, 12, &c., milligrams indicate 1, 2, 3, &c., per cent. of chloroform vapour present.

Thus, by simply counterpoising a 100 c.c. flask (or, preferably, a 250 c.c. bulb, so as to give weight increments of 10, 20, 30, &c., milligrams as indications of 1, 2, 3, &c., per cent.) filled with air against a similar bulb filled with chloroform mixture, the percentage of the mixture is read directly by the number of centigrams required to counterpoise. For instance, a bulb full of mixture being, say, 18 milligrams heavier than when it is full of air, the chloroform vapour percentage is known to be 1·8 per cent.

Evidently, with a ready means of estimating percentage, one is entitled to talk about the percentages that one considers from experiment to be necessary and sufficient and excessive.

My argument up to this point comprises one or two tacit assumptions that ought to be briefly dealt with, or, at any rate, mentioned.

In the first place, I have assumed that the great majority of accidents by anæsthetics are caused by chloroform.

This is accounted for by the fact that chloroform is the most powerful, the most convenient, and the most extensively used of all anæsthetic vapours. I hasten to add that, in my opinion, this fact is an argument not so much for the substitution of other less dangerous anæsthetics as for the more careful administration of chloroform itself.

In the second place, I have assumed that chloroform is a remarkably uniform and certain reagent, producing its physiological effects in strict conformity with the quantity of vapour administered, and by no means irregular in its action by reason of irregularities or impurities of manufacture. Pure chloroform is more powerful than impure chloroform.

I do not dwell upon these two points now; nevertheless I should like to say that these are not gratuitous assumptions, but, more properly speaking, results of observation

[1] Waller, *British Medical Journal*, April 23, 1898.
[2] Waller and Geets, *ibid.*, June 20, 1903.

and experiment, of which I can offer some evidence. I have tested purified chloroform against the concentrated residue of its impurities, and have found the former to be far more powerful than the latter. And I have compared with each other chloroform or trichlormethane, $CHCl_3$, dichlormethane, CH_2Cl_2, monochlormethane, CH_3Cl, tetrachlormethane, CCl_4, as well as many anæsthetics of the ether group, Et_2O, EtCl, EtBr, EtI, and several anæsthetics belonging to the series of chloroethanes, members of which have at various times been recommended as substitutes for chloroform—*e.g.*, ethylene chloride or "Dutch liquid," $CH_2Cl—CH_2Cl$, and ethyledene chloride, $CH_3—CHCl_2$. The conclusion I have drawn from this study is that of all these more or less powerful anæsthetics chloroform is the most powerful, the most certain, the most convenient, and the most trustworthy.

But I would repeat the statement that the safe administration of chloroform consists in its continuous administration at a strength of between 1 and 2 per cent. And if anyone now objects that it may be safe to go up to 3 per cent., or sufficient to go down to ½ per cent., I am content to accept the objection as being possibly well founded, because it carries with it the all-important admission that the question of safe anæsthesia is in first instance a question of quantity, and in second instance a question of idiosyncrasy and of clinical conditions.

Admitting, then, that the primary condition of the safe administration of chloroform consists in the continuous administration of an atmosphere in which chloroform vapour is between the limits of 1 and 2 per cent., the question is how best to secure this essential condition. It can be secured by many methods. Given the requisite care, skill, and experience on the part of the administrator, anæsthesia may be properly carried out by any method, empirically or otherwise. But some methods demand more skill and care than other methods, and the task of the anæsthetist may be lightened (or it may be aggravated) by various mechanical appliances. A folded towel drenched with chloroform may be safely used by an anæsthetist whom previous experience has rendered fully alive to the extreme danger of two or three deep inspirations of a concentrated vapour, and whose attention is never distracted from the paramount necessity of "plenty of air" with the "plenty of chloroform." On the other hand, a person unmindful of the physiological elements of chloroformisation is a dangerous administrator if he is content with the empirical use of any apparatus, however faithfully he may carry out the instructions of his instrument maker.

Methods and apparatus are legion, and it would be futile or invidious on my part to attempt to describe or criticise in detail any one method or apparatus. But I may usefully invite your consideration of certain principles and ask you to recognise that for their trial by experiment the chief necessity is a simple method, such as I have just described, enabling us to test percentages quickly. Thus, by the use of this method, Mr. Symes[1] has determined what are the usual percentages of chloroform vapour offered to inspiration by an ordinary Skinner's mask, and found them to range between the desirable limits of 1 and 2 per cent., with occasional fluctuations up to about 3 or 4 per cent.

All apparatus designed for the delivery of chloroform vapour of definite and controllable percentage is based upon one or other of two principles. On the first or vacuum system, of which the best known examples are the apparatus of Snow and that of Harcourt, the patient inspires air through a vessel containing liquid chloroform by a broad inlet tube and a closely fitting face-piece.

On the second or plenum system, of which the examples best known to me are the apparatus of Dubois and that to which I have given the name of the "wick vaporiser,"[2] the patient inspires from a freely open face-piece in which an excess of chloroform and air at required percentage is maintained by a pump.

In my opinion, if apparatus is to be adopted, the plenum is preferable to the vacuum principle: for in the latter case it is more difficult to secure uniformity of administration, which requires a perfect fit of the face-piece, stillness of the chloroform over which the inspired current of air is drawn, and which causes of necessity a considerable added resistance to inspiration. By the plenum system there is a more uniform percentage of supply, and the patient breathes freely from an open loosely fitting face-piece, the cavity of which is kept filled to overflowing by an excess of mixture of controllable strength.

But, whichever of these two systems be followed, the choice is obviously one that can only be determined by experience, both clinical and of the laboratory. Equally obviously the so-called accurate percentage afforded by any method can only be approximately accurate under the sometimes difficult conditions of practical administration, and it is therefore of principal importance to ascertain by a simple and ready method of estimating percentages such as I have described above what is the degree of accuracy or, if you prefer to say so, the range of inaccuracy to which any method or apparatus is subject under the ordinary conditions of its application.

You may indeed sometimes hear it said that the percentage can be judged of by the sense of smell, which therefore affords the readiest means of estimating the strength of a mixture, to which I should like to add yes certainly, provided the observer by previous experience of known percentages has formed some standard of comparison on which his opinion is based.

I have finished what I set myself to say to-day concerning the physiological problems involved in the question of safe anæsthesia by chloroform.

But I have reserved for my conclusion certain considerations by which it is customary to introduce the particular subject under review. May I briefly trespass further on your attention to say something about the conditions under which physiological inquiry is pursued in London?

Physiology, in the technical and restricted sense commonly received in this country, has become so closely associated in the public mind with vivisection, and, as dealt with in the medical curriculum, is so narrowly reduced to what is strictly necessary and practicable, that its real scope and value as a general science have been altogether lost sight of.

I do not propose on the present occasion to deal with the question of vivisection either on its ethical or on its utilitarian aspect. All I wish to do is to bring distinctly before your minds two considerations that may, I hope, contribute to a broader and truer conception of the place of physiology among the sciences, though they assuredly will not justify the claim of Dubois-Reymond that physiology is the queen of the sciences.

The first of these two considerations is that the province of vivisection, essential as it is, is a very narrow and restricted province indeed in the domain of physiology. In the ordinary routine of the physiological laboratory experiments involving vivisection are infinitely less numerous and infinitely less exacting than experiments that involve no vivisection. Vivisection is, in fact, an infinitesimal fraction of experimental physiology, whereas in the minds of many who should know better experimental physiology always means vivisection: the two terms are taken as synonymous, and an odium that should not have been attached either to physiology or to vivisection has been directed through vivisection upon the whole of physiology. Yet do not mistake my meaning. I do not for one moment surrender the claim that upon ethical and utilitarian grounds vivisection is lawful; I deprecate the perverted picture of vivisection that is presented to public opinion by sensational agitators and the perverted notion of physiology that is one of the evil results of the anti-vivisection crusade. But I do not desire to dwell on the vivisection question; I do not consider that it can be usefully considered by the general public without an intimate knowledge of the subject, itself possible only to the specialist. An ordinary normal person who should say he approved of vivisection would be, in my opinion, even more objectionable than an ordinary normal person who should express a detestation of vivisection, for the bare idea of vivisection is repugnant to every humane person. To bring dispassionate argument against such natural repugnance seems to me hardly less mischievous than to fan repugnance into hatred by passionate appeals to the

[1] Symes, *Lancet*, July 9, 1904.
[2] Waller, Proc. Physiol. Soc., August 19, 1904.

imagination. The surgeon to whom an ignorant crowd should impute cruelty would fail to serve the cause of humanity by the technical descriptions to them of the operations he is required to perform.

There are two great principles involved in the welfare of any applied science—in the welfare indeed of any living thing—the conservative principle and the progressive principle.

Any organised living mass—let it be an animal or an organised body of men—by virtue of the conservative principle of heredity, of repetition of like by like, of imitation of action that has proved to be successful, works more economically than it could have done if each individual mass had perforce to work out its own salvation, evolve for itself its own suitability to and temporary mastership of surrounding circumstances.

But the child that can only imitate and repeat the actions of its ancestors brings no positive addition to the excellence of the race the upward progress of which requires to be fed by the costly process of initiative efforts, by the sports of talent and of genius, by the cumulative effect of innumerable hits among innumerable misses of innumerable multitudes of individuals.

Transfer this thought to education—to medical education in particular. An educated person—a competent physician or surgeon—must in the first place learn at the feet of his masters, believe and learn what he is told, imitate what he sees done by his instructors, be the apprentice and follower of the experienced craftsman who shows him tried and approved ways of working.

But the apprentice who is to contribute to the commonwealth of knowledge and power has to be something more than the faithful imitator of his teacher; he must initiate, and he must make a hit among, it may be, his many misses. He will then have contributed to the advancement of knowledge and power.

In all provinces of human activity we may distinguish the result of our two complementary principles—imitation, the conservative principle; initiation, the progressive principle. But while in all provinces the conservative factor, being, so to speak, the means of wholesale economy, bulks the larger, the progressive factor, as the means of retail economy, is relatively insignificant.

Between the two extremes—imitation on the one hand, initiation on the other—there is room for numberless variations; and, by reason of the vastness of area of even the minutest province of human activity, the aim of education, even the most technical, is perforce more and more directed to teach the pupil to use his own mind in presence of the task set him rather than to copy minutely and to reproduce perfectly the model facts shown or described to him by the master.

But in every province, and in particular in that of education, the power of imitation is easier to exert and easier to develop than the power of initiation, which is a rare and costly ingredient, since at any given juncture the odds must be heavily in favour of the success of the time-honoured fact or method as compared with its yet untried competitor.

There are of necessity many misses and few hits among the novelties that come to trial.

The genius of our nation is admittedly a practical genius that looks upon the conservative way as the better way, and makes its changes by as small steps as can be from precedent to precedent. This is the safe and easy way, the way of nature; and to this predominance of fact copied over fancy realised may fairly be ascribed our own prolonged constitutional prosperity. We have found by long experience that it is very long odds indeed against any dark horse without a good pedigree of precedents, so we prefer to back the field; old methods are the safe thing and the good thing.

But one may have too much of a good thing, and in education I think we have had too much of the old methods, in which the keynote is imitation and examination of copy, and too little of that expensive and dangerous ingredient—so dangerous that to some authorities it appears in the light of a poison—initiative and originality of thought. I admit all the danger; I grant to the old authorities that there is a good deal of trash current under the label of original research. But I do not think we can have wheat without chaff, and I am convinced that the adherents of original research, as against the *clientèle* of the examiner and of the crammer, bring to the educational commonwealth the scanty and much needed ingredient of initiative. We want education still further urged in the direction of teaching the pupil to use his own mind upon unseen translation of new facts into effective conduct, and one of the best ways of obtaining that the teacher shall guide his pupils to use their own minds is that he should himself use his own mind, and not suffer himself to drop into the jog-trot of routine. We want our teachers to be learned men, but we also want them to continue to be learning men; and that is why, in spite of its defects, I want to urge that greater encouragement be given to original research.

I hope I shall not have taxed your patience too far if I bring these considerations to their natural conclusion by telling you as briefly as may be of an effort that is now being made in the University of London to strengthen and organise that spirit of initiative which is, I am convinced, of capital importance in all teaching, the most elementary no less than the most advanced. We have formed ourselves into a school of physiology, including every teacher of physiology in London, each of whom undertakes to give at the headquarters of the University lectures upon those portions of the science with which his own previous study has rendered him specially conversant. The teaching offered is of an advanced character, and is addressed more especially to post-graduate and to Honours students; and, in pursuance of the principle that such teaching is the immediate consequence of learning, the University has provided a research laboratory in which teachers and other post-graduate students find the necessary facilities for work. We believe that the experience of the last five years has sufficiently proved that a "college of learning" thus constituted renders valuable assistance to the teachers and students of the schools of London, and that it is helping to draw to a focus resources and efforts that are at present scattered and wasted among the several schools. I cannot do better in this connection than quote the words of the Chancellor of the University (Lord Rosebery):—"We hope to make this laboratory the central spot for medical research in London . . . an institute of studies ancillary to medicine, which may develop and complete the work of the University in that direction." And I think that you will agree with me that any movement that contributes to the good health of the University of London contributes to the good health of every university in the Empire, and of every school the teachers of which are animated by the university spirit—the love of learning for its own sake as well as for the sake of the mental and material power that is required of us.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The mastership of Downing College has been offered to Prof. Howard Marsh, who has, it is understood, given a favourable reply, but the election cannot take place until October.

Mr. Augustine Henry has been appointed reader in forestry for five years.

A university lectureship in botany will be vacant at Michaelmas in consequence of the resignation of Mr. Hill. The annual value of the post is 100*l*. Applications for the lectureship, accompanied by testimonials, should be sent to the Vice-Chancellor on or before October 11.

LONDON.—Dr. E. A. Westermarck has been appointed to one of the two professorships of sociology founded by Mr. Martin White—the one for five years; the appointment to the permanent professorship has not yet been made.

Dr. A. C. Haddon, F.R.S., has been appointed university lecturer in ethnology for the session 1907–8 under the Martin White benefaction. The teaching in these subjects will continue to be given at the London School of Economics, and the courses will be treated as intercollegiate courses.

Manchester.—Mr. J. L. Simonsen, Schunck research fellow, has been appointed a junior demonstrator in chemistry.

Oxford.—The professor of human anatomy has notified the Vice-Chancellor that the Welsh prize, 1907, has been awarded to Mr. Wathen E. Waller, of University College.

An election to the Philip Walker studentship in pathology will take place in October next. The studentship, which is of the annual value of 200*l*., is tenable for three years, is open to either sex, and the holder need not necessarily be a member of the University of Oxford nor be legally qualified to practise the profession of medicine, but while holding the studentship he or she must be devoted to original pathological research. If the work done by a student be of exceptional promise, the studentship may be extended for a second period not exceeding two years. Applications, accompanied by three testimonials, must reach the registrar of the University by September 14 next.

At the Convocation to be held on September 30 it will be proposed to confer the honorary degree of D.Sc. upon Dr. Ludwig Mond, F.R.S., who was unable to be present and receive the degree at the late Encænia.

Prof. W. Baldwin Spencer, F.R.S., the holder of the chair of biology in the University of Melbourne, has been elected to an honorary fellowship at Exeter College.

Dr. Norman Moore will deliver the first Finlayson lecture in Glasgow in February next. The lectureship was founded in commemoration of the late Dr. James Finlayson. The subject and actual date of the lecture will be announced later.

Mr. W. Erlam Smith, who is at present acting as temporary professor of natural science at Government College, Rangoon, has been appointed to succeed Dr. W. H. Wilson as professor of chemistry in the Presidency College, Madras, when the latter retires in October next.

For work carried on in the cancer research laboratories of the Middlesex Hospital, the Walter Emden research scholarship and the Richard Hollins scholarship have been awarded respectively to Dr. Victor Bonney and Mr. L. Courtauld.

The Joule studentship of the Royal Society has been awarded to Dr. T. H. Laby, of the University of Sydney, now of the Cavendish Laboratory, Cambridge, for the investigation of the conditions of condensation and supersaturation of vapours other than steam.

Mr. Richard Henry Curtis, principal assistant in the observatories branch, has been appointed superintendent of the instruments branch at the Meteorological Office. The observatories branch will in future be incorporated with the instruments branch. Mr. Richard Corless, of Sidney Sussex College, Cambridge, has been appointed special assistant to the director.

A fellowship in agriculture has been awarded to Mr. W. Dawson by the executive committee of the Carnegie trust for his thesis entitled "Production of Seed by Forest Trees," and a scholarship in agriculture has been awarded by the same committee to Mr. F. S. Marr for his paper on "The Stimulus of Phosphoric Acid on the Early Development of Plant Growth."

The following appointments have been made in connection with the Rothamsted Experimental Station:—Dr. E. J. Russell, lately of the South-Eastern Agricultural College, Wye, as the Goldsmiths' Company's assistant for the investigation of soils, and Dr. H. B. Hutchinson, of the Midland Agricultural and Dairy College, Kingston, Derby, as bacteriologist.

Mr. Murray has published at 5*s*. net a handsome memorial volume of the visit in June, 1906, to the University of London of representatives of the University of France, the Collège de France, and the French provincial universities. We published in our issue of June 14, 1906, an article on the visit, so do not need to say more about the volume than that it contains the names and particulars as to the standing of the guests, verbatim reports of the various addresses delivered, and accounts of the numerous receptions, luncheons, &c., arranged in honour of the distinguished visitors, concluding with the conversazione held at the University of London, South Kensington, at which about 2000 guests were present.

The council of the Institution of Civil Engineers is prepared to consider applications for a nomination to a Palmer scholarship. The annual value of the scholarship, which will be vacant at the end of next month, is 40*l*. Sons of civil engineers alone are eligible for nomination, and they must be desirous of matriculating, and subsequently graduating, at the University of Cambridge, and their circumstances must be such as to need the help afforded by the scholarship. Copies of the regulations may be obtained from the secretary of the Institution of Civil Engineers.

The following appointments in universities abroad are notified in *Science*:—Dr. G. L. Streeter, professor of anatomy in the University of Michigan; Dr. J. Heath Bawden, professor of philosophy in the University of Cincinnati; Dr. F. R. Noll, of the Agricultural Academy at Poppelsdorf, professor of botany at Halle; and the following appointments at Syracuse University have been made:—Joseph E. Kirkwood, professor of botany; W. M. Smallwood, professor of comparative anatomy; and George D. Babcock, professor of practical mechanics.

The most recent report of the U.S. Commissioner of Education deals with the year ending June 30, 1905, and has just been published. The growth of facilities for higher instruction as recorded in the report is remarkable. The total value of property possessed by the institutions for higher education increased during the year with which the volume deals by 10,000,000*l*. At the date mentioned the total value reached approximately 103,000,000*l*., of which 47,000,000*l*. represents endowment funds, the remainder being the value of the material equipment used for instruction purposes. Forty-one institutions have endowment funds of more than 200,000*l*. each. The rate of increase per year in the endowment funds was 41·3 per cent. during the five years 1900–1905. The total income for the year of these institutions for higher education, excluding benefactions, amounted to 8,355,000*l*., an increase of 289,200*l*. over the preceding year. Of this amount 23·6 per cent. was from endowment funds, 23·6 per cent. from State appropriations, and 6·9 per cent. from Federal appropriations. It is interesting to note that Harvard and Columbia had incomes exceeding 200,000*l*. each, eight other institutions had over 150,000*l*. each, three over 100,000*l*., and twelve more over 60,000*l*. The total amount of benefactions reported by all institutions during 1904–5 was 3,335,790*l*., of which 71 per cent. was received by thirty-three institutions which each obtained 20,000*l*. or more. Harvard received gifts amounting to 466,000*l*., Yale 279,000*l*., and Columbia 236,000*l*. The total number of men students in these institutions of higher education increased during the year under consideration from 86,006 to 92,161, and of women students from 32,023 to 34,243.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 27.—"On the Velocity of the Kathode Particles emitted by Various Metals under the Influence of Röntgen Rays, and its Bearing on the Theory of Atomic Disintegration." By P. D. **Innes**.

(1) The velocity of the electrons emitted by lead, silver, zinc, platinum, and gold under the influence of Röntgen rays has been measured, both for soft and hard rays.

(2) The values found are as follows, the accuracy being within about 3 per cent.:

	Soft rays		Hard rays
Lead	$6 \cdot 3$ to $7 \cdot 6 \times 10^9$	...	$6 \cdot 3$ to $8 \cdot 3 \times 10^9$
Silver	$6 \cdot 0$ to $7 \cdot 2 \times 10^9$	...	$6 \cdot 1$ to $8 \cdot 0 \times 10^9$
Zinc	$6 \cdot 0$ to $6 \cdot 4 \times 10^9$		
Platinum ...	$6 \cdot 1$ to $7 \cdot 5 \times 10^9$	...	$6 \cdot 4$ to $8 \cdot 1 \times 10^9$
Gold	$6 \cdot 1$ to $7 \cdot 5 \times 10^9$	...	$6 \cdot 2$ to $8 \cdot 1 \times 10^9$

(3) The velocity of the fastest electrons emitted from each metal is completely independent of the intensity of the primary rays, but increases with the hardness of the tube.

(4) The velocity decreases with the atomic weight, the difference between the speed of the fastest electron with hard rays and that with soft rays being practically the same for the various metals, if the variation in hardness of the rays is the same.

(5) A minimum velocity is necessary to enable the electron to emerge, and the minimum velocity is nearly the same in the different metals.

(6) The number of electrons given off decreases with decreasing intensity of the rays, as well as with increasing hardness.

(7) The number emitted also decreases with decreasing atomic weight and density.

(8) The conclusion is drawn from calculation and discussion of other theories that the most probable theory is that of atomic disintegration. It is shown that the velocity of the emitted electron is too great to be that acquired under the influence of the electric force in the X-ray pulse. The other theory of ejection is discussed and objections to it pointed out. A possible explanation is given of the increase of the velocity with increasing hardness of the rays, and this fact is shown not to be inconsistent with the disintegration theory.

EDINBURGH.

Royal Society, July 8.—Dr. Robert Munro, vice-president, in the chair.—The plant remains in the Scottish peat mosses, part iii.: F. J. **Lewis**. The third part dealt with the peat mosses of the east and north-west Highlands, Shetland, and the Outer Hebrides. All the Scottish peat mosses show a definite succession of plant remains. The oldest in the south of Scotland and the Shetland Islands have an Arctic plant bed at the base. This is succeeded by a forest of birch, hazel, and alder containing temperate plants. A second Arctic plant bed occurs above the lower forest, and is overlaid in all districts except the Hebrides, Cape Wrath, and the Shetland Islands by the upper forest, covered by several feet of peat bog plants. While it is difficult to reconcile the several stages in the peat with the theory of a single glaciation, the peat beds as a whole agree very closely with the scheme of classification proposed by Geikie in "The Great Ice Age."—Note on the abyssal temperature of fresh-water lakes: E. M. **Wedderburn**. Observed distributions of lake temperatures were brought forward as illustrations of the author's view that the surface current set up by wind action produces a back current at a moderate depth, with a slow movement of the bottom layers parallel to the surface current.—The action of sodium ethylate on trichloromethylsulphonic chloride: Prof. A. Crum **Brown** and T. F. **Cowie**.—A hybrid between Prejvalsky's horse and a Highland pony: Prof. J. C. **Ewart**. In most respects the hybrid differed little from an ordinary cross-bred pony. In its mane, however, it afforded striking evidence of its mixed origin. The front part of the mane projected forward, but failed to form a forelock. The rest consisted of hairs which were either erect or arched outward, some falling towards the right, others towards the left. The experiment gave further evidence in favour of the theory that our modern horses are descended from several distinct stocks, of which the Prejvalsky horse is one.—A note on a reflected mirage: Dr. C. G. **Knott**. This was an account of a curious mirage observed in South Africa by members of a cadet corps who were camping out to the south-east of Worcester. With the town at their back the observers saw about four miles off, apparently on the back of the river, a recognisable image of the town itself.—The system sulphur-iodine: Prof. Alex. **Smith** and C. M. **Carson**. The freezing points of mixtures of iodine and sulphur show that these elements neither combine chemically nor form solid solutions.—Precipitated sulphur: Prof. Alex. **Smith** and R. H. **Brownlee**. Sulphur precipitated from polysulphides by means of acids is almost wholly composed of soluble rhombic sulphur. The fluid droplets of which the precipitate is at first composed crystallise to monoclinic sulphur, and the masses of the latter afterwards turn into rhombic sulphur without change in their spherical form. The sulphur precipitated from sodium thiosulphate by means of acids is wholly soluble when acetic acid is used. With hydrochloric acid the precipitate is viscous. The amount of insoluble sulphur is proportional to the concentration of the acid, and varies from 6 per cent. to 96 per cent.—Preliminary note on the optical rotations (throughout the spectrum), the electrical conductivities, and the densities of mixtures of sodium-potassium-tartrate and ammonium molybdate in aqueous solutions. The essential feature of the method lay in the measurements being made for all kinds of light. Interesting results were obtained with respect to the influence of non-active substances when added to active solutions.

July 15.—Dr. Robert Munro, vice-president, in the chair.—The Pycnogonida of the Scottish National Antarctic Expedition: T. V. **Hodgson**. The main interest of the *Scotia* collection lay in the problem of distribution to which it gave rise. Antarctic and sub-Antarctic regions were distinguished, being separated provisionally by the sixtieth parallel south. Of the fifteen species recorded from the *Scotia* the most striking was the *Decolopoda australis*, a species discovered and accurately described some seventy years ago, but forgotten, and when first noticed despised as a monstrosity or as a sample of defective work.—The marine mollusca of the Scottish National Antarctic Expedition: J. C. **Melvill** and R. **Standen**. The collection is interesting because of the number of deep-sea forms brought for the first time from unusual depths, and because of the extension of the geographical range of certain species already known. A second example of the hitherto unique *Guivillea alabastrina*, Watson, was dredged from a station not far from the original *Challenger* locality. Of the ninety-five species described, the gastropods claim fifty-nine with eleven new species, the scaphopods two with one new species, and the pelecypods thirty-four with nine new forms.—Preliminary note on the internal structure of *Sigillaria mamillaris*, Brongt., and *Sigillaria scutellata*, Brongt.; and description of a new species of Lepidodendron (*L. pettycurense*) from Pettycur: Robert **Kidston**.—The periods of the elliptic functions of Weierstrass: R. T. A. **Innes**. The paper gave a new method of calculating the periods when the invariants of the cubic were given.—Hydrachnidæ collected by the Lake Survey: W. **Williamson**. Among the various forms described there was a species of Whitfeldtia, which until now had not been found outside Norway.—Degenerations following experimental lesions in the motor cortex of the monkey: Drs. W. A. **Jolly** and Sutherland **Simpson**. Lesions were made in the motor cortex of the monkey, *Macacus rhesus*, involving portions of the leg, arm, and face areas. The fibres of the pyramidal tract arising from these areas were traced by the method of secondary degeneration from their source to their termination. It was found that the fibres from these areas begin to intermingle soon after they leave the motor cortex. In the internal capsule there is already a good deal of overlapping, and this is more marked still in the pes pedunculi. Throughout the pons, medulla oblongata, and spinal cord the intermixture is practically complete, so that below the level of the mid-brain there is no localisation or grouping of the fibres within the pyramidal tract as there is of the cells from which they take origin in the motor cortex. Above this level some localisation of fibres does take place, but it is only partial, the degeneration from one area encroaching upon that from the neighbouring areas to a considerable extent.—Classification of igneous rocks according to their chemical composition: Dr. H. **Warth**.—Note on quaternion integrals: Dr. H. **Hermann**. This was an improved demonstration of the generalised quaternion form of the theorems which include those of Green, Gauss, and Stokes.

PARIS.

Academy of Sciences, August 5.—M. H. Poincaré in the chair.—M. A. Lacroix announced the death of J. F. C. Klein, correspondant for the section of mineralogy, and gave an account of his work in the field of mineral crystallography.—Report presented by the committee charged with the scientific control of the geodesic operations on the equator: H. **Poincaré** (secretary). The last report was presented in April, 1905. A summary is given of the work done at seventy-four geodesic stations. Three base lines were measured, and magnetic and pendulum observations were also carried on throughout. The provisional calculations are well advanced. The triangulation and the concordance of the bases measured and calculated appear to be of the same order of accuracy as those used in the revision of the meridian of France.—The law of the velocity of hæmolysis of the red blood corpuscles under the action of light, of heat, and of some hæmolytic bodies: Georges **Dreyer** and Olav **Hanssen.** The decrease of the corpuscles after treatment with light or heat can be expressed by the monomolecular formula, and examples of this are given in three tables.—The heat of combustion and formation of gaseous hydrogen phosphide: P. **Lemoult.** This measurement has hitherto been made by indirect methods only. The author has carried out direct measurements by exploding hydrogen phosphide with oxygen in the calorimetric bomb. Observations were made with a Mahler enamel lined bomb and with a Berthelot platinum lined bomb, the results agreeing to about 0·5 per cent. The molecular heat of combustion of phosphoretted hydrogen is 310 calories at constant volume, 311·2 calories at constant pressure.—The silicide of platinum, SiPt, and on a double silicide of platinum and copper: Em. **Vigouroux.** Referring to a recent publication concerning this silicide SiPt by M. Lebeau and A. Novitzky, the author points out that he recently described the same compound, further details of which are now given.—The use of foreign materials modifying the forms of a crystal in course of growth to determine its crystalline symmetry: Paul **Gaubert.** Crystals of nitrate of urea have been variously ascribed to the monoclinic and rhombic systems. By utilising the effects of the presence of methylene blue or picric acid in the mother liquor from which the urea nitrate crystals are separating it has been found that the crystals of urea nitrate are monoclinic, and it is by an association following a plane perpendicular to the base that the groups appear to show a rhombic symmetry. This macle presents the curious property of not being noticeable from the optical behaviour.—Concerning two notes of M. Gerber, on the ferment of the Cruciferæ and the ferment of the Rubiaceæ: M. **Javillier.**

NEW SOUTH WALES.

Linnean Society, June 26.—Mr. A. H. Lucas, president, in the chair.—New Australian species of the family Calopterygidæ (Neuroptera: Odonata): R. J. **Tillyard.** *Diphlebia lestoides*, Sélys, is the only species of this exceedingly beautiful and interesting family so far described from Australia. Two additions are now made, one a common East Indian species (*Rhinocypha tincta*, Ramb.), and the other a beautiful new Diphlebia from northern Queensland.—A contribution to the geology of Viti Levu, Fiji: Dr. W. G. **Woolnough.** This paper comprises the results of the author's second expedition to Fiji in 1905. The granitic rocks met with in 1901 were shown to occur at intervals over an area of at least 400 square miles; evidence is now adduced to prove that their surface represents an ancient peneplain. The sections at Nasaqo and Nadrau previously described, and new and very instructive ones at Rewasau and Nukuilau, were examined. These prove conclusively that the granite is very much older than the volcanic series which builds the bulk of the island. The slaty rocks associated with the granites are shown to be, in part at all events, altered eruptive rocks. Their geological relationship to the granites has not yet been definitely proved. The earliest stage of the Cainozoic history of the island is marked by extensive submarine eruptions, later stages by terrestrial eruptions of andesites; and a probable sequence of eruptive rocks is suggested. The causes which led to the separation of the Fiji mass from the continental land to the west were assumed to be faulting, but no definite evidence of such a phenomenon was cited. Now fairly definite evidence is adduced to show that heavy faulting has taken place along a N.N.W.-S.S.E. axis. It is suggested that a second faulting has taken place along a W.S.W.-E.N.E. axis, parallel to the long axis of the Viti Levu-Vanua Levu *massif*. Extensive movements of elevation have taken place, causing a maximum uplift of nearly 5000 feet on the north-west with a marked tilt towards the south-east. River development affords scope for very interesting speculations, and several theories are dealt with in the paper. The marked rectangular network arrangement of the rivers is commented on, and is explained as chiefly due to earth movement. River capture has subsequently modified the original drainage in some particulars, and adjustment of drainage is proceeding very rapidly under almost ideal conditions. All the evidence obtained up to the present confirms the opinion formerly expressed that Fiji at one time formed part of a great Austral-Papuan continent.—Revision of the Australian Curculionidæ belonging to the subfamily Cryptorhynchides, part viii.: Arthur M. **Lea.** In this contribution the revision of the genera allied to Cryptorhynchus is continued.

APPLIED OPTICS.

A System of Applied Optics, being a Complete System of Formulae of the Second Order, and the Foundation of a Complete System of the Third Order, with examples of their Application. By H. Dennis Taylor. Pp. xvi+334, with 24 plates. (London: Macmillan and Co., Ltd., 1906.) Price 30s. net.

THAT branch of geometrical optics which deals with the properties of lenses and lens systems has unfortunately been shamefully neglected in England during recent years. This neglect has extended from the theory to its practical applications, and the design and construction of lenses has, to a great extent, been relegated to other countries, notably Germany; although in the time of Dollond, M. Anthéaume was obliged to send to England in order to obtain lenses to carry into practice the theory of achromatism devised by M. Clairaut. Before the publication of the book which forms the subject of this review, there was no work, in English, by the guidance of which an ordinary photographic lens could be worked out in all particulars; and the fact that there has been practically no demand for translations of the numerous books on applied optics which have been published in Germany, shows how completely the subject has been neglected. If we seek for a reason to explain this state of affairs, it is not far to seek. The books on geometrical optics which have appeared in England during recent years have, for the most part, been written by mathematicians who could boast little or no acquaintance with the practical design of lenses; and as the formulæ which can be obtained for the correction and elimination of errors in lenses do not possess that "elegance" which is dear to the heart of the pure mathematician, practically no progress has been made since the time of Airy and Coddington: almost the only modern work which exhibits originality of treatment is a small volume [1] by Mr. Blakesley, published in 1903.

In these circumstances we cannot feel too grateful to Mr. Dennis Taylor for the volume before us. In this, everything which could aid the student in mastering the subject in the easiest and most pleasant way has been done, and done well. The numerous diagrams (drawn to scale, or as nearly to scale as is practicable), which are included in the twenty-four plates, must alone have entailed many hours of tedious labour. The principles underlying each problem that is attacked and solved are clearly and fully explained, while the steps in the analysis which have been omitted can easily be supplied by a reader with very moderate mathematical acquirements. But the chief interest of the book lies in the fact that it is the outcome of a successful attempt to design lenses for practical purposes. Finding that the formulæ arrived at by Coddington, for the curvature of the image formed by a lens, were not quite satisfactory, an attempt was made to solve the problem by some method not dependent on the calculus; and after several disappointments, Mr. Taylor was successful.

In this investigation the formulæ relating to "coma" or "side flare" were arrived at; it is significant that there is scarcely a book in English which even mentions this defect of lenses—a defect which is often of greater importance than those due to spherical aberration or astigmatism. As a practical outcome of the investigation, the Cooke lens was designed; and, finally, Mr. Taylor has embodied his investigations in the book before us.

It is, perhaps, a pity that Mr. Taylor has not adopted the usual convention as regards the signs of the quantities u, v, and r. In the end, one convention (when mastered) is as good as another; therefore, it would appear that the most suitable one is that which is most generally adopted. The convention adopted by Mr. Taylor makes u positive or negative (for a particular position of the object), according as the lens is collective or dispersive, while the signs of v, and the radii of curvature are determined in a similar manner. There appears to be no advantage in this procedure that is not shared equally with the one generally in use; and the reader accustomed to the latter is likely to experience some unnecessary difficulty in following Mr. Taylor's reasoning. This is, however, a detail of no vital importance.

The first chapter of Mr. Taylor's book is devoted to a brief recapitulation of the ordinary formulæ, of the first order of approximation, applied to mirrors and lenses. In the second chapter the "theorem of elements" is explained: a thick lens is shown to be equivalent to two thin lenses (called "elements"), and a plane parallel sheet of glass. The theory of thick lenses, and lens combinations, is discussed in chapter iii.; this theory, as explained by Mr. Taylor, is much simpler than that usually given in books on geometrical optics, although a further simplification is possible and desirable. At this early stage the reader is brought into touch with practice by using the formulæ that have been evolved, to calculate the focal lengths of some well-known lens combinations, including the Cooke process lens. Such calculations occur at short intervals throughout the book, and add much to its value.

Spherical aberration is discussed in chapter iv. The ordinary formula to the second degree of approximation is obtained, and is simplified by the aid of a device due to Coddington; a formula to the third degree of approximation is also worked out, but the reader may omit the investigation leading to this on a first reading, as it is somewhat complicated, though presenting no difficulty other than those generally met with in dealing with unwieldy formulæ. A geometrical device [1] due to Mr. Blakesley, might have been mentioned here with advantage. It can be easily proved that if all rays proceeding from a point on the axis of a lens pass through the lens in such a manner that the deviation of each is a minimum, then the spherical aberration is a minimum also; and Mr.

[1] "Geometrical Optics" By T. H. Blakesley. (London: Whittaker and Co., 1903.)

[1] "Geometrical Optics." By T. H. Blakesley, pp. 94-111.

Blakesley has given a simple geometrical means of designing a thin lens to comply with these conditions. Of course, spherical aberration is not the only, or even the most important defect of a lens; but the simplicity of the geometrical construction leads one to wish that expert mathematicians would devote some attention to the subject to see whether graphical methods could not be used in other cases.

Central and eccentric oblique refractions are discussed in chapters v. and vi. respectively. Eccentric oblique refraction is answerable for the phenomenon of "coma" or "side flare," which is discussed in great detail in chapters viii. and viii*a*. It would be impossible, in the short space of an article such as the present, to deal with the author's treatment of this interesting subject in detail; it must suffice to say that it has now for the first time been brought within the reach of any reader possessing ordinary mathematical attainments who will devote the necessary time and attention to the subject. Some of Mr. Taylor's results are similar to those obtained by Von Siedel, but many are novel. The most important advance effected by Mr. Taylor is the investigation of the foci of oblique and eccentric pencils of large aperture.

The distortion of the image formed by a system of lenses is very fully investigated in chapter ix., where it is shown that Coddington's method is defective in not carrying the spherical aberration of the first lens through to all succeeding lenses, a considerable error being thus introduced. The distortion produced by several combinations of lenses is worked out numerically, and it is shown that, in the case of an eye-piece of a telescope or microscope, an image which is really distorted *may* appear to be undistorted, owing to a peculiarity of the eye. Achromatism is dealt with in chapter x. In reading this, and, indeed, most other chapters of the book, one cannot help being struck by the care with which the author has experimentally tested the results obtained, sometimes finding that an extension of the theory is necessary (see, for example, p. 309). A brief sketch of the errors of the third order is given in chapter xi.

On closing Mr. Taylor's book, we are left to reflect on the living interest which he has given to mathematical investigations, essentially of a somewhat clumsy nature. Throughout the book, theory and practice go hand in hand, and we feel that the labour of solving the complicated problems which arise is well worth the while, for something tangible and useful is gained in the end. It would be well if the examining bodies of the various universities were to attach greater importance to geometrical optics, *studied from an essentially practical point of view*. At present the startling discoveries which have been made during recent years in other branches of physics absorb so much attention that many students who sit for advanced examinations in physics are culpably ignorant as to even fundamental properties of lenses. Questions on geometrical optics are rarely set by examiners; and when they are, they are too often merely mathematical exercises. Since accurate experimenting so often involves the use of lenses and other optical appliances, this state of things is greatly to be regretted.

EDWIN EDSER.

A THEORY OF THE ÆTHER.

Æther: A Theory of the Nature of Æther and of its Place in the Universe. By Dr. Hugh Woods. Pp. xii+100. (London: *The Electrician* Printing and Publishing Co., Ltd., n.d.) Price 4*s*. 6*d*. net.

THIS book is a more elaborated presentation of the views as to the nature of æther set forth by the author in a pamphlet published in 1808. The æther is "regarded as possessing properties such as might justify its being described as a gaseous fluid, composed of atoms almost indefinitely small as compared with recognised chemical atoms." Again, "Æther is a fluid whose ultimate particles, or atoms, are so small that they pass into the minute crevices of spaces in the most solid bodies." This view has much in common with some of the older theories of the æther, and is almost identical with that proposed by Mendeléeff in his tract, "An Attempt towards a Chemical Conception of the Æther" (1902), and which is referred to by the author in support of his views. No attempt is made to overcome the objection first urged by Maxwell to any theory as to the nature of the æther which postulates a discrete structure for it—that all the energy of the universe would have been transferred to it—and the same objection applies even if the æther is regarded as a limiting case of a medium possessing such a structure.

The theory proposed by the author cannot, therefore, be accepted as an ultimate theory of the æther. There remains the question whether this idea of the æther affords a satisfactory working model which could be used to give a concrete representation of physical and chemical phenomena, and enable their course to be definitely followed. The theory is applied to a wide range of phenomena, including gravitation, chemical changes and reactions, heat, light, electricity and magnetism. Many of the explanations that are claimed as consequences of the particular theory would follow from any theory of the æther that assigns to it the fundamental properties of a moving system. The reasoning is in general vague, and the argument is never pushed far enough to enable a quantitative comparison to be made. A few examples will suffice to show the character of the reasoning. On p. 3 the following argument is given:—

"The solar system appears to move through space, borne along in an enormous volume of swiftly flowing æther. Now the resistance offered to the free flow of the æther by the partially impervious bodies floating in it is evidently greatest in the line of greatest thickness of each body, and less as the thickness becomes diminished. Accordingly a difference of momentum is thereby caused in the mass of æther, dashing against the body, and there results a current in the æther from places of higher momentum to places where the momentum is lower, with the effect that a whirl, such as occurs in the air under similar circumstances, is produced. These whirls, then, by their continual action, make the bodies more or less spherical, and set them rotating, each on its largest axis, while the whirls, spreading out in ever widening circles, influence the movements of other bodies floating in the same medium." "In this way, the movements and mutual influence of the heavenly bodies may be explained, in a perfectly rational manner, and without imagining any occult power of attraction."

The reasoning here appears to be scarcely conclusive; there is some unexpressed assumption as to the nature of the action between æther and matter; and that whirls (by which some kind of vortex motion appears to be meant) would necessarily result wants demonstration. These whirls have, at a later stage in the book, to do duty in explaining terrestrial magnetism as well as the relations of the heavenly bodies and their gravitational attraction. Again, p. 11:—

"It has long ago been proved that in æther all bodies fall with equal rapidity towards the centre of the earth, and it may, therefore, be reasonably assumed that all atoms which displace equal amounts of æther have equal weight. There are, however, many and convincing reasons for believing that the atoms of different chemical elements have widely different weights." "The explanation, then, which suggests itself as accounting for this difference, according to the present theory, is the very simple one that the heavier atom is of larger bulk, and displaces more æther than the smaller atom. From this it follows that the sizes of chemical atoms are in the same ratio as their weights."

From this, Gay-Lussac's law and Avogadro's law are derived. Boyle's law and the deviations from it are treated much in the same fashion, and the author then finds it necessary to introduce another factor (p. 15), the *shape* of the molecules. A table of the chemical elements arranged with their atomic weights in ascending order of magnitude (the character—gas, liquid or solid—of each being stated) is given. Arguing from this table, the statement is made:—

"It must hence be admitted that elements with a low atomic weight are much more disposed to be gaseous than those of higher atomic weight, at ordinary temperature and pressure. This quite accords with the theory that their ultimate particles are smaller than those of elements with higher atomic weights."

The difficulty that there are so many solid elements of low atomic weight is got over by invoking the influence of shape. For example, the liquidity of mercury is explained by supposing the atom of mercury to be spherical. A curious reader might wish to know the approximate shapes of the atoms of argon or lithium, but on this point the author is silent. After some pages of the same kind of reasoning, two laws are enunciated: —

(1) "The condition of chemical elements or of chemical compounds, at similar temperature and pressure and under similar conditions generally, depends on their atomic or molecular weights (that is, on the size of their atoms or molecules) and on the shape of their atoms or molecules." (2) "The relative chemical activity and chemical properties of chemical elements or chemical compounds, at similar temperature and pressure and under similar conditions generally, depends on their atomic or molecular weights and on the shape of their atoms or molecules."

The term law appears to be used here in a somewhat unusual sense, as these statements do not constitute laws; to make them such, the laws of dependence should be known. Another good example of the author's mode of reasoning is to be found on pp. 53, 54, where the fact that glass is transparent to light but opaque to heat is explained by the peculiarities of the interstices filled with æther in the case of glass, the nature of these being inferred from the way in which glass fractures.

It will appear from these examples of the author's treatment that his theory cannot even make good a claim to be considered a reasonable working model. A great number, however, of the better known physical and chemical phenomena are brought together, and on this account the book may perhaps prove interesting to readers who have not sufficient leisure or inclination for the perusal of treatises and memoirs that have greater pretensions to scientific accuracy.

FOUNDRY PRACTICE.

General Foundry Practice. By A. McWilliam and P. Longmuir. Pp. vii + 383. (London: Charles Griffin and Co., Ltd., 1907.) Price 15s. net.

THE opinion is generally held among metallurgists that with the rapid progress made of recent years in Great Britain in the metallurgy of iron the foundry has hardly kept pace. Mr. McWilliam and Mr. Longmuir take a more optimistic view, and believe that advances have been, and are being, made of a magnitude commensurate with those of other industries. Certainly signs of progress are apparent in this important branch of metallurgy. The empirical method of charging the cupola is giving place to the system of weighing all materials in proportions determined by the chemist. High-temperature measurement is being practised in the core and drying stove. The field for machine moulding is extending. Permanent moulds made of carbon or similar material are being tried; and the founder is just realising the fact that micrographic analysis has a commercial value. In short, in all branches of his work he is showing a praiseworthy desire to emerge from the slipshod ways of the past. The literature of the subject has, however, remained meagre, and not of a strikingly scientific character. Scattered through the pages of the Journal of the Iron and Steel Institute and of the iron trade journals there is much information of permanent value; but the special treatises on the subject are mostly of an elementary character. The exhaustive work by Mr. McWilliam and Mr. Longmuir may therefore fairly be regarded as marking an epoch in the history of iron founding, and should help greatly in effecting a clear understanding of the subject. The authors possess special qualifications for the work they have undertaken. Mr. Longmuir has held the position of foundry foreman, and is a Carnegie research medallist of the Iron and Steel Institute, while Mr. McWilliam, a distinguished Associate of the Royal School of Mines, has at the University of Sheffield had ample opportunity of ascertaining the needs of students. They have therefore been able to draw upon experience gained under normal foundry conditions and under the conditions of experimental laboratories, and the operations they describe have been personally followed.

The subject-matter is dealt with under the following heads: General properties of matter; moulding sands; facing sands; foundry tools; moulding-boxes; handling material in the foundry; open sand moulding; cores; elementary aspects of moulding; green-sand moulding; securing cores in moulds; moulding from guides; bench, outside, and plate moulding; machine moulding; dry sand moulding; loam moulding; chill casting; casting on to other metals; weighing and binding moulds; shrinkage, contraction, and warping; dressing castings; common faults due to mould and pattern; wrought iron; cast iron; refractory materials; fuels and furnaces; mixing by analysis; further treatment of cast iron; high-temperature measurement; steel; metals other than iron; alloys; mechanical testing; micrographic analysis; common faults due to the metal; and foundry management. The illustrations, of which there are 246, have been carefully chosen, and, like the letterpress, are exceptionally well printed. From this enumeration of the contents it will be seen that, although bearing the comprehensive title of "General Foundry Practice," the work is almost entirely devoted to iron and steel founding. Metals other than iron are disposed of in some twenty pages, brass founding receiving chief attention. The ingenious *cire perdue* process of bronze casting is not mentioned, nor is the modern method of casting in sections bronze statuary of heroic size, such as Bartholdi's "Liberty" at New York and Schwanthaler's "Bavaria" at Munich. The plaster moulds used for this purpose might have been added to the green sand, dry sand, loam, and chilled moulds described by the authors. A few lines, too, might have been devoted to the moulds used for metals with low melting points, brass, slate (for toy soldiers), wood, and even paper (for stereotype plates) being employed.

As the eye of the metallurgist wanders up and down the authors' well-filled pages, it will be arrested by that section which deals with the influence of the various impurities in cast iron. Phosphorus, it is shown, increases the fluidity of cast iron and renders the metal suitable for art castings, such as those for which the Russian works at Kyschtym are famous. Sulphur tends to make castings harder and brittle. Silicon, by tending to throw the carbon out of the combined form and to make it appear in the metal as graphite, has a beneficent influence. Manganese, on the other hand, has a tendency to keep the carbon in the combined form. These facts have to be borne in mind in mixing by analysis, a method which, it is gratifying to find, is steadily replacing mixing by fracture, by guesswork, or by trial. As the underlying science of the founder's art becomes more and more clear, well-marshalled knowledge is increasingly helpful. As the authors point out, the real theoretical knowledge of the man of science is built on experiment, and his theories are tested by further experiment. The practical man constantly meets with difficulties in his work; and he also must, in a truly scientific way, devise a remedy by testing the results of his former experience. The apparatus may be cruder than that of the laboratory, but it will be used with a subtle judgment of the needs of the case. The man who combines a scientific training with practical experience is gradually, but surely, becoming the dominant type of industrial captain in the best equipped foundries.

The book is unusually free from typographical and other errors, and there is little in the arrangement of the material to which exception can be taken. It might perhaps have been well to have carried the subject a stage further, and to have given the student some information regarding the galvanising, nickel-plating, lacquering, and porcelain enamelling of castings, and regarding the repairing of faulty castings by melting in iron by means of the electric arc or the oxyhydrogen blowpipe. Pattern making is altogether ignored. It is true that it is a distinct trade involving the skill of the joiner and the turner. A practical founder should nevertheless have a general knowledge of the construction of foundry patterns; and the elaborate patterns, sharply chased in a tin-lead alloy, used for ornamental castings present many features of interest to the foundry managers and foremen for whom the work is primarily intended.

OUR BOOK SHELF.

Eversley Gardens and Others. By Miss R. G. Kingsley. Pp. x+280. (London: George Allen, 1907.) Price 6s. net.

It is always stimulating to meet with enthusiasm, and Miss Kingsley is not only an enthusiast with regard to individual plants, but possesses a keen eye for their artistic setting and arrangement. Eversley is situated on the Bagshot beds in a part of Hampshire that has received the *sobriquet* of "the rubbish-heap of the world"; and as much of Miss Kingsley's experience was gained in laying out and cultivating the garden of Keys House, in Eversley, her success may serve as a help to other amateurs whose energies are also concentrated on poor soil.

It would appear that roses have been Miss Kingsley's chief delight, especially the teas, hybrid teas, and climbers. She presents a lengthy choice, arranged in colour groups, containing besides such universal favourites as G. Narbonnand, Frau Karl Druschki, and Caroline Testout, others less generally known, as Madame Ravary, Coquette de Lyon, and Monsieur Trillier. The list of rhododendrons, a plant that finds a congenial home on the Bagshot soil, is especially noteworthy, and the plan of growing bulbs in peat fibre in bowls is recommended as a clean and rapid method for producing fine flowers. While it is probable that most gardeners will find many hints and references to species unknown to them, it is certain that all can learn much from the artistic combinations described by the author, some produced in her own garden, others in her friends' gardens.

The Friendly Stars. By Martha Evans Martin. With introductory note by Prof. Harold Jacoby. Pp. ix+253; illustrated. (London and New York: Harper and Brothers, 1907.) Price 5s. net.

Evidently written by one who for years has been in the habit of looking upon the stars as companions, rather than as conglomerations of known and unknown elements, this volume will appeal to the beginner in astronomy and to the general reader quite as much as to the astronomer.

After dealing generally with the apparent movements and with the brightest stars, the author proceeds to thirteen chapters containing causeries on particular stars, describing the relative position of each, its seasonal apparitions, its diurnal path, and its colour, &c., adding a few words as to the distance and physical conditions of each star.

More general problems are then discussed, such as the numbers, distances, and light of the stars. A brief chapter on double stars gives an excellent first idea of multiple systems, and is followed by nine chapters dealing with the constellations, frequent diagrams illustrating the text. By those who simply wish to recognise the individuals of the starry host, and to be *au fait* with sufficient characteristics of each to mark its individuality, the volume will be found a useful companion. W. E. R.

On the Evolution of Wound-treatment during the Last Forty Years. By Sir Hector C. Cameron, Professor of Clinical Surgery in the University of Glasgow. Pp. 96. (Glasgow: James MacLehose and Sons, 1907.)

THE appearance of this book at the present time is opportune, for the lectures deal very largely with Lord Lister's researches on antiseptic treatment, of which they form a brief history. Lister's treatment was founded on Pasteur's demonstrations and writings, and no man ever acknowledged an indebtedness more often and more unequivocally. At the commencement of the first lecture the procedure adopted in 1860, or thereabouts by Mr. Syme, the period immediately preceding the introduction of antiseptics, is detailed. In 1868 or so Lister's first method of treating wounds antiseptically was being tested by its author. This consisted in swabbing the wound with undiluted carbolic acid (a crude and impure preparation at that time) and covering it with lint saturated with the same substance, over which a piece of sheet-lead was placed; each day the lead was removed and the lint painted over with the carbolic. By such treatment, crude and simple as it may now appear, it was abundantly demonstrated that wounds, even the dreaded compound fracture, would heal without suppuration. Subsequently, a putty consisting of whiting and carbolic acid was used, and step by step carbolic gauze, corrosive sublimate, mercuric iodide, and the cyanide gauzes were evolved. The author holds that no mere dressing with dry sterilised wool or gauze, apart from germicidal solutions, will suffice to prevent suppuration in dirty wounds, and with this pronouncement many will cordially agree.

Vortex Philosophy: or the Geometry of Science Diagrammatically Illustrated. By C. S Wake. Pp. 36. (Chicago: Published by the Author, 1907.)

"As negation is the expression of energy and position is the expression of force, the elements of undulation, which is the dynamic aspect of the molar energy light, are expansion in the atomic field and ionisation in the molecular field; and the elements of spiralisation, which is the dynamic aspect of molar force (gravitation), are contraction in the atomic field and convergence in the molecular field" (p. 20). This extract shows that Mr. Wake has an extensive vocabulary. and a fund of unconscious humour. His pamphlet has no scientific value. but is amusing in its way as an attempt to classify all human knowledge on principles ostensibly scientific and logical. but really vague and æsthetic. Even from this point of view the coloured diagrams vii. and xii. are unsatisfactory.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The August Draconids—Perseid Fireballs.

IMMEDIATELY after coming out to watch the northern sky on August 15 at 9h. 23m., I observed a second-magnitude meteor appearing stationary at the point $288° + 61°$, near *o* Draconis. Four other meteors were seen directed from precisely the same position during a watch of forty minutes later on the same night, but clouds came over before 10h. 30m., and though the sky cleared at a later hour I did not look out again.

This radiant point in Draco is nearly identical with that of a brilliant shower of fifty-six slow-trained meteors which I observed on 1879 August 21 to 25. I also recorded it in several other years, but it was very feebly represented. It appears to be visible both in July and August, but though I have often eagerly awaited it, the striking activity it displayed in 1879 has never been repeated. Possibly this year it may have returned more richly than usual, and I trust other observers recorded it while watching the later stages of the Perseid shower.

The following are the positions I have obtained for the Draconic radiant in past years:—

(1)	1888, July	8-13	... $290° + 59°$ ...	4	Slow.
(2)	1885, ,,	9-13	.. $290 + 60$ ...	5	Slow.
(3)	1900, ,,	24-30	... $291 + 59$ ...	6	Rather slow.
(4)	1899, Aug.	12-16	... $293 + 60$ ...	8	Medium.
(5)	1901, ,,	15	.. $290 + 60$ ...	3	Rather swift, suspected.
(6)	1900, ,,	16-18	... $291 + 60$ ...	5	Slow.
(7)	1887, ,,	20-24	... $289 + 60$ ...	5	,,
(8)	1879, ,,	21-25	... $291 + 60$ ...	56	,,

Of all the meteors seen during the recent Perseid display, one of the finest appeared on August 12 about 11h. 12m. It was recorded at Bristol and at Stockport, and at the latter place Mr. J. P. Kenyon estimated that it burst out so brilliantly as to give a flash equal to the light of the full moon.

The object fell from a height of seventy-nine miles over Donington, Lincolnshire, to forty-four miles over Market Harborough, Leicestershire. Its length of visible course was fifty-two miles, and observed velocity forty-one miles per second. Other observers probably noticed this fine meteor, and I will be glad to receive further descriptions of its apparent path with a view to determine its real course more accurately.

There was another magnificent Perseid which gave a flash like lightning as it descended in the Milky Way north of Aquila, on August 13 at 14h. 10m., but the only account of this is one from Mr. W. Lucking, of Manuden, near Bishop's Stortford. W. F. DENNING.

Bishopston, Bristol, August 19.

The Heating of a Balloon Wire by Lightning.

THE following account of the heating of a balloon wire by a lightning discharge is interesting as furnishing approximate limits for the energy of the discharge.

Report by Mr. S. F. Cody on Striking of a Balloon by Lightning on July 22, 1907.

"At about 11 a.m. on Monday, July 22, a captive balloon, carrying meteorological instruments, was in the air. Some 4500 feet of 19 S.W.G. tin-plated piano wire was between the balloon and the winch. The balloon was probably about 3500 feet high. The winch was exceedingly well earthed, standing on a large solid iron plate, which was also buried about $1\frac{1}{2}$ feet in the earth.

"I was trying to locate the balloon, which was hidden by clouds at the time, when a flash of lightning came crossing horizontally, and then a quick stroke to the earth.

"Being unlike anything I had ever seen before, I set about inquiries to find out whether the wire had been struck or not. No smoke appeared from the flash. There was a deep hissing noise, followed by the natural crash of the thunder some seconds afterwards.

"The hissing noise was probably the wire falling, as it was in many cases driven 2 or 3 inches into the earth. I was about 180 yards from the winch in the same direction as the wire, and about forty yards from directly under the wire to the left, looking from the winch.

"The balloon went away free, carrying the instruments, and was watched for several minutes, as it happened to pass through a clear portion of the sky where no clouds were at the time. It has not since been recovered.

"On investigation of the wire I found that near the winch, say about 250 yards from it, the wire became less tempered; in fact, it would stand bending quite well in the portions found near the winch. It was fused right off at the first wheel of the winch, and was undamaged at the drum of the winch.

"The weather was sultry; there had been some rain. The wind was light but squally, W.N.W. There had been no lightning previously.

"The following are some observations taken on the ground about an hour before the wire was struck:—

Dry bulb	18° C.
Wet bulb	15°·8 C.
Barometer	29·85

Wind, N.W. to W.N.W.

"Specimens of the wire enclosed."

It appears from the specimens of wire that the heat developed was sufficient to melt the tin but not to fuse the wire. If then we assume that the process is too rapid for loss of heat by conduction, we get for the limits between which the heat energy must lie $6\times1400\times200\times0{\cdot}11$ and $6\times1400\times1300\times0{\cdot}18$ in gram degree units, the wire weighing about 6 grams per metre, and the mean specific heat of steel from 0° C. to 1300° C. being taken to be 0·18.

In ergs the limits become $7{\cdot}12\times10^{12}$ and $8{\cdot}28\times10^{13}$, or, assuming the height of the cloud to be 100 metres, the energy was sufficient to raise 73 kilograms, but not sufficient to raise 840 kilograms, to the cloud level.

The fact of the wire being less brittle in the lower portion points to a diminution of the energy developed, but no reasonable explanation of this is apparent unless it is due to an induction effect.

In the case of a similar discharge on April 11 of this year, the wire was completely fused from the balloon to the winch; the length of wire out was half a mile, and the height of the balloon 2000 feet. The balloon was in the clouds at the time. The discharge in this case also took place by a cross flash from cloud to balloon. An account of the occurrence is given in a paper by Colonel Capper, read before the Royal Meteorological Society in May. E. GOLD.

Meteorological Office, 63 Victoria Street, London, S.W., August 19.

The Origin of the Domestic Striped Tabby Cat.

IN the Proceedings of the Zoological Society for February of this year I attempted to prove that English domestic cats are to be referred by their patterns to two distinct kinds, which were described as the blotched and striped tabbies; and in discussing the possible origin of these two cats, I set the blotched tabby aside as of unknown descent, and stated it as my conviction that the striped tabby was to be traced to the interbreeding of two well-known wild species, namely, the European wild cat (*Felis sylvestris*) and the so-called Egyptian or African wild cat (*Felis ocreata*). There were living at that time in the Zoological Gardens a male example of *F. sylvestris* from Scotland and a female example of *F. ocreata* from Uganda. The latter was captured as a kitten near Nairobi in March, 1906, and had never been put to a male. To test the truth of my belief that the progeny of these two species would resemble our domestic striped tabby, and also to discover if there was any foundation for the theory some authors had put forward previously that the blotched tabby was the result of such a cross, the two cats in question were placed in the same cage this summer. They took to one another at once, and last week the female produced a litter of kittens resembling in every respect a typical striped tabby such as may be seen any day in the streets of London. R. I. POCOCK.

Zoological Society's Gardens, August 18.

A Fossil Tsetse-fly in Colorado.

AMONG the interesting materials obtained this year in the Miocene shales of Florissant, Colorado, is a large "biting" fly, with a remarkably long and strong proboscis, very well preserved. A very superficial examination was sufficient to show that it was no ordinary Tabanid or Muscid, and it at once occurred to me that it was a tsetse-fly. Having no specimen of the latter at hand, I turned to the admirable coloured figures in the second report of the Wellcome Laboratories at Khartoum, and, as was expected, it matched so nearly that it might well go in Glossina. There is a slight difference in the venation which may or may not be of generic value, but if the insect is not a Glossina it is at least closely allied. Curiously, it is not new, for it appears to be the species described by Scudder in 1892 as *Palocstrus oligocenus*, a supposed new genus of Œstridæ. The new specimen, practically complete, and with the mouth-parts, shows that it has nothing to do with Œstridæ, and anyone who will refer to Scudder's figure will see how closely the venation resembles that of Glossina.

The specimen obtained this year was found by Mr. George N. Rohwer, a member of our party from the University of Colorado. It is an obvious suggestion, following some remarks lately published by Prof. Osborn, that the existence of such flies may have had something to do with the extinction of some of the Tertiary Mammalia of America. T. D. A. COCKERELL.

University of Colorado.

PHYSICS AND CHEMISTRY.

"ONE of the penalties of devotion to a progressive science is the constant feeling of being left behind." So says the president of Section B, in his address from the chair, at the recent meeting of the British Association; and although he adds that he does "not think there is any occasion for panic," yet the concluding portion of his address seems to indicate that something approaching fear accompanies the impression that the progress of science at the present time is almost too rapid. There were some other indications, also, at the meeting, that physics at the present time is mistrusted by some chemists, to an extent perhaps beyond ordinary and necessary caution.

With a great part of the address agreement is easy. The plea that chemists should continue chemists, and that accurate manipulation and careful experimenting should be strenuously cultivated, is so reasonable as to be almost trite: for who would have it otherwise? That an atomic theory of matter, which has proved so useful in the past, should be adhered to as a guide in the future is also a natural desire against which no physicist has a word to say. Indeed, very much the contrary: the atom of matter is as useful a conception as ever, and has become even more real and concrete owing to the actual counting and measuring of individual atoms by physicists. But that physicists and mathematicians should leave the atom alone, and refrain from discomposing examination into its probable internal structure, should cease to break it up and otherwise modify it by appropriate agencies, and should turn a blind eye to any spontaneous explosions of energy whenever they have the bad taste to occur; also that no element shall be discovered and named which has zero chemical affinity, or which cannot be obtained in weighable amounts—all that is surely more than Section B has any right to expect, nor do I suppose that it seriously makes such a demand.

But the worst of a pessimistic outcry about the over-rapid development of science is that it is taken up by the general public, one section of which is always hoping that what is unintelligible is really meaningless, and may be safely ridiculed or ignored. So it has happened that a strange sentence in Prof. Smithells's address, which I will quote directly, is made the text for a singular attack by a leading article writer in the *Times* of August 6 apparently against the Cambridge school of mathematical and experimental physicists, which for a long time now has been in the eyes of the world one of the scientific glories of this island. The quotation is as follows:—

"There is never more cause for anxiety than when we see a mathematical theory awaiting the delivery of the confirmatory facts; and there is nothing more important for chemistry than the continual recruiting of that old guard which will be ever ready to stand to arms on the appearance of an eager theorist."

Now it is an old and recognised tradition that mathematical prediction of a fact to be subsequently confirmed by experiment is the highest achievement of science. The clearer the prediction, and the more rigorous the subsequent verification, the greater should be the joy among all those who wish for the advancement of natural knowledge.

That the theory should be completely intelligible to those comparatively ignorant of mathematics, until the fact has been arrived at experimentally, is not to be expected; and that a few should suppose that the prediction is only really forthcoming after the event—which is when they first hear of it—is also not unnatural. But the preparation of a theoretical niche for a fact, either just discovered or just on the verge of being discovered, is a piece of work involving the highest faculty of scientific insight; and it is to be hoped that the public are not going to be misled into a depreciation of the work of all except those who, very rightly, collect an assemblage of facts.

There is room for workers of all kinds towards the progress of science, and the encouragement and countenance of the public is one of the conditions; for often enough the difficulties of the work itself are more than discouraging, and if uncertainty as to its reception or appreciation by the contemporary human race is to be added, then it is to be feared that the discouragement may in some cases become complete. Such a catastrophe actually happened in the case of Thomas Young; but it was not the outcome of a meeting of the British Association for the Advancement of Science.

Probably the real intention of the president of Section B was to caution certain physical chemists, and perhaps to restrain or rebuke some of the Ostwald school in his own section; a matter well within his jurisdiction. Indeed, if he only wishes to express dislike at an attempted replacement of ordinary dynamics by a vaguer "energetics," he will find sympathisers among the physicists; as witness the following quotation from an article by the late G. F. FitzGerald in NATURE for March 12, 1896 (reproduced in his collection, "Scientific Writings," p. 387), with reference to an article by Prof. Ostwald called "Emancipation from Scientific Materialism." I must add, however, that FitzGerald was a keen admirer of the work of Prof. Ostwald in general, though in this particular doctrine, especially on its negative side, he did not consider that he was on a hopeful path. The quotation is as follows:—

"There are so many vague fallacies underlying it, that it would hardly be worth answering, only that there is considerable risk that others, chemists especially, may be carried away by the arguments of one whom they rightly value as a leader in their own domain, when he descants positively about the realm of mechanics."

For the present purpose I need not enter upon a discussion of this matter: there is doubtless much that can be said on both sides. If the president of Section B had so expressed himself as to drive home this kind of caution among the members of his own section, without appearing to refer to better known and more immediately prominent subjects of debate, I should have said no word; and I desire it to be clearly understood that I am not now expressing any opinion on this subject. But, unfortunately, that is not how his address has been regarded from outside, nor is it the interpretation to which certain phrases, such as "chemistry of phantoms," "exuberance of mathematical speculation," readily lend themselves. It is in the hope that damaging misunderstanding may be avoided that this article is written. OLIVER LODGE.

A TRIAD OF SPORTING BOOKS.[1]

TO the author of the volume standing first on the list given below, the wilderness from time to time calls with such persistence and force that to hear is practically to obey; and, whether to shoot wild goats in the Taurus, to collect vultures' and eagles' eggs in Asia Minor or Spain, or to track the lordly moose and the branching-antlered caribou in the wilds of the far North-West, Mr. Selous returns year after year with unabated zest to the roving life of his earlier South African days. That the public benefits from this restless disposition can scarcely be denied, for although he cannot be credited with anything special in the matter of literary style, the author of "Recent Hunting Trips" writes with that freshness and *verve* that almost transports the reader to the very scenes of his adventures and triumphs. Nor is this all, for Mr. Selous is essentially of a generous nature, and it is but seldom that he returns from one of his sporting trips without some important addition accruing to the national museum.

In the volume now before us, the author gives an account of his experiences during several shooting trips to British North America, undertaken between the years 1900 and 1906 (inclusive) in search of moose, caribou, and wild sheep; these, which include two visits to Newfoundland, comprising the whole of his hunting in this portion of the New World. In the preface, Mr. Selous records his opinion with regard to the closure to the sportsman of the central districts of American Alaska—an opinion worth quoting, as it has a bearing on so-called game-preservation in other parts of the world. Although the sportsman, who would be content with a few good trophies of male animals to add to his collection, is completely shut out, the game is by no means protected. The Indians, for instance, armed with modern weapons, can apparently shoot as they will, and spare no animals of either sex or of whatever age which come in their way, while meat-hunters of European blood are no less destructive. Although the Indian doubtless has the justification that he shoots, in part, at any rate, for his own maintenance, yet it is he and his white fellow-countrymen who, in the author's opinion, will ultimately bring about the extermination of the game with which the land now abounds, unless the whole system of game legislature is altered, and that speedily.

[1] "Recent Hunting Trips in British North America." By F. C. Selous. Pp. 400; illustrated. (London: Witherby and Co., 1907.) Price 16s. net.
"Game and Game Coverts." By John Simpson. Pp. 83; 15 plates. (Sheffield: Pawson and Brailsford.) London: County Gentlemen's Association, Ltd., 1907.) Price 15s.
"How to Fish: a Treatise on Trout and Trout-fishing." By W. E. Hodgson. Pp. xii+377. (London: A. and C. Black, 1907.) Price 3s. 6d. net.

Although from the point of view of bodily stature the moose (or elk, as it is commonly called in England) is undoubtedly the finest animal in this part of the world, the various races of caribou (or reindeer) are calculated to attract the interest of naturalists to a special degree on account of the incredible numbers in which they occur, not only on the mainland, but also in the almost untrodden heart of Newfoundland; while their periodical migrations in certain districts are among the most wonderful phenomena in big-game life. Not the least marvellous feature in these "treks" is the manner in which whole herds sometimes swim in company, so as to form in certain cases, as described by a recent traveller in Labrador, a veritable living bridge. In other cases, however, they travel in small parties, or even in pairs, lying down to rest or pausing to feed as their inclinations prompt.

FIG. 1.—Caribou on migration. From "Recent Hunting Trips in British North America."

"On one occasion," writes the author, "herd after herd of caribou passed the end of the lake in full view from where we were sitting. These herds were all small, consisting of from three or four to ten animals. They were all following the same trail, and were evidently migrating from the north-east to the south-west. Although they kept stopping to feed they travelled fast, often trotting as if alarmed."

With the assistance of various friends, the author has been able to illustrate his book with a number of striking photographs of migrating caribou, some showing the animals as they traverse the scrub in well-beaten tracks, and others their appearance when swimming lakes or rivers. As a permanent memento of the latest trip, reference may be made to the two magnificent caribou shot by the author and presented by him to the British Museum (Nat. Hist.), where they are now set up in the mammal gallery, one of these representing the large dark-coloured *Rangifer tarandus osborni*, and the other the smaller and whiter *R. t. terrae-novae*. Special interest, it may be added, attaches to the mention (p. 73) of the manner in which the spreading feet of the caribou enable the animal to traverse boggy ground, where horse, ox, or ass would be helplessly mired. Lack of space prevents mention of a number of interesting points in this fascinating book of adventure and sport, but we must refer to the author's measurement of his finest bull moose (p. 215), the height of which is given as 6 feet 11 inches. Reference must also be made to an interesting opinion in connection with wild sheep, namely, that the white *Ovis dalli* probably grades into the grey *O. fannini*, and the latter into the black *O. stonei*. The view that these sheep are but local races of the Kamchatcan *O. nivicola* is supported; the true *O. canadensis*, like the true grizzly bear, having departed further from the northern type owing to its having travelled further south, and perhaps having entered the country at an earlier date than the others.

The second (like the third) work on our list is entirely for the stay-at-home sportsman, and is intended to emphasise the importance of much greater care being exercised by game-preservers as to the culture of covert suitable for different kinds of game. Hitherto the general practice has been to let coverts grow more or less as they will; but the author, who has had great practical experience of the subject, shows that this is altogether wrong. Not only is one kind of tree or bush specially suited to particular species of game, but care is needed in order that such trees or bushes may have proper opportunities for full development. A case in point is afforded by the blackberry bramble, which needs open space and sun, when it affords not only excellent covert, but also a valuable food-supply. In this connection it may be mentioned that in Mr. Simpson's opinion gamekeepers err in over-feeding their charges; which, to say nothing of economical considerations, would be far better in many ways if left to get their own living in properly planted coverts. Game-preservation, according to the author, is likely to become more and more profitable to English landlords; and special attention is directed to the economic value of rabbits on estates. The special feature of the book, which should be in the library of every landowner and game-preserver, is the beauty of the illustrations of different kinds of covert, when properly developed; the most exquisite of all being the photograph of a mound of blackberry bramble in fruit.

Sometimes we venture to think that authors do not select sufficiently comprehensive titles, but in the case of Mr. W. E. Hodgson's book, standing third on our list, the main title seems to err in the opposite direction. For in place of instructing the angler in the art of alluring river-fish of all kinds, this volume, as, indeed, is indicated in its supplementary title, tells him only how to capture the wily trout. Since, however this is, *par excellence*, the sporting fish of English rivers, there may be some justification for the designation. The author has already published a more ambitious work on trout-fishing, which has, we believe, been well received by anglers; but that volume is intended mainly for the benefit of those who are already experts in the gentle art, whereas in the one now before us it is sought to instruct the beginner in the elementary principles of trout-fishing.

Mr. Hodgson is evidently one of those who believe that salvation is to be found otherwise than by "dry-fly" fishing; and a considerable portion of his work is accordingly devoted to other methods, inclusive of spinning with minnows, and luring with the luscious wasp-grub. That the author will not please every angler in all details may be regarded as a matter of course; but, speaking generally, he seems to have treated his subject in a manner which ought to satisfy those who are making their first essays at trout-fishing. The book is well illustrated, and likewise contains a number of observations on the natural history of the subject, and, indeed, on nature-study generally.

R. L.

GENETICS.[1]

THE last contribution to the fast-increasing pile of Mendelian literature is unique. It is at once the bulkiest, within the limits of two covers, that has been made to this subject, and at the same time the most condensed, the most varied, and the most valuable.

The third International Conference on Genetics, held under the auspices of the Royal Horticultural Society, and under the presidency of Mr. Bateson, was a veritable Mendelian orgie. The history of all new theories is the same. They are judged not so much on their own merits as on the number and variety of natural processes, previously unintelligible, which they explain. The result of the publication of the "Origin of Species" was, as Mr. Bateson has pointed out, the distraction of the attention of biologists from the process of evolution itself and its diversion into the hitherto dry channels of palæontology, classification, embryology, comparative anatomy, and distribution. It was not until the end of the nineteenth century that men returned to the study of evolution. The relation between man and a new theory is the same as that between a child and a new toy. When we first get the toy we are occupied in playing with it in every possible way, and as often and as much as we can. But when all legitimate sources of interest have been tapped, we tire of playing with the toy and begin to wonder how it works; and to satisfy our curiosity, we pull it to pieces. The result of the attempt to satisfy this curiosity in the case of Darwin's theory was the growth of a conviction that natural selection did not provide a sufficient explanation of the diversity of organic forms. The history of Mendelism has been like that of Darwinism. The flood of energy let loose by the re-discovery of Mendel's papers has spent itself rather in work based on the assumption that the interpretation which Mendel put on the facts he discovered was true than in the attempt to discover whether that interpretation were true or not; and in our opinion it is right that this should be so. The merely critical spirit is a barren one. The enthusiasm of the kind which follows the birth of a new theory such as Darwin's or Mendel's has been as productive of discovery in the case of the latter as it was in that of the former. At the same time, we should not forget that Mendelism is now in the stage in which Darwinism was before it was subjected to the process of being overhauled; and though we may perhaps be right in holding that criticism is barren of discovery, we should guard against the possibility of entering that frame of mind which regards criticism as blasphemy. Mendel's peas have already been called classical; and it is a very remarkable fact that no one has repeated Mendel's experiments with the deliberate intention of testing the Mendelian interpretation of the results. People speak as if Mendel got to the bottom of the inheritance of roundness and wrinkledness, yellowness and greenness, and as if there was nothing more to be said on the subject. On p. 88 of the report before us there is a table exhibiting the result of crossing a yellow with a green pea to the fifth generation. The proportion of pure yellows, impure yellows, and greens is given both for the fourth and for the fifth generation as 1 : 2 : 1, and it is stated on the bottom of p. 88 that this process of segregation "will be continued "practically for ever." It is highly probable that the three categories do form respectively 25, 50, and 25 per cent. of generations four and five; but Mendel never published any figures which prove this to be so. All he said was: "The proportions in which the descendants of the hybrids develop and split up in the first and second generations presumably hold good for all subsequent progeny. Experiments one and two have already been carried through six generations, three and seven through five, and four, five, and six through four, these experiments being continued from the third generation with a small number of plants, and no departure from the rule has been perceptible."[1]

We offer no apology for adopting this critical attitude towards Mendelism. There is plenty of admiration for "Mendel's incomparable achievement," and we share it; but we do not find it impossible to combine it with a suspicion that Mendel's interpretation of his results may not have been right after all.

The report is, of course, absolutely indispensable to every student of genetics, whether his interest is purely scientific or purely horticultural, or both. The keynote of the conference was struck by a pealing of the marriage bells of Science and Practice. We could have no better guarantee that their union will be fertile than that their hands were joined by the Rev. W. Wilks, who has earned the gratitude of every student of heredity by editing this report, and of every lover of flowers by creating the Shirley poppy.

NOTES.

PROF. H. LE CHATELIER has been officially nominated professor of chemistry at the Paris Faculty of Science in succession to the late Prof. Henri Moissan.

IT has been decided by the Paris Municipal Council to perpetuate the memory of Prof. Berthelot by renaming the Place du Collège de France the Place Marcelin Berthelot.

WE regret to have to record that Prof. Karl Vogel, director of the Astrophysical Observatory at Potsdam, died on August 13.

WE regret also to have to announce the death of the Rev. Dr. John Kerr, F.R.S., formerly lecturer on mathematics in the Glasgow Free Church Training College.

[1] Report of the Third International Conference, 1906, on Genetics. Edited by Rev. W. Wilks. Pp. 486. (Printed for the Royal Horticultural Society by Spottiswoode and Co., Ltd., n.d.) Price 15s.

[1] This is Bateson's translation in Mendel's Principles, p. 57. The original may be consulted most accessibly at p. 26 of No. 121 of Ostwald's Klassiker der exakten Wissenschaften, Versuche über Pflanzenhybriden. Price 1 mark.

THE death, from heart failure, of Sir William Robertson Copland took place at Glasgow on Monday last. Sir William Copland made a special study of drainage and of water supply, and took great interest in promoting technical and university education, being chairman of the governing body of the Glasgow and West of Scotland Technical College, and a member of the Glasgow University Court. He was knighted last year.

DR. WILLIAM THOMSON, who died at Philadelphia on August 3 at the age of seventy-four, had not only written largely on medical and surgical subjects, but had introduced several reforms in field service. At the battle of Antietam, in the American Civil War, he abandoned the old practice of bringing all the wounded into one hospital, and improvised a number of smaller hospitals in various parts of the field. The success of this innovation led to its adoption during the rest of the war, and later in the Franco-German War. Dr. Thomson will be further remembered for adopting the local application of carbolic acid as a disinfectant in the treatment of wounds, and for the introduction, in connection with the Pennsylvania Railroad, of the testing of engine-drivers for colour-blindness.

A REUTER telegram states that the instruments of the chief seismographical station at Hamburg registered several earthquake shocks in the afternoon of Saturday last. Slight shocks were recorded at about 1.22 p.m. and shortly after 2 p.m., while at 6.40 p.m. the instruments began to record a series of distant shocks of medium strength, which lasted nearly two hours. The disturbance reached its height shortly before 7 p.m., and ceased at about 8.45 p.m. It is estimated that the earthquake occurred at a spot 8000 kilometres south-east of Hamburg; a seismic shock was also recorded at Grenoble at 5h. 43m. 40s. on the same day.

IT is announced in *Science* that the yearly sum of 5000 dollars has been voted by the Minnesota Legislature towards the maintenance of a Pasteur institute at Minneapolis.

A CIRCULAR letter has been distributed by the president and general secretaries of the second International Congress on School Hygiene concerning the important new departure made by the congress in the matter of school hygiene. Arising out of the question of whether it would not be advisable to establish a bureau, with a permanent staff, library and museum, &c., in some central but neutral spot, such as a Swiss or Dutch town, it was decided that it would probably lead to greater progress if such bureau was not localised, but if each country had its own centre for the diffusion of knowledge, and to act as a clearing-house in the matter of school hygiene, statistics, laws, and regulations. Finally, to supervise in scientific matters and generally to do all that is possible at all times or places to forward the human interests which are bound up in the special lines of knowledge included in school hygiene, the International Committee has formed a small council, consisting of the president of the past congress, the president of the one lately held, the president of the next congress, and nine other members to be elected, which will have all the powers of an ordinary committee. The following questions will come under the consideration of the council almost immediately:—How medical inspection of schools can best be carried out with the maximum of efficiency and minimum of cost; how far the laws of health can best be imparted to the coming generation, so that later they will know how to care for themselves and those dependent on them; the best systems or methods of physical training for both sexes at various ages; and the feeding of children requiring proper nutrition, so that it shall be done without developing pauperism and with regard to those upon whom the cost falls.

IN reply to an inquiry put to him in the House of Commons as to whether, in view of the work already accomplished by the Liverpool School of Tropical Medicine in combating tropical diseases, he could arrange for an increased grant to be made in order that the work might be further extended, the Under Secretary for the Colonies said that a further grant will be made, of which the Secretary of State will be able to specify the amount after consultation with the Treasury.

THE Keith prize (consisting of a gold medal and 50*l.*) has been awarded by the council of the Royal Society, Edinburgh, to Dr. T. H. Bryce for his two papers on "The Histology of the Blood of the Larvæ of *Lepidosiren paradoxa*," published in the Transactions of the society.

THE seventh International Physiological Congress met in Heidelberg last week, with Prof. Kossel as president. About 300 members were present, and 200 communications were made in the four sections into which the congress was divided. At the opening meeting Prof. Kronecker paid a glowing tribute to the late Sir Michael Foster. Prof. Dastre, of Paris, gave a short biography of the late Sir J. Burdon-Sanderson, while Prof. Sherrington spoke of the loss sustained by the congress through the deaths of Prof. Errera, of Brussels, and Prof. A. Herzen, of Lausanne. By order of Grand Duke Friedrich of Baden each member of the congress was given a bronze medal in memory of the meeting. The medal bears on one side an impress of "Helmholtz—MDCCCLVIII–MDCCCLXXI."

THE French Congress of Medicine will be held in Paris under the presidency of Prof. Debove from October 14 to 16. It is proposed to hold discussions on, among other subjects, the question as to the origin of pulmonary tuberculosis; acid-resistant bacilli; the therapeutic action of radium; ionic medication; the use of collargol; the therapeutic value of tuberculin; and the serumtherapy of dysentery and cutaneous sporotrichoses.

THE third International Sanitary Convention is to be held in the city of Mexico from December 2 to 7 next. Each delegate attending is expected to bring a paper relating to the nation represented by him, with a report on the existence of any transmissible diseases—especially bubonic plague, yellow fever, cholera, malaria, beri-beri, and trachoma—that may prevail within its boundaries. Among the questions to be discussed are the transmission of yellow fever, the means to be used in combating the *Stegomyia fasciata*, tuberculosis, and various administrative measures.

THE eighteenth annual general meeting of the Institution of Mining Engineers will take place in the Firth Hall of the University of Sheffield on September 4, when the following papers will be read, or taken as read:—The sinking of Bentley Colliery, by Messrs. J. W. Fryar and Robert Clive; roof-weights in mines, by Mr. H. T. Foster; and deep boring at Barlow, near Selby, by Mr. H. St. John Durnford. A number of visits to collieries, works, &c., have been arranged.

THE recent opening of the medical academy at Düsseldorf was, according to the Berlin correspondent of the *Lancet*, an event of some importance, and was attended with considerable display. The academy and that at

Cologne have a two-fold object. In the first place they import a new feature into medical study by introducing newly qualified men to the practical side of medicine more than is done at the universities. After the university medical curriculum has been completed and the State examination has been passed, the practical year which is required by recent regulations may be spent at the academics. Their second purpose is to supply the medical practitioners of the district with opportunities for post-graduate study. The Düsseldorf Academy is the first for which clinics and lecture-rooms were specially built, because at Cologne the existing municipal hospitals were adapted for teaching purposes. The structural and other arrangements are described as excellent, and the clinical material will be abundant. Prof. Witzel, formerly of the University of Bonn, is the director of the new academy, while the teaching staff includes Prof. Schlossmann in the subject of pædiatrics and Prof. Lubarsch in the subjects of pathology and pathological anatomy.

THE Paris correspondent of the *Chemist and Druggist* states that the committee on analytical methods has defined the programme for the competitions for the prizes offered for alcohol-denaturation in connection with the law of November 29, 1905. This Act instituted two prizes, one of 800*l.* for the discovery of a "denaturator" more advantageous than those now used while safeguarding the revenue against frauds, and a second (value 2000*l.*) for a system of utilising alcohol for lighting in the same manner as paraffin. The denaturator must have a taste and smell which will effectually discourage any desire to use the alcohol as a beverage; wine or date must, oil of thyme and rosemary, and similar flavours are thus eliminated. The denaturant should not be sufficiently objectionable in smell to prevent its domestic or industrial use—thus acetylene, asafetida, and garlic are excluded. No soluble substance which could leave a deposit on lamp-wicks, and thus render combustion difficult, may be used, such as sea-salt, sodium sulphate, alum, ammonium chloride, potassium ferrocyanide, picric acid, tobacco-juice, and aloes. It must not consist of a substance much more or less volatile than alcohol, and which could thus (besides other disadvantages) be removed by fractional distillation, as ether, carbon bisulphide, light fractions of petroleum or turpentine, cresyl, carbolic acid, camphor, or naphthalene. It should contain no substance which might injure the metallic part of lamps or motors (ammonia, nitrobenzene, sulphuric acid). It should not be poisonous (as mercuric chloride, methyl cyanide, sodium arseniate, and aniline) or contain poison (hyoscyamus, aconite, or digitalis). It should be sufficiently inexpensive, should not normally exist in commercial alcohol, and its presence in alcohol should be capable of easy and certain detection.

A PRIZE of 150*l.* is offered by the German Colonial Society for a method to produce an extract from mangrove bark that will impart as light a colour as possible to leather, and such as will only slightly darken by exposure to light. The mangrove bark contains a large amount of tannin, and also a red colouring matter that prevents the bark and its extract from successfully competing with other tanning agents. The problem to be solved is the practical removal of this red colour. Competitors are invited to send in particulars of their methods by July 20, 1908, to Deutsche Kolonialgesellschaft, Schellingstrasse 4, Berlin.

THE Board of Agriculture is considering the terms of an order prohibiting the importation of plants and bushes bearing edible fruit, except by a licence to which conditions will be attached, with the object of preventing the introduction of the gooseberry mildew and other pests injurious to horticulture.

ACCORDING to *Engineering*, an Australian record in wireless telegraphy has been achieved by the successful transmission of messages from H.M.S. *Challenger*, one of the Australian squadron at present stationed in Hobson's Bay, to the flagship *Powerful*, which at the time was moored in Farm Cove, Port Jackson. The *Challenger* was in communication with the flagship by means of wireless telegraphy the whole of her voyage. The longest message was one flashed over a distance of 410 miles in a direct line, and this constitutes an Australian record, as previously never more than 240 miles had been achieved by warships on the Australian station.

ACCORDING to *Science*, an equatorial telescope has been given to the Nantucket Maria Mitchell Association, and plans of an observatory to house the instrument are being considered. An appeal has been made for funds properly to equip the observatory that it may be available for astronomy classes in the near future.

A MEMORANDUM, dated August 5, issued by the Director-General of the Egyptian Survey Department, on the meteorological conditions of the monsoon season and the prospects of the Nile flood, is far from encouraging. The rains in June and July have been exceptionally weak, and some 16 per cent. of an average flood volume may be considered as deficient at the above date. On the whole, Captain Lyons thinks it more probable that this deficiency will be increased in August than that it will be diminished.

IN the *Meteorologische Zeitschrift* (part iv., 1907) Dr. V. Conrad gives an epitome of an interesting lecture delivered by him on the formation and constitution of the clouds. The author points out that to obtain a clear idea of the subject we require to know (1) the size of the separate fluid drops, (2) the rate of their descent, and (3) the number contained in a cubic centimetre. An idea of the pains bestowed upon the inquiry may be formed from the fact that sixty-nine references to authorities are quoted in the paper. The size appears to have been first microscopically measured by Kratzenstein, who published the results at Halle in 1746; recent measurements by Assmann, Dines, and others give their mean diameter as about 20 μ, or 10^{-3} cm. radius. The vesicular theory was not displaced until A. Waller published his paper in the Phil. Trans. in 1847, and subsequent investigators showed that the optical phenomena observed in clouds could only be explained by the existence of complete drops; much information upon this subject will be found in Dr. Pernter's "Meteorologische Optik." The researches of Stokes and others have shown that a droplet of 10^{-3} cm. radius would fall 1 cm. per second in calm air; with increasing radius, up to a certain limit, V increases with r^2, so that a drop of 10^{-2} cm. radius would attain a velocity of 1 metre per second. From independent investigations the author found the number of drops ($r=10^{-3}$ cm.) in a cubic metre of dense cloud to be 10^9 (a thousand millions), or 1000 in a cubic centimetre. The question of the formation of the first condensation elements is one of great difficulty, since it has been shown by Aitken and others that the presence of some nucleus in the atmosphere is necessary; possibly observations made in balloons may eventually elucidate the matter.

The important position occupied by the electric spark in wireless telegraphy will account for the many attempts which have been made in recent years to obtain some knowledge as to its effective resistance. The principal methods used fall into two groups, based either on the original resonance arrangement of Bjerknes or on the substitution process of Simons. Unfortunately, the two groups give different results, and Dr. W. Eickhoff has rendered valuable service by his examination of the validity of the various methods which appears in the *Physikalische Zeitschrift* for August 1. He comes to the conclusion that deductions as to the most suitable arrangements for telegraphic purposes cannot legitimately be made from results obtained by the method of Simons.

The memorandum of the Manchester Steam Users' Association for the year 1906 consists mainly of a report on the tests of pressure gauges carried out at the National Physical Laboratory and the remarks of the chief engineer of the association on these tests, and on pressure gauges in general. The ten gauges tested were all by trustworthy makers and of first-class workmanship, and the report of the tests states that, as regards freedom from friction and backlash, they leave little to be desired. Greater agreement between the records at different temperatures ought to be aimed at, and for gauges subject to vibration some form of balancing should be adopted. The whole report will be of great value to pressure-gauge makers, and may be taken as a typical illustration of the way in which improvements can be brought about by the cooperation of manufacturers and an institution like the National Physical Laboratory.

Dr. C. Nordmann, of the Paris Observatory, published several years ago in the *Annales de l'Observatoire de Nice*, vol. ix., a theory of the diurnal variation of terrestrial magnetism, according to which the convection currents of the upper atmosphere, crossing the lines of magnetic force, generate electromotive forces which, in a region rendered conducting by solar radiation, produce electric currents and so affect the magnetic needle. In the March number of *Terrestrial Magnetism* he shows that the observations he made in Algiers during the total solar eclipse of August 30, 1905, confirm a deduction from his theory, namely, that during an eclipse the magnetic needle should tend to return from its normal position at the time of occurrence of the eclipse towards its mean position for the day.

Parts i. and ii. (comprising 335 pp. and 18 plates) of vol. lxxxvii. of the *Zeitschrift fur wissenschaftliche Zoologie* are occupied by an elaborate paper on the comparative developmental history of sexual individuals in the hydroid polyps. The author, Mr. A. Goette, of Strassburg, formulates some important conclusions with regard to this development, which are, however, too complex to be summarised within our limitations of space.

In a paper on the navicular of the tarsus of man and monkeys, published in vol. xli., part iv., of the *Journal of Anatomy and Physiology*, Mr. T. Manners-Smith describes and illustrates the remarkable variations obtaining in that bone in the human subject. In some degree, at any rate, these variations appear to be connected with the degree of mobility of the foot, certain features being more constantly developed in this bone in the skeletons of ancient Egyptians than among modern Europeans. The occasional existence of a separate element in the tuberosity of the navicular is also noticed.

From the astounding feat accomplished by Prince Borghese in his wonderful journey in a motor-car from Pekin to Paris, many lessons may be drawn. The greatest, the *Engineer* of August 16 points out, is the wonderful adaptability of the power-driven vehicle. The distance traversed is estimated at 7000 to 8000 miles, and the time occupied was sixty-two days, the daily average being about 121 miles. When the time is taken off for pulling the car through loose sand and for extricating it from morasses, the speed seems almost incredible, considering that for half the journey there were practically no roads. Serious obstacles were encountered. Overwhelmed in a cyclonic sandstorm, dragged through rivers, precipitated from a weak bridge into a fast-running river below, immersed in bogs, the wood-work of the car on fire, and being nearly run into by a train on the Trans-Siberian Railway, were a few of the experiences of the intrepid traveller, any one of which would be sufficient to stop most people from continuing such a perilous journey.

On August 17, 1807, Robert Fulton's steamer, the *Clermont*, ran her trial trip from New York to Clermont, and in order to commemorate the centenary of steam navigation, an interesting account is given in the *Engineer* of August 16 of the events that led up to this development. Illustrations are given of the paddle-wheel steamboat *Clermont* and of her machinery.

The prospects of the Indian manganese ore industry are discussed by Mr. A. Ghose in the Journal of the Society of Arts (August 2). The demand for Indian manganese ore has grown with great rapidity. In 1905 the export to Great Britain amounted to 71,600 tons, whilst last year the total amounted to 490,612 tons, valued at 865,443*l*. India supplied most of the manganese ore used in the British furnaces, Brazil with 127,257 tons being second, and Russia following with 103,270 tons.

An interesting account of the Museum of Traffic and Engineering at Berlin is to be found in the August number of the *Engineering Magazine*. The museum is located in the old Hamburg passenger railway station, which has, however, been thoroughly reconstructed for the purpose so far as its basement is concerned. The museum has three main departments, devoted to railway, naval, and civil engineering respectively. Explanatory notes are added to many of the exhibits, and in some instances a cross-section is given to illustrate the internal arrangement. Some of the models may be worked by visitors, and to these a special notification is attached. Models of plant of exceptional interest are to be demonstrated and explained from time to time by officials of the institution. In addition to models, the museum possesses many diagrams, photographs, statistical tables, a reading room, and library, all of which should make it of real service to engineers.

The extension section of the Manchester Microscopical Society has sent us its new list of lectures arranged for delivery by members of the society during the coming winter in Yorkshire, Manchester and district. The work of lecturing and demonstrating is entirely voluntary and gratuitous on the part of the members, but a charge is made for the hire of slides, travelling, and out-of-pocket expenses. The purpose of the section is to bring scientific knowledge, in a popular form, before societies unable to pay large fees to professional lecturers, but in all cases where lectures are given before societies which are commercial undertakings, or are subsidised out of Government or public grants, a fee is charged in addition to the out-of-pocket expenses. All fees paid for lectures are devoted to the working expenses of the section.

In a paper by Mr. W. F. Allen on the subcutaneous vessels of the head in certain fishes, published in the Proceedings of the Washington Academy of Sciences (vol. ix., p. 79), we regret to observe that Lepidosteus, the well-known name of the bony pike, is changed to Lepisosteus. Even if the latter be the original rendering, the former is grammatically correct, and should be maintained. We have also received copies of two papers on Mendelism, one by Mr. C. B. Davenport and the other by Mr. O. F. Cook, published in the same series. Variation and correlation in the crayfish, by Messrs. Pearl and Clawson, and researches on North American Acrididæ, by Mr. A. P. Morse, form the subject of papers issued by the Carnegie Institution of Washington, of which copies have reached us.

ACCORDING to the report in the July number of the *Victorian Naturalist*, Mr. F. C. A. Bernard selected as the subject of his presidential address to the last annual meeting of the Field Naturalists' Club of Victoria the increased facilities for the study of natural history in Australasia since 1880. After a well-deserved compliment to the Linnean Society of New South Wales, which he believed to be the only organisation existing at that date in Australia devoted solely to promoting the interests of natural history, the president traced the origin and progress of the numerous bodies which now exist for the same purpose.

IN an illustrated pamphlet entitled "The Brent Valley Bird Sanctuary" (published, at the price of sixpence, by the local branch of the Selborne Society) Mr. W. M. Webb gives a picturesque account of an attempt to encourage and protect the bird-life of the district. A wood of some nineteen acres in extent has been secured and put in charge of a keeper, and it is satisfactory to learn that it has afforded nesting sites for twenty-seven species of birds.

AN addition to the fauna of the British Isles is recorded by Mr. J. W. Taylor (in the *Irish Naturalist* for August) in the shape of *Vitrina elongata*, a land mollusc inhabiting the mountains of many parts of the Continent. The Irish specimens were discovered in 1904 and 1905 near Collon, county Louth.

THE contents of vol. xl. of *Neue Denkschriften der allg. schweiz. Gesellschaft* (1906) include an article by Dr. Theodor Studer on additional remains of the ground-sloth, *Grypotherium listaei*, from the well-known cavern of Ultima Esperanza, S. Patagonia. Separate copies of this article were issued in 1905. The author confirms the opinion that this ground-sloth inhabited the cave contemporaneously with aboriginal man, by whom it appears to have been kept in a semi-domesticated state. These aborigines seem to have been identical with the ancient Patagonians. Grypotherium appears to have been a stouter-built animal than Mylodon, with the orbital region of the skull smaller. Stratigraphists will find much to interest them in an article in the same volume by Dr. E. Gerber, of Bonn, on the geology of the Alps to the eastward of Kienthal, embracing the district between that valley and Lunterbrunnen.

A BULLETIN (No. 4) from the Agricultural Research Institute, Pusa, indicates the preliminary arrangements in connection with a series of fruit experiments initiated under the direction of Mr. A. Howard. The planting, pruning, and manurial experiments are in the main similar to those at Woburn. In addition, weathering experiments are proposed, which consist in removing the soil from round the stems and laying bare the roots for a period after the close of the rains; the object is to check vegetative growth, especially before the flowering period. The largest plots are planted with citrus fruits, peaches, mangoes, litchis, and figs.

IN plant experiments to test Mendelian principles several apparently anomalous results have been obtained by crossing white-seeded strains with plants having coloured seeds. In papers published in *Science*, vol. xxv., Nos. 646 and 647, Dr. G. H. Shull refers to results obtained by crossing the flowers of white flageolet beans with those of black-, brown-, and yellow-seeded forms in which the hybrids showed purple and mottled characters. The author adopts the explanation offered by Cuénot that in such a case there are three characters, the pigment character P, the purple modification B, and the mottling M. The black beans show PB dominant, M recessive, the white beans show all three characters dominant. Therefore, instead of considering the *allelomorph* or distinguishing character as necessarily single, Dr. Shull holds the view that it may be compound.

SEVERAL important contributions to the study of the proteins of the wheat grain have been made from time to time by Dr. T. B. Osborne in conjunction with other collaborators. The results have been brought together in Publication No. 84 of the Carnegie Institution of Washington, in which is given a full account of the experimental work, as well as a brief review of the literature. It is found that ***gliadin***, a protein soluble in 70 per cent. alcohol, and ***glutenin***, which together constitute the substance ***gluten*** obtained by washing the dough, form nearly the whole of the proteins in the endosperm; in the embryo the proteins are much smaller in amount, and consist chiefly of globulin, an albumin termed ***leucosin***, and a proteose.

AN article by Mr. H. A. Smith entitled "Saving the Forests" appears in the *National Geographic Magazine* for the present month, and deals with the work of the United States Forest Service, which has charge of Government resources valued at 1,500,000,000 dollars. The U.S. national forests contain more than 150,000,000 acres. In economic usefulness the forests increase in importance almost day by day, and they are fast becoming self-supporting. In the year ending June 30, 1904, the national forests yielded a total revenue of 60,000 dollars, while for the year 1906–7 the sum realised amounted to 1,600,000 dollars, and it is thought that by 1910 the receipts from this source will be equal to the appropriations for the forest service.

ON account of a remarkable discovery of reptilian footprints, the Higher Bebington sandstone quarry at Storeton, Cheshire, has been visited by many geologists during the past year. From time to time Cheirotheroid, Rhynchosauroid, and Chelonoid footprints have been found at this quarry, but since the present owner introduced a stone-channelling machine much more work is being done, and the slabs are got out with less breakage. The quarry, which is worked in the Keuper Sandstone, has a vertical face of 130 feet, and at two horizons half-way down the face occur two thin beds of marl on which the interesting footprints are found, and casts of them occur on the layer of sandstone immediately overlying the marl. Photographs, by Mr. G. J. Williams, of the face of the quarry and of some of the footprints are reproduced in the report of H.M. Inspector of Mines for the Liverpool district for 1906 (Cd. 3449, vi.).

THE *Journal of Hygiene* for July (vii., No. 4) contains a number of interesting articles. Among others, Castellani shows that human yaws is transmissible to monkeys, and that in the lesions, spleen, and glands the same spirochæte (*S. pertenuis*) is present as in man.

AN interesting account of the evolution of the steam turbine and a sketch of the career of its inventor—the Hon. C. A. Parsons, F.R.S.—by Mr. A. A. Campbell Swinton, appears in the current issue of the *World's Work*. Other articles of scientific interest in the number are "Lobster Farming," by Mr. F. A. Talbot, dealing mainly with the work carried on at Mill Cove, Wickford, Rhode Island, by Dr. A. D. Mead, and "Scientific Taxidermy," by Mr. H. J. Shepstone. The two last-named contributions are strikingly illustrated.

WE recently published a review of part i., vol. i., of "Research in China," dealing with descriptive topography and geology (NATURE, August 8), and have now to record the receipt of part ii. of the same volume of the work. The bulk of the section before us treats of petrography and zoology, and is the work of Mr. Eliot Blackwelder, but there is also a syllabary of Chinese sounds by Dr. Friedrich Hirth, professor of Chinese at Columbia University. The work is issued by the Carnegie Institution of Washington.

A SECOND edition of "Impianti Elettrici a Correnti alternate semplici, bifasi e trifasi" has recently been received from Mr. U. Hoepli, Milan. The book forms one of the very practical series of Manuali Hoepli, and will be of service to students and electrical engineers able to read Italian.

MESSRS. A. AND C. BLACK announce a book entitled "The Norwegian Fjords," which is to be written and illustrated by Mr. A. H. Cooper. The work will describe the home life, domestic industries, religion, superstition, and folk-lore of the peasants of Norway.

THE Patent Office has just published a subject list of works on military and naval arts, including marine engineering, in the library of the Patent Office.

OUR ASTRONOMICAL COLUMN.

DANIEL'S COMET, 1907*d*.—This comet is now at its maximum brightness, and with a clear sky and good horizon may be seen quite easily by the naked eye for some time before sunrise. Its naked-eye magnitude on August 12 was estimated to be equal to that of μ Geminorum, about 3·5.

The comet rises about 25° north of east, in London, at about 2 a.m., and on August 22 will be some 12° 11′ directly south of Pollux.

Two excellent photographs of this object were secured by M. Quenisset, at Juvisy, at 2 a.m. on July 19 and 20 respectively, and are reproduced in the August number of the *Bulletin de la Société astronomique de France*. On the former date the photograph showed five tail streamers, but on the latter seven were to be seen on the plate. The longest tail extended some 4° from the nucleus, representing at least some 12,000,000 kilometres (7,500,000 miles); on July 20 the diameter of the nucleus was about 4′, or 173,000 kilometres (about 108,000 miles).

SEARCH-EPHEMERIDES FOR COMETS 1894 IV. AND 1900 III. —No. 4195 of the *Astronomische Nachrichten* (p. 319, August 7) contains two sets of search-ephemerides, one by Prof. Seares for the De Vico-E. Swift comet (1894 IV.) discovered in 1894, but not seen on its return in 1901, the other by Herr Scharbe for Giacobini's comet, 1900 III.

The former was referred to in these columns on August 1, and the comet's brightness on August 25, according to the ephemerides, will be either 0·61 or 0·86, its brightness when its magnitude was 13·1 (November 21, 1894) being taken as unity.

Ten alternative ephemerides are given for comet 1900 III.

MARS.—In a telegram published in No. 4195 of the *Astronomische Nachrichten* (p. 323, August 7), Prof. Lowell announces that the Martian double canal Gihon has been photographed as double both by Mr. Lampland and himself.

In Bulletin No. 30 of the Lowell Observatory the same observer discusses the results of the observations of the North Polar Cap of Mars during the period March–June, 1907. It appears that the cap commenced quite suddenly and in an extensive manner just as it did in 1903 and 1905, and on practically the same date, the Martian August 22–23. Further, the first frost melted again on the succeeding days and was followed by another fall a little later, again as it did in 1903 and 1905.

This striking fact led Prof. Lowell to investigate mathematically the problem of the daily insolation upon a planet, and he shows that the Martian phenomenon is in accordance with his deductions.

Among other points he demonstrates the existence of an atmosphere sufficient to retard the general deposition of frost by some nineteen days. He also states that the arctic and antarctic regions of Mars are actually warmer in the Martian summer than are ours, although the mean temperature of the planet, 48° F., is some twelve degrees less than the mean temperature of the earth.

THE TOTAL ECLIPSE OF JANUARY, 1908.—From No. 114 (p. 167, vol. xix., June 10) of the Publications of the Astronomical Society of the Pacific we learn that arrangements have been made for an expedition from the Lick Observatory to observe the total solar eclipse of January 3, 1908.

Only two islands are crossed by the shadow-path, and of these the Lick expedition has selected Flint Island (long. 151° 48′ W., lat. 11° 26′ S.), which lies in the central Pacific Ocean some 390 miles north-west of Tahiti.

Under the existing conditions the eclipse will occur at 11h. 18m. (local mean time), with the sun 15° from the zenith. The duration of totality, according to the American ephemeris, will be 4m. 6s.

The expedition, the sending of which has been made possible by the generosity of Mr. William H. Crocker, will leave San Francisco on November 22, journeying thence to Tahiti, and will be conveyed from the latter island by a U.S. gunboat.

At the instigation of Prof. Campbell, Prof. Abbot, of the Smithsonian Institution, will accompany the Lick expedition in order to secure bolometric observations of the corona. The two expeditions will be independent scientifically, but will be united in the travelling and subsistence arrangements.

In the August number of the *Observatory* (p. 333, No. 386) it is tentatively suggested that it may be possible for some European astronomer, who could not otherwise see the eclipse, to obtain some assistance from the Lick expedition.

THE LEEDS ASTRONOMICAL SOCIETY.—The fourteenth annual Journal and Transactions of the Leeds Astronomical Society contains some interesting papers communicated by the members during 1906.

An observatory, in connection with the University and the city council, was opened on May 4, 1906, on Woodhouse Moor, and contains an 18¼-inch Newtonian reflector and a transit instrument. These instruments are to be used by members of the University staff, certain university students, teachers and selected students from the Education Committee's schools and by members of the astronomical societies.

Among the papers published in the Journal, one may mention a discussion of the existence of an intra-Mercurial planet, an illustrated description of the immense Jai Singh observatories located at Benares, Delhi, and Jaipur, and a lengthy discussion of Tennyson's astronomy.

THE MAKING OF MOUNTAINS.

THE profound impression made on contemporary geological thought by what is known as the Schardt-Lugeon theory of overfolding is well seen in Herr H. Hoek's last paper on "Das zentrale Plessurgebirge" (*Berichte d. Naturforsch. Gesell. zu Freiburg i. B.*, Bd. xvi., 1906, p. 367). In this he completely modifies his reading of the district, published three years ago, in favour of one that brings it into structural harmony with recent views as to the existence of "Ueberschiebungsdecken," "Nappes de recouvrement," or overlapping and overthrust recumbent folds. The region south-east of Chur has received a good deal of geological attention, and Herr Hoek claims that it now falls into its place as a structural link between the overfolded areas of Switzerland and the Austrian Alps. His paper is written in a considerately argumentative spirit that provides cheerful reading, and concludes with a tilt at Rothpletz, who has sprung into the same field of inquiry. Both writers agree, however, that the overlying rock-sheets of the Plessurgebirge have been brought into the area from a distance; and that is the point which interests the watchers of the tourney.

Dr. W. Hammer, in a review of the above paper (*Verhandl. d. k.k. geol. Reichsanstalt*, 1906, p. 383), evidently regards it as an attempt to put an old wine of good quality into new and uncertain bottles. But Herr G. Steinmann adopts Hoek's typical landscape of the four overthrust sheets above Parpan in his "Geologische Probleme des Alpengebirgs" (p. 40), and he has had ample opportunity of discussing the structure with the author. Steinmann's paper, published by the Deutscher und Österreichischer Alpenverein at Innsbruck in 1906 (Bd. 37 of their *Zeitschrift*), is a delightful exposition of the older and later views, beginning with the Juras and ending in the east of Switzerland, and is written for the ordinary traveller as well as for the geologist. The landscapes, in which the beds are duly labelled, are accompanied by an admirable series of sections, often showing the two rival readings, and gathered from various authors. Steinmann's own sections show clearly the stages of growth which are held to have culminated in the system of overfolds in Switzerland. This lucid paper seems to us perfect for its purpose, and the author is able, in his separately issued copies, to reproduce Dr. von Seidlitz's panorama from the Künihorn, which was published in part only in the *Zeitschrift des Alpenvereins*.

Herr Schardt himself has furnished, in the *Verhandlungen der Schweizerischen Naturforschenden Gesellschaft*, St. Gallen meeting, 1906, p. 308, a welcome account of "die modernen Anschauungen über den Bau und die Enstehung des Alpengebirges." Already this distinguished author suffers from an extremist group of followers, and he humorously characterises some of Termier's work as an exhibition of "Ultranappismus." The coloured sections illustrating Schardt's paper supplement this very clear exposition of his views. On p. 343 he emphasises the importance of gravitational sliding in producing certain features of steeply elevated and compressed folds, and points out that this influence has been too often underestimated.

Travellers in the most familiar part of Europe will also profit greatly by Herr A. Baltzer's "Das Berneroberland und Nachbargebiete" (Berlin: Gebrüder Borntraeger, 1906, pp. xv+347). The price of this handy book, 12.50 marks, includes a general volume, which has not yet reached us, though it was announced to appear during last winter. Rothpletz's work on the overfolded area of the Rhætic Alps, to which Hoek refers in the paper above noticed, has been published in the same "Sammlung geologischer Führer." Baltzer's volume starts in the Bernese Juras, among the romantic *cluses*, guides the pedestrian of geological tastes to the typical sections around Grindelwald, and brings him back by the St. Gothard railway and Lucerne. The illustrations are not always so neat as those of Steinmann, but cover a great amount of detail. The transparent sheets on which the names of the rock-layers are printed, which are used as indexes to several of the photographs, strike us as a little awkward in a book that must be used in all weathers in the field. Among the many useful diagrams is one (Fig. 69) showing the folded strata as viewed from the steamer on both sides of the lake of Uri.

Dr. C. Sandberg (Transactions of the Geological Society of South Africa, vol. ix., Johannesburg, 1906, p. 82) gives a new reading of the folded structure underlying "the innocent looking, softly undulating Karroo Formation" in the Prince Albert district of Cape Colony. The country, with its bare kopjes and its abundance of rock-exposures, lends itself to stratigraphical investigation. The Tygerberg shows on its south side the Witteberg series resting on the Dwyka conglomerate, which properly overlies it, while the Dwyka series occurs again on the north side of the hill. This can be explained by fan-structure, the Witteberg series coming up along a local anticline, which has expanded southward as an overfold. Though various authors show various dips, the anticlinal view has been generally accepted. Dr. Sandberg, however, quoting the magic names of Schardt, Lugeon, and Termier, reads the structure as the downward-turned, or, shall we say, pseudo-synclinal, end of an overpushed anticline, the root of which lies away in the Zwartebergen to the south. Mr. A. W. Rogers, who is invoked by the writer, points out that a section quoted from him in support does not touch the Tygerberg, and he evidently prefers the older view for the present (Proceedings to accompany the above volume, 1907, p. liii.). But Dr. Sandberg's paper serves as a fresh indication of the keenness and vitality that prevail in South African geology.

It is evident that very few geologists now doubt that overfolds occur in the earth's crust, whereby strata are moved from their place of deposition over distances amounting to even 100 kilometres. If we grant ten miles for such movements in the north of Scotland, we do not find it unreasonable to allow seventy miles of overthrusting in the more crumpled region of the Alps (see Sir A. Geikie's remarks, Abstracts of the Proceedings of the Geol. Soc. of London, April 10, p. 67). But the admission raises serious questions as to what happens in the foundations underlying these compressed areas of the crust. Dr. Ampferer, in a lengthy and closely reasoned paper on "Das Bewegungsbild von Faltengebirgen" (*Jahrb. der k.k. geol. Reichsanstalt*, Bd. lvi., 1906, pp. 539–622), rejects the theory that localised crumpling is due to the approach of great earth-blocks in the contracting crust. He urges, moreover, that there is nothing in any complex group of rocks, such as we ordinarily find folded together in a mountain-chain, to account for the folding in that particular locality. The local structure determines the details of the architecture (p. 607), but the position of the chain on the earth must be referred to the nature of the plastic foundation, the "Untergrund." The composition of the earth's interior is by no means uniform (pp. 608 and 609), and both physical and chemical changes in it may produce considerable alterations of volume in one portion or another. These alterations are manifested at the surface, in the sensitive skin of the earth, as local subsidences or elevations. The vertical movements of the foundation lead to gravitational sliding, which affects the overlying skin (p. 601), and it is suggested that the folded mountain-chains are formed along lines of more or less intense vertical upheaval, from which the fundamental masses then flow away sideways, producing the overfolds and crumplings that we perceive upon the surface. The underflow, the "Unterströmung," is thus Ampferer's main cause of surface-folding, and changes in the living and mobile "Untergrund" determine where "Unterströmung" shall occur.

We trust that in these few words we have correctly represented Dr. Ampferer; for the paper is not an easy one, and the absence of references to the details shown in many of the diagrams renders these of little help as illustrations. Fig. 41, however, on p. 611, shows suggestively how the irregularities of the foundation or "Untergrund" may be ascertained by a comparison of the geological history of areas on the earth's surface. Areas with similar foundations may be expected to subside together or to be elevated together during geological time. It is easier to estimate the amount of subsidence that took place during any epoch than the amount of elevation, the latter being marked by no characteristic sediments; but we may hope eventually to represent the history of an area by a curve rising or falling in reference to a datum-line, the time-scale being indicated on the latter. Prof. Steinmann, in the paper above noticed, has employed similar curves for various regions in the Alps. Dr. Ampferer holds that a similarity in the curves for two or more areas would imply a general similarity in the foundation. This seems to leave out of count Mr. Osmond Fisher's suggestion of convection-currents in a liquid interior, which might produce considerable local differences in the curves; but the absence of all reference to previous workers, except a passing one to Schardt's and Lugeon's theory of over-folding, makes it uncertain how far Dr. Ampferer wishes to link himself with his predecessors. While admitting (p. 620) that his criticism has been largely of a destructive order, he feels hopeful that future research may make us better acquainted with the "Untergrund."

Dr. Ampferer's paper was written in March, 1906, but was not issued until December. Meanwhile, Mr. R. A. Daly had published a paper on abyssal igneous injection as a causal condition and as an effect of mountain-building (*American Journ. of Sci.*, vol. xxii., September, 1906, p. 195). Ampferer does not believe in geosynclinals and subsequent lateral compression; but it is precisely these that Daly sets out to explain. He urges that the underlying molten magma, which he believes to be of basaltic composition, is always ready to leap into any cracks that arise in the plastic layer above it and in the "shell of tension" in the lower portion of the crust. Cracks may arise in the plastic layer by the effects of tidal torsion on the crust, and in the shell of tension by the general contraction due to cooling. The igneous mass in the great dykes thus produced, so long as it remains liquid, exercises a hydrostatic pressure on its walls, and forces them further apart. Here we have a cause that may close up other cracks in the shell of tension, and the total lateral creep "involves a strong downward pull exerted on the shell of compression," *i.e.* that part of the crust above the level of no strain. The resulting geosynclinal area finally becomes weakened, as sediments accumulate in it and its underlying rocks are bent down into hotter regions; and then, in some way which is rather lightly dealt with, an "orogenic collapse" takes place, and a mountain-chain begins to rise. The increase in bulk of the crust by magmatic injection, which was, by the by, well pointed out by Mr. Osmond Fisher, is urged as an additional cause of its crumpling, and the hydration of its minerals gives similar assistance. The shearing apart of the shell of compression and the shell of tension "during the orogenic revolution releases the tensions still unrelieved in the underlying shell," and allows of further abyssal injection on a large scale. The location and elongation of mountain-chains and geosynclinals are all (p. 216) related to special zones of abyssal injections from the substratum. Here we see Mr. Daly looking, like Dr. Ampferer, for final causes in the "Untergrund," and with this point of agreement we must for the moment rest content.

Still more recently (March, 1907), Dr. L. Waagen publishes in the *Verhandlungen der k.k. geologischen Reichsanstalt* a general review of the relations of ocean-basins and mountain-chains. He finds the origin of folding in the subsidence of continental masses, and the continued sinking of the moving *Hinterland* of a chain may bring this region below sea-level, and so promote an interchange between continental and oceanic areas. Marine transgressions (p. 121) are thus the natural accompaniments of epochs of considerable mountain-building.

G. A. J. C.

THE SOUTH AFRICAN ASSOCIATION.

The report of the South African Association for the Advancement of Science (Cape Town, 1907), a handsome volume of 640 pages, affords striking evidence of the large amount of attention that is being devoted to scientific research in South Africa. The report includes the presidential address delivered by Mr. T. Reunert at Johannesburg in 1905, in which year the usual sectional meetings were not held, and minutes of the proceedings of the fourth meeting of the association at Kimberley in 1906. The address of the president, Mr. G. F. Williams, who was unable to attend the Kimberley meeting in 1906, contains an interesting historical sketch of the settlement of the Cape, of the adventurous spirit of the Portuguese, of the influence of the Dutch pioneers, and of the rush of adventurers from almost every part of the world, who laid the foundation of the mining industry of to-day.

The president of Section A, Mr. J. R. Sutton, gave a valuable summary of our present knowledge of the diurnal variation of barometric pressure, which may be considered as the fundamental problem in meteorology—the rise and fall of the barometer twice a day, the precise cause of which has never been satisfactorily explained. After referring to the efforts of Herschel, Dove, and others, the author pointed out that Dr. Buchan made a material advance in distinguishing between the weight and elasticity of the air. Perhaps the most important contribution to the subject is due to Prof. J. Hann, who by classifying and generalising the harmonic elements for a great number of stations succeeded in establishing some noteworthy results. Among the various papers read in this section, some of which have been published elsewhere, we may specially mention:—(1) Anticyclones and their influence on South African weather, by Colonel H. E. Rawson. An examination of the charts published by the London Meteorological Office, and of other data, showed that the weather in South Africa is under the direct influence of the movements of two great anticyclonic systems lying to the west and east. (2) The barometer in South Africa, by Mr. R. T. A. Innes. The author states that the annual variation of the barometer consists of a well-marked single oscillation, pressure being greatest in winter and least in summer. (3) Variability of temperature in South Africa, by Mr. J. R. Sutton, as represented by three typical stations, showing the mean difference between the temperatures of one day and the next. Prof. J. Milne contributed a paper on the observation of earthquakes and other earth movements, and Prof. R. A. Lehfeldt one on accelerations of gravity at Johannesburg.

At the various sectional meetings sixty papers were read, which are published in full or in abstract. Among these, noteworthy papers dealing with matters of local interest are, in addition to those already mentioned:—Rev. H. A. Junod, on the theory of witchcraft among South African natives; Rev. F. Reuter, on northern Transvaal ethnology; Mr. A. W. Rogers, on the glacial beds of the Griqua Town series; Mr. R. H. Rastall, on the petrography of the Kimberley district; Mr. F. P. Mennell, on the Somabula diamond field of Rhodesia; Mr. J. P. Johnson, on the Stone age of South Africa; Mr. F. A. Hurley and Mr. C. D. H. Braine, on irrigation in South Africa; Mr. K. A. H. Hought, on native education in its higher branches; and Mr. T. Lowden, on the place of manual training in South African education.

Of the sectional presidential addresses, that by Mr. Sidney J. Jennings, on wastes in mining, waste of thought, waste of labour, and waste of material, should be mentioned. Nothing has proved so efficacious for the prevention of waste of thought as the free interchange of ideas made possible by the numerous societies and associations. Centralised management can also be made to perform a valuable function in preventing thought-waste. In preventing waste of labour, the fundamental difficulties lie in the untrained condition of the Kafir for manual labour, and in the ineptitude of many white overseers for transforming a semi-savage population into an industrial one. The best prevention of waste of stores is the continued thought of the management combined with the loyal and interested cooperation of the men.

An account of a discussion on university education in South Africa is contained in the report. The discussion was opened by Prof. Lyster Jameson with a brief survey of the past history and present position of university education in South Africa, followed by a summary of the more obvious remedies for the present unsatisfactory state of affairs. There is a single university, the University of the Cape of Good Hope, an examining body pure and simple. In addition to the University, several institutions calling themselves colleges have arisen. In the Transvaal the only institution seriously doing university work is the Transvaal University College, which was founded as a full faculty of mining and engineering, adding its arts department at a later date. However great the disadvantage of federation or of separation, the greatest peril to university education in South Africa lies in the excessive multiplication of institutions with poor endowment and small, underpaid and overworked staffs. The discussion was well sustained; and, in summing up, the chairman, Mr. S. J. Jennings, pointed out that in Germany and England a population of a million could support a university. Roughly speaking, a population of a million in South Africa would correspond in fee-paying capacity with a population of two millions in Germany or England. It therefore seemed within the range of possibility that South Africa could support two universities.

INTERNATIONAL MARINE INVESTIGATIONS.[1]

THIS summary of the results so far obtained by the international investigation of the North and adjacent seas is drawn up by the executive committee of the Swedish Hydrographic-biological Commission, and is the second of its kind. Being well written, illustrated by good charts and plates, and demanding no great previous knowledge from the reader, it is one of those accurate yet popular accounts which, by educating public opinion in the utility of research, possess a real public value. Its slight unevenness is probably inevitable in the rapid survey of so wide a field, and it is to be regretted that the language in which it appears will restrict so narrowly the number of its readers.

The introduction patriotically reminds us that Sweden took the initiative in cooperation in marine research when King Oscar issued invitations to the conferences of Stockholm (1899) and Christiania (1900), and states the aim of the work to be, in the terms of a resolution of the latter meeting, "to prepare for the rational exploitation of the sea on a scientific basis." The aim is thus practical; the writers proceed at once to discuss the urgent practical question which played a considerable part in securing British participation in the international scheme, namely, the over-fishing question.

The belief that the catch of fish (mainly trawl-caught fish) was greater than nature replaced had arisen, declined, and revived when the international work began. Remedies had been proposed, and, being based on insufficient knowledge of the sea, had failed. The authors unreservedly include among the failures the closure of areas to trawling and the replenishment of the sea by fish-hatcheries; they speak hopefully of the value of market statistics, recognise the recent improvements in English methods of collection, and pass to the biological attack on the problem. This section is a little disappointing. Much has been ascertained concerning intensity of fishing, migration, &c., the bearing of which on over-fishing is not clearly brought out in the text. Since, for instance, over-fishing is stated to affect plaice mainly by reducing the average size at which they are caught, any experimental evidence of a possibility of increasing the rate of growth deserves close consideration; yet the promising results of transplanting plaice from crowded "nurseries" to good feeding-grounds where growth is more rapid are very briefly dealt with.

To make any proposal for restrictive legislation before the International Council has fully sifted the evidence collected on over-fishing seems premature, and, from the representatives of a country not greatly interested in trawling, even a little out of place. The writers, however, advise that each country fix an inshore size limit independently, while no plaice should be landed from offshore grounds of less length than 28 cm., that limit to be gradually increased to 33 cm. As to the practicability of enforcing this rather complicated scheme they are silent; possibly wisely.

Numerous biological researches are described, but by far the greatest detail is accorded to hydrography. Even Prof. Petterssen's theory of the effect of ice melting is included, although, as Nansen's "Northern Waters" has shown, it is still controversial. The Baltic hydrography is perhaps the freshest section for English readers. Hydrography gained much from cooperation; the standardising of instruments and reagents removed one frequent source of wasted opportunity in earlier voyages, by making all observations more strictly comparable, while the periodic cruises of the numerous vessels employed ensured regular observations over the whole great area involved. The main result has been the discovery that European seas are flooded every autumn by Atlantic water (of 35 per mille salinity or more) which withdraws in spring, and that many fisheries depend on these movements. Such a fishery is that of the Swedish "winter herring"; the fish is abundant, and the fishery prosperous when southern bank-water, of characteristic salinity, temperature and plankton, forms a thick layer in the Baltic entrances, while in years of exceptional abundance of Atlantic water this displaces the overlying bank-water, and a "bad herring year" results. These years occasion considerable distress.

The summary closes with appendices, some of which, semi-diplomatic documents now apparently published for the first time, are worth careful perusal by all interested in fishery legislation and research. One, written by Prof. Petterssen in reply to a question from the English Board of Agriculture and Fisheries, as to the probability of practical results shortly appearing, is especially interesting. Prof. Petterssen mentions the confusion of ideas and opinions that, owing to lack of knowledge of the sea, prevailed before the international work began, describes the results attained and the value set on cooperation by the investigators, and, speaking of the protection of immature fish, he makes the noteworthy remark, "International measures of this kind must be founded on strong and indisputable evidence. . . . Such evidence can only be the outcome of a joint investigation of the total area in question, executed by the best specialists of every nation concerned." These words constitute now, as they did three years ago, a weighty defence of international cooperation in fishery research.

[1] "Resultaten af den Internationella Hafsforkningens arbete under åren 1902–1906, och Sveriges andel därfuti. By G. Ekman, O. Pettersen, F. Trybom. Pp. 164. (Stockholm: Isaac Marcus, 1907.)

THE TRANSVAAL DEPARTMENT OF AGRICULTURE.

WE have received from the director a copy of the annual report of the Transvaal Department of Agriculture for the year 1905–6. The department was formed soon after the close of the war, and was placed under the charge of Mr. F. B. Smith, who had been trained at Cambridge and had gained experience as an agriculturist at Wye College, of which he was for some years the vice-principal. On his arrival in the Transvaal, Mr. Smith gathered round him a band of zealous and competent workers, and organised the new department on American lines, assigning the work to a number of "divisions." Each of these, while independent and under the charge of separate heads, was kept in close touch with the work of the other divisions through the director of the department and his office staff.

The report for the past year gives a *résumé* of the work on which the new department is now engaged, which should prove of interest not only to those directly concerned, but to many in our own country who may wish to know what the trained agriculturist can do to assist the development of the colonies. The most obviously beneficial work of the department is that of the veterinary division, which was formed partly to investigate the numerous diseases which threatened the live stock of the colony at the close of the war, but chiefly to check the spread of disease by treating diseased animals and by administering acts regulating their movements. The need for this type of work may be inferred from the fact that during the year 726 outbreaks of contagious disease were dealt with, 140,000 animals inspected, and 660,000 examined for soundness at the ports or on the borders of the Transvaal before being admitted into the country.

The acts regulating the movement of diseased animals have caused stock-owners some inconvenience and have been the subject of occasional complaints, but they have succeeded in a remarkable way in improving the health of the live-stock. For example, the disease known as East Coast fever, which at the close of the war was a serious menace to the cattle of the colony, has been overcome, and large areas have been altogether freed from it. In 1904–5 about 8000 cattle died of this disease; in 1905–6 the number was reduced to 800. As an instance of the protective measures adopted by the department, we may cite the case of rabies. The Transvaal is free from this disease, but it is found in Rhodesia, and in the hope of preventing its introduction a strip of country fifty miles wide, along the northern border of the Transvaal, has been entirely cleared of dogs.

A large part of the time of the chief of the division of botany is taken up by consultative work. Information upon new crops, weeds, poisonous plants, forest trees, &c., is in constant demand, and, apart from interviews and attendances at shows, this work alone involves the writing of some 3000 letters per annum. A herbarium is being formed. Some progress has been made in crossing and selecting maize, but it is remarked that, owing to the pressure of other work, plant-breeding has not hitherto received the attention it deserves. An important section of the work of the division is that which deals with plant pathology. A pathologist was recently appointed by the department, and the number of diseases which he has already observed is referred to in the director's report as "amazing." Special attention has been directed to the rusts, and five have been so far identified, viz. *Puccinia graminis* on wheat and barley, a second form of *P. graminis* on oats, *P. triticini* on wheat, *P. coronifera* on oats, and *P. maydis* on maize. Some attention has been directed to disease-resistant varieties, and stress is laid on the fact that a cereal which may be immune to the attacks of one rust may be very susceptible to infection by another; the practical conclusion is drawn that every effort should be made to obtain disease-resisting varieties, and that the continued growing year after year of the same variety of any cereal should be avoided as much as possible.

The chemical division has been engaged in an examination of soils, and attention is directed to the fact that the soils of the Transvaal are generally well supplied with potash, but are deficient in phosphoric acid, lime, and organic nitrogen. In conjunction with the veterinary division, the chemist has carried out an investigation into the composition of the bone of animals suffering from osteo-porosis, and he finds that affected bones are deficient in total ash, lime, and phosphoric acid. The normal proportion of nitrogen to total ash is about 1 : 14; in diseased animals the proportion is approximately 1 : 11.

The "division of publications" issues a quarterly journal, each number of which extends to some 300 pages; there are two editions, an English of some 8000 copies, and a Dutch of about 2000 copies. The journal contains original articles, notes from the various divisions, extracts from foreign journals and Government circulars, market prices, customs returns and other figures of interest to farmers. In addition to the journal, this division publishes leaflets and bulletins; among the latter, those written by members of the veterinary division upon the common diseases of the live stock of the colony have been of most importance.

It is satisfactory to learn that the work of the department commended itself to the Public Service Commission which inquired into the working of all branches of the Civil Service. The commissinn report emphasises the importance to the Transvaal of agricultural research, and goes on to state that it "has been impressed by the zeal, devotion, and business-like methods which characterise the Department at present, and that it finds itself unable to suggest any improvements in the organisation, or in the distribution of the business."

THE ARC AND THE SPARK IN RADIO-TELEGRAPHY.[1]

THE discovery by Heinrich Hertz between 1887 and 1889 of experimental means for the production of electric waves, and Branley's discovery that the conductivity of metallic particles is affected by electric waves, form the foundation on which, in 1896, Signor Marconi built up his system of wireless telegraphy.

Many of the early investigators certainly had glimpses of a future system of being able to transmit messages without connecting wires, for as early as 1892 Sir William Crookes predicted in the *Fortnightly Review* the possibility of telegraphy without wires, posts, cables, or any of our costly appliances, and said, granting a few reasonable postulates, the whole thing comes well within the realms of possible fulfilment.

Two years later Sir Oliver Lodge gave his memorable lecture on the work of Hertz, and carried the matter a step nearer the practical stage.

There will not be time to dwell to-night on the early history of the art and its development. It will be necessary, however, to explain some of the fundamental properties of signalling by means of Hertzian waves in order to be able to bring out clearly the relative advantages and disadvantages of the two rival methods now in practical use for producing Hertzian waves for wireless telegraphy.

The fundamental part of the transmitting apparatus may be said to consist of a long conductor generally placed vertically, in which an alternating or oscillating current is set up by some suitable means. Such a conductor radiates energy in the form of Hertzian waves at right angles to itself into space, in very much the same way that an ordinary candle sends out light in all directions. This radiation, though it is strictly in the nature of light, is invisible to our eyes, as the frequency is too low.

If we set up any other conductor approximately parallel to the first, there will be produced in this second conductor alternating or oscillating currents having the same frequency as those in the first conductor, and which can be detected by suitable instruments.

The simplest and one of the earliest methods for producing Hertzian waves for use in wireless telegraphy consisted in charging up, by means of an induction coil, a vertical insulated conductor, which was allowed to discharge itself to earth by means of a spark taking place between its lower end and another conductor which was connected to earth. To detect the Hertzian waves Marconi employed an improved form of the Branley filings tube, which is known as the coherer.

In order to transmit messages the radiation is started and stopped so as to form short and long signals, or dots and dashes of the Morse code, out of which the whole alphabet is built up in the well-known way.

As I have already stated, the radiation takes place round the vertical conductor approximately equally in all directions. Suppose that I set up my transmitting apparatus here in Leicester, a receiving station set up either in Nottingham, Derby, Rugby, or Peterborough would be able to receive the message equally well. Should I wish to send a message from here to Nottingham at the same time that Derby wishes to speak to Rugby, then the receiving station at Nottingham would receive both the message from Leicester which it should receive, and the message from Derby which it was not required to receive.

To get over this difficulty, known as "interference," a large number of devices have been patented. The most successful in practice is syntony, or tuning; in this method each station has allotted to it one definite frequency or tune, and the apparatus is so arranged at each station that it will only be affected by messages which are radiated by other stations on its own frequency or tune, and not by any other radiations. To take a musical analogy, supposing I had somebody who was either deaf to all notes of the piano except, say, the middle "C," or had such a musical ability that he could tell at once when I struck the middle "C," then I could transmit to that person a message in the ordinary Morse code by playing on the middle "C," and that person, whom I shall call Mr. C., would not take any notice of the fact that I might also be playing on the notes D, E, F, G, &c., but Mr. C. would confine his attention entirely to what is being done with the middle "C." It is conceivable that I might find a series of persons or train them so that they could each pick out and hear one note only of the piano, irrespective of what was being played on the other notes or of any other noises that were taking place. Taking an ordinary seven-octave piano, and neglecting for a moment the black notes, this would give me fifty-six distinct notes on which I could transmit messages; so that, transmitting from Leicester, I might send messages simultaneously to fifty-six different towns.

[1] Discourse delivered at the Leicester meeting of the British Association on Friday evening, August 2, by Mr. W. Duddell, F.R.S.

The number of possible simultaneous messages depends on the number of octaves there are on the piano used, and on how close together the different notes are which can be used without producing confusion. For instance, it might be quite easy to train someone to distinguish with certainty between "C" and "E," and pick out signals on "C" at the same time that signals are being sent on "E." It is certainly more difficult to do this with two notes that are closer together, say "C" and "D," and still more difficult if the half-tones are used as well. The problem, therefore, in wireless telegraphy is to arrange the receiving apparatus so that it can hear, or perhaps I should say, more accurately, so that it can only see, notes of one definite frequency or pitch, and not be affected by any other notes, even though of but slightly different pitch. Another requirement to obtain good working is that we should use as little power as possible at our transmitting station consistent with obtaining enough power in our receiving instruments to work them with certainty.

I have a mechanical model to illustrate how we are able to make our receiving instruments very sensitive to one frequency, and only slightly affected by frequencies which differ but slightly from its proper frequency.

The transmitter in the model consists of a disc that can be rotated slowly at any speed I like, with a pin fixed eccentrically on its face. This pin can be connected to a vertical wire which moves up and down as the disc rotates. I shall assume that the movement of this wire corresponds with the movement of the electricity in the vertical conductor. As a receiving apparatus I have a pendulum, and representing the ether between the transmitter and receiver I have an elastic thread connecting the pin in the disc to the pendulum.

When I set the disc rotating slowly the elastic thread is alternately stretched out and relaxed, and the pendulum is a little affected. If I gradually increase the speed of the disc at one definite speed it will be found that the pendulum is set into violent oscillation, and by observation it will be found that when this is the case the disc makes one complete revolution in exactly the same time that the pendulum would make one complete swing if left to itself; that is to say that the disc and the pendulum make the same number of swings per second or have the same frequency; in music they would be said to be in tune with each other. If instead of allowing the disc to rotate continuously I allow it to make only half a dozen revolutions, then the pendulum will be affected, but much less strongly. The greater the number of revolutions the disc makes up to a certain maximum number, the more the pendulum will be caused to swing.

Instead of starting and stopping the disc, I can keep the disc rotating, and start and stop the pulls on the elastic thread by moving the pin in the face of the disc in and out from the centre, which produces a movement which much more nearly corresponds with the actual current in the vertical wire as used in spark telegraphy.

It is necessary here to explain the relationship that exists between the wave-length, the frequency, and the velocity of propagation of Hertzian waves. The waves travel with, as far as we know, the same velocity as light, namely, 300,000,000 metres, or 186,000 miles, per second. Between these quantities we have the relationship that the product of the wave-length by the frequency is equal to the velocity of propagation, or, as I have already mentioned, the velocity of light.

The wave-lengths which are of practical use in wireless telegraphy at the present time range between 100 and 3000 metres, though, of course, it is quite possible to use for special purposes wave-lengths outside these limits. The corresponding frequencies in practical use are therefore between 3,000,000 and 100,000 complete periods per second. We require, therefore, to produce in the vertical conductor alternating or oscillating currents of any frequency within this range, and to have a sufficient number of oscillations following one another without interruption to allow of good syntony being obtained.

There are three methods of producing these currents—namely, the alternator, the spark, and the arc methods.

There are great difficulties in the way of constructing an alternator to give such high-frequency currents, and I can best illustrate this by taking an example. Suppose that it is required to build an alternator to work at the lowest frequency, namely, 100,000 periods per second, and let us assume that we can drive this alternator by means of a turbine at the high speed of 30,000 revolutions per minute. This alternator could not have a diameter much above 6 inches for fear of bursting; and, as it makes 500 revolutions per second, it would have to generate 200 complete periods for each revolution, so that the space available for the windings and poles for one complete period will be less than 1/10 inch, a space into which it is quite impossible to crush the necessary iron and copper to obtain any considerable amount of power. In spite of the small space that we have allotted to each period, as there are 100,000 periods per second, the speed of the surface of the moving part works out at more than 500 miles per hour. A small alternator has been built to give more than 100,000 frequency, but the amount of power it produced was extremely small. Several experimenters have stated lately that they have built alternators giving these high frequencies and a considerable amount of power, but, so far as I am aware, there is no trustworthy data available as to the design of these machines.

If it should prove possible to construct alternators for these very high frequencies, we shall be able to obtain a sufficient number of consecutive oscillations of the current in the aërial of definite frequency to enable very sharp syntony to be obtained. Not only will this greatly reduce interference troubles in wireless telegraphy, but such alternators will be of the greatest value for wireless telephony.

The earliest method of producing high-frequency oscillations was proposed by Lord Kelvin, who pointed out that if a Leyden jar or condenser be allowed to discharge through a circuit possessing self-induction or electrical inertia, then under certain conditions the discharge of the jar is oscillatory, that is to say, that the electricity flows backwards and forwards in the circuit several times before the jar or condenser becomes finally discharged. I think that perhaps the best way to make this matter clear is by demonstrating experimentally with an oscillograph the nature of the discharge of a condenser and how it is affected by the resistance and self-induction in the circuit. As a mechanical analogy one may look upon the charged condenser as a weight attached to a spring which has been pulled away from its position of rest. To discharge the condenser we let go the weight, and it begins to oscillate backwards and forwards, and, after making a greater or less number of oscillations, finally comes to rest. The number of oscillations per second will depend upon the strength of the spring and the mass of the weight, which correspond with the capacity and self-induction in our electrical circuit. The number of oscillations before the weight finally comes to rest is determined by the friction which tends to stop the weight, or by the resistances and other losses in the electrical circuit.

In practice the aërial conductor acts as a Leyden jar or condenser. It is charged with electricity and allowed to discharge, the current oscillating backwards and forwards in the aërial during the discharge. In many installations Leyden jars or condensers are electrically connected to the aërial, so that the oscillations taking place in them are transmitted to the aërial. Any remarks, therefore, that I may make as to the oscillations which may be set up in condensers apply equally well to the oscillations in the aërial in wireless telegraphy.

For wireless telegraphy it is usual to charge the condenser or aërial by means of an induction coil or an alternator to a very high voltage, and it is allowed to discharge by means of a spark between the two electrodes which form the ends, so to speak, of a gap in the electrical circuit. As long as the pressure is low the spark gap is a perfect insulator; when the pressure becomes high enough, the air between the electrodes breaks down and a spark passes the gap, becomes conducting, and allows the condenser to discharge. The property of the spark gap of passing almost instantaneously from a condition of being an insulator for electricity to being an extremely good conductor for electricity is of the utmost value in the spark method of wireless telegraphy. The more perfectly the spark gap insulated before the discharge takes place, and the more perfectly it conducts after the discharge has taken place, the better it is for our purpose.

If I take two electrodes sufficiently far apart in air, and gradually raise the electrical pressure between them, the first indication that anything is going to happen is the formation of fine violet aigrettes on the more pointed or rougher parts of the electrodes. This is known as the brush discharge. By gradually raising the pressure, this brush discharge extends further out into the air, until finally the air between the two electrodes becomes so strained that it breaks down and the real spark passes.

The long thin spark that occurs in this case is not very suitable for wireless telegraphy, as its resistance is too high. Ordinary lightning flashes are good examples of long sparks on a very large scale. If instead of working with the electrodes far apart they are placed nearer together, and if the electrical pressure is supplied from a very powerful source, then directly the spark passes it forms a thick discharge having the appearance of a flame in which the nitrogen of the air is actually being burnt; a process which, it is hoped, in the future may have immense importance in the supply of artificial nitrates for agriculture. This flame-like discharge has a low electrical resistance, but has the effect that it so heats or modifies the air that it is difficult to get the air to insulate again, after one discharge, ready for the next.

If a large quantity of electricity is discharged through the spark gap, and if the spark lasts a very short time compared with the interval between successive sparks, then a highly-conducting spark can be obtained, as well as a good insulation between the sparking terminals when no discharge is passing.

In order to help to bring the gap back to its insulating condition after each discharge, many devices are employed, such as subdividing the spark into several shorter sparks, cooling the electrodes, blowing air across the spark gap, &c. When the condenser or antenna discharges through the spark gap, oscillations are set up which radiate Hertzian waves.

In practice in wireless telegraphy it is difficult to obtain a large number of oscillations during each discharge as corresponding with each oscillation; the antenna radiates energy. A large number of oscillations means, if we keep amplitude of each the same, that we are radiating a large quantity of energy. Besides this radiated energy, which is useful for transmitting messages, there is also energy wasted in heat in the spark gap, in the conductors, in the glass or other insulation of the condensers. It is this useless part which we require to make as small as possible.

I have lately had an opportunity to determine how many oscillations actually take place in a certain wireless transmission. The experiment was made by photographing the spark as seen in a mirror rotated at a very high speed, and it was found that each spark consisted of nine or ten complete oscillations.

If all the oscillations had been of equal strength or amplitude, and if the receiving circuit had been similar to my pendulum in my mechanical model, then there would be very little to be gained by increasing the number of oscillations. As the oscillations die away in the spark method, two or three times this number would probably be required for the best effect. As a matter of experiment, very good tuning was obtained with the wireless transmission referred to above.

As an example of the sharpness of tuning obtainable by the spark method, the following test carried out on the Lodge-Muirhead installation at Hythe may be of interest.

The station at Hythe had to receive messages from Elmer's End at a distance of fifty-eight miles over land, in spite of the fact that the Admiralty station at Dover, only $9\frac{1}{4}$ miles distant, was transmitting as powerfully as it could, in order to produce interference, and that the regular communications were going on in the Channel between the shipping. It was found possible with a difference of wave-length of 6 per cent. to cut out the interference from the Dover station.

In the arc method of producing continuous oscillations we employ, as before, a condenser and self-induction; but, instead of charging the condenser to a high voltage and allowing it to discharge by means of oscillations which die away, and then repeating the process over and over again, we actually maintain the condenser charging and discharging continuously without any intermission, so that we practically obtained a high-frequency alternating current in the aërial.

To impress the difference on your minds, I have an incandescent lamp, which I switch on and off rapidly about ten times, and then after a short time I repeat the same flickering of the light, and so on. The flickering of the light corresponds with the oscillations in the ordinary spark method, and the time spaces between the flickers represent the times during which the condenser or antenna is being charged ready to produce a fresh series of oscillations. In practice we may have as many as, say, a couple of hundred discharges of the condenser a second, and during each discharge we may get, say, ten complete oscillations, each oscillation lasting one-millionth of a second, if the wave-length is 300 metres; thus the total time that the condenser is discharging is only one one-hundred-thousandth of a second, or the five-hundredth part of the interval of time between two successive discharges. My lamp here flickers about five times per second, and makes ten flickers before it goes out; the total time that it is flickering is two seconds, and the time before it should start to flicker again to correspond with the practical wireless case is therefore 1000 seconds, or rather more than a quarter of an hour. If now I represent continuous oscillations, such as are obtained by the arc method with this lamp, I shall simply keep the lamp flickering continuously, and there will be no intervals whatever.

The arc method of producing continuous oscillations is founded on my musical arc. In order to explain this I must demonstrate some of the properties of the direct-current arc. If I vary the current flowing through the arc very slowly and note the potential difference corresponding with each value of the current, keeping everything else constant, I obtain a curve generally spoken of as the characteristic of the arc. These curves under different conditions have been very thoroughly investigated by Mrs. Ayrton.

With the carbon arc between electrodes in air the voltage decreases very rapidly when the current is gradually increased, starting from very low values. As the current becomes larger the rate of decrease of the voltage becomes less and less until it is, comparatively speaking, quite small, with a current of ten or twelve amperes. With the arc between metal electrodes similar results are obtained, except that the discontinuity in the curves, called the hissing point by Mrs. Ayrton, takes place at very small currents, generally well below one ampere.

With arcs burning in hydrogen, Mr. Upson has found that the curves are generally much steeper for the larger values of the current than for the corresponding arcs burning in air. This point is of great importance as explaining the value of the hydrogenic atmosphere used by Poulsen and referred to later.

In general, I may therefore say for the above arcs that increase in current through the arc is accompanied by decrease of the potential difference between its electrodes, and *vice versâ* decrease of the current causes increase in the potential difference; on the other hand, certain arcs, such as the arc between cored carbons, behave in an opposite manner, that is to say, current and potential difference increase and decrease together.

I demonstrated in 1900 that if I connect between the electrodes of a direct-current arc (or other conductor of electricity for which an increase in current is accompanied by a decrease in potential difference between the terminals) a condenser and a self-induction connected in series, I obtain in this shunt circuit an alternating current. I called this phenomenon the musical arc. The frequency of the alternating current obtained in this shunt circuit depends on the value of the self-induction and the capacity of the condenser, and may practically be calculated by Kelvin's well-known formula.

Besides the condition that an increase of current must be accompanied by a decrease in potential difference, it is necessary that the relative decrease in potential difference produced by a given increase in current, that is to say, the steepness of the characteristic, shall exceed a certain minimum value which depends on the losses in the shunt circuit. It is also necessary that an increase in current shall be accompanied by a decrease in potential difference, even when the current is varied very rapidly.

Let us consider what takes place when I connect this shunt circuit to an arc. At the moment of connection a current flows from the arc circuit into the condenser circuit, which tends to reduce the current flowing through the arc. This reduction of the current through the arc tends to raise the potential difference between its terminals, and causes still more current to flow into the condenser circuit, and I now have a condenser charged above the normal voltage of the arc. The condenser, therefore, begins to discharge through the arc, which increases the arc current and decreases the potential difference, so that the condenser discharges too much; the reverse process then sets in; the condenser becomes successively overcharged and undercharged, due to the fact that, instead of the potential difference between the terminals of the arc remaining constant and allowing the condenser to settle down with its proper corresponding charge, the potential difference actually decreases when the condenser is discharged and increases when it is charging, so as to help to keep up the flowing backwards and forwards of the current indefinitely.

The oscillograph wave forms show what is going on very clearly, and they show that in general the swing of the current in the condenser circuit attains such a magnitude that when the condenser is charging it takes the whole of the current away from the arc, so as to make the arc, although burning on a direct current circuit, a pulsatory arc. The pulsation of the current through the arc causes the vapour column to grow bigger and smaller, and the light to vary. When the vapour column grows bigger and smaller it displaces the air around it and produces a note the pitch of which is determined by the frequency of the current in the shunt circuit.

The values of the capacities of a series of condensers have been calculated by Kelvin's formula to give the frequencies corresponding with a musical octave, and the nearest values in an ordinary laboratory box of condensers have been taken and connected to a keyboard. The result shows how nearly Kelvin's law is obeyed.

With this apparatus I can demonstrate the importance of tuning in electrical circuits, and perform electrically some experiments which I have already performed mechanically earlier this evening. I use the large coil which forms the self-induction in the circuit shunting the arc as a transmitting circuit for wireless telegraphy by the magnetic induction or Preece method; and I have a receiving circuit consisting of a coil of wire connected to a small lamp, and not connected in any way to the transmitting circuit. At a certain short distance between the transmitting coil and the receiving coils, the indicating lamp lights if I cause my arc to sound *any* one of the notes of the octave, and so produce an alternating current of corresponding frequency in the transmitting coil. If I now tune the receiving circuit, by connecting a condenser in it, the lamp on the receiving circuit will light at about five times the distance; but it will only light when one definite note is sounded by the arc. These are the two distinct advantages of tuning, namely, greater distance and syntony, or responding to only one definite note.

For wireless telegraphy by means of Hertzian waves, based on my arc method, we require much higher frequencies in the shunt circuit. If we attempt to obtain this higher frequency from the ordinary arc burning between solid carbons in air, we find that above a certain limit the oscillations will no longer take place. This is due to the fact that we are varying the current through the arc at this higher frequency too quickly for an increase in current to be accompanied by a decrease in potential difference. I have demonstrated that if I only vary the current through the ordinary current arc sufficiently rapidly, then an increase in current is accompanied by a proportionate increase in the potential difference, and the arc behaves just like an ordinary resistance. If we work with very small current arcs, we can obtain high-frequency musical arcs burning in air either between carbon or metal electrodes.

In a paper read before the International Electrical Congress at St. Louis in 1904, Mr. Poulsen showed that, by placing the arc in a flame, it was possible to obtain higher frequencies than when the arc was burning in air. Following this up, Mr. Poulsen came to the conclusion that the best results were obtained when the arc was burning in hydrogen, or a gas containing hydrogen; and he further added a magnetic field around the arc somewhat similar to that which has been previously used by Elihu Thomson.

The arc burning in coal gas in a powerful transverse magnetic field was used by Poulsen in his early experiments to produce the high-frequency current necessary for wireless telegraphy between Lyngby and Esbjerg, in Denmark. This apparatus has been further improved, and is now employed by the Amalgamated Radio-Telegraph Company in their station at Cullercoats and the other stations that they are erecting.

In both the arc and the spark methods of wireless telegraphy we employ a high-frequency alternating current in the aërial conductor. The essential difference between the two methods lies in the fact that with the spark method our alternating current in the aërial conductor first increased to a maximum value and then dies away rapidly, making only a limited number of oscillations, whereas in the arc method the oscillations are maintained continuously of unvarying amplitude.

With the arc method we are further able to choose the number of consecutive oscillations which make up each signal sufficiently great to obtain the very best syntony. On the other hand, improvement in the arrangement and construction of the apparatus for the spark method has so increased the number of oscillations corresponding with each spark that it may be that we shall be able to obtain a sufficient number in each train to give as good syntony by this method as that obtained with the arc method.

The arc method seems eminently suitable for very high speeds of working. As the oscillations are quite continuous, we can cut them up into groups to form the dots and dashes of the Morse alphabet, just as if we were working with a continuous current such as is used on land lines, so that there seems no reason why as high a speed of working should not be obtained from the arc method of wireless telegraphy as is obtainable by automatic signalling on land lines; for it is to be noted that the dot or shortest signal of the Morse alphabet, even at a speed of three or four hundred words per minute, will last long enough to consist of many hundreds of oscillations of the current in the aërial, so that there will be plenty of oscillations in the group forming the dot to give good syntony.

Turning to the spark method for high working speeds, we find a difficulty in that the dot of the Morse alphabet must at least occupy the average time required to charge the condenser or aërial and produce one spark, and preferably sufficiently long for several. We are therefore obliged in the spark method to use a high rate of sparking for high-speed signalling. This difficulty has not become very serious with the present low speeds of sending. When we come to use considerable amounts of power to transmit messages over long distances, and we also require a high speed of working, the practical difficulty in constructing apparatus suitable for sufficiently rapid sparking will become serious.

Mr. Marconi in 1905 claimed to have already reached a speed of 100 words per minute by the spark method, and lately there has appeared in the technical Press examples of high-speed signalling by the British Post Office over a distance of fifteen miles in which readable signals were received at a speed of seventy words per minute.

Turning to the receiving end, almost all the receivers that have been used in the spark method can be equally well used for the arc method; for it must be remembered that the transmission in either case is affected by Hertzian waves traversing space, and that the only fundamental difference consists in the number of oscillations in each train of waves. It must be noted, however, that in those methods in which a telephone receiver is used it is necessary to break up the continuous oscillations of the arc method into groups succeeding one another sufficiently rapidly to produce an audible sound in the receiver; for in the spark method the sounds we hear in the receiver correspond with the succession of impulses of the diagram, one for each spark at the transmitter. This chopping up of the continuous wave-train so as to produce audible signals in the receiving apparatus can be done either at the transmitting end or in the receiving apparatus. An example of this latter method is Poulsen's ticker.

The question whether receiving apparatus can be arranged so as to receive messages from stations equipped with the spark apparatus and from stations equipped with the arc apparatus is a matter of enormous importance at the present moment in view of the probable ratification of the Berlin Convention, which imposes an obligation on all commercial stations to inter-communicate without regard to the make or system of transmitting apparatus employed. I am of the opinion that there will be no difficulty in carrying this into effect provided that the stations using the spark method send out long trains of waves, as they should do to obtain syntonic working, which is also called for by the Berlin Convention.

An extremely interesting development which is now progressing rapidly owing to the possibility of producing continuous oscillations by the arc method is wireless telephony. Suppose that we can vary the intensity of the oscillations in a manner corresponding with the vibrations of the air which constitute sound and speech, then we should obtain at the receiving stations a train of Hertzian waves the amplitude of which varies in a corresponding way; by allowing these waves to act on a telephonic receiver which is sensitive to the intensity of the waves we shall obtain in the telephone a reproduction of the sounds. This has actually been carried into effect by employing an ordinary microphone to modify the current through the transmitting arc so as to vary the intensity of the oscillation current produced, and by employing what is known as a point-detector and a telephone at the receiving station.

Another method which may be used consists in causing the microphone to vary the frequency of the oscillations of the generator, and by arranging the receiver so that it is more or less strongly affected according to the frequency of the received waves.

I am informed that experiments have been made in wireless telephony in Berlin by the Amalgamated Radio-Telegraph Company between their stations in Mathieustrasse and Weissensee, 6·5 km. apart, with good results, and that it is now proposed to equip the stations at Oxford and Cambridge for the further perfecting of this application.

It is greatly to be desired that wireless telephony may develop rapidly, as it seems to me that for the purpose of communicating with ships wireless telephony will have great advantages over wireless telegraphy.

I am deeply indebted to Mr. Colson for all the facilities that he has placed at my disposal, and to his engineers for their assistance, which has enabled me to carry out the experiments in the lecture; and I have also to thank the Tramway Department for the special supply of current.

THE BRITISH ASSOCIATION.

SECTION K.

BOTANY.

OPENING ADDRESS BY PROF. J. B. FARMER, M.A., F.R.S., PRESIDENT OF THE SECTION.

CUSTOM has decreed that those who are charged with the responsibilities that to-day fall to my lot should endeavour to address themselves to the consideration of matters such as they may deem to be of advantage to others, or, at any rate, of interest to themselves. It is not, perhaps, always easy to combine these two courses, and if I choose the less altruistic one I experience the smaller compunction in doing so because the undisturbed repose that most Addresses enjoy when they have been decently put away between the covers of our Annual Report seems to indicate that an attempt to express the passing thought, however ephemeral its interest, may not be the worst introduction to the business of the advancement of our science.

Any attempt to give a survey of the progress and present position of botanical science, even were so large a task at all within my power, has almost ceased to be necessary, owing to the enterprise which has so admirably provided for its adequate fulfilment elsewhere. I propose, therefore, to try to put together, in a form as intelligible as I can, the result of reflections on some of the aspects of botany that are often not seriously regarded; perhaps because they belong rather to the nebulous region of speculation than to the hard (and sometimes dry) ground of accepted fact.

I am by no means blind to the risks incurred in venturing on such a course, but I believe that a glance directed, however imperfectly, towards some of the less obvious sides of our science may not be altogether futile, even though the attempts should evoke the criticism:

Dum vitat humum, nubes et inania captat.

The problems that confront us as botanists are far more numerous and far more complex than formerly. We are attached to a science that is rapidly growing, and this rapid advance is carrying with it a process of corresponding differentiation. Some years ago a danger arose, even within this Association, that we might have replaced differentiation, that quality which distinguishes the higher organisms, by a process of fission which is more characteristic of the lower ranks of life.

The products of the threatened fission would doubtless have pursued divergent paths, and the botanist of to-day would have been the poorer for it. He would have been lost to physiology, and all that physiology implies. Happily that danger was averted, and, to our lasting advantage as members of the botanical organism, our science escaped disruption, and physiological investigation still continues both to inspire, and to be aided by, other branches of botanical research. A physiological conception of morphological phenomena is the one that to me seems to afford the broadest outlook over our territory. It serves to check a tendency towards mere formalism on the one hand and to correct the not less baneful effects of a superficial teleology on the other. Both are real dangers, and we have all encountered examples of them.

In rating highly the value of maintaining a physiological attitude of mind towards the phenomena presented by the vegetable kingdom, one is mainly influenced by the logical necessity which such a position carries with it of constantly attempting to analyse our problems, as far as may be possible, into their chemical and physical components. It seems to me that this is the only really profitable method that we can bring to bear on the difficulties that lie before us, because in using it we are constantly forced to consider the *causes* which have led to the final result. Of course I am well aware that to some minds the very attempt to apply such a method beyond a very limited range may appear futile, or at least premature. But the goal of all scientific inquiry lies in the ultimate ascertaining of cause and effect, and only with this knowledge can we hope to get control over the results.

Chemistry and physics each present to their followers problems far more elementary than those with which we have to grapple; but the explanation of the great advances which these two branches have made lies essentially in the fact that an analysis of the factors involved has enabled the investigator intelligently to interfere with, and so to control, the mode of presentation of the reacting bodies to each other. And our own special problems, whether we confine ourselves to the simpler ones, or whether we approach the obscurer matters of organisation, heredity, and the like, are assuredly susceptible of a similar method of treatment. We can never expect to get further than to be able to modify the mode of presentation to each other of the materials that interact to produce what we call the manifestations of life; but the measure of our achievement will depend on the degree in which we are successful in accomplishing this.

Indeed, until we have analysed the nature of the reacting bodies, and also especially the particular conditions under which the reactions themselves are conducted, we are avoiding the first steps in the direction of ultimate success. At present, when we desire to know the taxonomic value of this or that character, we are perforce largely guided by purely empirical considerations. We find, for example, that a particular structure is very constant through a group of species otherwise closely resembling each other, and we rightly (but quite empirically) regard the possession of that character as a valuable indication of affinity within that alliance. But the very same feature in other groups may be highly variable, and lack all importance amongst them for systematic purposes. It may be, and very probably is, optimistic to look forward to the time when we shall know *why* the character is good in one, and worthless in another, alliance. But when we do, I am convinced that the reason will be found to lie in chemical and physical causes. We are very ignorant as yet of the details, but we can nevertheless even now form a fair guess at their general nature.

In this connection I would venture to express the opinion that much real harm is done by the toleration of an uncritical habit of mind, all too common, as to the significance of structures which are regarded as adaptive responses to stimuli of various sorts. It is *not* enough to explain the appearance of a structure on the ground of its utility; properly speaking, such attempts, so far from providing any explanation, actually tend to bar the way of inquiry just where scientific investigation ought to commence.

That many of the responses to such stimuli are of a kind to render the organism "adapted" to its environment no one, of course, will dispute; but to put forward the *adaptedness* as an explanation of the process is both unscientific and superficial. The size and the spherical shape of duckshot are admirably adapted to the purposes for which duckshot is used; but this affords no insight into the necessary sequence of cause and effect, which makes the melted lead assume the characters in question as it falls down the shot-tower.

But many people still find consolation and satisfaction in an anthropomorphic and somewhat slipshod application of a kind of doctrine of free-will to matters that really call for rigorous examination into the causes which, under given conditions, must inevitably and of necessity bring about their definite result.

One of the commonest responses to the stimulus of wounding in the higher plants is the formation of a layer of cork over the injured and exposed tissue. No one can deny that this is a reaction of great utility, checking as it does the undue evaporation of water and the entrance of other parasitic organisms. And yet I suppose that no one would go so far as seriously to maintain that the obviousness of these advantages satisfactorily explains *why* the cork layer is produced. It seems to me that an investigation of the real underlying conditions which govern such a modified reaction would be of immense value, and that the information we might gain therefrom as to the nature of the chemical processes involved would prove to be of first-rate importance in tracking to their sources some of the factors that influence the course of carbohydrate metabolism within the cell. Again, we know how easy it is to produce colour-changes in the leaves of certain plants—*e.g.*, rhubarb—by severing the vascular bundles, and thereby interfering with the process of translocation. Overton has shown how the accumulation of soluble carbohydrates within the leaf of such a plant as Hydrocharis modifies the metabolic processes within the cells. Thus in bright light, under conditions of cold sufficient to arrest starch formation, but not enough to stop photosynthesis, a red-coloured substance makes its appearance in the cell, and this again disappears on raising the temperature, so that the accumulation of soluble carbohydrates diminishes. The red colour which is associated with the change may possibly by absorbing the heat ray aid in restoring metabolism to its "normal" course; but such a teleological explanation is not of general application, and gives no real insight into the nature of the processes involved. The well-known laboratory method, which we owe to Klebs, of inducing Eurotium to enter on a sexual phase by keeping it at a temperature of 26° C. is another example of the same order. The particular reaction that occurs in each of these instances is that which necessarily results under the specified conditions, and no other course of chemical change is possible.

In the last-mentioned example, Eurotium acts in a way similar to that of drought, only the result is more quickly produced. This perhaps indicates that we are dealing with a definite series of changes which are inhibited by the presence of too much available nutriment supplied at a temperature too low to enable it to be sufficiently rapidly altered within the organism so as to give rise to the specific substance, which is more directly responsible for the ascogonial phase of the life-history. Something of an analogous character is probably effective in the formation of "fairy-rings," so typical of the growth of certain agarics. This appearance of fairy-rings may be easily reproduced in artificial cultures of moulds by appropriate means. Thus if the nutriment agar be kept fairly dry, so that the rate of diffusion of soluble materials is slowed down, it is found that concentric zones of sterile and sporiferous hyphæ regularly alternate with each other. An explanation of this behaviour, which seems most probable, is that the hyphæ, after they have been growing over the substratum for a certain distance, have acquired sufficient raw material to provide for the building-up of the substance which stimulates spore-production. When this has taken place the substance so elaborated is used up and spore-production ceases until a fresh supply of material, under the conditions of the experiment, has been formed to act in its turn as a new stimulus. This suggestion is supported by the interference with the circular form of zones that can be brought about by artificially interfering with the rate of diffusion of the supply of nutriment in the jelly. The rhythmical alternation of sterile and fertile zones seems to prove that *quantity* of elaborated material is an essential factor in the process, just as in the stimulation of a motile organ the stimulus itself has to reach a certain minimal intensity in order to cause a movement.

The parallelism between the nutritive, *i.e.*, the chemical, stimulus in the case of the fungus and the minimal time-stimulus required to provoke geotropic movement is very striking. For it will be remembered that there is evidence in the latter instance also of the occurrence of a definite chemical change as the result of the disturbance of normal gravitational relations. This finds expression in the accumulation of homogentisinic acid as the result of the formation of an anti-oxidative substance which arrests the complete disruption of tyrosin in the cells. Whether this is the immediate cause of the geotropic movement, or merely a concomitant of it, we cannot settle at present. But it is of the highest interest to know that chemical change is initiated as a result of the external gravitational impulse, even when the latter is of too short duration to produce an actual geotropic movement. And although we may not at present be able to identify the exact material which is directly concerned in these stimulatory or formative processes, we have, as it seems to me, irresistible evidence in favour of its real existence. It is more than mere analogy that leads us to believe that the various kinds of galls, for example, that may be formed on an oak leaf owe their formation to the specific interference of the secretion of the grub with the higher metabolic processes going on in the cells of the leaf.

I have alluded to the different conditions under which given reagents may interact, and these may in turn very materially affect the final result by modifying the course of the reaction itself. We are coming to realise the fact that the physical conditions of the cellular constituents exercise an important influence on the course of chemical activity manifested within their range. We all know what an important part water plays in ordinary chemical reactions, but the water question assumes a special prominence when the reactions are going on in a colloidal matrix, or rather in a mixture of colloids, such as the various proteins that occur in the cell. Questions of rates of diffusion, physical absorption, and the like have to be taken into account; and beyond all these there remain the series of remarkable electrical relations which the proteins exhibit, as well as those changes in surface-tension that are, in part at least, connected with them.

It is impossible to resist the belief that a closer study of the physico-chemical changes that accompany a nuclear division will yet throw much light on the mechanics of this wonderful process. Indeed, we already possess some data which are serving as starting-points for further investigation, and they have placed some of the known facts in a very suggestive light.

It has often been urged as a reproach against the histological methods employed in the study of the cell that all such investigations can, after all, only give information as to the character of coagulations or precipitations. Of course this is perfectly true; but provided we have sufficiently good grounds for enabling us to feel confident that the precipitation or coagulation faithfully maps out the positions originally occupied by the respective colloids during life, there is no real force in the objection. No one would call in question the accuracy of a photographic negative on the ground that after development it no longer consisted of the actual substances which had been formed in the film by the exposure to the action of light. All that is required is that the deposited silver shall accurately express the limits of, and be proportionate in amount to, the alteration in the composition of the salt which was produced when the plate was exposed in the camera.

Much of the general detail of a nuclear division can be followed even in the living cell, and we therefore possess direct as well as indirect means of testing the degree of accuracy with which the fixed preparation represents the original pattern of distribution of the colloids within the cell. No one who has studied the behaviour of artificially prepared mixtures, the colloidal proteins and nucleins after "fixing" and staining them, can entertain reasonable doubts as to the substantial identity of the structures visible in a well-fixed cytological preparation with those present during life. For the substances, even in these artificial mixtures, keep remarkably distinct, as indeed Fischer showed some years ago.

Few things are more striking than the remarkable series of evolutions passed through by the linin, and by the chromosomes which finally emerge from it during the progress of a mitosis. We have clear evidence that the nucleus at this period is the seat of rapid chemical change. The process of distribution of the nuclein within the linin is sufficient proof in itself of this. But we have also, I believe, evidence of physical disturbances of an electrical nature which accompany, and indeed in a measure determine, the course of mitosis. This is indicated, not only by the movements that proceed within the nucleus, and concern the linin and chromosomes, but also by the remarkable alterations in surface-tension exhibited by the nuclear membrane.

It is well known that at a certain stage of the heterotype division, for example, the chromosomes move to the periphery of the nucleus, and each one is removed as far as possible from every other chromosome. At this stage, to which Haecker has given the name of "diakinesis," the nucleus reaches its maximal size. Diakinesis is not the only stage in which there is an indication of repulsion between the elements of the chromatic linin. Measurements prove that all such periods of repulsion are also marked by an increase of nuclear size which is transitory, and either disappears or alters in a synchronous fashion with them. These phases of enlargement have been generally regarded as directly connected with the intake of liquid by the nucleus, due to a hypothetical change in osmotic conditions. But, so far as I am aware, no satisfactory explanation has yet been given as to why, or how, the supposed increase of osmotically active molecules within the assumed semi-permeable nuclear membrane could be effected. On the other hand, an enlargement of the surface-membrane of the nucleus would necessarily follow on the migration towards it of chromosomes or other bodies carrying similar electrical charges. For the induced charge in the particles of the membrane would of course weaken its coherence, for the same reason that the free chromosomes repel and move away from one another.

There is evidence to show that the proteins *are* able to carry such charges, and this is a matter of the highest importance as affording a clue to many other processes in which changes of surface-tension play a part, besides those connected with nuclear division.

Not the least of the many remarkable properties exhibited by the proteins lies in their capacity of taking on either a positive or a negative charge of electricity. A clear proof of this was afforded by the beautiful experiments of Billitzer, who showed that, when so charged, the colloid moves as a whole towards one pole or the other on sending a current through the liquid in which it was suspended. At first sight it may not be easy to understand how it is possible for a colloid to receive and retain a charge under the conditions which obtain either in the solution or in the cell. It must, however, be remembered that the liquid contains electrolytes in solution also, and any disturbance in the equilibrium of the products of ionic dissociation will be accompanied by corresponding differences of potential. The most reasonable explanation of the phenomenon in question seems to be that the colloids are unequally permeable to the ions, whereby there comes to be a preponderance of one or the other group associated with the proteins. Perhaps this should be connected with the remarkable though still imperfectly understood property of adsorption which is characteristic of many colloids.

Much, however, still remains to be done before a complete survey of the electrical changes that are associated with mitosis can be made. We especially desire more complete information on the nature of the chemical processes which are involved. For it is obvious that the physical changes must ultimately be connected with the transformation of materials which goes on so energetically at these recurrent periods of nuclear activity. We do not yet know how or why the chromosomes that have been dispersed at diakinesis should again congregate on the spindle prior to their final separation. Possibly this is to be connected with the signs of disturbance in the extra-nuclear cytoplasm, which in its turn finds expression in the differentiation of the achromatic spindle. The character of this body has long aroused the suspicion that its existence is to be attributed to electrical causes. The more recent work serves to indicate that this suspicion was well founded.

The more complete study of the chemistry and physics of karyokinesis is certain to prove valuable for another reason. The successive changes which the nuclei of both animals and plants exhibit when they are undergoing division are so remarkably similar that it seems exceedingly probable that the processes actually involved may turn out to be relatively simple, at any rate in their broader features. I mean that they probably belong to what we might term the lower grade of metabolic problems. For the great uniformity of the process as a whole, complex though it undoubtedly is, hardly suggests direct relations as existing between it and those more specialised forms of metabolism on which the properties of specific form, and such like characters, depend. This view of the matter is not in any way weakened by the fact that the materials providing for the multiplication of nuclei have themselves passed through the very highest stages of anabolic construction. There are, indeed, some grounds for believing that the composition of the higher proteins is distinctly specific for different groups of organisms; but apart from this it is difficult to resist the conviction that, in so far as its essential constituents are concerned, the nucleus is the seat of a complex organisation which is superadded to its chemical composition. But this conception of the nucleus does not affect the position of the lower-grade chemical changes, with their physical accompaniments which are periodically rendered apparent during the rhythmical series of changes that culminate in the division of the nucleus. It is true that there are some who refuse to admit the necessity of what I might perhaps call architectural complexity in protoplasm. They prefer to regard all the phenomena of organisation and heredity as the outcome of dynamical, rather than of structural, conditions. It seems to me that it is impossible to reconcile such a view with the known facts respecting the inheritance of characters, and that we are driven to postulate the existence of material units which are to either responsible for the sum of the characters represented in any individual. There are grounds for believing that their entities, whatever be their nature, are doubled, and then equally distributed to the two daughter cells at every ordinary nuclear division; and thus the properties of organisation are preserved and transmitted over and above the flux of chemical change.

Most people who have concerned themselves with cytological studies agree that the salient features of karyokinesis strongly emphasise the probability of a conservation of definite material; and that an extremely accurate distribution of it occurs where two daughter cells arise from a parent cell by division. And this inference is greatly strengthened by what occurs, more or less immediately, in connection with the formation of the sexual cells. The origin of these in all the higher animals and plants, as is well known, can invariably be traced to a nuclear division of remarkable complexity. In this, the so-called heterotype division, the special feature consists in the sorting-out of the nuclear constituents originally furnished by the two parents of the individual. This sorting or distribution takes place in such a way that each of the two daughter nuclei which arise as the result of the division receives only half the total number of chromosomes previously contributed by the two parents. The essential point of interest lies in the fact that the process does not consist in the mere halving of nuclear *substance*, but in the distribution of nuclear *constituents*. When two sexual cells which have been formed in this way unite to give rise to a new individual, the total number of nuclear chromosomes is again made good; but the resulting nuclear constitution will not exactly resemble that of either parent. That such is really the case is borne out by innumerable experiments that have been made by breeders. Furthermore the extensive investigations on the results of crosses, both in animals and plants, have confirmed the view that particular characters can be treated as entities. For they are distributed amongst the posterity of the original parents in proportions that closely approximate to mathematical expectation. In this distribution the separate characters behave independently. For instance, the green colour and round form of peas are two characters which may occur in the same or in different individuals. The numerical proportions in which they *will* appear can be foretold with a considerable degree of accuracy.

With these facts before us—and many others could be adduced, all pointing in the same direction—it is not easy to resist the conviction that within the nucleus there must exist material entities which are severally responsible for the appearance of the characteristic traits of any given individual. The question is, What conception can we form as to their nature, and how are they able to produce the observed results? It is not necessary to discuss the evidence that the chromosomes, or the materials of which they are composed, play a most important part in connection with development. All the work of the last decades has tended to emphasise their importance in the transmission of hereditary qualities, and this is equivalent to admitting that they contain factors that determine the path of development, and are responsible for the production, from the egg, of the form and structure of the adult.

Now it is certain that it is not the *chromosome-substance acting as a whole* which is effective in those processes summed up in the term Ontogeny. It might be, and until recently was, thought that in those plants in which there is a marked alternation of generations a definite relation existed between the number of the chromosomes and the particular stage of the life-history. The double number was supposed to be essential for the sporophyte, whilst the halved number was similarly regarded as causally related with the appearance of the gametophyte or prothallial generation.

But Loeb and others had already shown that the eggs of echinoderms might be stimulated to parthenogenetic development by means other than fertilisation, and Wilson found that such larvæ only contained the half number of nuclear chromosomes, as, indeed, was only to be expected. But the idea of a close parallelism between chromosome number and the alternative phases of the life-history was so deeply rooted that the full significance of Wilson's discovery was not at once grasped. The comparative neglect was, perhaps, partly justified, inasmuch as the larvæ could not be reared. It may, however, be incidentally remarked that no one, so far as I am aware, has yet succeeded in raising the *normal* echinoderm larva beyond the pluteus stage.

The investigation of cases of apospory that occur in the pteridophytes have proved that no causal relation can exist between the number of the chromosomes and the characters that distinguish the gametophyte and the sporophyte respectively. For the sporophyte may give rise to the gametophyte aposporously without any reduction, whilst the various types of apogamy with which we are now acquainted exhibit all gradations between a coalescence of more or less differentiated nuclei and the complete absence of all semblance of nuclear fusion. In the latter case, when the sporophyte springs from a gametophyte that has itself arisen after nuclear reduction, the sporophyte continues to retain the smaller number of chromosomes normally associated with the other generation only.

We thus have a complete proof that a single sexual cell which has undergone reduction in the number of its chromosomes retains, in so far as its architectural configuration is concerned, the capacity of giving rise to a plant possessed of the full complement of characters belonging to the species. But this, after all, is only what the facts of heredity might have led us to anticipate. For, whilst we are ignorant of the fundamental *significance* of the sexual fusion of the gametes, one of its most obvious *results* consists in the duplication of the primordia of the specific characters in the cells of the individual thus produced. This statement is not only in accord with results of experiments in breeding, but it is also in harmony with the essential features of the heterotype mitosis; and no other satisfactory interpretation of the latter series of phenomena has yet been found.

Furthermore, the facts of Mendelian dominance clearly show that each parent, through the gametes to which it gives rise, contributes an independent organisation responsible for at least some of its own distinctive characters, as well as those which distinguish the species. Consequently, when two gametes fuse, the embryo will be provided with a duplicate stock of agents or primordia which determine the appearance of its own specific and individual characters. These will not always be similar in the two parents, and when this is the case it often happens that the offspring resembles one parent only in respect of a particular feature. Nevertheless the results of further breeding show that the corresponding, but apparently lost, character only is latent, for it reappears in a proportion—and often a fixed proportion—of the individuals of the succeeding generations. In such an example, where both agents or primordia are present, one of them lies dormant, whilst the dominant one alone influences the course of metabolic processes, and thus brings about the appearance of the character itself. The dormant primordium can be transmitted as such through many generations, betraying its existence in each by the occurrence of individuals in which it finds its perfect expression. This happens when the opposite dominant agent or primordium has been removed from some of the gametes by the sorting-out process during the heterotype mitosis to which I have already alluded.

The particulate character of inheritance seems, as many writers have pointed out, to demand a structural organisation for its basis; and the units or primordia of which the latter is composed must be relatively permanent, inasmuch as heredity itself is so stable. The agents or primordia themselves probably act by definitely influencing the course of chemical reactions that proceed within the living protoplasm, somewhat after the fashion of the ferments. But whether this influence on the course of metabolism is to be attributed more directly to the chemical or the physical aspect of the organisation must, of course, remain an open question, though I incline to the latter alternative on grounds which I have already indicated.

The processes of the higher metabolism offer suggestive analogies with those reactions for which the ferments are responsible. In contemplating them one can hardly fail to be struck by the orderly way in which ferment succeeds ferment on an appropriate medium. Each one produces its own special change, which it is unable to carry further itself, but it thereby provides a substratum suitable for its successor. Starting, for example, with a complex substance like cane sugar, we see it acted on by a series of ferments, each the result of protoplasmic differentiation, and each one carrying the process of disintegration a little further, but strictly limited in its power to act, and only able to take the change on to a definite stage.

Everyone who has experimented with plants with the view of inducing the formation of some structure foreign to the species or individual by artificial means must have become impressed by the great difficulty of getting into touch, so to speak, with the higher metabolism at all. It is often easy enough to divert the life-history into either the vegetative or the reproductive channel, as every gardener is more or less consciously aware, and as Klebs has conclusively shown in his remarkable series of carefully conducted experiments. But even here it is sometimes difficult exactly to hit off the conditions requisite to ensure the production of one or other of the various phases of the life-history. There are many fungi, for example, which are believed to represent vegetative stages of Ascomycetes or Basidiomycetes, but it has not yet been found possible to ascertain the conditions that would cause them to form the highest fructifications. Even in simpler instances a similar difficulty is sometimes encountered. Thus *Bispora moniliforme*, a mould that often occurs on the wood and stumps of oak or hornbeam, is not readily cultivated as the Bispora form, whether it be grown on wood or on various nutritive media. The usual result of raising it under artificial conditions is to obtain a luxuriant crop of Eurotium-like mould. But the Bispora form can be reproduced from such a culture by growing it in strong solutions of cane sugar under certain conditions, all of which are not as yet understood.

I take it we shall agree that the properties of structure and form are to be interpreted as the necessary result of the action of particular substances on the protoplasm, and that these cause it to assume those definite attributes which we term specific on account of their constancy through a larger or smaller range of individuals. But this constancy of form must then be the result of a corresponding definiteness in the series of changes undergone by the raw materials supplied as food in their upward transformations; each stage in the process limits the possible range of those that follow, as in the case of the ferments to which I have alluded; and thus it becomes increasingly difficult to modify the final result.

In this way we may see, perhaps, an explanation of the circumstance that in amphibious plants the particular structure, whether adapted for land or water, that will arise in conformity with the environment is irrevocably determined long before the organs themselves are sufficiently developed to be exposed to the direct influence of the conditions to which they are supposed to be specially adapted.

Now it is a matter of common knowledge that the formative processes can be, and sometimes *are*, disturbed with the most surprising results. I may again refer to the fungal or insect galls as examples that will be familiar to everyone. It appears to me that these exceptional developments are of extraordinary importance in relation to any endeavour to probe the mysteries of organisation. The very difficulty experienced in imitating the effect of the insect's secretion strongly emphasises the specialised nature of the particular substance which is able to modify the "normal" reactions of the plant. The latter are dependent on the way in which the organic apparatus determines the fashion of the molecular presentations, so that, as I have said, the course of the reactions themselves become increasingly limited in their range. Now as regards the manner in which the secretion of the insect operates, it seems clear that it can produce no permanent change in the organising apparatus of the protoplasm, since the growth is at once arrested on the removal or death of the insect. But whether the influence is one that more directly affects the physical state of the apparatus for the time being, or whether it acts more directly by introducing new substances into the final chemical reactions, are questions which are plainly worth investigation, but at present certainly do not admit of an answer.

Another example of interference with the developmental processes is afforded by the well-known "lithium larva," which was discovered by Herbst to arise when the eggs of some species of sea-urchins are allowed to segment in sea-water that has been altered by the addition of lithium salts. The monstrosity produced under these conditions was just as constant and specific in character as are the different galls which can be induced to develop on an oak leaf by the corresponding species of insect.

Extending these considerations a little further, one sees that what we call disease also falls into the same category. For disease represents the necessary outcome of a disturbance, however introduced, into the course of metabolism, which diverts it from the "normal" channels. Pathology has long recognised that the explanation and the consequent control of disease lies, ultimately, in the correct appreciation of the cellular reactions as the result of their experimental study. We cannot pride ourselves on the advances that have been made in the study of plant pathology as yet. Our remedies are commonly of the crudest kind, and we have only recently begun to take serious count of the facts of organisation in the scientific attempt to breed races of plants immune from the attack of certain diseases. The results that have already been obtained, both abroad and by Biffen and others in this country, are full of hope at the present time. The study of the causes of immunity along scientific lines ought assuredly to form a fruitful field of investigation in the near future.

From what we already know it seems clear that the proximate causes of immunity may be diverse in character, and may consist in very different reactions in different cases. It may be that the response becomes expressed in a modification of the carbohydrate metabolism, leading to the formation of an excluding layer of cork; or it may lie in the direction of those substances, as yet so little understood, the anti-toxins; or, again, it may be due to still other and even less apparent causes. But whatever the true nature of the response, it will have to be investigated for individual cases, and its secrets will only be unlocked when the chemical and physical processes involved in its operation are understood.

In making these remarks I dare say I may be accused of putting forward an impossible ideal, or at any rate one that is impracticable of attainment. I am not very much concerned about that. Progress is only to be made by trying to penetrate further than we can at present see, and I believe we have gained enough insight into the chemistry and physics of the living processes to warrant us in hoping that we shall penetrate a good deal deeper still. But if we are to ever unravel the tangle, it can only be by applying such methods as have been successful in dealing with material things elsewhere.

For the problems that rise up before us are seen, as we become able to get at close quarters with them, to resolve themselves more and more into questions of chemistry and physics. I believe that it is only by the help of these elder branches of science that the accurate formulation, to say nothing of the final solution, of the problems will be achieved. A recent writer has suggested that life is not the cause of the reactions underlying the phenomena of life. Nevertheless the reactions that go on in the living body are obviously guided as to the particular directions they take by the apparatus or mechanism of the individual organism. When the conditions for the manifestation of life, and all that it implies, are satisfied, what will be produced depends partly on the structure of the apparatus itself (*i.e.*, on the hereditary organisation), partly on the nature of the substances fed into the apparatus, and finally on the physical conditions under which it is working. It is probably along the last two lines that investigation will continue to be pursued with more immediate profit; but the goal will not be finally reached until we have solved the problem as to the nature of organisation itself.

SECTION L.

EDUCATIONAL SCIENCE.

OPENING ADDRESS BY SIR PHILIP MAGNUS, B.Sc., B.A., M.P., PRESIDENT OF THE SECTION.

The Application of Scientific Method to Educational Problems.

NOTWITHSTANDING the fact that the greater part of my life has been spent in educational work, in teaching, in examining, in organisation, and in the investigation of foreign systems of instruction, I have experienced considerable difficulty in selecting, from the large number of subjects that crowd upon me, a suitable one on which to address you as President of a Section of the British Association devoted to educational science.

At the outset I am troubled by the title of the section over which I have the honour to preside. I cannot refrain from asking myself the question, Is there an educational Science, and if so, what is its scope and on what foundations does it rest? The object of the British Association is the advancement of Science, and year by year new facts are recorded in different branches of inquiry, on which fresh conclusions can be based. The progress of past years, whether in Chemistry, Physics or Biology, can be stated. Can the same be said, and in the same sense, of Education? It is true that the area of educational influence is being constantly extended. Schools of every type and grade are multiplied, but is there any corresponding advance in our knowledge of the principles that should govern and determine our educational efforts, or which can justify us in describing such knowledge as Science? If we take Science to mean, as commonly understood, organised knowledge, and if we are to test the claim of any body of facts and principles to be regarded as Science by the ability to predict, which the knowledge of those facts and principles confers, can we say that there exists an organised and orderly arrangement of educational truths, or that we can logically, by any causative sequence, connect training and character either in the individual or in the nation? Can we indicate, with any approach to certainty, the effects on either the one or the other of any particular scheme of education which may be provided? It is very doubtful whether we can say that educational science is yet sufficiently advanced to satisfy these tests.

But although education may not yet fulfil all the conditions which justify its claim to be regarded as a science, we are able to affirm that the methods of science, applicable to investigations in other branches of knowledge, are equally applicable to the elucidation of educational problems. To have reached this position is to have made some progress. For we now see that if we are ever to succeed in arriving at fixed principles for guidance in determining the many difficult and intricate questions which arise in connection with the provision of a national system of education, or the solution of educational problems, we must proceed by the same methods of logical inquiry as we should adopt in investigating any other subject-matter.

In order to bring Education within the range of subjects which should occupy a place in the work of this Association, our first efforts should be directed towards obtaining a sufficient body of information from all available sources, past and present, to afford data for the comparisons on which our conclusions may be based. One of the five articles of what is known as the Japanese Imperial Oath states, "Knowledge shall be sought for throughout the whole world, so that the welfare of the Empire may be promoted"; and it may certainly be said that, as the welfare of our own Empire is largely dependent on educational progress, a wide knowledge of matters connected with Education is indispensable, if we are to make advances with any feeling of certainty that we are moving on the right lines.

There can be no doubt that of late years we have acquired a mass of valuable information on all sorts of educational questions. We are greatly indebted for much of our knowledge of what is being done in foreign countries to the Reports of different Commissions, and more particularly to those special reports issued from the Board of Education, first under the direction of my predecessor in this Chair, Prof. Sadler, and latterly of his successor at the Board, Dr. Heath. But much of the information we have obtained is still awaiting the hand of the scientific worker to be properly coordinated and arranged. A careful collation of facts is indispensable if we are to deduce from them useful principles for our guidance, and unfortunately we in this country are too apt to rest content when we have provided the machinery for the acquisition of such facts without taking the necessary steps to compare, to coordinate, and to arrange them on some scientific principle for future use. Within the last week or two a Bill has passed through several stages in Parliament for requiring Local Authorities to undertake the medical inspection of school children, but, unless the medical inspectors throughout the country conduct their investigations on certain well-considered lines laid down for them by some Central Authority, we shall fail to obtain the necessary data to enable us to associate educational and physical conditions with a view to the improvement of the training given in our schools.[1] On the other hand, although I personally am sceptical as to the results, we have reason to believe that the inquiry recently undertaken into the methods adopted here and elsewhere for securing ethical as distinct from specifically religious training will be so conducted as to give us not only facts, but the means of inferring from those facts certain trustworthy conclusions.

The consideration of Education as a subject capable of scientific investigation is complicated by the fact that it necessarily involves a relation—the relation of the child or adult to his surroundings. It cannot be adequately considered apart from that relation. We may make a study of the conditions of the physical, intellectual, and ethical development of the child, but the knowledge so obtained is only useful to the educator when considered in connection with his environment and future needs, and the means to be adopted to enable him, as he grows in physical, intellectual, and moral strength, to obtain a mastery over the things external to him. Education must be so directed as to prove the proposition that "Knowledge is Power." It can only be scientifically treated when so considered. Education is imperfectly described when regarded as the means of drawing out and strengthening a child's faculties. It is more than this. Any practical definition takes into consideration the social and economic conditions in which the child is being trained, and the means of developing his faculties with a view to the attainment of certain ends.

It is in Germany that this fact has received the highest recognition and the widest application, and for this reason we have been accustomed to look to that country for guidance in the organisation of our schools. We have looked to Germany because we perceived that some relation had been there established between the teaching given to the people and their industrial and social needs; and further, that their success in commerce, in military and other pursuits was largely due to the training provided in their schools. Unmindful of the fact that Education is a relation, and that consequently the same system of education is not equally applicable to different conditions, there were many in this country who were only too ready to recommend the adoption of German methods in our own schools. Experience soon showed, however, that what may have been good for Germany did not apply to England, and that, in educational matters certainly, we do well to follow Emerson, who, when addressing his fellow citizens, declared: "We will walk on our own feet; we will work with our own hands, and we will speak our own minds." Still, the example of Germany and the detailed information which we have obtained as to her school organisation and methods of instruction have been serviceable to us.

Whilst all information on educational subjects is valuable, I am disposed to think that in our efforts to construct an educational science we may gain more by inquiring what has been effected in some of the newer countries. Wherever educational problems have been carefully considered and schemes have been introduced with the express intention and design of training citizens for the service of the State and of increasing knowledge with a view to such service, those schemes may be studied with advantage. Thus we may learn much from what is now being done in our Colonies. Their efforts are more in the nature of experiments. Our Colonies have been wise enough not to imitate too closely our own or any foreign system. They have started afresh, free from prejudice and traditions, and it is for this reason that I look forward with interest to the closer connection in educational matters of the Colonies with the mother country, and I believe that we shall gain much knowledge and valuable experience from the discussions of the Federal Conference which has recently been held in London, and which, I understand, is to be repeated a few years hence.

But valuable as are the facts, properly collated and systematically arranged, which a knowledge of British and foreign methods may afford us in dealing scientifically with any educational problem, it is essential that we should be able to test and to supplement the conclusions based on such knowledge, whenever it is possible, by direct experiments, applicable to the matter under investigation. We have not yet recognised the extent to which experiments in education, as in other branches of know-

[1] Since this was written the President of the Board of Education has stated in the House of Commons that "it was the intention of the Board, if the Bill now before Parliament passed, to establish a medical bureau, which would guide and advise the local authorities as to the nature of the work they would have to do under the Act."

ledge, may help in enabling us to build up an educational science. Some years since there was established in Brussels an *École modèle* in which educational experiments were tried. I visited the school in the year 1880, and I could easily point to many improvements in primary education which found their way from that school through the schools of Belgium and France to our own country, and, indeed, to other parts of the world. From a special Report on Schools in the North of Europe, recently published by the Board of Education, we learn that in Sweden the value of such experiments is fully recognised. We are told that in that country "it was early felt that the uniformity in State Schools was of so strict a kind that some special provision should be made for carrying out educational experiments," and experiments in many directions have been made, mainly in private schools, which receive, however, special subventions from the State. We gather from the same Report that the State regards the money as well earned "if the school occasionally originates new methods from which the schools can derive profit." I venture to think that experimental schools might with advantage be organised under the direction of some of our larger local authorities. The children would certainly not suffer by being made the subjects of such experiments. The intelligent teaching which they would receive—for it is only the most capable teachers who should be trusted with such experiments—would more than compensate for any diminution in the amount of knowledge which the children might acquire, and indeed such experimental schools might be conducted under conditions which would ensure sound instruction. Many improved methods of teaching are constantly advocated, but fail to be adopted because there is no opportunity of giving them a fair trial. As a general rule it is only by the effort of private individuals or associations that changes in system are effected, and teachers are enabled to escape from the old grooves on to new lines of educational thought and practice. It is not difficult to refer to many successful experiments. The general introduction into our schools of manual training was the direct result of experiments carefully arranged and conducted by a Joint Committee of the City Guilds and the late London School Board. Experiments in the methods of teaching Physical Science, Chemistry, and Geometry have been tried, with results that have led to changes which have revolutionised the teaching of those subjects. The age at which the study of Latin should be commenced with a view to the general education of the scholar has been the subject of frequent trial. I would like to see such experiments more systematically organised, and I am quite certain that the curriculum of our rural and of our urban schools would soon undergo very considerable changes, if the suggestions of competent authorities could receive a fair trial under conditions that would leave no manner of doubt as to the character of the results.

It would seem, therefore, that if our knowledge of the facts and principles of education is not yet sufficiently organised to enable us to determine *a priori* the effect on individual or national character of any suggested changes, education is a subject that may be studied and improved by the application to it of scientific method, by accurate observation of what is going on around us, and by experiments thoughtfully conducted. This is the justification of the inclusion of the subject among those that occupy the attention of a separate section of this Association. Our aim here should be to apply to educational problems the well-known canons of scientific inquiry; and, seeing that the conditions under which alone any investigation can be conducted are in themselves both numerous and complicated, it is essential that we should endeavour to liberate, as far as possible, the discussion of the subject from all political considerations. Such investigations are necessarily difficult. We have to determine both statically and dynamically the physical, mental, and moral condition of the child in relation to his activities and surroundings, and we have further to discover how he is influenced by them, how he can affect them, and the character of the training which will best enable him to utilise his experiences, and to add something to the knowledge of to-day for future service.

Notwithstanding the undoubted progress which we have made, it cannot be denied that in this country there still exists a large amount of educational unrest, of dissatisfaction with the results of our efforts during the last thirty years. This is partly due to the fact that there is much loose thinking and uninformed expression of opinion on educational questions. No one knows so little as not to believe that his own opinion is worth as much as another's on matters relating to the education of the people. In this way statements, the value of which has not been tested, pass current as ascertained knowledge, and very often ill-considered legislation follows. In this country, too, the difficulty of breaking away from ancient modes of thought is a great drawback to educational progress. Suggestions for moderate changes, which have been most carefully considered, are deferred and decried if they depart, to any great extent, from established custom, and the objection to change very often rests on no historical foundation. Occasionally, too, the change proposed is itself only a reversion to a previous practice, which was rudely broken by thoughtless and unscientific reformers. The opposition which was so long raised to the establishment of local universities was largely due to want of knowledge on the subject; and certainly the creation, some seventy years ago, of a teaching University in London was actually hindered through a mere prejudice, which broader views as to the real purposes of University teaching and fuller information on the course of University development would have removed.

There never was a time perhaps when it was more necessary than now that education should be regarded dispassionately, apart from political bias, as a matter of vital interest to the people as a whole. Education nowadays is a question which affects not only the life of a few privileged, selected persons, but of the entire body of citizens. The progress that has been made during the last few years in nationalising our education has been very rapid. It may be that it has been too rapid, that sufficient thought has not been given to the altered social and industrial conditions which have to be considered. We have witnessed a strong desire and a successful effort to multiply Secondary and Technical Schools and to open more widely the portals of our Universities. The object of the desire is good in itself. As the people grow in knowledge the demand for higher education will increase, but the serious question to be considered is whether the kind of education which was supplied in schools, founded centuries ago to meet requirements very different from our own, is equally well adapted to the conditions which have arisen in a state of society having other needs and new ideals. Very rightly our students in training for the profession of teachers are expected to study the writings of Locke, Rousseau, Milton, Montaigne, and others; but many are apt to overlook the fact that these writers had in view a different kind of education from that in which modern teachers are engaged, and that their suggestions, excellent as many of them are, were mainly applicable to the instruction to be given by a tutor to his private pupil, and had little or no reference to the teaching of the children of the people in schools expressly organised for the education of the many. Only recently have we come to realise that a democratic system of education, a system intended to provide an intellectual and moral training for all citizens of the State, and so organised that, apart from any consideration of social position or pecuniary means, it affords facilities for the full development of capacity and skill wherever they may occur, must be essentially different in its aims and methods from that under which many of us now living have been trained. It has also been brought home to us that the marvellous changes in our environment, in the conditions under which we live and work, whether in the field, the factory, or the office, have necessitated corresponding changes in the education to be provided as a preparation for the several different pursuits in which the people generally are occupied. Yet, notwithstanding these great forces which have broken in upon and disturbed our former ideals, forces the strength and far-reaching effects of which we readily admit, we still hesitate to face the newly arisen circumstances and to adapt our educational work to its vastly extended area of operation and to the altered conditions and requirements of modern life.

When I say we hesitate to face the existing circumstances I do not wish to be misunderstood. As a fact, changes are continually being discussed, and are from time to time introduced into our schools. But such modifications of our existing methods are generally isolated and detached, and have little reference to the more comprehensive measures of reform which are now needed to bring our teaching into closer relation with the changed conditions of existence consequent on the alterations that have taken place in our social life and surroundings.

Four years ago, it will be remembered, a committee of this section was appointed to consider and to report upon the "Courses of Experimental, Observational, and Practical Studies most suitable for Elementary Schools." That committee, of which I had the honour to be chairman, presented a report to this section at the meeting of the Association held last year at York. The general conclusion at which they arrived was that "the intellectual and moral training, and indeed to some extent the physical training, of boys and girls between the ages of seven and fourteen would be greatly improved if active and constructive work on the part of the children were largely substituted for ordinary class teaching, and if much of the present instruction were made to arise incidentally out of, and to be centred around, such work." It is too early, perhaps, to expect that the suggestions made in that report should have borne fruit, but I refer to it because it illustrates the difference between the spasmodic reforms which from time to time are adopted, under pressure from bodies of well-meaning representatives of special interests, and the well-considered changes recommended by a committee of men and women of educational experience who have carefully tested the conclusions at which they have arrived.

There can be no doubt that, as regards our elementary education, there is very general dissatisfaction with its results, since it was first nationalised thirty-seven years ago. Our merchants and manufacturers and employers of labour, our teachers in secondary and technical schools all join in the chorus of complaint. They tell us that the children have gained very little useful knowledge and still less power of applying it. There is enough in this general expression of discontent to give us pause and to make us seek for a rational explanation of our comparative failure. The inadequacy of the results attained to the money and effort that have been expended is in no way due to any want of zeal or ability on the part of the teachers, or of energy on the part of school boards or local authorities. They have all discharged the duties which were imposed upon them. It is due rather to the fact that the problem has been imperfectly understood, that our controlling authorities have had only a vague and indistinct idea of the aim and end of the important work which they were charged to administer. If we look back upon the history of elementary education in this country since 1870, we cannot fail to realise how much its progress has been retarded by errors of administration due very largely to the want of scientific method in its direction. It is painful to reflect, for instance, on the waste of time and effort, and on the false impressions produced as to the real aim and end of education, owing to the system of payment on results, which dominated for so many years a large part of our educational system. We must remember that it is only within the last few decades that education has been brought within reach of all classes of the population. Previously it was for the few; for those who could pay high fees; for those who were training for professional life, whether for the Church, the Army, the Navy, Law, or Medicine, or for the higher duties of citizen life. This had been the case for centuries, not only in this country, but in nearly all parts of the civilised world. If we read the history of education in ancient Greece or Rome, or mediæval Europe, we shall see that popular education, as now understood, was unknown. All that was written about education applied to the few who got it, and not to the great mass of the people engaged in pursuits altogether apart from those in which the privileged classes were employed. Trade and manual work were despised, and were considered degrading and unworthy of the dignity of a gentleman. I need scarcely say that these social ideas are no longer held. The fabric of society is changed, and we have to ask ourselves whether the methods of education have been similarly changed, whether they have been wisely and carefully adapted to the new order of things. What is it that has really happened? Is it not true that we have annexed the methods and subjects of teaching which had been employed during many centuries in the training of the few and applied them to the education of the people as a whole—to those who are engaged in the very callings which were more or less contemned? Surely it is so, and the results are all too manifest. We have applied the principles and methods of the secondary education of the Middle Ages to our new wants, to the training of the people for other duties than those to which such education was considered applicable, and it is only within the last few years that we have begun to see the error of our ways. In the report of your committee, to which I have referred, it is pointed out that the problem of primary education has been complicated by the introduction of the methods which for many years prevailed in secondary schools, and at a meeting of the National Education Association, held only a few weeks since, it was truly said: "In this country secondary education preceded primary by several centuries, and so the nation now finds itself with the aristocratic cart attempting to draw the democratic horse."

Let it not be supposed that in the days not so far distant, yet stretching back into the remote past, the people as a whole were uneducated. This was not so. But we have to widen the meaning of education to include the special training which the people then received—an education that was acquired without even the use of books. It cannot for one moment be said that the artisans, the mechanics, the farm hands, male and female, were wholly uneducated in those far-off days. In one sense possibly they were. Very few of them could read or write. But from earliest childhood they had received a kind of training the want of which their descendants have sadly felt in the cloistered seclusion of the modern elementary school. They were brought face to face with Nature. They learned the practical lessons of experience; and as they grew up their trade apprenticeship was an education which we have been trying vainly to reproduce. They gained some knowledge of the arts and sciences, as then understood, underlying their work. Their contact with their surroundings made them thoughtful and resourceful, for Nature is the most exacting and merciless of teachers. The difficulties they had to overcome compelled them to think, and of all occupations none is more difficult. They were constantly putting forth energy, adapting means to ends, and engaging in practical research. In the field, in the workshop, and in their own homes boys and girls acquired knowledge by personal experience. Their outlook was broad. They learned by doing. It is true that nearly all their occupations were manual, but Emerson has told us, "Manual training is the study of the external world."

Compare for a moment this training with that provided in a public elementary school, and you cannot be surprised to find that our artificial teaching has failed in its results, that our young people have gained very little practical knowledge, and that what they have gained they are unable to apply; that they lack initiative and too often the ability to use books for their own guidance, or the desire to read for self-improvement. We seem to have erred in neglecting to utilise practical pursuits as the basis of education, and in failing to build upon them and to evolve from them the mental discipline and knowledge that would have proved valuable to the child in any subsequent occupation or as a basis for future attainments. We have made the mistake of arresting, by means of an artificial literary training, the spontaneous development of activity which begins in earliest infancy and continues to strengthen as the child is brought into ever closer contact with his natural surroundings. We have provided an education for our boys which might have been suitable for clerks; and, what is worse, we have gone some way, although we have happily cried a halt to make our girls into "ladies," and we have run some risk of failing to produce women.

If we are to correct the errors into which we have drifted, if we are to avert the consequences that must overtake us through having equipped our children for their life-struggle with implements unfitted for their use, we must consider afresh the fundamental ideas on which a system of elementary education should be based. Instead of excluding the child from contact with the outer world we must bring him into close relationship with his surroundings. It was given to man to have dominion over all other created things, but he must first know them. It is in early years that such knowledge is most rapidly acquired, and it is in gaining it that the child's intellectual activities are most surely quickened.

It is unfortunate that we failed to realise this great function of Elementary Education when we first essayed to construct for ourselves a national system. The three R's, and much more than that, are essential and incidental parts of Elementary Education. But what is needed is a *Leitmotif*—a fundamental idea underlying all our efforts and dominating all our practice, and I venture to think that that idea is found in basing our primary education on practical pursuits, on the knowledge gained from actual things, whether in the Field, the Workshop, or the Home.

Instead of fetching our ideas as to the training to be given in the people's schools from that provided in our old grammar schools, we should look to the occupations in which the great mass of the population of all countries are necessarily engaged, and endeavour to construct thereon a system with all such additions and improvements as may be needed to adapt it to the varied requirements of modern life. By this process—one of simple evolution adjusted to everyday needs—a national system of education might be built up fitted for the nation as a whole—a system founded on ideas very different from those which, through many centuries, have governed the teaching in our schools. In the practical pursuits connected with the Field, the Workshop, and the Home, and in the elementary teaching of science and letters incidental thereto, we might lay the foundation of a rational system of primary education.

These three objects—the Field, the Workshop, and the Home—should be the pivots on which the scheme of instruction should be fixed, the central thoughts determining the character of the teaching to be given in rural and urban schools for boys and girls. It was Herbart who insisted on the importance of creating a sort of centre around which school studies should be grouped with a view to giving unity and interest to the subjects of instruction. I have elsewhere shown how a complete system of primary education may be evolved from the practical lessons to be learned in connection with out-door pursuits, with workshop exercises and with the domestic arts, and how, by means of such lessons, the child's interest may be excited and maintained in the ordinary subjects of school instruction, in English, arithmetic, elementary science, and drawing. In the proposals I am now advocating I am not suggesting any narrow or restricted curriculum. On the contrary, I believe that, by widening the child's outlook, by closely associating school work with familiar objects, you will accelerate his mental development and quicken his power of acquiring knowledge. I would strongly urge, however, that the child should receive less formal teaching, that opportunities for self-instruction, through out-door pursuits, or manual exercises, or the free use of books, should be increased, so that as far as possible the teacher should keep in view the process by which in infancy and in early life the child's intelligence is so rapidly and marvellously stimulated. Already we have discovered that our unscientific attitude towards primary education has caused us to overlook the essential difference between the requirements of country and of town life, and the training proper to boys and girls. Our mechanical methods of instruction, as laid down in codes, make for uniformity rather than diversity, and we are only now endeavouring, by piecemeal changes, to bring our teaching somewhat more closely into relation with existing needs. But the inherent defect of our system is that we have started at the wrong end, and, instead of evolving our teaching from the things with which the child is already familiar, and in which he is likely to find his life's work, we have taken him away from those surroundings and placed him in strange and artificial conditions, in which his education seems to have no necessary connection with the realities of life.

The problem of primary education is to teach by practical methods the elements of letters and of science, the art of accurate expression, the ability to think and to control the will; and the ordinary school lessons should be such as lead to the clear apprehension of the processes that bring the child into intimate relation with the world in which he moves. During the last few years the importance of such teaching has dimly dawned upon our educational authorities, but, instead of being regarded as essential, it has been treated as a sort of *extra* to be added to a literary curriculum, already overcrowded. What is known as manual training is to some extent encouraged in our schools, but it forms no part of the child's continuous education. It is still hampered with conditions inconsistent with its proper place in the curriculum, and is uncoordinated with other subjects of instruction. Moreover, no connecting link has yet been forged between the teaching of the Kindergarten and workshop practice in the school. We speak of lessons in manual training as something apart from the school instruction, as something outside the school course, on the teaching of which special grants are paid. Twenty or thirty years ago people used to talk about "teaching technical education," and from this unscientific way of treating the close connection that should exist between hand-work and brain-work our authorities have not yet freed themselves.

It is true we have long since passed that stage when it was thought that the object of instruction in the use of tools was to make carpenters or joiners; but, judging from a report recently issued by the Board of Education, it would seem that it is still thought that the object of cookery lessons to children of twelve to fourteen years of age is the training of professional cooks. Until the Board's inspectors can be brought to realise that the aim and purpose of practical instruction in primary schools, whether in cookery or in other subjects, is to train the intelligence through familiar occupations, to show how scientific method may be usefully applied in ordinary pursuits, and how valuable manipulative skill may thus be incidentally acquired, it does not seem to me that they themselves have learned the most elementary principles of their own profession. An anonymous teacher, writing some weeks since in the *Morning Post*, said: "The cookery class can be made an invaluable mental and moral training ground for the pupils, the most stimulating part of primary education. It teaches unforgettable lessons of cleanliness and order, of quickness and deftness of movements. The use of the weights and scales demands accuracy and carefulness, and the raw materials punish slovenliness or want of attention with a thoroughness which the most severe of schoolmasters might hesitate to use. Practical lessons in chemistry should form an important feature of each class. . . . The action of heat and moisture on grains of rice provides an interesting lesson on the bursting of starch cells, and the children's imagination is awakened by watching the hard isolated atoms floating in milk change slowly to the creamy softness of a properly made rice pudding. The miraculous change in the oily white of egg when it is beaten into a mountain of snowy whiteness gives them interest in the action of air and its use in cookery."

Can the teaching of grammar or the analysis of sentences provide lessons of equal value in quickening the intelligence of young children?

I must add one word before passing from this suggestive illustration of the value of scientific method in the treatment of educational questions. We live in a democratic age, and any proposed reform in the teaching of our primary schools must be tested by the requirement that the revised curriculum shall be such as will provide not only the most suitable preparatory training for the occupations in which four-fifths of the children will be subsequently engaged, but will, at the same time, enable them or some of them to pass without any breach of continuity from the primary to the secondary school. There must be no class distinctions separating the public elementary from the State-aided secondary school. The reform I have suggested is unaffected by such criticism. The practical training I have advocated, whether founded on object-lessons furnished by the Field, the Workshop, or the Home, would prove the most suitable for developing the child's intelligence and aptitudes and for enabling him to derive the utmost advantage from attendance at any one of the different types of secondary schools best fitted for his ascertained abilities and knowledge. The bent of the child's intellect would be fully determined before the age when the earliest specialisation would be desirable. No scheme of instruction for primary schools can be regarded as satisfactory which is not so arranged that, whilst providing the most suitable teaching for children who perforce must enter some wage-earning pursuit at the age of fourteen, or at the close of their elementary school course, shall at the same time afford a sound and satisfactory basis on which secondary and higher education may be built. And I hold the opinion, in which I am sure all teachers will concur, that a scheme of primary education pervaded by the spirit of the Kindergarten which, by practical exercises, encourages observation and develops the reasoning faculties, and creates in the pupil an understanding of the use of books, would form a fitting foundation for either a literary or a scientific training in a secondary school.

I have purposely chosen to illustrate the main subject of this address by reference to defects in our primary instruction, because the success of our entire system of education will be found, year by year, to depend more and more upon the results of the training given in our public elementary schools. We have scarcely yet begun to realise the social and political effects of the momentous changes in our national life, consequent on the first steps which were taken less than forty years ago to provide full facilities under State control and local management for the education of the people.

At present all sorts of ideas are afloat which have to be carefully and scientifically considered. The working classes have to be further and somewhat differently educated, in order that they may better understand their own wants and how they are to be satisfied. We have placed vast powers in the hands of local bodies, popularly elected, powers not only of administration, for which they are well adapted, but powers of determining to a very great extent, by the free use of the rates, the kind of instruction to be given in our schools, and the qualifications of the teachers to impart it. Moreover, these local bodies have shown, in many instances, a distrust of expert advice and a desire to act independently as elected representatives of the people, which cannot fail for some time at least to lead to waste of effort and of means. It was said years ago, when the centre of our political forces received a marked displacement, that we must educate our masters. Our masters now, both in politics and education, are the people, and it is only, I believe, by improving their education that we can enable them to understand the essential difficulties of the problems which they are expected to solve, and can induce them to rely, to a greater extent than they do at present, on the results of the application to such problems of scientific method, founded on the fullest information obtainable from historical and contemporary sources.

I might have illustrated my subject by reference to the acknowledged chaotic condition of our secondary education. In the report of the Board of Education published in December last we read: "While the development of secondary education is the most important question of the present day, and is the pivot of the whole education as it affects the efficiency, intelligence, and well-being of the nation, yet its present position may be described as 'chaos.'" The "chaos" by which the present position of our secondary education is here described is intimately connected with the questions relating to primary education, which I have been engaged in considering. If we construct a system of primary education which serves equally for children of all classes, apart from social conditions—a system educationally sound, both as a preparation for immediate wage-earning pursuits and for more advanced and somewhat more specialised training in a secondary school—many of the difficulties which confront the Board of Education, and which are largely of an administrative order, would disappear. The difficulties are in part dependent on the question of curriculum, to the discussion of which a day will be devoted during the present meeting.

University education in this country, and indeed in other countries, has also suffered much from the hands of the unscientific reformer. In Germany, owing to many causes, the higher education has made considerable advances during the past century; but, even in that country, a more critical study of the development of University education and a truer recognition of the twofold function of a University might have prevented the early separation in distinct institutions and under separate regulations of the higher technical from University instruction. Only within recent years has France retraced her steps and returned to the University ideal of seven centuries ago. But perhaps the climax of unscientific thinking was reached in the scheme, happily abandoned, of founding a new University in Dublin on the lines suggested by Mr. Bryce in his now famous speech of January last.

Our conception of the functions of a University has undergone many violent changes. Between the ideal of the University of London prior to its reorganisation and that of a mediæval University, in which students were never plucked, obtaining their degrees whether they did their work well or badly, there have been many variations; but I think it may be said that, recently at any rate, we have come to realise the fact that our Universities, to fulfil their great purpose, must be schools for the preparation of students for the discharge of the higher duties of citizenship and professional life, and Institutions for the prosecution of research, with a view to the promotion of learning in all its branches, and that examinations for degrees, necessary, as they undoubtedly are, as tests of the extent of a student's acquired knowledge, must be regarded as subordinate to these two great functions.

I will not detain you longer. I have endeavoured to show under what limitations education may lay claim to be included among the sciences, and how a knowledge of the history of education and the application of the methods of scientific inquiry may help in enabling us to solve many of the intricate and complicated questions which are involved in the establishment on a firm foundation of a national system of education. I have taken my illustrations mainly from the reform of elementary, or, as I prefer to call it, primary education, and I have sought to indicate some of the errors into which we may fall when we fail to apply to the consideration of the problem the same principles of inductive inquiry as are employed in all investigations for the attainment of Truth.

I believe that this Section of the British Association has the opportunity of rendering a great service to the State. Numerous educational societies exist, in which questions of importance are discussed, and all, perhaps, do useful work. But none is so detached from separate and special interests; none stands so essentially apart from all political considerations; none is so competent to discuss educational problems from the purely scientific standpoint as are the members of this Association. If, in the remarks I have offered, somewhat hastily prepared under the pressure of many different kinds of work, I have contributed anything to the solution of a problem the difficulty and national importance of which all will admit, I shall feel that I have not been altogether unworthy of the honour of occupying this Chair.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Liverpool.—Mr. Percy E. Newbury has been appointed professor of Egyptology in the University.

London.—University College:—With the assistance of the Chadwick trustees, arrangements have been completed to hold a new course on school hygiene, including lectures, demonstrations, and practical work, beginning on October 16. The course will be given by Prof. Henry Kenwood and Dr. H. Meredith Richards. It is designed to meet the requirements of school teachers, school lecturers, and those qualifying to become school inspectors and school medical officers. A certificate of proficiency will be granted to those who qualify themselves.

A programme of the courses of study in the departments of pure and applied mathematics and astronomy of University College, London, has just been issued. In it are to be found full particulars as to the courses in the departments for students preparing for honours in the subjects above referred to, also of the facilities for research in the college. The programme may be obtained on application to the secretary of the college.

OXFORD.—Owing to the great increase in the number of students at Ruskin College, the staff is being increased. Prof. Lees Smith has retired from the position of vice-principal, and has been elected director of studies and chairman of the executive committee. He will for the present combine this with his duties in the newly created chair of economics and public administration at University College, Bristol, and with his work at the London School of Economics. Mr. Charles S. Buxton, of Balliol College, has been appointed vice-principal. Mr. H. S. Furniss, of Hertford College, has been appointed lecturer in economics. The plans for the new building are now under consideration. The building will be erected on the site of the temporary buildings adjoining Worcester College, and will accommodate 100 students. For this purpose the college will require about 20,000*l.*

A FURTHER 2000*l.* has been given by Sir Donald Currie towards the equipment fund of Queen's College, Belfast, bringing up his contributions to the sum of 22,000*l.*

THE calendar of the Merchant Venturers' Technical College, Bristol, has just been issued, and gives particulars of the courses of instruction at the institution and much other information. Although the main building of the college was partially destroyed by fire, the work of the institution has not been crippled, owing to the Bristol Education Committee having placed at the disposal of the governors large buildings planned to accommodate more than 1000 pupils. These buildings, temporarily known as the Castle Branch of the Merchant Venturers' Technical College, Castle Green, have been fitted with the necessary lecture theatres, laboratories, and workshops.

AN amendment to the Education Administrative Provisions Bill, recommending that power should be given to local authorities to make periodic anthropometric records of children which would afford definite information as to the physical condition and development of the children, was moved last week in the House of Commons by Sir Philip Magnus, who referred to the resolution upon the subject adopted at the joint meeting of the Anthropological and Educational Sections of the British Association, and the report upon such measurements conducted by the Glasgow School Board, which has just been issued by the Scotch Education Department; but upon the President of the Board of Education saying that clause 13 of the Bill as it stands gives the necessary powers the amendment was not carried. It is well, perhaps, to emphasise the fact that local authorities possess under the new Act the necessary powers to institute a system of scientific measurements.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 12.—M. Bouquet de la Grye in the chair.—Integral curves of differential equations: Georges **Rémoundos**.—The accidents arising during the manipulation of compressed oxygen, and on an arrangement permitting of their avoidance: Georges **Claude**. The ordinary forms of regulator for reducing the pressure contain a piece of ebonite, and this is liable to catch fire and even to inflame the steel cylinder. The author describes a simple modification of the regulator by which any local elevation of temperature in the neighbourhood of the ebonite is avoided.—A dynamo designed for wireless telegraphy: P. **Villard**. This dynamo has been designed so that the voltage curve is analogous to that of a Ruhmkorff coil, and, in addition, allows the time interval between the successive sparks to be regulated mechanically. The nature of the voltage curve produced has been studied by means of the oscillograph, curves from which are reproduced in the paper. Experiments have been made with this instrument both in the laboratory and in the field, and for equal motive power the results are much superior to those obtained with a coil. The dynamo is also useful for the production of X-rays.—The maximum of phosphorescence: J. **de Kowalski** and C. **Garnier**. A discussion of some recent results on the same subject by L. Bruninghaus.—The cause of the beating of the heart: H. **Kronecker**. Serum from the blood of a calf was subjected to diffusion in a current of flowing water so that the amount of sodium chloride was reduced to 0·6 per cent. This fluid was used to replace the blood in the cardiac cavities of the frog, toad, and tortoise, and it was found possible to suppress completely the beats of the heart for one hour. Any stimulus applied during this period of arrest caused either a strong pulsation or a group of pulsations. The effects of other solutions are also recorded. The conclusion is drawn from these experiments that the heart does not beat automatically, but requires stimulants of a chemical nature to act on the nervous plexus of the heart.—The reaction of tuberculin in leprosy (subcutaneous, dermic, and conjunctival inoculations): Charles **Nicolle**.—Observations on the Eocene and Oligocene in Hampshire: Jean **Boussac**.—The results of observations of the intensity of gravity at the island of Booth-Wandel, Grahamsland, by the Antarctic expedition of Dr. J. Charcot: M. **Matha**. An account is given of the experimental method used and the accuracy attained. The value of g found, 982·439, is higher than the value calculated from the formula of Defforges, $g = 978{\cdot}106(1 - 0{\cdot}005243 \sin^2 A)$, by 0·116 cm. This difference is in full accord with the results of Foster in the same regions.—The paroxysms of Stromboli: A. **Riccò**.

THE CONSTITUENTS OF THE EUROPEAN FAUNA.

European Animals: their Geological History and Geographical Distribution. By R. F. Scharff. Pp. 14+258; illustrated. (London: Archibald Constable and Co., Ltd., 1907.) Price 7s. 6d. net.

CHOOSING a suitable and expressive title is not unfrequently one of the most difficult tasks (next to writing a preface) in preparing a work relating to natural history, and in this particular instance we venture to think that the author has not done himself anything like justice in the one he has selected. "Animals" in popular estimation are still regarded (and to a certain extent we think justly so) as forming only one section of the animal kingdom; while, altogether apart from this, the title, "European Animals," which alone appears on the cover, suggests a work of a nature totally different from the one before us. At any rate, such was the impression in our own case, and we expected to find something in the shape of a text-book of at least the mammalian section of the European fauna. When the full title is read the situation is of course changed, although even then there seems something lacking. As a matter of fact, the volume, which is based on a course of (we believe much appreciated) lectures delivered at South Kensington, may be regarded as a sequel to and amplification of the author's previous work on the "History of the European Fauna."

After an introductory chapter, in which general matters affecting zoological distribution and the value of land mammals and molluscs as a basis for zoological geography are discussed, the author, as perhaps in duty bound, commences with Ireland, directing special attention to and attempting to account for the absence in that island of many types common in Great Britain. Scotland, England, and Wales form the subject of the next two chapters, after which the Spanish peninsula, the Alps, eastern Europe and the Caucasus, the western plain of Europe, and, finally, the east and west Mediterranean provinces are discussed in turn. Having expressed his belief in the supreme value of mammals and land-snails to the student of distribution, the author, as might be expected, takes these groups as his text, using other sections of the animal kingdom as collateral evidence whenever occasion may require. A special feature is formed by a series of maps of the geographical distribution of a number of mammals and land-molluscs, these being illustrated by insets displaying a portrait either of the animal itself or of its shell. Assuming these maps to be trustworthy (and such of them as we have examined appear to be so), they have a very considerable value, for few things are more difficult than to obtain accurate information in such matters.

The mention of the insets in these maps naturally leads to a few words with regard to the illustrations generally. Where photographs of shells, like the one of Clausilia on p. 95, have been reproduced, nothing can be better than the result. With regard to most of the other illustrations, we regret, however, that we are unable to congratulate the author. They start with the disadvantage that they are taken from stuffed specimens—a style of illustration which does not appeal to our taste. Added to this is the circumstance that they have been largely "faked" by the addition of false backgrounds. The least unsatisfactory is the frontispiece, representing a group of blue hares and grouse in the Dublin Museum, but even this is blurred and indistinct; while the group of badgers on p. 24, taken from a case in the British Museum, with an added background, is hopelessly bad. Worst of all is the portrait in the inset to the map on p. 78 of an apparently enraged hippopotamus careering on a mountain-top!

Lack of space prevents detailed reference to the views of the author as to the factors which have combined to form the modern fauna of Europe; but this is a matter of less moment since most of these are familiar through his previous work. An especially interesting chapter is the one dealing with the Caucasus and east Europe, in which the view of a former connection between the polar ocean and the Aralo-Caspian system is stoutly maintained; much importance in this respect being attached to the crustaceans of the genus Pontoporeia, which are common to the Caspian and the Arctic Ocean. The distinctness of the fauna of the Caucasus from that of south Russia generally (due, it is supposed, to a connection between the Caspian and Black seas) and its affinity to that of Asia Minor is another feature on which special stress is laid.

In conclusion, we may endorse the opinion of Sir E. Ray Lankester, that the lectures (whether or no we accept all the views therein expressed) on which this volume is founded contain so much valuable information that their publication was practically a duty owed by their author to the scientific world. The volume should be in the library of every naturalist. R. L.

THE GEOGRAPHY OF AUSTRALIA AND NEW ZEALAND.

Stanford's Compendium of Geography and Travel. (New issue.) Australia. Vol. i. Australia and New Zealand. Second edition, re-written. By Prof. J. W. Gregory, F.R.S. Pp. xxiv+657. (London: E. Stanford, 1907.) Price 15s.

ONE of the characteristics of the age of synthesis in which we live is a desire on the part of the people of Great Britain for a better knowledge of the Britains beyond the seas. Hence spring Imperial conferences and schemes for reciprocal education; hence, also, a crop of volumes dealing with the geography, history, and conditions of the colonies. Among these not one has been written with a deeper insight into the problems which confront a young nation than Prof. Gregory's work on Australia and New Zealand. It is too much the custom for writers to judge the measures of a new country by old-world standards, and to commend or condemn them according to the degree of their correspondence. But a moment's

 T

reflection will disclose the fallacy of such a criterion. If the problem of colonial administration could be satisfactorily solved by imitating ancestral patterns, what is the reason for the frequent failure of nations which systematically follow this course? why should it be thought necessary to utter warnings against the attempt to import Berlin into Uganda? and how is the success which attends the experimental and empirical methods of Great Britain to be explained?

Readers of NATURE are aware that evolution depends on the power of adaptation to environment, and will have no difficulty in recognising that the secret of the British Empire lies in the plasticity which permits the free play of variation, so as to fit novel functions to new requirements. A perusal of Prof. Gregory's book will disclose numerous experiments in social and industrial legislation which have been made to meet Australian conditions; and his appreciation of many of these departures presents an interesting contrast to the undiscriminating denunciations of most British observers. The volume is a compendium of geography; but the geography of to-day is a much wider subject than the dry-bone catalogues which formerly stood for that science, and which were so repulsive to students of the previous generation. Under the heading of Physical, Economic, and Political Geography, the author has succeeded in presenting a life-like picture of the countries he describes.

Isolation, according to Prof. Gregory, is the explanation of the physical, biological, and political features of Australasia. The strange forms of fauna in Australia are due to its long separation from other continents. The unique aspect of its vegetation is similarly due to development in what is happily called "a biological backwater"; but it is a mistake on that account to regard the flora as primitive in character; it is in reality highly specialised, and the author quotes with approval Spencer Moore's statement that in adaptation of plant life to a dry climate "the Australian flora is without a parallel the world over." It is also a common error to regard the Australian aborigines as archaic. They are closely allied to the hill tribes of Southern India; and here, again, the evidence of specialisation is abundant. The social system of the aborigines is elaborate, and on their own plane they have attained a fair degree of civilisation. Their mental capacity is considerable, and their disposition is described as "kindly, peaceful, and amiable." They are possessed of poetical imagination, and have an intense belief in the immanence of the spiritual world.

Prof. Gregory regards the prevailing aspect of Australian scenery as hopefulness, and this quality is reflected in the temperament of the inhabitants. Although Australians are happy in their dispositions, they are accustomed to make some present sacrifice of comfort for the sake of the future. This has been repeatedly shown by the labour party, to whose efforts advanced temperance legislation is largely due. Although, as a conservative in British politics, Prof. Gregory went to Australia with the "bogey" idea of the Australian Labour Party, he sees much to admire in their ideals. His observations on the White Australia policy show both sympathy and discernment. He remarks that "no nation has yet become great which left aliens to do its manual labour." Labour in Australia, though high-priced, is cheap because it is so efficient; dividends are paid out of deep quartz mines producing 2 dwts. of gold to the ton, and Australia holds the record of cheap and rapid deep-shaft sinking. The arguments for an Australian navy are fairly stated, as also are those for the Alien Immigration Acts. The chapters on the exploration and discovery of Australia are full of interest, and there is a concise description of Australian federation. Prof. Gregory's volume will well repay perusal, and is a welcome addition to descriptive works on Australasia.

JOHN A. COCKBURN.

AIR CURRENTS AND VENTILATION.

Air Currents and the Laws of Ventilation. By Dr. W. N. Shaw, F.R.S. Pp. xii+94. (Cambridge: University Press, 1907.) Price 3s. net.

THIS book contains the substance of a course of lectures delivered by Dr. Shaw at Cambridge in 1903. The author's reputation as a physicist will naturally lead those who open these pages to expect a scholarly treatment of the subject, and they will not be disappointed; and although we are told in the preface that "this volume is in a sense my last will and testament on the subject of ventilation," we venture, after a careful perusal of the book, to express a hope that Dr. Shaw may find time to extend so judicious and original a treatment of this difficult branch of applied science.

Writers on the subject of ventilation are apt either to deal with individual schemes which have come under their notice, leaving useful general inferences to be constructed by the reader, or, armed with mathematics, to plunge *in medias res* among all the factors of the problem in a manner which entirely obscures the main issue. It is the more satisfactory, therefore, to find a book free from such shortcomings.

While admitting the many and complex problems which deserve consideration, the author of this volume brings us, by a wise process of selection and rejection, to issues which, while admittedly approximate to truth, are at the same time most valuable generalisations, and this with a mathematical restraint which should considerably increase the field in which the utility of his work will be felt.

The leading feature of the book is the development of the subject by the utilisation of an analogy between pneumatic and electrical flow and resistance, originated by Dr. Shaw some years ago. We are shown, for example, the relation of air flow to "head," or "aëromotive force," and how to deal with pneumatic resistances in parallel and multiple arc, and the analogy is even taken so far as the use of null methods in such determinations. In this spirit we are conducted through a network of difficulties in a manner which anyone with the most elementary knowledge of the laws of electricity will much appreciate. This analogy is not confined to mere theorising. Actual apparatus consisting of thin plate orifices, large connecting boxes and delicately poised vanes, is figured and described by which the fundamental pneumatic laws may be demonstrated. For example, if H be the head or aëromotive force, R the resistance, or sum of resistances, and V the volume of air delivered, using comparable units, the relation $H=RV^2$, corresponding with Ohm's law $E=RC$, is shown to exist.

The book is divided into three chapters comprising respectively 26, 19, and 33 pages. The first deals with the laws of flow in air circuits and their verification, in the manner already referred to. The second with the physical principles applicable to the ventilated space, in which the important effects of changes of temperature and the convection currents resulting therefrom are discussed, and some sketches of delicate and simple apparatus used by the author in his investigations, together with some real and ideal thermal diagrams, are given. In the third chapter are discussed the essentials for practical ventilation, and, so far as the limits of the book permit, the various systems in general use. Here again the electrical analogy is given full play, and applied to the consideration of the open fire, the cowl, the vacuum and plenum systems, and to simple cross-ventilation.

The diction throughout the book is so clear and concise that we cannot even quarrel with Dr. Shaw when he refers to a draught along the floor as likely to set up "the reversed correlative of the therapeutic action" of putting one's feet in water, and we heartily endorse his suggestion that this important subject should receive more attention at the hands of those engaged in scientific research in our technical institutions.

OUR BOOK SHELF.

The Aim and Achievements of Scientific Method: an Epistemological Essay. By Dr. T. Percy Nunn. Pp. x+144. (London: Macmillan and Co., Ltd., 1907.) Price 3*s.* 6*d.* net.

This essay is an expansion of a paper read before the Aristotelian Society in February, 1906, and was in its present form printed in September, 1906, and presented to the University of London as a thesis for the degree of Doctor of Science. The results described were reached in the course of a study of the problems of science teaching in schools, but its pedagogical applications are not considered in the present volume.

The essence of the doctrine presented by the author is the view that a large part of the contents of our consciousness from moment to moment consists of elements which exhibit themselves as having a certain unique "priority" to our conscious processes. These elements constitute what he describes as the objective. The aim of the scientific process is to render objective facts intelligible to an individual consciousness by building up the primary facts into "secondary constructions" by means of ideas drawn from other contexts of experience. No hypothesis is considered essentially incapable of making primary facts intelligible on the ground of the context of experience from which it is drawn, while the hypothesis is in no case to replace (in the sense of accounting for the "reality" of) the objective facts which it has been employed to render intelligible. The extent to which unification of the various provinces of scientific inquiry can be brought about is identical with the range over which hypotheses drawn from a single context of experience can be applied to illustrate facts.

The author examines briefly the most systematic of the attempts that have been made to render the whole range of sensible facts intelligible by means of the concepts of "mass" and "motion," which are themselves drawn only from one province of primary facts. Huygens, in his discussion of the collision of elastic bodies, made use of what Mach calls an "instinctive perception," that the centre of gravity of a system left to itself cannot rise; this was by the Bernoullis developed into the principle of *vis viva*, upon which Helmholtz based his wider principle of the conservation of energy, which first brought the facts of heat into a line with those of mechanics. But though temperature changes are thus connected with mechanical facts, the doctrine does not effect a reduction of the former to the latter, nor is Lord Kelvin's absolute thermodynamic scale more successful, as it makes no attempt to deduce from dynamical data the experiences to which the notion of temperature refers. Even the theory of Helmholtz is only partially successful. The modern science of energetics expressly declines to attempt to explain one set of objective phenomena in terms of another, contenting itself with trying to bring physical facts into a form of unity without reducing them to one type. In doing so it exhibits a practice that accords with the philosophical tenets of Dr. Nunn's essay. The hypothesis has, as he shows, merely a transient function, to point the way to new facts, including relations between things, and should then efface itself.

The Principles and Practice of Brewing. By Dr. Walter J. Sykes. Third edition, revised by the author and Arthur R. Ling. Pp. xviii+588; illustrated. (London: C. Griffin and Co., Ltd., 1907.) Price 21*s.* net.

The publication of a new edition of this well-known book, which has been thoroughly revised by its author, the late Dr. Sykes, in conjunction with Mr. Ling, and brought well up to date, should be welcomed by all interested in the scientific aspect of the brewing industry. In one respect we think the late author and his colleague have lost an opportunity in not revising the original plan of the book, together with the matter it contains, for we have always considered that the book suffered to some extent in usefulness from the manner in which it was arranged; but, however this may be, the work in its present form stands easily first among books in our language devoted to a consideration of the complex scientific problems underlying the brewer's art.

The present edition, like the previous ones, is essentially a treatise on the scientific principles which underlie brewing technology, and although the word "practice" is included in its title, the space actually devoted to a description of the various processes of brewing and malting is comparatively small. In a book which deals in a somewhat encyclopædic manner with many different branches of science, naturally some unevenness is noticeable in the treatment of the various subjects included, but none of the more recent investigations of importance which bear on the subjects discussed appears to have been overlooked, and the references which are given add much to the value of the book. The strongest part of the book is undoubtedly the one which deals with the chemistry of the carbohydrates, more especially the chemistry of starch, and the author's *résumé* of the investigations which have been made in this country and abroad in connection with the transformation of starch by diastase is the most complete account of the subject we have yet seen. We recommend the book not only to those directly interested in the scientific aspect of brewing, but also to those chemists and biologists whose work in any way trends in the direction of brewing or malting problems.

Oberharzer Gangbilder. By Dr. Phil. B. Baumgärtel. Pp. 23+six plates. (Leipzig: Engelmann, 1907.) Price 7 marks.

THE text of this book describes the geological features of the Upper Harz, and the mineral veins that, according to von Koenen, were injected into the old rocks of the region as recently as Miocene times. It serves as an introduction to six very beautiful photographs of large rock-surfaces in the mines. The various minerals of the lodes have been coloured in effective but harmonious tints, so that the relations of each can be traced out precisely. This combination of photographic accuracy with diagrammatic clearness may serve as a model for reproductions in other branches of science. The old coloured geological landscapes of the days of Weaver and Delabeche occur to one's mind, and might thus with advantage be revived.

LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Atmospheric Absorption of Wireless Signals.

IN the *Electrical Review*, May 11 and 18, the writer has given curves which show that telegraph messages exchanged between Scotland and Massachusetts are received on some nights with practically no absorption, while on other nights and in daytime nine hundred and ninety-nine one-thousandths (0·999) of the energy is absorbed.

The fact that the daylight absorption was largely reduced between two stations 150 miles apart in Brazil by the use of a longer wave-length suggested that the masses of ionised air which are supposed to produce the absorption are broken up somewhat as clouds are. During the past six months experiments have been made between Massachusetts and stations at Porto Rico, Cuba, Washington (D.C.), and New York which seem to point to the same conclusion.

Two types of transmitting apparatus were used.

The first was an alternating-current dynamo giving 250 sparks per second and generating feebly damped waves. The energy used was between 10 and 12 kw., and the frequencies used were 200,000 per second and 81,700 per second.

Messages sent with the higher frequency from Massachusetts were received very strongly at night-time at Porto Rico and Cuba, and were officially reported on several occasions as having been received by naval vessels in the neighbourhood of Alexandria, Egypt (a distance of nearly 4000 miles), but no messages were received during daytime. The absorption comes on very suddenly, and in the West Indies increases sometimes nearly a thousand-fold in fifteen minutes as the sun rises.

With the longer frequency, however, though at night signals were considerably weaker, probably on account of the receiving stations not being adapted for such a long wave-length, the daylight signals were many times stronger, and it was found possible to work in daylight between Massachusetts and Cuba (a distance of nearly 1700 miles) when using the lower frequency without any increase in sending power. Tests between Boston and Washington now continuing for nearly six months show the same phenomena, *i.e.* that there is great daylight absorption at a frequency of 200,000, but almost no absorption at a frequency of 81,700.

The second type of apparatus used consisted of a high-frequency alternator capable of giving a frequency of 100,000, but for the purposes of this test run at a frequency of 81,700. The open-circuit voltage at this frequency is 150 volts, and its armature resistance six ohms. This apparatus is used for telephoning wirelessly between Brant Rock, Massachusetts, and the City of New York. A detailed description of a similar but less powerful apparatus used for telephoning between Brant Rock and Plymouth, Massachusetts, will be found in the *Electrical Review* of February 15, 22, and March 1, and in the *American Telephone Journal* of January 26 and February 2. The current used in the antennæ is from four to six amperes, and the speech received by the New York station is approximately five or six times louder than the limit of audibility. Tests have now been made with this apparatus over a period of nearly a month, wireless telephonic communication having been first established between these points about July 17. While this apparatus has not been tested for so long a period as the former type, the results obtained are in substantial agreement.

If the masses of ionised air were continuous there is no apparent reason why there should be less absorption with a long wave-length. The above experiments seem to point to the conclusion that the masses of ionised air which are supposed to produce the absorption are not continuous but are broken up in somewhat the same manner that water vapour is into clouds.

The fact that the wave-lengths must be increased as the transmission distance is increased in order to overcome the absorption does not necessarily indicate that the masses are of larger size as the distance above sea-level increases, though it is possible that this is the case.

The writer has found that the absorption at night-time varies with the direction from which the waves are received, and has obtained some results which seem to indicate that measurements of this phenomenon may have a meteorological value, and may assist in extending the range of weather forecasts.

REGINALD A. FESSENDEN.

Brant Rock, Mass., August 9.

PRACTICAL TELEPHOTOGRAPHY.

EARLY in 1881 I described in NATURE (vol. xxiii., p. 334) an experimental apparatus for the electrical transmission of pictures to a distance, in which use was made of one of the sensitive selenium cells devised a few months previously (*ibid.*, p. 58). Fig. 1 shows the arrangement diagrammatically. The transmitting cylinder T is mounted upon a screwed spindle, which moves it laterally through 1/64 inch at each revolution; a selenium cell S is fixed behind the pinhole H, 1/20 inch in diameter, and is electrically connected through the spindle with the line wires L, E; the picture to be transmitted—about two inches square—is projected upon the front surface of the cylinder by the lens *l*. The brass receiving cylinder R is of the same dimensions as T, and is similarly mounted; F is a platinum stylus, which is pressed vertically against the metal by the flat spring G; W is a variable resistance, and B_1, B_2 are batteries at the transmitting and receiving stations respectively. A piece of paper moistened with a solution of potassium iodide is wrapped round R, and, the pinhole H having first been brought to the brightest part of the focussed picture (thereby reducing the resistance of S to its minimum value), the resistance W is adjusted so that no current passes along the "bridge" C D, which, assuming the two batteries to be equal, will be the case when the resistance of W is the same as that of S. If now the Se cell is darkened, its resistance will be increased and a current will pass through the receiver in the direction C D, liberating iodine at the point of the stylus F.

To transmit a picture, the two cylinders are caused to rotate synchronously, at the same time moving from end to end of their traverses; in the course of its spiral path the pinhole H covers successively every point of the focussed image, the illumination of the Se cell being proportional at any moment to the brightness of the spot occupied by the pinhole; the consequent variation in the resistance of the cell causes the stylus F to trace upon the paper a brown line which is lighter or darker in correspondence with the illumination of the Se. The close spiral line with breaks in its uniformity constitutes a picture, which should be a counterpart of that projected upon T. The earliest achievement of the apparatus consisted in the reproduction of the image of a hole cut in a piece of black paper; after some improvements simple black and white pictures painted upon glass were very perfectly transmitted, as was demonstrated upon several occasions when the apparatus was exhibited in operation.[1] It was, however, unable to cope with half-tones, and owing to pressure of work the experiments were shortly afterwards discontinued.

The problem of telegraphic photography has recently been attacked with conspicuous success by Prof. A. Korn, of Munich, whose work is described in a little book entitled "Elektrische Fernphotographie und Ähnliches" (Leipzig, 1907). His latest

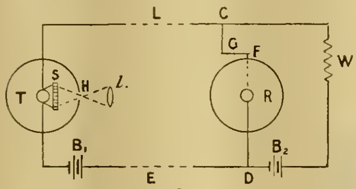

FIG. 1.

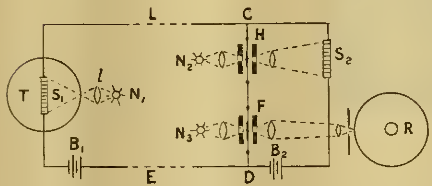

FIG. 2.

method is indicated in Fig. 2. The transmitting and receiving cylinders T, R turn synchronously on screwed axes, the regulating mechanism of the receiver is situated in the bridge C D, and a suitable resistance is placed at S_2. A celluloid film negative of the picture to be transmitted is wrapped round the cylinder T, which is made of glass. The light of a Nernst lamp N_1 is concentrated by a lens upon an element of the film, through which it passes more or less freely according to the translucency of the film at the spot, to the Se cell S_1, which is fixed in position, and does not, like mine, move with the cylinder; thus the resistance of the Se is varied in correspondence with the lights and shades of the picture. The receiving cylinder R is covered with a sensitised photographic film or paper, upon a point of which light from a lamp N_3 is concentrated. Before reaching the paper the light passes through perforations in two iron plates at F, which are, in fact, the pole-pieces of a strong electromagnet; between these is a shutter of aluminium leaf, which is attached to two parallel wires or thin strips forming the bridge C D. When there is no current through C D, the opening is covered by the shutter; when a current traverses the wires, they are depressed by electromagnetic action, carrying the shutter with them, and a quantity of light proportional to the strength of the current is admitted through the perforations. By means of this "light-relay," as it is termed, the intensity of the light acting at any moment upon the sensitised paper is made proportional to the illumination of the selenium in the transmitter.

It remains to mention a device of admirable ingenuity which has rendered it possible to transmit half-tones with fidelity. In its response to changes of illumination selenium exhibits a peculiar kind of sluggishness, to which reference was made in my old article: "Some alteration takes place almost instantaneously with a variation of the light, but for the greater part of the change an appreciable period of time is required." Prof. Korn has succeeded in eliminating the effects of the sluggish component by substituting for my box of resistance coils R a second

FIG. 3.

Se cell S_2, which is as nearly as possible similar to S_1, and which, by means of a second light-relay H, placed in series with the first, is subjected to similar changes of illumination. Thus any subpermanent fall in the resistance of S_1 due to the action of light is compensated by an equal fall in that of S_2, and only such changes as respond immediately to the varying illumination of S_1 are utilised for regulating the transmission current.

Such is in brief outline the nature of the new process. As regards the many carefully considered details which have made it a practical success, those interested will find ample information in the pamphlet mentioned above. The apparatus has been worked with excellent effect over long distances; a specimen of its performance, for which I am indebted to the kindness of Prof. Korn, is given in Fig. 3. The parallel lines traced by the point of concentrated light—in this case about 50 to the inch—are easily recognisable.

SHELFORD BIDWELL.

[1] Among others, at the Telegraph Engineers' *soirée* in 1881 (*see* NATURE, vol. xxiii., p. 563).

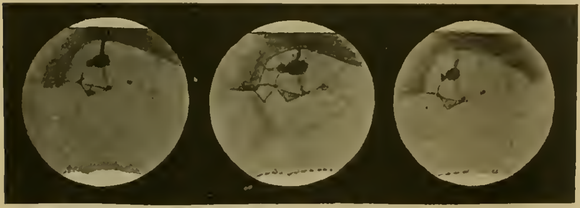
MARS IN 1907.

OBSERVATIONS AT THE LOWELL OBSERVATORY.

IN answer to the request of the editor of NATURE for an authoritative statement of the observations so far made here at this opposition, I have the honour to communicate two or three of the more important results obtained. They exceed what seemed likely, in view of the unfavourable declination of the planet, a position so southern as to render it practically unobservable in England, France, or the northern part of the United States.

The first of these relates to the polar caps. From the fact that the observations were begun in March, three months and a half before opposition, it was possible to catch both caps at an interesting phase of their careers—the southern one at its maximum, the northern at its minimum, extent. The moment was more propitious than has ever been the case before at the times at which the planet has been observed, because it was then upon an even keel as regards the earth, the equator lying nearly in the plane of sight. The southern cap at this epoch stretched across ninety-five degrees of latitude, counting from one side of it to the other; the northern only over eight.

From that date the dwindling of the southern cap and the making of the northern has been carefully watched to a complete confirmation of the curious manner in which the latter is formed, as witnessed here at the two previous oppositions.[1]



Photographs of Mars in 1907.

The next point has been the observed development of the canal system in the antarctic and south temperate zones. After the melting of the south polar cap had got well under way, canals began to make their appearance about it, running thence down the disc. These canals left its edge and joined the rest of the system in lower latitudes. Connected with such polar phenomena was the appearance of the most southern of the light regions of the planet, Thaumasia. This region, lying around the Solis Lacus, or Lake of the Sun, first showed symptoms of awaking activity. The Solis Lacus stood composed of two portions, a large oval patch on the east and a smaller round one to the west; from both of which canals ran into the dark areas. Now those on the south, such as the Ambrosia and the Bathys, were darker and more pronounced than those running north, the Tithonius, for example, which showed evidence of being in its dead or skeleton condition, while the former were in full tide of development. Meanwhile, the equatorial canals were steadily fading out. The process of evolution was in keeping with the method of development found here for the northern canals in 1903. The fact is of the nature of a prophecy fulfilled, and not only supports the previous observations, but proves the theory deduced from them to have been correct. It is a direct *sequitur* from this that the planet is at present the abode of intelligent, constructive life.

I may say in this connection that the theory of such life upon Mars was in no way an *a priori* hypothesis on my part, but the deduced outcome of observation, and that my observations since have fully confirmed it. No other supposition is consonant with all the facts observed here.

Another result of this opposition has been the success of the photographs taken of the planet. These have proved delineatory beyond expectation. The increased size of disc has enabled the method worked up by Mr. Lampland to be put into even more effective practice than at the last opposition. Plates have been taken by both Mr. Lampland and myself, and the amount of detail they show may be judged from the fact that I have already counted fifty-six canals on my plates, that the twin Gihon has been photographed double, and that such delicate markings as the Fons Juventae and the little canals leading to it appear unmistakably in the prints. Such grosser matters as the dwindling of the southern snow-cap show beautifully, and it looks as if a result in which Mr. Crommelin was much interested, the positioning of points of Martian topography by measures of the photographs, was in process of realisation.

Of the success of the expedition to the Andes to observe and photograph the planet sent out by this observatory under Prof. Todd, and with Mr. E. C. Slipher as the photographer, I prefer to speak later when fuller details come to hand. We already know by cable that their success has been beyond expectation.

PERCIVAL LOWELL.

PROF. H. C. VOGEL.

ASTRONOMERS, and especially spectroscopists, will have received with profound regret the brief announcement from the Potsdam Observatory which conveyed the sad intelligence that Prof. H. C. Vogel, the director of that institution, had died on August 13. His scientific life extends over a period during which all the great triumphs of the spectroscope have been won, and he has been in the front rank of that energetic band of astronomers who have given new direction and increased interest to the science of astronomy. Hence to sketch his life would be to trace the history of spectroscopy from the time that Angstrom published the map of the normal spectrum, or from that of the epoch-marking Indian eclipse, when the riddle of the chromosphere was first read; when the application of the Doppler principle was first applied to star spectra; or when cometary spectra were first studied. Men's minds were still excited over these novel pursuits, and the possibilities they suggested, when Vogel took charge of the Bothkamp Observatory and began that career of continued and successful observation which only terminated with his death. How much has been accomplished since will be appreciated if we recall the fact, that Vogel's earliest work gave us accurate information of the peculiarities of the planetary spectra, and showed the effect of solar rotation in displacing the Fraünhofer lines.

In 1874 came the foundation of the Potsdam Observatory, and Prof. Vogel was seen in a new light as the director of the first purely astrophysical observatory. The staff was small, and the instruments were modest, but enthusiasm was great, and the outcome has been of the widest interest. One of the early fruits from this new observatory was the spectrum catalogue of 4051 stars, important, not only because it illustrated the manner in which large masses of work could be dealt with in the new institution, but for the extensive application of the method of classifying stellar spectra to which the name of Vogel is particularly attached. He early appreciated the probability that the phase of development of a particular star was in general mirrored in its spectrum, and that any rational classification of the stars could only be obtained by giving prominence to that central fact.

Another class of work which largely occupied Prof. Vogel's attention was his investigation by means of photography of the motions in the line of sight of all the brighter stars visible in Potsdam. If he was not the first to apply photography in this particular direction, he was certainly among the most successful. This success was due in a great measure to the fact that he recognised, more fully than was generally the case thirty years ago, the necessity of constructing an instrument to a definite end, of making it exclusively available for one particular object. The possession of the most suitable apparatus not only gave improved and consistent values for the motion of stars in the line of sight, but satisfactorily explained the cause of the variability of Algol and stars of that type. His determination of the elements of that spectroscopic binary is typical of an immense amount of work which Vogel effected in the case of many other binaries. In observing variable and temporary stars his energy found another large field for its display, but it is impossible to enter into details. His was a busy life with many interests, and he assisted science in various directions.

Although aided by able and zealous colleagues, he was responsible as director of the observatory for the conduct of several large pieces of work. It will be sufficient to refer here to his participation in the work of the International Chart of the Heavens, to which in its early days he devoted much attention. The rigorous determination of the magnitude of all the brighter stars in the *Bonn Durchmusterung* by means of the Zöllner photometer is another piece of heavy observation which he brought to a successful issue. Simultaneously with the steady progress of these and other inquiries has gone the remodelling of the observatory, and the substitution of larger and more powerful instruments for those which tended to grow obsolete. The mounting of the 80-centimetre refractor offers a proof of the care and foresight which he devoted to this part of his duties.

We believe that when the effect of Vogel's work is considered and judged, his capacity as a director must be fully and generously recognised. As guardian of a new institution for which there were no traditions to guide the future development, as a conductor of an untried experiment, uncertain in what direction progress might be anticipated, he has maintained the observatory at a uniformly high level, and produced a quantity of work of the most accurate character. This has been shown to some extent by his election into many learned societies, the members of which have appreciated his work and acknowledged his influence. He has left an example to be followed, and a reputation to be honoured. To his colleagues, some of whom have served with him many years, and who have suffered the loss of his experience and his kindly assistance, we offer our respectful sympathies.

W. E. P.

NOTES.

It is announced in the *Electrician* that the "John Scott Legacy Medal and Premium" of the Franklin Institute has been awarded to Prof. J. A. Ewing, F.R.S., and Mr. L. H. Walter for their method of detecting electrical oscillations.

The programme of proceedings of the forthcoming meeting (on September 23 and 24) of the Iron and Steel Institute in Vienna has now been issued; from it we learn that the following papers may be expected to be submitted:—on the development of the iron industry of Austria since 1882, by W. Kestranek; on the Styrian Erzberg iron-ore mines, by Prof. H. Bauerman; on steel and meteoric iron, by Prof. F. Berwerth; on the determination of the quantity of blast-furnace gas for a given make of pig iron, by Prof. Josef von Ehrenwerth; on the application of the laws of physical chemistry to the metallurgy of iron, by Baron H. von Jüptner; on case hardening of mild steel, by C. O. Bannister and J. W. Lambert; on a new blue-black paint as a protective covering for iron, by F. J. R. Carulla; on the hardening of steel, by L. Demozay; on the structure of hardened steel, by Percy Longmuir; on case hardening, by G. Shaw Scott; on the ageing of mild steel: further notes, by C. E. Stromeyer; and on the economical distribution of electric power from blast furnaces, by B. H. Thwaite.

Prince Henry zu Schönaich-Carolath has consented to act as president of the fourteenth International Congress for Hygiene and Demography, which is to take place in Berlin next month, and Dr. Rubner, Privy Councillor of Medicine and professor of hygiene at the Royal University of Berlin, and Prof. von Mayr, Under-Secretary of State, Munich, will be vice-presidents.

The eleventh congress of Flemish naturalists will be held from September 21 to 23 at Malines under the presidency of Prof. C. de Bruyn, professor of botany and zoology in the University of Ghent. The secretary of the congress is Dr. de Bruycker, place du Grand-Canon, Ghent.

An International Exhibition is to be held in Tokio from April 1 to October 15 of next year. The estimated cost is 2,000,000*l*., towards which the Japanese Government has set aside 1,000,000*l*.

According to a telegram in the *Times*, two sharp shocks of earthquake occurred at 4.32 of the afternoon of August 22 at Kingston, Jamaica.

Particulars of the preparations in progress for the Wellman Polar Expedition are given in a Reuter message dated from Spitsbergen, July 25, from which we learn it was expected that the expedition would be ready to start for the far north by the middle of August. One of the many difficult pieces of work which had to be accomplished was the packing and making ready for the *America* of the two "serpents" which form an important part of the project. One of the serpents—a pipe of strong, water-tight leather, 6 inches in diameter and 123 feet long, its outside surface covered with more than 29,000 steel scales, each about as big as a silver quarter, very thin, and riveted to the leather, overlapping like the scales of a fish—has been designed to have the smallest possible resistance in sliding over the ice or snow, or floating on the water, in which element it is buoyant. The retarder serpent, on the other hand, is designed to make the greatest possible resistance in proportion to its weight in dragging over the ice-floes, which are usually covered with a snow-crust and rarely present a smooth surface. The function of the retarder is to drag like a drag-anchor when the wind is adverse to the course and it is wished to drift gently with it, and without losing either too much headway or burning too much fuel in the motor. Hence this serpent is covered with 1875 steel scratchers, each with six sharp points about 1 inch in length, or a total of 11,250 points on the 75 feet of body. The equilibrer is intended always to have more or less of its length upon the surface of the earth; the retarder is to be let down to touch the earth only when necessary. Reserve supplies of food to the amount of 1438 lb. have been packed in the interior of the serpents.

THE Prince of Monaco has arrived at Tromsö on board the *Princess Alice*, having left the *Hjalmar*, the vessel conveying the Johansen expedition, at Kved Fjord about the middle of August. The *Hjalmar* left for Prince Charles Foreland, where it is the intention of Johansen to meet the Bruce expedition, and which will probably be the winter quarters of the explorers.

MR. W. F. DENNING writes to say that a rather fine meteor, presumably from the Draconid radiant, to which he referred in a letter in our last number, was seen at Bristol on August 26, 9h. 18m. The curious feature about the object was its fluctuation in brilliancy. At first nearly equal to Jupiter, it quickly dropped to about two magnitudes, and finally burst out with a lustre rivalling that of Sirius. Its path was from about $231°+57°$ to $213°+50°$. As viewed from Wales, the meteor must have been very conspicuous and striking, and Mr. Denning will be glad of any descriptions of it.

THE secretary of the Kite Committee of the Royal Meteorological Society has written to the Press to say that, of the twenty-four meteorographs sent up in July last in connection with the international investigations of the upper air, only a few have been returned. He thinks it possible that some may have fallen among the standing corn and other crops, and so have not yet been seen. The secretary requests that a sharp look-out may be kept for the cylinders containing the meteorographs, and that if any be found they may be carefully handled and returned to the address given on the label or to himself at the Royal Meteorological Society. The next special series of ascents will take place from September 4 to 6 next.

WITH a view to supplying Paris with electric energy for its railways and lighting, three Paris engineers have drawn up a project for establishing an immense power station by barring the Rhône Valley, at Gresin, near Bellegarde. The enterprise has, says the *Engineer*, received the support of the French authorities. The estimated cost is 2,400,000*l*.

WE are sorry to learn from the annual report on the British Museum that there has been a falling off in the number of persons visiting the institution during the year 1906. The total number of visits paid to the museum at Bloomsbury was 691,950, showing a decrease of nearly 122,000 from the number in 1905. The Sunday total of 55,738 was less by 4369 than that of the previous year. Not since the year 1900, with its 689,249 visits, has the total been so low as that of the past year. The report upon the Natural History Museum also shows a decline in the number of visitors. In 1905, 566,313 visits were paid, and in 1906 only 472,557. The attendance on Sundays was, in 1906, 61,151, and in 1905 70,084. The gifts to the Natural History Museum in 1906 numbered 2057, against 2092 in 1905; the principal donors were the Government of India (collections of Tibetan insects), the Duke of Bedford (zoological specimens from Japan and Korea), Mr. C. D. Rudd (specimens in continuation of his systematic survey of South African fauna), and Mr. W. E. Balston (natural history specimens from Western Australia).

PROF. F. A. FOREL has favoured us with a note of a very unusual shifting of the wind observed by him during a storm at Morges (north of Lake of Geneva) on August 15. At 6h. p.m. the wind, which was blowing strongly from S.W., veered during a succession of violent squalls to N.W., N.E., and S.E., back again to S.W. by 10h. p.m., making a complete gyration in four hours. The weather in north-west Europe was very unsettled; a cyclonic disturbance which had passed across England lay over the Skager Rack at 6h. p.m., and a heavy thunderstorm was in progress at Berlin. Prof. Forel thinks that the sudden changes of wind could only have been caused by thunderstorms which occurred in various quarters in the vicinity of Morges. The barometer, which previously had been slowly falling, rose 0·2 inch between 6h. and 10h. p.m.

IN an editorial article in *Symons's Meteorological Magazine* for August, objection is taken to the way in which meteorological papers are dealt with at the British Association meetings. Several papers this year were of special interest, *e.g.* examples of modern methods of treating observations, by W. P. Elderton, and recent developments of the methods of forecasting by means of synoptic charts, by Dr. W. N. Shaw, but they were sandwiched with papers on astronomy and other subjects with which meteorologists were not particularly concerned. The difficulties in the way of hearing and discussing the papers were aggravated this year owing to the bewildering acoustic properties of the hall, and Dr. Shaw's paper was cut cruelly short owing to want of compression in the case of a previous astronomical paper. The writer of the article considers that unless at least a subsection is devoted to the subject in future, it will not be worth while for meteorologists to contribute papers to the British Association.

IN the same magazine Colonel Bentley refers to a very severe thunderstorm which occurred in County Clare on July 22. On the east of the Kilbane Mountains, near Killaloe, gaps of 10 feet and one of 30 feet deep were made in the road, and five large stone bridges and one wooden bridge were carried away by the floods in a district three miles long and one mile wide. During the storm hail fell in large rugged lumps, and the damage to property is estimated at 6000*l*.

FROM the annual report of the principal chemist on the work of the Government Laboratory, we learn that during the past year there has been a notable increase in the number of samples analysed in the two branches of the laboratory (Customs and Inland Revenue). The total number of analyses and examinations made was 173,606, against 158,939 for the previous year, the increase being mainly in respect of tobacco examined under the various fiscal regulations. Among other points of interest, we note that manufacturers appear fully to appreciate the advantages of the new or "industrial" variety of methylated spirit, which, by reason of its lower price and greater purity compared with that formerly used, is expected to find increasing employment in manufacturing operations. The use of pure duty-free ethyl and methyl alcohols in the science laboratories of universities and colleges is also extending, 4017 proof gallons having been utilised last year against 2277 in 1905. In addition, 3783 bulk gallons of the denatured (industrial) alcohol were used for ordinary teaching purposes. For departments other than the revenue branches some 7000 samples were analysed. To check the importation of adulterated butter, legal proceedings were instituted in a number of cases, and it is satisfactory to learn that, as a result, there has been a great improvement in the character of the butter emanating from certain parts of the Continent. An interesting examination of dog-fish eggs was made for the Board of Agriculture and Fisheries in connection with the depredations committed by these fish along the coasts of Devonshire and Cornwall. With the view of ascertaining their economic possibilities, the eggs were analysed, and found to contain about one-fourth of their weight of protein and the same quantity of fat, or about twice as much of the two substances together as is found in an ordinary hen's egg. It is remarked that, apart from the question of using the eggs for food—as to which there is an obstacle in their fishy odour—the utilisation of the protein matter and oil would be quite feasible if some enterprise were shown in obtaining a regular and sufficient supply of the eggs.

REFERRING to a note published in NATURE (this vol., p. 280) on the recent series of determinations of fundamental atomic weights by Prof. Richards and his colleagues, Prof. Bohuslav Brauner, of Prague, writes to say that he considers that there can be no doubt as to the correctness of the recently advocated low value of the atomic weight of nitrogen (14·01); the physico-chemical researches of Leduc, D. Berthelot, Lord Rayleigh, Guye, and Gray, as well as those of Scott in 1901, all tend to show that the atomic weight of nitrogen does not exceed 14·009. Prof. Brauner refers to a paper which he read before the Bunsen Gesellschaft in May (reprinted in the *Chemiker Zeitung*, No. 38) for a full discussion of the question, and to his article on the atomic weight of nitrogen in Abegg's "Handbuch der anorganischen Chemie." The new value for the atomic weight of nitrogen has the advantage that it is directly related to the atomic weight standard O = 16, whereas that of silver is related very indirectly and only by imperfectly determined ratios to the oxygen standard. The recent work of Guye would indicate that potassium chlorate always contains potassium chloride, the quantity of the latter being sufficient to reduce the atomic weight of silver from 107·93, as found by Stas, to 107·89. Prof. Brauner considers that the results of Prof. T. W. Richards should be stated as follows:—"The atomic weight of nitrogen cannot be higher than 14·10 and lower than 14·08, and so the atomic weight of silver must lie between Ag = 107·880 and 107·883. The atomic weight of sulphur cannot be higher than S = 32·069, and therefore the atomic weight of silver cannot be higher than Ag = 107·88."

A REPORT by Dr. Leslie Mackenzie on the teaching of school and personal hygiene to students in training as teachers in Scotland has been issued by the Scotch Education Department. The object of the course of instruction which has been instituted is to assist the teacher in discovering such gross mental or physical defects as may unfit, or tend to unfit, the child for school work. The methods of instruction include lectures and demonstrations on elementary anatomy, physiology, and hygiene, and visitation of schools with inspection of classes and premises. Among other matters, the place of the subject in the curriculum, the relation of the course to medical inspection, and tests of proficiency are discussed, and selected illustrations of the work done in various training colleges are given. The Department has also issued a memorandum on systems of physical training, viz. military drill and physiological and hygienic exercises, and their relation to the personal hygiene of school life. The special education of the teacher for this is insisted upon, and it is recommended that a medical officer ought to be in charge of this branch at every training centre.

THE annual report of the British Consul at Dakar gives particulars of the steps which are being taken by the French Government in French West Africa to safeguard and develop the rubber resources of the country. A special survey is being made of the chief rubber-producing districts, and when the investigations have been completed the worst districts will be closed to rubber collection so that the plants may have time to recuperate. It is expected that a beginning in this direction will be made in 1908. For the purpose of stocking plantations with rubber-producing trees, a credit of 3200*l*. has been provided for the present year, with which sum it is expected that from 300,000 to 400,000 trees will be planted, in addition to nursery plantations for succeeding years. The intention is to set apart from 4800*l*. to 6000*l*. each year for this purpose, and to plant on an average 500,000 trees every year.

ACCORDING to the *Agricultural News* of Barbados, a plant has been discovered in Portuguese West Africa possessing a fleshy, tuberous, turnip-shaped root, the entire substance of which is permeated with laticiferous ducts, that yield a supply of rubber latex. The plant belongs to the natural order Asclepiadaceæ. Rubber has been obtained from the tubers by slicing them, applying pressure, and coagulating with alcohol. Tubers two years old weighed nearly 1½ lb., and yielded rubber of half of 1 per cent. of the total weight. It is estimated that more than 180 lb. of rubber per acre can be produced at the end of two years.

AMONG the various subjects dealt with in the Journal of the Royal Horticultural Society, vol. xxxii., an article by Mr. M. H. F. Sutton furnishes practical directions on the formation and care of lawns and golf greens. The author attributes great value to manuring the soil when laying out a lawn. In connection with the choice of seeds, a list of grass seeds is given, also the use of clover is discussed and its disadvantage for tennis lawns or putting greens is explained. Growers of campanulas will find a useful list of species and synonyms prepared by Colonel R. H. Beddome. A method of checking black-currant gall mites by the application of grease is described by Mr. Massee. The substance of a lecture by Sir George Watt on the cultivation and manufacture of tea is published, also an account of the West Indian lime by Mr. A. J. Brooks, and a description by Mr. J. C. Umney of the source and extraction of perfumes.

WITH regard to the flowering of bamboos, it has been noted that this takes place only after a period of years, that some species show sporadic or partial flowering, while the flowering of others is simultaneous or complete, and is always or nearly always followed by the death of the plant. Mr. W. J. Bean has collated in the *Kew Bulletin* (No. 6) some data regarding species that have flowered under cultivation within the last thirty years.

Arundinaria Falconeri flowered sporadically in localities in England and India in 1876, and partial flowering occurred in other localities in 1875 and 1877. Another partial flowering has been proceeding for the last three years; the author suggests that the present more protracted period may be due to cultivation. *Arundinaria Simoni*, after partial flowering for some years, flowered completely in 1904–5, and then the plants died off. Most of the varieties of *Phyllostachys nigra* have also succumbed to the efforts attending complete flowering.

To the popular series of garden pamphlets issued by the Agricultural and Horticultural Association has been added one by Mr. S. Arnott on hardy garden bulbs and how to grow them. The precise notes on planting details will be found useful, as also the selection of hardy and choice species. Another pamphlet, on the weather, by Hon. H. A. Stanhope, the president of the association, is not of such direct interest, but contains a number of facts that the weather-wise—and with good reason many gardeners have such a reputation—should know.

TEACHERS of geology and travellers in India will alike welcome Mr. Vredenburg's pamphlet of seventy pages, entitled "A Summary of the Geology of India" (Calcutta: Thacker, Spink and Co., 1907). It is a summary that is full of information, and yet it is both readable and attractive. The most recent work of the Geological Survey of India is included, as may be seen from the account of the Cretaceous Deccan Trap and the references to Burma and Baluchistan. The recession of the sea at the close of Cretaceous times is regarded as a "universal" phenomenon, while the "Glacial period" is spoken of lightly, as resulting in a "temporary glaciation of high latitudes." In both these statements we note a little more dogma than is prudent in an abstract, where discussion is impossible. Mr. Vredenburg is, however, no mere abstractor of the work of others, but an observer and a discoverer, whose personality adds weight to the present lucid summary.

A NEW gem is reported to have been discovered in San Benito County, California. It is described as a clear, transparent, blue stone with violet tints in the deeper-coloured portion, and to be about as hard as chrysolite and harder than moonstone or opal. Under heat it turns a bright red, but on cooling it resumes its normal colour. It has been given the name of Benito, from the county in which it was found.

A LARGE and remarkable cave was, according to the *Scientific American*, recently discovered in the Santa Susanna Mountains, some fifty miles from Los Angeles, California, U.S.A. The cave contains many halls, some of very large extent, and the walls of one are covered with rude drawings, some of which are almost obliterated, but others are quite clear. The drawings, says our contemporary, represent incidents of the chase, showing Indians on foot pursuing bear, deer, and other animals. One wall-drawing shows the bear pursuing the hunter. The work is executed by soft red stone.

THE connection between radium and the safe working of collieries does not at first sight appear to be a very intimate one, but the discovery announced by Profs. Elster and Geitel in *Die Welt der Technik*, that fire-damp contains six or seven times the amount of radium emanation that is generally found in the air of coal mines, brings the two into close relation with each other. Comparative tests of the electrical conductivity of the air due to the presence of the emanation can readily be made by means of a simple aluminium foil electroscope, and as only a comparatively small sample of the gas is necessary, the tests may be carried out outside the mine. It will be interesting to see the electroscope become part of the normal equipment of a colliery.

IN the July number of the *Bulletin de la Société d'Encouragement pour l'Industrie nationale*, M. O. de Faria gives a description and an account of the tests of his alternating electric current rectifier. The electrodes are of aluminium and an alloy of lead and antimony respectively, and the electrolyte a solution of phosphate of soda. The cell is so arranged that during working a rapid circulation of the electrolyte is maintained. In one of the tests of which details are given a rectifier intended for 10 amperes was run for five hours at 15 amperes on a 100-volt circuit, and showed an efficiency of 66 per cent. with a final temperature of 47° C. The efficiency appears to be independent of the temperature of the cell.

THE origin and relationships of the so-called Atlantic animals and plants of western Norway are discussed at considerable length by Dr. L. Stejneger in vol. xlviii., part iv., of Smithsonian Miscellaneous Collections. The mammals include the west Norwegian red deer (which the author regards as inseparable from the Scottish representative of the species, although markedly distinct from the Swedish race), the so-called Celtic horse or pony, the reindeer, lemming, and Arctic fox. It is concluded that if the more characteristic types of this "Atlantic biota" came from Scotland, they travelled by way of a land-bridge connecting that country with western Norway to the northward of lat. 59°. This bridge existed subsequent to the first great (Scandinavian) glaciation, and this portion of the "biota" certainly survived the second glaciation. The red deer and Arctic animals reached Scotland from Central Europe, whence they migrated first into Ireland and then into Scotland. Reindeer, on the other hand, appear to have reached Scandinavia by several routes, one stock having probably entered Sweden from the south and a second from the north-east *via* Finland and Russia, while the Norwegian stock arrived from the west. If well founded, these conclusions absolutely cut away the ground from Dr. Scharff's theory that reindeer reached Europe from Greenland, a theory controverted by several other considerations.

IN a paper on the birds of Labrador, forming No. 7 of vol. xxxiii. of the Proceedings of the Boston Society of Natural History, Messrs. C. W. Townsend and G. M. Allen take occasion to refer to the appalling destruction of birds and their eggs which is still allowed to go on in Newfoundland, Labrador. The fishermen, who use single-barrel, muzzle-loading guns, make no secret of the fact that they take every bird and egg upon which they can lay hands. If efficient means of protection are not promptly put in force, the authors are of opinion that the bird-nurseries of the district will become things of the past.

HAVING observed sand-martins in Hampshire during the winter—November to January—Mr. H. Beeston, in the July number of the *Zoologist*, confesses himself unable to explain where these birds passed the nights during the period in question. As there appear to be no sand-banks in the district where the observations were made, it seems impossible for the birds to follow their usual practice of sleeping in their nesting-burrows.

IN the *Entomologists' Monthly Magazine* for August, the attention of collectors is directed to the possibility that the south European wingless earwig (*Forficula decipiens*) may be indigenous to England, since two earwigs with aborted wings recently taken in the Isle of Wight appear indistinguishable from that species.

AN elaborate cloth-bound illustrated catalogue (in English) of the physical apparatus made by the firm of E. Leybold's Nachfolger, of Cologne, has been sent to us. It contains full descriptions of many pieces of apparatus, with instructions for use, and should be seen by all science teachers.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER :—

Sept. 3. 8h. Mercury and Venus in conjunction. Mercury 0° 26′ N.
4. Daniel's comet in perihelion.
12. 11h. 15m. Minimum of Algol (β Persei).
14. 13h. Venus in superior conjunction with Sun.
15. 8h. 4m. Minimum of Algol (β Persei).
,, 14h. 1m. Transit (egress) of Jupiter's Sat. III. (Ganymede).
16. 11h. 13m. Mars in conjunction with Moon. (Mars 4° 27′ S.).
17. 14h. Saturn in opposition to the Sun.
21. 7h. 10m. to 7h. 59m. Moon occults 30 Piscium (mag. 4·7).
,, 9h. 4m. to 9h. 37m. Moon occults 33 Piscium (mag. 4·6).
22. 14h. 42m. to 18h. 20m. Transit of Jupiter's Sat. III. (Ganymede).
23. 18h. Sun enters Libra. Autumn commences.
24. 12h. 51m. to 13h. 46m. Moon occults μ Ceti (mag. 4·4).
,, 18h. 1m. Transit (ingress) of Jupiter's Sat. IV. (Callisto).
26. 11h. 57m. to 12h. 59m. Moon occults δ^2 Tauri (mag. 4·7).
29. 18h. 58m. Transit (ingress) of Jupiter's Sat. III. (Ganymede).

DANIEL'S COMET (1907*d*).—The following is an extract from the continuation of Dr. Stromgren's ephemeris for comet 1907*d* as published in No. 4196 of the *Astronomische Nachrichten* (p. 337, August 23).—

Ephemeris 12h. (M.T. Berlin).

1907	α (true) h. m.	δ (true) ° ′	log r	log Δ	Brightness
Sept. 1	8 50·8	+13 34·6	9·7144	0·0534	19·1
,, 3	9 4·0	+12 59·3			
,, 5	9 16·8	+12 22·6	9·7123	0·0847	16·7
,, 7	9 29·4	+11 44·6			
,, 9	9 41·5	+11 5·7	9·7250	0·1139	13·7

An observation at Padua on August 18 gave corrections of +30s. and −0′·7 to this ephemeris.

On September 1 the comet will be 81′·5 N. of α Cancri, whilst on September 8 it will be 66′·4 N. of *o* Leonis.

The comet will rise about $2\frac{1}{4}$ hours before the sun on September 1, and about two hours before the sun on September 9.

FURTHER OBSERVATIONS OF MARS.—The August number of the *Bulletin de la Société astronomique de France* contains an interesting paper by M. Jarry-Desloges giving the results of observations of Mars made during July last at a temporary observatory erected on the summit of the Revard at an altitude of 1550 metres.

M. Jarry-Desloges and his collaborator, M. G. Fournier, confirmed the doubling of the Solis Lacus announced by Mr. Lowell. They also comment upon the cloudy appearance of the Martian landscape in the northern hemisphere as compared with the clear-cut features of the southern hemisphere of the planet.

The faint canals were difficult to observe, but the Ganges was seen to be very broad and appeared double, the two points where it emerges from the Auroræ Sinus being seen quite sharply; the observer states, however, that this observation needs confirming.

On July 19 the region north of Lacus Niliacus was clear, but twenty hours later, on July 20, details of white spots could be seen; thus it appears that in less than twenty hours the clouds or mists which covered this part of the planet vanished.

A SUSPECTED, LARGE PROPER MOTION.—Having occasion to measure the places of three B.D. stars (B.D. + 1°·2720, + 1°·2722, and + 0°·2957) on his star photographs, Prof. Barnard found that the positions determined by him for two of the stars differed considerably from the B.D. positions. That of 1°·2720 is unusually discordant with the B.D., though the difference may be due to an error in the latter; but in the case of 0°·2957 the difference between Prof. Barnard's position and that determined at Bonn amounts to nearly a second of time. Therefore, if the observations are correct, the star B.D. + 0°·2957 must have a considerable proper motion (*Astronomische Nachrichten*, No. 4195, p. 313, August 7).

THE ASTROGRAPHIC CHART.—From No. 386 of the *Observatory* (p. 329, August) we learn that the Potsdam Observatory does not intend to take and distribute the long-exposure photographs (chart plates) of the zone (+32° to +39°) allotted to it. The work will be done at the Royal Observatory of Belgium, which is being reorganised on a somewhat liberal scale.

THE SIMULTANEOUS INVISIBILITY OF JUPITER'S SATELLITES. —On March 7 we referred in these columns to the simultaneous invisibility of Jupiter's four major satellites on October 3 next. In the August number of the *Bulletin de la Société astronomique de France* (p. 356) M. Flammarion gives fuller details of the phenomenon, and shows, by means of a diagram, the disposition of the four satellites, in regard to Jupiter, between the hours of 19h. 56m. and 20h. 6m. on the date named. As Jupiter does not rise until after midnight, European observers will not be able to watch this unusual spectacle; it will, however, be visible in Asia and Oceania.

The first observation of this phenomenon was made by Galileo on March 15, 1611, and only on eight occasions since then has it been observed.

LATITUDE-VARIATION AND LONGITUDE DETERMINATIONS.— Part i., vol. ix., of the *Annalen der Sternwarte in Leiden* contains accounts of a series of latitude-variation observations made by Father J. W. J. A. Stein during the period June, 1899, to July, 1900, and of a determination of the difference of longitude between Leyden and Ubagsberg made by the director of Leyden Observatory, Dr. H. G. van de Sande Bakhuyzen, and M. J. H. Wilterdink.

Father Stein employed the Horrebow method, making 1590 observations on 117 nights. He discusses the observations, the instrument, and the reductions at some length.

Ubagsberg is a geodetic station situated in the province of Limbourg, between Maastricht and Aix-la-Chapelle, and is an important point from the fact of its having been made a station in three distinct triangulations. The difference of longitude between the geodetic pillar at Ubagsberg and the meridian circle at Leyden was found to be +5m. 52·314s. ± 0·015s.

THE COLOURS AND SPECTRA OF STARS.—A paper by Mr. W. S. Franks, appearing in No. 8, vol. lxvii., of the Monthly Notices (R.A.S.), discusses the relation between the colours and spectra of star classes.

He tabulates 1360 stars under colour, as observed by members of the B.A.A., and spectra as given in the Harvard publications, and finds, in general, a very close connection between the two features. Of 282 helium stars, 125 belong to the white or O colour class, whilst 168 of the 377 hydrogen stars come under the same heading. On the other hand, 210 of the 241 solar stars come under the colours between Y^2 and Y^3.

Whilst making the investigation Mr. Franks was impressed by the marked affinity of helium and bright-line stars (types B and O) with the galaxy. All the bright-line spectra met with were in or near the Milky Way, and when one remembers that the Wolf-Rayet stars, all the Novæ, and the majority of short-period variables are also galactical, it is obvious that the Milky Way is, in some way yet undetermined, probably the seat of cosmical actions of primary importance.

THE BRITISH ASSOCIATION.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY WILLIAM E. HOYLE, M.A., D.Sc., PRESIDENT OF THE SECTION.

(*Abridged.*)

THE impression left upon my mind by a score of Presidential Addresses to this Section, which it has been my privilege to hear, is that the speaker who treats of the subject matter of his own researches has the best prospect of making his remarks interesting and profitable to his audience. It is, therefore, in no spirit of egotism that I invite your attention this morning to the small and economically unimportant group of the Cephalopoda.

Some of my predecessors have been men who walked, so to speak, on the heights; who undertook the culture, or at all events the surveillance, of large domains. The extensive views and broad principles which they have thus been able to lay before the Section have been such as at once to compel the attention of all who are interested in any department of biology, or indeed of any branch of science at all. My own case has been far different; the plot I have tried to cultivate has been a very small one, and I have had but little leisure to peep over the fence and see what my neighbours were doing. I come before you, therefore, as a specialist, and not only so, but as that most humble kind of specialist—a systematist (a "mere systematist" is, I believe, the common phrase)—one whose main work has been the discrimination and definition of genera and species. I feel that some apology is necessary in asking zoologists of all departments to step for an hour into my particular allotment and see what has been going on there during the last few decades.

Before inviting you to enter, however, I should like to plead that even the systematist has his uses; for, properly considered, what is the systematic arrangement of any group of animals but the condensed formal expression of our present knowledge regarding its morphology, ontogeny, and phylogeny? Furthermore, how could the varied and complex problems of geographical distribution be attacked without the materials prepared by the systematist?

Having said this much by way of apology and defence, let me invite you without further prelude to consider two or three questions suggested by the study of the Cephalopoda.

Just half a century ago (August 1, 1857), there appeared in the *Annals and Magazine of Natural History* the translation of a paper by the late Prof. Steenstrup, of Copenhagen, which has ever since been regarded as marking an epoch in our knowledge of the Cephalopoda. The consideration of the scope and significance of this memoir may profitably engage our attention for a short time. In researches which were then comparatively recent, Vérany and Vogt and Heinrich Müller had shown that, in the genera *Tremoctopus* and *Argonauta*, the hectocotylus, a supposed parasitic worm which had been found in the mantle-cavity of the female, was in reality one of the arms of the male which had become detached and found its way thither, bearing with it the fertilising element—a procedure quite unique, not only among the Cephalopoda, but also among the Mollusca, if not in the whole animal kingdom. The gist of Steenstrup's discovery was that, although the separation of an arm was peculiar to very few forms, the modification of one or other of the arms for reproductive purposes was of common occurrence among the Cephalopoda; and, furthermore, that the situation of the particular arm, which was so modified, varied with the systematic position of the genus in question, and was constant through the main divisions of the class. To this less extensive modification of the arm he gave the name "hectocotylisation."

Stimulated by this discovery, other zoologists examined the Cephalopoda in their possession, and described the modifications in various genera, and now it is universally recognised that no definition of the Cephalopod is complete which does not include a description of the position and form of the hectocotylised arm. The descriptive anatomy of this organ is fairly well known. Out of twenty-two families, which may be regarded as well established, its structure is known in a number of genera in no fewer than twelve, whilst of the remaining ten it has been more or less conclusively shown that in seven no modification of the arm takes place, so that there are only three families in which we are still without any information regarding it.

Our knowledge of the physiology of the apparatus has not, however, advanced with anything like the same rapidity. Even in the case of those forms where a true hectocotylus is found (*Argonauta*, *Tremoctopus*, and *Ocythoë*) it is not known for certain whether the fertilising arm is deposited by the male in the mantle-cavity of the female (as I think is most probable), or whether (as is stated by some writers) the arm breaks off when mature and finds its own way to its destination. This much is certain, that for some time after its detachment it possesses the power of independent movement.

As regards the function of the modified but not detachable arm, we have the important and interesting observations of Racovitza made at Roscoff and Banyuls on the genera *Polypus* (*Octopus*) and *Sepiola*. It appears that in the first of these forms the extremity of the hectocotylised arm of the male is introduced into the mantle-cavity of the female, both individuals resting on the sea-bottom and at some distance from each other (about 25 cm. in the case of a male measuring 1·25 m. in total length). Although after an encounter the female appeared to flee the embraces of the male, and although the males, when two were placed in the same tank, fought with each other, there was no sign of any combat between the sexes as was described by Kollmann. In *Sepiola* the female is roughly seized by the male, and held with the ventral surface uppermost; the two dorsal arms are introduced into the mantle-cavity, whilst the other three pairs hold the female firmly. The efforts of the male are directed to keeping the female from attaching herself to any firm support. It would appear that the introduction of the arms of the male into the mantle-cavity interferes with the respiration of the female, and that she makes desperate efforts to escape as soon as she can attach herself to any neighbouring object. In this respect there is a marked contrast between the behaviour of these two genera, and it is greatly to be desired that observations should be made on other forms, but the difficulties in the way of this have hitherto proved insuperable.

Although, as we have seen, but little is known of the actual working of the hectocotylised arm, there are differences in the structures set apart in the female for the reception of the spermatophores, which correspond with the different arrangements of the hectocotylus in the male. For example, in *Polypus* (*Octopus*) the spermatophores are deposited in the termination of the oviduct; in *Rossia* there is a large plicated area surrounding the mouth of the oviduct for their reception; whilst in the nearly related *Sepiola* there is a pouch-like depression of the integument lying beside the mouth of the oviduct for the same purpose (von Maehrenthal). In *Sepia*, *Loligo*, and the other Myopsids in which the ventral arms are hectocotylised the spermatophores are received upon a specially modified area lying just to the ventral side of the mouth.

From this all too brief sketch of the function of these organs we may now return to the question of the systematic value of the modified arm of the male. Prof. Steenstrup was firmly convinced of the paramount importance of the hectocotylisation as a classificatory character, and he seemed to cling to this belief almost with the ardour of a devotee for a religious principle. In 1881 he published a memoir in which a new classification of the genera *Sepia*, *Loligo*, *Rossia*, and some other forms was propounded, based avowedly on the position of the hectocotylised arm; and when this scheme was attacked by the late Dr. Brock of Göttingen, he defended it vigorously in a further communication, placing at its head the following thesis much in the same spirit as Luther nailed his famous theses to the church door at Wittenberg: "Hectocotylatio bene observata et rite considerata divisionibus naturae semper congruit; incongrua divisionibus, eas arbitrarias et factitias esse indicat."

Steenstrup further explains that the point of most consequence is which pair of arms is affected by the hectocotylisation, whether the first, third, or fourth pair; next in importance comes the nature of the modification; while the question whether the right or left arm is affected is quite insignificant. It will be our business to consider how far the Danish naturalist's position is justified in the light of our present knowledge.

An inspection of the facts known up to the present time shows, first of all, that where hectocotylisation is known to take place it affects either the first, third, or fourth pair of arms; no instance is yet known where the second pair is modified, except in subsidiary relation to another pair, or in one or two rather doubtful cases in which all the arms are said to be modified. It appears, furthermore, that hectocotylisation of the third pair is confined to the Octopoda, while the first and fourth pairs are affected in the Decapoda, so that, as far as the main divisions of the Dibranchiata are concerned, the position of the hectocotylus is a correct index to them. We may, however, go a step further still, and point out that in every family, with one exception, the position of the hectocotylised arm is constant within the limits of the family, so that there is a very strong *prima facie* case for the truth of Professor Steenstrup's dictum. The difficulty arises when we come to consider the family Sepiolidæ and its allies, and endeavour to form an idea of their relationships to each other.

Steenstrup was so convinced of the truth of his thesis that he divided the Myopsida into two main divisions according to whether hectocotylisation affected the first or fourth pair of arms, and placed the four genera *Sepiadarium*, *Sepioloidea*, and *Idiosepius* (notwithstanding their *Sepiola*-like form) with *Spirula*, apart from *Sepiola* and *Rossia*, and along with *Sepia* and *Loligo*. It becomes necessary now to inquire how far this classification is justified by what we know of the morphology of the forms concerned.

It will be convenient to deal in the first place with *Spirula*, which has always been of great interest on account of the unique structure and position of its shell. It still belongs to the greatest of zoological varieties, only a dozen specimens with the soft parts having been obtained, of which one alone proved to be a male. This was examined by Sir Richard Owen, who described the hectocotylisation as affecting both the ventral arms, which are much enlarged, exceeding the others both in length and thickness: they are quadrangular in section, devoid of suckers, and the right is much larger than the left. The other arms appear to have a round truncated extremity which may be a secondary modification. The relationships of *Spirula* have recently been made the subject of inquiry by Prof. Paul Pelseneer, who completed the memoir in the *Challenger* reports begun by Prof. Huxley, and by Dr. Einar Lönnberg of Stockholm, who dissected a specimen obtained for him from Madeira by the late Captain Eckman. These two investigators arrived at different conclusions regarding its systematic position.

Pelseneer regards it as an Œgopsid, Lönnberg as a Myopsid, but the anatomical characters on which they are agreed are enough to show that, at any rate, these two forms cannot be so closely related to each other as to belong to the same sub-family, or even family.

With regard to the question at issue between them as to the Œgopsid or Myopsid nature of *Spirula*, I think, on the whole, that its resemblance is to the former rather than to the latter; but I believe that the branch of the ancestral tree which terminates in *Spirula* was given off from the main Cephalopod stem before the Œgopsida and Myopsida, as we now know them, had been separately evolved. Palæontology reveals a possible descent of *Spirula* from a Belemnitoid through such an intermediate form as *Spirulirostra*; and from this, on the other hand, it is easy to conceive of the descent of *Sepia* through a form resembling *Belosepia*. Such a relation could be expressed by the following diagram, which is, however, only a rough illustration of possibilities, for *Spirulirostra* is a Miocene form and *Belosepia* an Eocene, so that the former could hardly be the ancestor of the latter. It is only contended that these forms indicate a possible line of descent.

Unfortunately, in the present state of our knowledge, it is impossible to correlate the above diagram with one based upon the study of the soft parts of recent forms. It is sufficient if they do not contradict each other. We know nothing of the soft parts of the fossils, and there is no recent form, which exhibits shell characters, bridging over the gulf between *Sepia* and *Spirula*. To sum up, *Spirula* must be regarded as, at all events, the representative of a distinct family: it is not unlikely that it may one day become the type of a division coequal with Myopsida and Œgopsida, and it does not appear to me that the structure of its hectocotylised arms would be any argument against such a view.

We may now consider the genera *Idiosepius*, *Sepiadarium*, and *Sepioloidea*, regarding which there can be no doubt that on morphological grounds these three genera are more nearly allied to the Sepiolidæ than to the Sepiidæ or Loliginidæ; in fact, practically the only character of any importance which points in the opposite direction is the hectocotylisation. This portion of the subject has been very fully and clearly handled by Dr. Appellöf of Bergen, and to his memoir I refer those who desire more detailed information. We have here, then, a case in which forms the ventral arms of which are hectocotylised are more nearly related to forms with dorsal hectocotylisation than to others with ventral, and this shows that the position of the modified arm (or arms) is not by itself an infallible guide to systematic affinity. It is a striking instance of an aphorism of the late Prof. Rolleston, that "no single character can be regarded as a safe basis for a natural classification until it has been proved to be so."

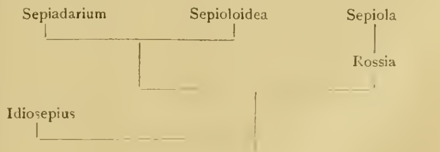
It may, however, be worth while to look a little further into the relationships of these forms, and to see whether the hectocotylisation of the dorsal arms is quite as sporadic and irregular as it at first appears.

After the separation of *Idiosepius* two possibilities present themselves as to the further evolution of this group.

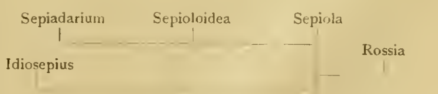
A. The main stem divided into two branches leading to *Rossia* and *Sepiola* on the one hand, and to *Sepiadarium* and *Sepioloidea* on the other.

B. The stem gave off first a branch leading to *Rossia*, and subsequently divided into two, one leading to *Sepiola* and the other to *Sepiadarium* and *Sepioloidea*.

These two alternatives may be expressed graphically thus:



(A)



(B)

These schemes are not entirely satisfactory. Certain difficulties are common to them both. The posterior salivary glands, which, it is assumed, were inherited in a fused condition from the primitive Œgopsid stem, and remain in that condition in *Rossia*, have been separated in *Idiosepius*, *Sepiadarium*, and *Sepiola*, as well as in *Sepia* and *Loligo*.

Furthermore, A presents the difficulty that the fusion of the mantle with the head in the nuchal region has been acquired independently by *Idiosepius*, *Sepiadarium* and *Sepioloidea*, and *Sepiola*.

On the other hand, B has the disadvantage of assuming that the hectocotylisation has been transferred from the fourth to the first pair of arms independently in *Rossia* and *Sepiola*.

If, as I believe to be the case, scheme A is admitted to offer the lesser of the two difficulties, it has the advantage of indicating that the hectocotylisation of the ventral arms has been directly inherited from the main stem common to Myopsids and Œgopsids, and has only been transferred to the dorsal arms in the branch common to *Rossia* and *Sepiola*.

Hence we reach the conclusion that, although the variations in the structure and position of the hectocotylus follow pretty closely the systematic divisions of the Dibranchiata, we are not justified in maintaining that the position of the hectocotylised arm is by itself a sufficient guide to the systematic position of a doubtful form; it is only one of many characters that must be taken into consideration.

The subject of fossil Cephalopoda has not formed any part of my own special researches, but a contribution has recently been made to our knowledge of these forms to which it seems desirable to allude, because it deals, not with systematic or stratigraphical facts, but with conclusions which may be drawn from shell structure as to the life-history and habits of certain important and interesting forms. Prof. Jaekel, formerly of Berlin, now of Greifswald, the author of the memoir referred to, lays down a number of theses regarding the organisation and mode of life of these extinct species, and I venture to give an abstract of his views, premising that my acquaintance with palæontology does not justify me in expressing a definite opinion as to the validity of his conclusions, though they seem extremely reasonable.

His opening statement is that *Orthoceras* and its allies were not free-swimming but sessile organisms, and this is based on the following arguments amongst others. The shells were thicker and heavier than any that are found in pelagic organisms; the external sculpture shows that the shell was not embedded in the soft parts, and if it were exposed the annulate arrangement of many forms is inconsistent with their easy passage through the water; the "lines" (in the naval architect's sense of the word) of an organism intended for navigation are always smooth and not wavy; otherwise undue friction against the water would be created; whilst the straight transverse margin of the aperture of the shell shows that it was not carried by a creeping body like that of a snail. Their sessile nature is further shown in the first place by the radial symmetry, which is rare in free-swimming forms, and almost unknown in those the axis of which is long in proportion to their diameter. Further, the termination of the shell is generally broken off: of all the thousands of specimens which have been examined, but very few show the initial chamber; in those cases in which the apex is preserved it shows a scar, where the siphuncle entered the protoconch. The separation of the shell into chambers by transverse septa occurs only in sessile forms, but in such it is found in many divisions of the animal kingdom. The reason of this cameration is to be found in a constant effort to keep the body of the animal above the surface of the mud in which it is rooted. On this view the siphuncle admits of a simple explanation; it is the vestigial part of the body which has been contracted and partially cut off as the body has moved successively forward to the enlarged superior portion of the shell.

It may be added that J. M. Clarke has recorded a case in the American Upper Devonian rocks in which the majority of the large Orthoceratidæ were fossilised in a vertical or but slightly sloping position.

The forms such as *Phragmoceras*, &c., in which the aperture of the shell is contracted, and often shows bilaterally symmetrical notches, are interpreted as having lived buried in the mud. The notches served for the protrusion of the arms, vent, and siphon, which latter were probably elongated tubes stretching up through apertures excavated in the mud, much in the same way as the heart-urchin (*Echinocardium*) among the sea-urchins lives buried in the mud, and obtains nourishment by stretching its tube feet up to its surface. The arrangement of the arms was probably like that seen in the embryos of Dibranchiata, or of the circumoral appendages of *Nautilus*.

Turning to the extensive and interesting group of Belemnites, Prof. Jaekel enunciates the view that these were not, as has been commonly believed, active free-swimming forms, the rostrum (guard) serving as the pointed ram of a battleship, but stationary, the rostrum playing the part of a pile by which they were rooted in the mud at the sea-bottom, like the pointed base of a *Flabellum* or other deep-sea coral, or the anchor-spicules of a glass-rope sponge. In favour of this view may be adduced the size, weight, and solidity of the rostrum, which, if the animal moved about in a horizontal attitude, would have thrown its centre of gravity too far towards that end of the body: its circular section, which points to a radial, not a bilateral, symmetry, and hence, as above mentioned, to a sessile rather than a free-swimming habit. The pointed form of the rostrum would be admirably adapted to fixation in a muddy bottom, whilst its weight would render it a very effective anchor. Further, it is to be noted that Belemnites are found abundantly in strata of argillaceous origin.

This view has a strong recommendation in the fact that it presupposes gradual progress in the Cephalopoda in the direction of greater mobility as evolution advanced, thus:

A. Orthoceras—firmly attached.
B. Belemnites—anchored in the mud.
C. Recent Dibranchiata—free-swimming.

Another interesting discovery of Prof. Jaekel is that of a slab of Solenhofen stone, upon which are certain specially arranged impressions, apparently made by the hooks on the arms of a Cephalopod. If this determination is correct, the fact is of the greatest interest, for it would show that these animals walked upon the ground with the head downwards and the distal extremity of the body elevated; that in them the arms were not merely morphologically, but also functionally, the equivalent of a foot.

In conclusion let me direct your attention to a subject which is almost entirely the growth of the last fifteen years. I mean the discovery and investigation of luminous organs in the Cephalopoda. These have now been observed in no fewer than twenty-nine out of about seventy well-characterised genera of Decapoda, and have been found to present a most interesting variety in position and in structure.

Before passing on, however, to consider the structure of these organs, it may be well to lay before you the evidence on the strength of which a photogenic function has been ascribed to them. The actual observations are remarkable chiefly for their paucity; indeed, it may seem to some that the foundation of solid fact is too slender for the superstructure raised upon it, but still due consideration will show that this is not the case. The first recorded occurrence of phosphorescence in the Cephalopoda is due to Vérany, and dates back rather more than seventy years, though it was not published till 1851. The description is so definite and concise as to be well worth quoting:

"As often as other engagements permitted, I watched the fishing carried on by the dredge on the shingly beaches which extend from the town of Nice to the mouth of the Var. On the afternoon of September 7, 1834, I arrived at the beach when the dredge had just been drawn in, and saw in the hands of a child a cuttle-fish, unfortunately greatly damaged. I was so struck by the singularity of its form and the brilliance of its colour that I at once secured it, and, showing it to the fishermen, asked whether they were acquainted with it. Upon their replying in the negative I called their special attention to it, and offered a handsome reward for the next specimen secured, either alive or in good condition, and then passed on to other fishermen and repeated my promise. Shortly afterwards I was summoned and shown a specimen clinging to the net, which I seized and placed in a vessel of water. At that moment I enjoyed the astonishing spectacle of the brilliant spots, which appeared upon the skin of this animal, whose remarkable form had already impressed me: sometimes it was a ray of sapphire blue which blinded me; sometimes of opalescent topaz yellow, which rendered it still more striking; at other times these two rich colours mingled their magnificent rays. During the night these opalescent spots emitted a phosphorescent brilliance which rendered this mollusc one of the most splendid of Nature's products. Its existence was, however, of short duration, though I had placed it in a large vessel of water. Probably it lives at great depths."

The species thus referred to was *Histioteuthis bonelliana*, which we shall have occasion to refer to in the sequel.

The next observation, so far as I am aware, was made by Prof. Chun, on board the *Valdivia* during the German deep-sea expedition, on a form which he has called *Thaumatolampas diadema*. The specimen captured lived long enough to allow of a photograph being made of it whilst in a state of functional activity, and the appearance it presented is thus described by the observer:

"Among all the marvels of coloration which the animals of the deep sea exhibited to us nothing can be even distantly compared with the hues of these organs. One would think that the body was adorned with a diadem of brilliant gems. The middle organs of the eyes shone with ultramarine-blue, the lateral ones with a pearly sheen. Those towards the front of the lower surface of the body gave out a ruby-red light, while those behind were snow-white or pearly, except the median one, which was sky-blue. It was indeed a glorious spectacle."

Finally we have the genera *Heteroteuthis* and *Sepiola*, the phosphorescent properties of which were seen last year by Dr. W. T. Meyer and Dr. W. Marchand in the Zoological Station at Naples.

This short list comprises all the actual observations on the luminosity of these animals; in these, however, the photogenic function has been definitely associated with special organs, and it is by comparison with these that other organs in other species have been regarded as having the same significance.

The history of the anatomical examination of these organs dates back only to the early 'nineties, and, so far as I can ascertain, the right of priority of the discovery rests with Prof. Joubin, who made a communication to the Société scientifique et médicale de l'Ouest at Rennes on February 3, 1893, a brief account of which was published by the Société de Biologie of Paris on the 10th of the same month: this communication related to *Histioteuthis rüppelli*, and in it attention was called to Vérany's observation quoted above. Sections of the organs of *Abraliopsis* were exhibited at the Göttingen meeting of the German Zoological Society and at the Nottingham meeting of this Association in the same year. Successive memoirs by Joubin and others followed, and in 1903 Prof. Chun delivered an address to the German Zoological Society at Würzburg, in which he gave a masterly survey of the whole subject, brought forward instances of similar organs previously overlooked, and showed the great variety in structure, not only in the organs of different species, but even in organs of one and the same individual.

More or less adequately authenticated luminous organs have now been recorded in no fewer than thirty-three species of Cephalopoda, and they have been found to occur in the following situations:

(1) Ventral surface of mantle.
(2) Ventral surface of body-wall within the mantle-cavity.
(3) Ventral surface of siphon.
(4) Ventral surface of head.
(5) Ventral surface of arms (usually confined to the ventral and ventro-lateral, rarely found on the dorso-lateral, and very rarely on the dorsal).
(6) Ventral surface of eyeball.
(7) Ventral surface of tentacles.
(8) Dorsal aspect of the dorsal arms.
(9) Dorsal surface of fin.

The most striking fact apparent from this summary is that luminous organs are practically confined to the ventral aspect of the animal. Another remarkable fact is the existence of organs concealed beneath the mantle and beneath the integument covering the eyeball, which can only be effective by reason of the transparence of the tissues in the living creature.

To give a detailed description of the structure of these many and varied organs would be out of place on the present occasion; it must suffice to group them into more or less well-defined classes and take an example from each.

The luminous organs of Cephalopoda may be divided in the first instance into

A. Glandular.
B. Non-glandular.

A. *Glandular Organs.*—In this class we have to deal only with the type of structure found in *Heteroteuthis, Sepiola,* and *Rossia,* which has been investigated by Dr. W. T. Meyer, of Hamburg, a pupil of Prof. Chun. When working at the Naples Zoological Station he was fortunate enough to obtain a specimen of *Heteroteuthis dispar*, and Dr. Lo Bianco called his attention to its luminous properties. On examination in a dark room it was easy to see the organ lying on the ventral surface of the body, just behind the funnel, showing through the transparent mantle with a pale greenish light like that of the glowworm. It appeared, further, that when the animal was irritated it shot rapidly through the water, leaving behind it a trail of luminous secretion which floated in the form of separate globules, and were afterwards drawn out by the currents into long threads. Dr. Meyer was able to repeat this exhibition of fireworks several times.

In *Sepiola* the luminous secretion is not ejected, but remains attached to the surface of the gland; and, furthermore, the light is only given off on powerful stimulation, as, for example, when the mantle is cut open. The structure of these organs has as yet been only very briefly described by their discoverer: they consist of paired glands, situated as above described one on either side of the anus, and partially concealed by the lateral margin of the ink-sac, which forms a recess for their reception. Beneath and to the inner side of the gland there is a reflector, and above it is a rounded gelatinous mass, fibrous in structure, transparent during life, covered with a delicate muscular layer. Dr. Meyer hesitates as to the function of this mass; but I think, in view of the structure of the luminous organs in other species, we may hazard the suggestion that it is some kind of lens. This organ is of particular interest, because it is the only instance yet recorded of a luminous organ among the Myopsida and the only glandular luminous organ in the Cephalopoda. Glandular luminous organs are, however, known in many species of fish, and in *Pholas* among the Mollusca.

B. *Non-glandular Organs.*—These may perhaps be divided into

(i.) Simple, without special optical apparatus.
(ii.) Complex, with more or fewer of the following structures: pigment layer, reflector, lens, diaphragm.

(i.) As a type of the simpler kind we may take the branchial organ of *Pterygioteuthis giardi*, in which we have a central mass of parenchymatous tissue, with a delicate superficial membrane (consisting of two thin layers), and resting upon a rather thick layer of close, compact tissue, which stains very deeply; beneath this organ is a single layer of cells containing a reddish-brown pigment. The corresponding organ in the nearly allied *Pyroteuthis* (or *Pterygioteuthis*) *margaritifera* is a degree more complex, for underneath the central cell mass is a thick layer of scale-like bodies, similar in structure to that regarded in other cases as a reflector ("tapetum" of Chun). In both these cases it seems necessary to regard the central cells as the source of light (see Fig. A).

Another organ, almost equally simple, is that found in the tentacles of *Thaumatolampas*, where the central portion of the stem of the tentacle for about 2 mm. of its length is occupied by a large rounded cell-mass whose diameter is more than half that of the tentacle. The nerve which usually occupies this position is pushed to one side and flattened out like a ribband. Most curious is the fact that on the side opposite to the nerve a second organ is superposed on the first, which is of more complex structure, inasmuch as it has in its centre a mass of photogenic cells surrounded by a system of radiating fibrils with a pigment layer and tapetum at one side (see Fig. 1

(ii.) As an example of the complex organs we may conveniently take those of *Histioteuthis rüppelli*, where they are scattered over the ventral surface of the mantle, siphon, head, and arms, forming in particular a definite ring round the ventral half of the margin of the ocular aperture. The organ itself is an ovoid body, about 1 mm. in length and somewhat less in diameter. The deeper three-fourths of this cup are covered with a thin layer of pigment, which is lined with a thick coating made up of small lenticular bodies packed closely together and forming a kind of mirror. The space within this, equal in diameter

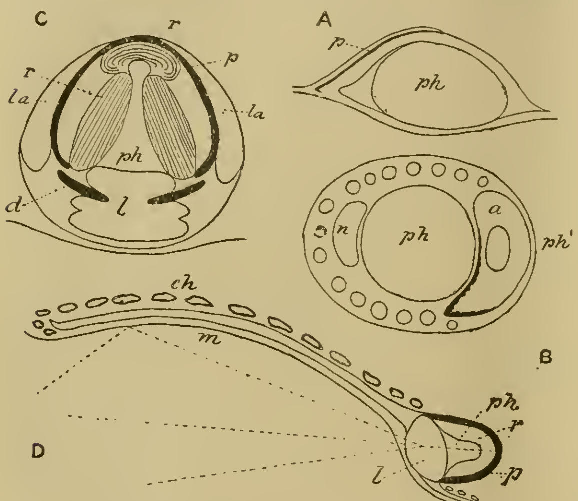


FIG. 1.—Semi-diagrammatic sections of typical luminous organs:—A, Branchial organs of *Pterygioteuthis giardi* B, Tentacular organs of *Thaumatolampas*, C, Pallial organ of *Abraliopsis*. D, Pallial organ of *Histioteuthis rüppelli*. *a*, Accessory tentacular organ. *ch*, Chromatophores. *d*, Diaphragm. *l*, Lens. *la*, Lacuna. *m*, Mirror (external). *n*, Nerve. *p*, Pigment. *ph*, Photogenic cells. *ph'*, Photogenic cells of accessory organ. *r*, Reflector (internal).

to about half the diameter of the organ, is filled with a mass of large deeply staining cells with large distinct nuclei. The more superficial portion of the organ is made up of what seem to be refractive structures. The deeper portion is conical, fitting into a hollow in the photogenic mass, whilst the upper part is bounded by a definite convex surface, the function of which is obviously lenticular. Nerves have been traced passing through the mirror to the light-producing cells in the centre. This ovoid body is situated at the posterior end of a somewhat hollowed patch of an elongated oval shape, which may measure as much as 10–12 mm. in its antero-posterior diameter. A consideration of the form and position of this hollowed patch and of its relation to the axis of the organ shows pretty clearly that it is an external mirror, destined to throw the rays of light downwards and forwards (see Fig. D).

One of the most complicated organs known is that found in the mantle of *Abraliopsis*. Here the whole apparatus is spheroidal in form and surrounded by a black coating, derived apparently from a number of confluent chromatophores. The photogenic cells lie rather in front of the centre, and before them again a ring of black cells seems to discharge the functions of an iris diaphragm. Behind the source of light is a reflector consisting of two parts: the deeper is concave, spheroidal, and made up of numerous concentric layers; the more superficial portion is conical, and also composed of concentric lamellæ. Partly in front of and partly behind the diaphragm is a lenticular mass of tissue. These little lanterns are scattered in considerable numbers over the ventral surface of the mantle, funnel, head, and arms, and the appearance of the animal when they are functionally active must be brilliant in the extreme (see Fig. C).

If we examine the organs just described and the others above enumerated, we see that certain conditions are fulfilled in all cases—namely, the presence of a mass of deeply staining, active cells with distinct nuclei, supplied with blood-vessels and nerves. These, then, are the essential parts of the apparatus, though even here differences obtain: for example, in *Thaumatolampas* the cells are polyhedral, highly refractile, and clearly defined, with spherical nuclei and distinct nucleoli. In *Chiroteuthopsis* the cells are few and large, and partially fuse one with another. In *Pterygioteuthis* the fusion has proceeded so far that the cell-boundaries are no longer recognisable, and there is present a finely granular mass in which numerous nuclei of varying size may be distinguished. In other cases the cells branch out into fibres and form a reticulate structure (*Calliteuthis*). In rare cases, as, for instance, the tentacular organ of *Thaumatolampas*, above described, this essential part constitutes the whole organ; but generally other structures are superadded, such as a pigment coat, reflector ("tapetum" of Chun), lens, and diaphragm, as has been mentioned in the complex organs just described.

Numerous interesting questions at once suggest themselves in regard to these structures, and it is very disappointing to admit that in regard to almost every one the answer is a confession of ignorance.

The first inquiry is: What is the origin of these organs, and from what primitive structures are they evolved? Here it is possible to say but little; there is no instance in which the development of these organs in the embryo has as yet been studied. A larva, believed to be that of *Histioteuthis*, came into my hands a short time ago, and full of hope I had a portion of the mantle cut into sections, but with no result whatever; there was nothing which I could interpret as the rudiment of such an organ.

Those organs occur in so many and such scattered families that it seems clear they must be polyphyletic. Furthermore, even in one and the same species the different organs are not all constructed on the same plan. In *Abraliopsis*, for example, the pallial organs are quite different from the ocular; but the most striking example of this sort of complexity is found in the remarkable *Thaumatolampas*, which has altogether twenty-two organs constructed on no fewer than ten different principles. It seems difficult in such a case to resist the conclusion that these organs have been separately evolved at different times, and perhaps from different origins, during the phylogenetic history of the species.

This variety in the structure of these organs naturally suggests the query: Do these differently designed lamps give out different kinds of lights? Here we have the observation of Prof. Chun on board the *Valdivia* to guide us, according to which in the living animal the middle ocular organ shines with an ultramarine light, whilst the middle of the five ventral organs is sky-blue and the anal organs are ruby-red. It may also be observed that even in preserved specimens, when examined in a strong light, the different organs seem to shine with different colours, although there is under such conditions no actual emission of light. Furthermore, in some forms (*e.g.*, *Calliteuthis*) there are chromatophores in the superficial layers of the integument over the luminous organs, through which the light admitted must pass. A somewhat similar arrangement obtains in the curious structures in *Chiroteuthis*, which were regarded by Joubin at the time of their discovery as "thermoscopic eyes," but which are, I think rightly, in the present state of our knowledge, considered to be a special kind of luminous organ. In these instances the function of the superficial chromatophores may be to colour the light which passes through them.

The question of the utility of these variously coloured lights to the creature possessing them admits of an answer which is, at all events, extremely plausible. It was suggested in the case of deep-sea fishes by Brauer, and has been adopted by Chun in reference to the Cephalopoda. They serve as recognition marks by which the various species can identify their fellows; just as certain colour patches in the plumage of birds enable them to find their mates, so in the darkness of the ocean abysses do these fairy lamps serve their possessors. Another and perhaps even more obvious utility is suggested by the general distribution of these organs. It has above been pointed out that they are, almost without exception, on the ventral aspect of the body, that is, the inferior surface in the position in which the animal habitually swims. It must happen, therefore, that when the creature is moving over the floor of the ocean in the quest for food, this must be illuminated by its lamps, and the advantage of a series of searchlights playing over the ground will be at once apparent.

Finally we have the question: How is the light produced? To this we can only say that this is an instance of the transformation of one kind of energy into another. We are quite familiar with the production of heat in the animal body by the processes of oxidation which go on in it; we are also familiar with the production of kinetic energy when a muscle contracts under a nervous stimulus; and we are also aware that electric discharges are produced under similar conditions in certain organs of the Torpedo and other fish. The production of light is a phenomenon of the same kind. When we can explain how stimulation applied to a nerve causes contraction in a muscle, then, and not till then (so far as I can see), shall we be within reasonable distance of explaining the action of these living lamps.

One point is worthy of notice which has been ascertained, not by experiments on the Cephalopoda, but on other animals, namely, the remarkable economy of this illuminant. A perfectly infinitesimal proportion of the energy expended is wasted on the production of heat. From this point of view animal phosphorescence puts to shame our most modern devices. Whether we shall ever be able to rival Nature in this respect remains to be seen.

We have thus shown how rapid has been the growth of our knowledge regarding the distribution and structure of these fascinating organs, and yet how little we have learned of the mode of their operation, and we end, as all scientific inquiries end when pursued far enough, with a confession of ignorance.

What I have ventured to lay before you are a few of the fruits of the little garden plot in whose culture I have been privileged to take a humble share. If it has appeared to you that the labour spent upon their production by a few enthusiastic workers has been well expended; if they show that in this, as in any other group of animals, the study of small details conscientiously carried out leads to problems of the deepest interest, my object in the preparation of this Address will have been fully achieved.

MATHEMATICS AND PHYSICS AT THE BRITISH ASSOCIATION.

ON Thursday, August 1, at 10 a.m., Prof. A. E. H. Love, F.R.S., read his presidential address, which has already appeared in full in these columns (see NATURE, August 1). A vote of thanks, moved by Sir D. Gill and seconded by Sir G. Darwin, was carried with acclamation.

The Hon. R. J. Strutt commenced the ordinary proceedings with a paper on helium and radio-activity in common ores and minerals. He was inclined to attribute the helium which can be obtained from minerals, not to a radio-activity of the rocks themselves, but to the radium which they contain. The evidence on which this conclusion was based is that the ratio of radium to helium present is nearly constant. A great exception occurs in the case of beryl, which shows no radio-activity, but contains a large quantity of helium. Prof. Rutherford suggested that thorium should be looked for in beryl as a source of the discrepancy. In his reply, Mr. Strutt stated that he had found thorium in granite but not in beryl in sufficient quantities to afford an explanation of its peculiar behaviour.

Lord Kelvin followed with a paper on the motions of ether produced by collisions of atoms or molecules containing or not containing electrions. To him it seems extremely improbable that differences of grouping atoms all equal and similar should suffice to explain all the different chemical and other properties of the great number of substances now commonly called chemical elements. The impossibility of the transmutation of one element into any other he declared to be almost absolutely certain. The ether he takes as an elastic, compressible, non-gravitational solid. It is, however, only under the *enormous* forces of attraction or repulsion exerted by atoms on ether that augmentation or diminution of its density is practically influential. Purely dynamical reasoning leads him to infer generally similar theorems for an atom to those worked out by Heaviside for an electron. The association of atoms with electrions (or atoms of resinous electricity), and the interaction of both with the ether, form the basis of a general explanation of physical phenomena.

In a paper on secular stability, Prof. Lamb explained the difference between ordinary or temporary stability, *i.e.* stability as asserted by the method of small oscillations, and secular stability, *i.e.* stability when account is held of possible frictional forces; and he gave an experimental illustration of the latter kind. A pendulum hangs by a Hooke's joint from the lower end of a vertical shaft which can be made to rotate by a pulley with constant angular velocity ω. The effect of the rotation is that its two circular component vibrations have different periods, that one being the faster the direction of revolution of which agrees with that of the shaft. The criterion of secular stability imposes a limit to the speed for which the vertical position of the shaft is stable; for speeds higher than the limiting one a new position of equilibrium is possible in which the pendulum rotates at a constant inclination θ given by $\cos\theta = Mgh/(A-C)\omega^2$, where A and C are the two principal moments of inertia of the pendulum at the joint.

The beginning of the session on Friday had been allotted to a discussion on the constitution of the atom, and the committee of the section had not been in error in expecting that this would be of intense interest. Prof. Rutherford, whom we now have permanently in this country, opened it with a speech which was specially intended to suggest lines for discussion rather than to be a dogmatic statement of his own views. It was perfectly clear, however, that he regarded the electron as having come to stay, although at present it is impossible to decide whether the electrons which are set free in radio-activity or are revealed by the optical properties of an atom are merely an outer circle or are a revelation of the internal constitution of the inner core of the atom. He declared in favour of a kinetic view of the atom in opposition to statical views such as that developed by Lord Kelvin. Only on a kinetic theory could the great velocity of the β particles be explained. Sir O. Lodge in his contribution to the discussion took up a very definite line: "The electrical theory explains both inertia and radiation; and when a satisfactory explanation is given it ought to be supposed to be the right explanation, inasmuch as it is unlikely that two different systems will both fit the facts." One difficulty that has to be faced is that dispersion, absorption, and radiation (which are all connected) appear to indicate that the electronic constituents of an atom are few, but the electrons so tested may be only those which are comparatively free, and are not completely encased or submerged in an opposite charge. Such deep-seated or constitutional electrons would be inaccessible to light vibrations, and would take no part in dispersion unless violently shaken by chemical clash. The real difficulty is our present ignorance of the nature of positive electricity. Sir Wm. Ramsay urged that the chemist is at present more interested in the detachable electrons, and leaves the nature of the constitution of the atom as non-essential from the point of view of chemistry. These detachable electrons are the cause of valency, and chemical elements of the metallic class must be regarded as compounds; for example, HE may represent an atom of hydrogen the E of which is an electron; for hydrogen chloride, dissolved in water, gives as one of its products H, while the E is transferred to the chlorine atom. He referred to Prof. Rutherford's statement that no profound change had been discovered to take place in matter by the *loss* of electrons, and he pointed out that nickel under combined bombardment by electrons is partially transformed into a radio-active body belonging to that series of metals which yield insoluble sulphates. A *gain* of electrons, therefore, produces a permanent change in matter.

To Mr. F. Soddy, the philosophic unification for which Sir O. Lodge had pleaded seemed "unphilosophic and strained." It was possible to retain the idea of the inertia of electricity as being due to the magnetic field around the moving charge without taking the further step of supposing that matter was ultimately electrical in character. The subject is being approached from both the speculative and experimental sides, and the hypotheses of the former side often failed when subjected to the supreme test of prediction, and were sometimes little more than an ingenious mimicry of known facts. Mr. G. A. Schott considered that it was too soon to expect the mathematical physicist to predict new phenomena, since it is only within the last few years that he has been supplied with the materials necessary for his method, *e.g.* the electron. He adduced one positive result which may help to decide between the static and the kinetic view of the atom. A uniform magnetic force acting on a *rotating* ring gives a periodic mechanical force capable of producing resonance. In consequence, a rotating ring is capable of yielding a magnetic moment very much larger than it would do if at rest relatively in the field. Prof. Larmor claimed the right of physicists to make hypotheses even with regard to the atom. He considered that our views about the electron would have been just the same as they now are if radio-activity had not been discovered, and he gave a short historical account of the development of electronic theory from Faraday through Maxwell to modern times. Lord Kelvin preferred to regard the atom as a big gun loaded with an explosive shell. The firing of a shell does not cause the destruction of the gun; the electron, however, changes its nature in a way analogous to the bursting of the shell after explosion.

The discussion throughout was very stimulating, even if few decisive statements could be made. It was noteworthy that no allusion was made to the latest optical papers of Drude, in which he allocated the parts played by bodies the mass of which is that of an electron, and bodies the mass of which is comparable with the mass of an atom, in determining the optical dispersion of solids, *e.g.* fluorspar.

A paper was next read by Sir Wm. Ramsay detailing the remarkable discoveries announced in a letter to NATURE, July 18. Briefly stated, it appears that helium, neon, or argon is formed from radium emanation according as it is dry, dissolved in water, or dissolved in a strong solution of a copper salt. Simultaneously, lithium and perhaps sodium are formed, the presumption being that they are formed at the expense of the copper. The importance of the former discovery is that this is the first time the nature of the products of radio-active disintegration has been found to be controllable.

In a paper by Mr. F. Soddy and T. D. Mackenzie (Carnegie research scholar) on pseudo-high vacua, it was shown that the electrical characteristics of a high vacuum occur in helium (purified by calcium and subjected to further purification by the passage of the discharge) at pressures between $\frac{1}{4}$ mm. and $\frac{1}{3}$ mm. of mercury, whereas in hydrogen the same holds at 1.25 mm. These pressures are far higher than is commonly supposed. The absorption of helium, argon, and neon in spectrum tubes after continuous running occurs mainly in the volatilised film of aluminium deposited from the electrodes. The gas can be mainly recovered by dissolving the film in mercury or heating the tube.

Prof. Larmor gave a very brief summary of a paper on the range of freedom of electrons in metals. It was remarked that a hopeful plan for elucidating the mechanism of the transfer of electricity (electrons) from molecule to molecule is to study the time relations. The optical phenomena of metals introduce times, viz. the periodic times of the vibrations which are small enough for this purpose. Hagen and Rubens's experiments on the connection between infra-red radiation and electric conductivity show that the time required to establish conduction completely is a small fraction of the period of such waves. If the semi-free electrons to which conduction is due have a velocity of mean square determined by the gas laws, this restricts their range of freedom almost to the interspaces between the molecules. On the other hand, the fact that the square of the quasi-index of refraction of light for the nobler metals is not far removed from being a real negative quantity, indicates that the number of such free electrons is of about the same order of magnitude as the number of molecules.

The proceedings on Monday, August 5, opened with a paper by Dr. L. Holborn on optical pyrometry, in which he outlined the various radiation methods of measuring temperature. The most recent optical experiments give for the melting point of platinum the value 1790° C. if the melting point of gold (1064° C.) is taken as the fundamental point. Prof. C. Féry followed with a discussion of the various difficulties which are met with in connection with the subject. He mentioned that an apparatus had recently been devised in which there is nothing electrical. In this the thermometric receiver, instead of being a thermo-element, is a bimetallic spiral which deflects a pointer over a scale attached to the instrument.

Dr. Harker, who had in recent years obtained a considerably lower value for the melting point of platinum, pointed out some of the defects to which the optical method was liable. In particular, there is an uncertainty arising from the absorption of the light by the vapour given off the walls of the furnace.

After the end of this discussion the section divided into two departments. In the department of mathematics Prof. Forsyth led the way with a brief review of the progress of the calculus of variations during the last century, and in particular of the work of Weierstrass. After referring to later developments of the subject, he gave an outline of the set of four conditions to be satisfied by an integral involving a derivative of the first order of a single dependent variable, and discussed the necessity and sufficiency of these conditions.

Dr. W. H. Young gave an outline of some new results reached by himself in the theory of functions of a real variable. He proved that there could be no difference between the right- and left-hand discontinuities of a function except at a countable number of points, and that a similar result held good for non-uniform convergence. Dr. W. de Sitter, in a paper on a remarkable periodic solution of the restricted problem of three bodies, showed that one of the orbits worked out by Sir G. Darwin is very nearly of the type called by Poincaré a periodic solution *de seconde espèce*.

Mr. H. Bateman followed with a paper on essentially double integrals, and the part which they play in the theory of integral equations. Starting with the integral equation of the first kind, $f(s)=\int_a^b \kappa(s,t)\ \phi(t)dt$, in which the forms of κ and f are known and ϕ is to be determined, he showed that the solution of this equation was unique if no solution could be found of the so-called "homogeneous" allied equation

$$0=\int_a^b \kappa(s,t)\ \phi(t)dt$$

if

$$\int_a^b\int_a^b \kappa(s,t)\ \omega(s)\ \omega(t)dsdt$$

is essentially positive whatever the form of the (continuous) function $\omega(t)$. Types of such functions $\kappa(s,t)$ are given in the paper, and also a simple proof of a theorem of Hilbert.

Major MacMahon read a paper on operational invariants, in which he obtained several interesting and elegant results in this abstruse department of analysis.

Prof. Love read the first of a group of papers on the best methods of introducing certain fundamental results in analysis. In this he detailed a method of proving the fundamental properties of the exponential function. Starting from the attempt to differentiate a^x, he introduced the number e as the limit of $(1+1/n)^n$ when n is infinite, and by applying the theorem of the mean value to the expression

$$\phi(x)=e^b-e^x-(b-x)e^x-\frac{(b-x)^2e^x}{\lfloor 2}-\frac{(b-x)^{n-1}e^x}{\lfloor(n-1)}-\frac{(b-x)^n}{b^n}\mathrm{R}$$

where R is the difference between e^b and the first n terms of the series for e^b, he obtained readily the exponential theorem. In the interesting discussion which followed this paper Dr. Young suggested that the concept of an infinite series was really simpler than that of a limit, since the former involved only a countably infinite number of steps, which was not necessarily true of the second. Dr. Hobson emphasised the value of Prof. Love's method as making the student familiar with a type of proof of great generality and power, but Mr. C. S. Jackson deprecated the too early introduction to beginners of difficult mathematical concepts.

In the department of general physics, which proceeded simultaneously with the above, Mr. Sidney Russ read a paper on the transmission of the active deposit from radium emanation to the anode. He showed that, whereas the amount of active deposit obtained on the negative electrode diminishes as the pressure of the air is diminished, as has already been found by Makower, it is found that the amount obtained on a positive electrode simultaneously increases. Experiments have also been made in various gases on the amount of active deposit on the two electrodes, and it is shown that between the pressures of 0·1 mm. and 1 mm. hydrogen behaves differently from air.

Miss I. Homfray detailed a series of experiments on the absorption of argon by charcoal. Miss Homfray finds that a formula of the same type as Bertrand employed for vapour pressures holds for the equilibrium pressures of the absorbed gas at various temperatures and constant concentration. The constants in the equation change with the concentration, and moderately simple equations are obtained expressing the mode of dependence. The resulting equation is much more satisfactory than the experimental formula usually taken.

Sir Oliver Lodge then read a paper on the density of the ether, in which he summarised the arguments for a very high density of the ether which had been given by him in NATURE, March 28, p. 519. His conclusion is that every cubic millimetre of the universal ether of space must possess the equivalent of a thousand tons, and every part of it must be squirming internally with the velocity of light. The latter part of this statement is based on the fact that the existence of transverse waves in the interior of a fluid can be explained only on gyrostatic principles, and the internal circulatory speed of the intrinsic motion of such a fluid must be comparable with the velocity with which such waves are transmitted.

Prof. Trouton showed an electrical experiment illustrating the two modes of condensation of water vapour upon surfaces. If a bell jar be placed over a Bunsen and then placed over a charged gold-leaf electroscope, this often leaks as though the air were ionised. The action is, however, somewhat uncertain. If the insulating shellac of the electroscope is gently dried with a flame, the experiment if made fails, but if the shellac be now moistened and wiped so dry with a cloth as not to conduct, the experiment if made will be successful. The action is therefore due to the moisture, but in the former case it is deposited with difficulty for the same reason that well-dried phosphorus pentoxide absorbs moisture with difficulty.

An important paper was read by Mr. A. O. Rankine on a theoretical method of attempting to detect relative motion between the ether and the earth. If a dumb-bell shaped body shortens in accordance with the Lorentz hypothesis in the direction of the ether drift, its moment of inertia will depend upon its azimuth unless its effective mass changes in a compensating manner. The change in its mass necessary for compensation turns out to be of opposite sign to that which would be indicated by the ratio between longitudinal and transverse mass, as given by any of the current theories. Thus there is either something very wrong in these theories or a real effect arising from motion relative to the ether is theoretically detectable in opposition to the view held by Larmor, Einstein, and others. Unfortunately, it has to be recognised that the effect is too small to be actually detected by experiment. In the discussion Sir Oliver Lodge advised caution amongst the many pitfalls in this difficult subject, and appeared to be in favour of the view that when allowance is made in accordance with a complete theory which holds good for large as well as small velocities, the supposed effect will be found to vanish. Prof. Trouton mentioned another experiment which he was making in collaboration with Mr. Rankine. If a wire changes in dimension with its azimuth, it might be expected that its electrical resistance will simultaneously change. Four coils are connected to form the arms of a Wheatstone's bridge, adjacent arms having their axes at right angles to one another. Balance is obtained, and then the framework on which the coils are mounted is rotated through a right angle. When the temporary disturbance has subsided, the arrangement is again tested for balance. The experiments are in progress, and so far a small positive effect has been obtained, but it requires confirmation before so minute though important an effect can be considered certain.

The afternoon meeting began with a challenging paper by Prof. H. E. Armstrong on the nature of ionisation. This attracted the physical chemists in particular, who appeared with the object of combating Prof. Armstrong's views. These may be summarised as follows:—

We do not "need to imply more by the term *ionisation* than that the medium is in a state in which it will conduct electricity." "The doctrine of electrolytic dissociation is destitute of common sense." Ohm's law is consistent with a modified Grotthus hypothesis. "The assumption that any electromotive force, however small, will condition sensible electrolysis" is a fact which cannot be regarded as established, as it is impossible to avoid some polarisation. Electrolytic conductivity and chemical activity *se confonde* (Arrhenius). Chemical interactions are dependent on "mutual attractive relations of the particles." In effecting hydrolysis in the case of sugars, "enzymes act selectively; therefore their action cannot be attributed to dissociated hydrogen ions." "The mistake has been made that liquids are comparable with gases—a preposterous contention." "'Ionised' molecules are complex, reversible systems formed of solvent and solute under the influence of the force of residual affinity." "As such systems break down under the influence of the current new ones to take their place must arise spontaneously in the solution: the molecules, therefore, would draw one another apart at a rate proportional to the polarisation," and hence Ohm's law would be satisfied. In the discussion Sir O. Lodge emphasised the distinction between the terms "electrolyse" and "ionise." Electrolyse signifies decomposition, ionise means making ready for decomposition, or, if we like, to decompose and to leave the products of decomposition in the fluid instead of getting rid of them at the electrodes. It really means converting a substance into an electrolytic conductor, and for that process the term is wanted. As to the nature of ionisation, the facts to be expressed are that the atoms are perfectly free to travel, that an extremely minute force will set them in motion. They are either free, therefore, or else potentially free. The merest trace of E.M.F. suffices to practically transfer them in one direction. To account for this, we may suppose a certain proportion of the atoms are either continually or persistently free, which is improbable; or that they are constantly interchanging with others, in such a way that they are free between their combinations; or else that they are combined into such a loose and large aggregate that the attraction in all directions is equal—which is really a case of potential freedom barely distinguishable from actual freedom. If the instinct of chemists really prefers this view to the idea of actual dissociation, then great weight should be attached to that instinct, and the aggregation mode of specification should be preferred; but for practical purposes it makes very little difference, and in treating the matter mathematically, actual dissociation is the idea most easily expressible.

He was not surprised that Prof. Armstrong prefers this hypothesis of aggregation, inasmuch as he has for twenty years preached the doctrine of residual affinity as explanatory of solution, of molecular combination, and of many other such things, as distinct from simple and undivided units of valency. Now this doctrine is entirely consistent with the electrical theory of chemical attraction. For the single bond with which, say, sodium is attached to chlorine is, on the electrical view, not a unit of which no fractions are possible, as perhaps it used to be regarded, but a group or bundle of lines of force which can be split up into any number of fractions, a few lines being easily diverted. Thus a few are thrown off to encounter any water molecules which may come into the molecular neighbourhood; and although the attraction of each water molecule for the sodium or the chlorine must be much less than the attraction of sodium and chlorine for each other, yet in a dilute solution, when the water molecules are numerous, the cooperation of a lot of them may exert a pull sufficient to balance the attraction of the atoms of the salt itself, and either actually or potentially to tear the salt molecule asunder. But whether it is really torn asunder or not, or whether it goes about with an aggregate of water molecules hanging on to it, ready to be torn asunder by the slightest addition of applied electric force, is a matter on which as a physicist, at least from the electrolytic point of view, he would express no opinion. It is possible that some of the phenomena now known to physical chemists may afford a criterion for distinguishing between these two extremely adjacent hypotheses. But he wished to testify to the fact that the residual affinity doctrine, when developed in accordance with the electrical theory of chemical action, is a luminous one, and explains, not only the influence of a solvent, but mass action generally; and that we owe a debt to Prof. Armstrong for keeping the chemical reality of the facts thus able to be explained always before us.

As to the objection to thermodynamical reasoning; he should allow that thermodynamics is a method of arriving at results, but it is not ultimately to be regarded as the most satisfactory method. For it does not pay attention to the process by which the results are obtained: it is rather a method of proceeding blindfold, or in blinkers, and reaching the result by an ingenious scheme of argument without attention to the process involved. It is remarkable that reasoning can be carried on in this way, but it is undeniable that so it is.

So far from chemistry being cold-shouldered by physics, it would appear rather to be the other way; and the great interest of the present state of things is that the facts of chemistry, or at any rate the most fundamental of them, seem now able to be tackled by mathematical methods, and to show signs of being more completely understood than ever before.

This is a process which, however puzzling it may be in its early stages, will surely be welcomed by chemists in the long run; and it will be a great day when such an empirical generalisation as the periodic law really yields up its secret to mathematical analysis—based, as that probably will be, on the hypothesis of the electric constitution of the atom.

With all that had been said about Prof. G. F. FitzGerald he heartily concurred, but he seldom or never found himself in disagreement with that great man; and inasmuch as Prof. Armstrong seems to agree with him too, at any rate to a great extent, there appears to be less difference between the physicist and the chemist than might superficially appear.

Meanwhile, we should not avoid the use of the word "ionisation," but should use it carefully, and should determine the nature of the process which it represents.

Prof. Abegg reminded Prof. Armstrong that combination between solute and solvent is admitted by everyone. But this alone does not explain the duplication of the number of molecules which is indicated by any method of counting, such as lowering of freezing point, osmotic pressure, &c. The difficulty felt by some chemists in realising how simple solution should effect such a thorough change of molecular state is lessened if it is recognised that even in the solid state the molecules are often dissociated. Internal friction is the cause of the small conductivity of solids, not want of dissociation. No theory explains the same number of facts as the dissociation theory. Prof. Werner emphasised the necessity for postulating association as well as dissociation, bringing forward his own work on complex inorganic combinations. Without association there is no ionisation. Dr. T. M. Lowry said he had been led to advocate a hydrate theory of ionisation. The molecule does not fall to pieces, but is torn apart by the affinity of the solvent for the ionic nuclei of which the salt is composed (Trans. Faraday Society, July, 1905). Dr. Burch said chemists and physicists had attacked the subject from opposite ends, like engineers driving a tunnel, and the question was whether they would meet in the middle, and he thought they would.

Dr. Senter directed attention to Werner's demonstration that in such compounds as $Co(H_2O)_6Cl_3$ the water was associated with the positive ion, and that it had also been shown that the positive ions of the alkali and alkaline earth salts were also hydrated to a considerable extent in solution (*cf.* Senter, *Science Progress*, January, 1907). He considered that Armstrong's theory that the variation of electrical conductivity with dilution could be accounted for by hydration alone was opposed to the law of mass action; the requirements of this law will be satisfied only if the molecule splits up into two parts which convey the current.

Dr. N. T. M. Wilsmore claimed that the ionisation theory was a growing one, as was indicated by the recognition to-day of the influence of the solvent. Against a Grotthus theory he urged that, since two molecules are involved, the conductivity would vary as the square of the concentration. Dr. Haber inquired how the theory of a concentration cell could be worked out if no dissociation occurs. He also discussed the bearing of solubility, *e.g.* with regard to the decrement of solubility of AgCl by addition of sodium the quantitative relations are the same as we deduce from conduction experiments. He would express the solution of a salt such as sodium chloride by the equation

$$\mathrm{ClNa} + (+)(-) \rightleftharpoons \mathrm{Cl}(-) + \mathrm{Na}(+)$$

where $(+)$ stands for a unit positive and $(-)$ a unit negative charge.

Throughout the discussion the term hydration was employed. We may point out that we believe Prof. Armstrong would not take this term as adequately connoting the formation of the complexes that he postulates.

Two papers were read by Prof. Rutherford, the first on the production and origin of radium, in which he gave evidence that there must be an intermediate substance formed in the derivation of radium from uranium. Sir O. Lodge drew from Prof. Rutherford the statement that he did not know whether or not this substance was radioactive. The second paper, in collaboration with J. E. Petavel, was on the effect of high temperatures on the activity of the products of radium, in which they detailed experiments made with radium inside an explosion chamber, proving that a *sudden* rise of temperature does not affect the rate of disintegration, but that subsequent effects are due to a change as if of B and C together.

In the discussion on the latter Mr. Makower stated that the experiments afforded a confirmation of his own experiments and those made by him in conjunction with Mr. Russ. The only point in which the experiments do not agree with the view that it is radium C which is affected by temperature is that after the diminution of activity succeeding the explosion the rate of recovery is too slow. This might be accounted for by assuming a sudden change in the activity of radium C accompanied by a change in its period instead of assuming a change of activity in both B and C.

Mr. H. Stansfield read a note on the echelon spectroscope and the resolution of the green mercury line, in which the detection of several faint new components is described; and a paper by Mr. L. F. Richardson, on a freehand potential method, had to be taken as read owing to lack of time.

The proceedings on Tuesday, August 6, opened with a discussion on modern methods of treating observations. This was initiated by a paper by Mr. W. Palin Elderton expository of the methods developed by Prof. Karl Pearson. After defining the principal quantities involved in the new methods, the paper dealt with correlation and its calculation. Examples were given examining possible correlation between rainfall in different districts, rainfall and typhoid in Surrey districts, and other meteorological questions. In the case of rainfall and typhoid, the statistics made use of indicated so little correlation that "it is impossible to assert definitely that there is any relation" between them. In the discussion Dr. W. N. Shaw emphasised the present need of a consideration of "departures from the mean." He directed attention to other methods of treating observations besides that of Prof. Pearson; for example, Prof. Schuster's periodogram method and the "method of residuation" adopted by Prof. Chrystal in discussing the component periods of oscillation of the seiches of Scottish lochs. He showed diagrams, prepared in the Meteorological Office, which illustrated the relation of the mean to the frequency of occurrence of the various values. Mr. G. Udny Yule explained that to be content with the arithmetic mean was to neglect all the other characters in which two frequency distributions might differ. The standard deviation was the most convenient measure of "scatter," but the difference between the two values, which were just exceeded by one-quarter and three-quarters of all the observations respectively, was the most readily calculated. The correlation coefficient was a measure of the approach towards a simple linear relation between two variables, and could be extended to cover more complex cases.

Mr. A. R. Hinks, who was somewhat sceptical as to the general applicability of the new methods, inquired what meaning could be attached to the value 0·3 of the correlation coefficient in such cases as $y = \log x$. He also gave an example in which questionable conclusions had been arrived at by the method, the reason being that certain groups of stars had been studied for special purposes, while others had been neglected. The choice of observations introduced a fictitious law of distribution. The discussion was continued by Mr. Hooker, Prof. Turner, and Prof. Edgeworth.

Prof. Hicks then read a paper on the use of calcite in spectroscopy. In order to be able to make use in spectroscopy of the large dispersion in the ultra-violet produced by calcite, Prof. Hicks first polarises the light in order to do away with the duplication of the spectral lines. When a quartz lens is employed in the collimator it is made a compound lens of right- and left-hand quartz; the polariser for very short wave-lengths (down to λ 2300) was a small Foucault fixed like a comparison prism. The Hon. R. J. Strutt pointed out the great advantages that fused quartz would have.

A series of papers on astronomy and cosmical physics were now taken. Dr. O. Backlund detailed the work done in determining the variation of latitude. Dr. W. N. Shaw read a paper on some recent developments of the method of forecasting by means of synoptic charts. These are the methods of M. D. Gréville, of Paris, and M. Guilbert, of the Meteorological Society of Calvados, for obtaining an approach to a second approximation in forecasting weather. Mr. C. Michie Smith gave an account of the Kodaikanal Observatory in South India. The Rev. A. L. Cortie, S.J., read a paper entitled "The Variability in Light of Mira Ceti and the Temperature of Sun-spots," the purport of which was to indicate the relatively low temperature of sun-spots from the behaviour of the bands of titanium oxide in *o* Ceti, when the star is at two different temperature levels represented by a whole magnitude in luminous power. Concomitant evidence of the variation of temperature of the star was furnished by the character of the hydrogen lines.

Prof. H. H. Turner read a paper descriptive of a method which is being tried at Oxford for improving the constants of the plates for the Astrographic Catalogue. He also read one on the determination of periodicity from a broken series of maxima. For example, observations of the light curve of a variable such as U Geminorum are generally absent altogether near a minimum, and cannot be supplied; moreover, the maxima are often lost from cloudy weather, &c. The paper suggests a method of examining these for the detection of periodicity. Let E_1, E_2, E_3 be the epochs of maxima. Find the differences between these and the *nearest* theoretical maxima E_0, $E_0 + 2n$, $E_0 + 4n$, &c., where $2n$ is a period to be tried. Find (*a*) the algebraic mean of these differences, (*b*) the sum of their squares. In certain circumstances (*b*) should be a minimum when we have hit on a real periodicity. If (*a*) comes out sensibly different from zero, we must alter E_0 until (*a*) is small enough. When there is no periodicity near $2n$, (*b*) will approximate to $mn^2/3$, m being the number of maxima treated. Miss M. White, T. V. Pring, and J. E. Petavel communicated a note on an analytical study of the meteorological observations made at the Glossop Moor kite station during the session 1906–7, and a preliminary note by W. A. Harwood and J. E. Petavel was read on the recent international balloon ascents (Manchester station). A paper by T. J. J. See, on results of recent researches on the physics of the earth, was taken as read.

Meanwhile, the mathematical department had been meeting separately, continuing the group of papers on the elements of analysis with one by Dr. W. H. Young on the introduction of the mathematical idea of infinity. Dr. Young stated that, of the three types of mathematics, viz. the logical, formal, and practical, his sympathies were with the first and third rather than with the second. He pointed out a number of instances in which learners were brought into contact with the notion of infinity, and advocated the policy of boldly facing the difficulty instead of trying to avoid it. A paper by Mr. C. O. Tuckey on the teaching of the elements of analysis unfortunately had to be cut short owing to lack of time.

Mrs. Boole-Stott exhibited a series of beautifully constructed models of three-dimensional sections of regular hyper-solids in four dimensions, and models illustrating the rotation of a four-dimensional body about a plane. Prof. Schoute showed some lantern slides in connection with this subject. He also exhibited three models of developable surfaces the tangent planes of which are given by the equations

$$u^3 + 3u^2x + 3uy + z = 0$$
$$u^4 + 6u^2x + 4uy + z = 0$$
$$u^6 - 15u^4 + 15u^2x + 6uy + z = 0$$

and indicated certain results when the parameter u in the equation of the plane occurs to a higher degree. Prof. A. M. Worthington showed a series of slides, directing attention to the fact that the impact of a drop excavates a perfectly spherical hollow which reaches its greatest depth at apparently the same time that the water thrown up attains its maximum height. The volume of this pit is enormously greater than that of the drop. The object of the paper was to obtain suggestions from mathematicians explanatory of this phenomenon, but none were forthcoming. Prof. Hilton gave an account of a new property of Abelian groups, and Lieut.-Colonel A. Cunningham read a paper on the factorisation of the terms τ_n, v_n, of the Pellian equation $\tau_n^2 - Dv_n^2 = 1$.

Besides these papers, reports were presented by various committees nominated by the section. Owing to the plethora of papers, these, as a rule, were taken as read, printed copies being distributed to members present.

The committees presenting reports were those denoted by their well-known abbreviated names of "electrical standards," "kites," "Ben Nevis," "Bessel functions," "teaching of elementary mechanics," "Falmouth," and "seismology." An account was given of the last by Prof. Milne.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE most noticeable feature about the proceedings of the Anthropological Section was the great predominance of papers of an archæological character, those on physical anthropology and general ethnography being far fewer in number than usual. The general level of the papers was, however, quite up to the usual standard, and several of the communications were of the first importance.

As the archæological papers were so much the more numerous, it may be advisable to deal with them first. On the Monday morning an important discussion on the Iron age was initiated by Prof. Ridgeway in a paper on the beginnings of iron. He argued that Central Europe was the true centre of the use of iron as a metal, and that it was first diffused from Noricum. He considered that the general opinion as to the early knowledge and use of iron in Egypt is explained by the fact that hæmatite was known and used, but that it was not treated as a metal, but as a stone. That iron was worked from a remote period in Central Africa he considered unlikely, as it only became known for the first time in Uganda some five hundred years ago, and there was no reason to suppose that it was worked much earlier in the more central part of the continent. As it was also certain that the peoples beyond the Caspian and along the shores of the Indian Ocean did not use iron until a late date, it seemed clear that its use as a metal was due to Central Europe.

In the discussion which followed Prof. Edouard Naville drew a distinction between the knowledge of iron and its general use. Referring to the two or three cases of iron being found of the time of the Old Empire, he pointed out that, in spite of this, it did not seem to be in common use under the New Empire, and that no iron tools were discovered in the Deir el-Behari excavations. His own feeling was that the general use of iron in Egypt was not anterior to Greek times.

Prof. Petrie emphasised the necessity of keeping clearly in view the distinction between the general and sporadic use ot iron. Iron was known for 4000 years before its use became general, and this sporadic use strongly supported Prof. Ridgeway's views of the use of iron in its native state, as, had processes of reduction been known, it was unlikely that it would have taken 4000 years for its adoption to have become general.

Prof. J. L. Myres argued that there was no logical connection between Prof. Ridgeway's view that the knowledge of iron, as a useful metal, spread from a centre in Noricum and his assumption that the question of the early Iron age in Europe was that of the first use of iron at all. He pointed out that materials, for example tobacco and gunpowder, were not infrequently looked upon as mere curiosities in one area, and that their real utility was not discovered until they were transferred to another district. He also dwelt on the effect which the introduction of the blast furnace from the north must have had upon the output.

Mr. Arthur Evans considered that the great objection to Prof. Ridgeway's theory was the comparatively late date of the Iron-age civilisation of Hallstatt. Earlier phases are seen in southern Bosnia, and still earlier in the geometrical and sub-Minoan tombs of Greece and Crete. He considered that the general adoption of iron in the countries of the Ægean corresponded with the break-up of the earlier Minoan and Mycenæan type of culture.

Prof. Bosanquet felt that a great difficulty in the way of accepting the views of Prof. Ridgeway was the impossibility of testing the theory that the general use of iron had made its way into Greece from the north, owing to the very little available evidence as to Bronze-age culture in Macedonia and Epirus.

Mr. Crooke considered that India may have been the seat of an independent discovery of the metal.

As usual, Egypt took a prominent place in the proceedings, and the section had the advantage of numbering Prof. Naville among those who read papers. Besides giving a descriptive account of the excavations at Deir el-Bahari, which have now been brought to a satisfactory conclusion, Dr. Naville read an important paper on the beginnings of Egyptian civilisation. The conclusion at which he arrived was that the Egyptians were a nation formed of a mixture of Hamitic conquerors from Arabia settling among an indigenous stock of Hamitic-African origin, an amalgamation made the easier as both races were of the same stock and had no religious differences. Prof. Petrie also gave a paper to the section describing the excavations carried out by the British School of Archæology, under his direction, at Gizeh and Rifeh. In this communication he described the interesting series of pottery soul-houses, found on the latter site, which are of great importance apart from their religious significance as showing the design and evolution of the ordinary Egyptian house, about which little had previously been known.

Greek archæology was dealt with in papers by Prof. Bosanquet and Mr. R. M. Dawkins. Both of these papers dealt with the work now in progress at Sparta, but while Mr. Dawkins gave a general description of the excavations, Mr. Bosanquet dealt especially with the scourging of the Spartan boys before the altar of Artemis Orthia, which was shown by the excavations to have occupied the same position for more than a thousand years. Prof. Bosanquet traced the history of the scourging festival, and showed that the cruel whippings described by Roman writers are an artificial revival of an old discipline which apparently originated in a rough game played by the Spartan youths, in which at first there was no element of passive endurance so characteristic of the later ordeal. This game itself seems possibly to have originated in a still earlier custom, in which the lads hit each other, for luck, with boughs cut from the sacred tree, the *Agnus castus*.

The recent expedition undertaken by the University of Liverpool to northern Syria and Asia Minor was described by Prof. Garstang. The work done was of very great interest, the most important find being what is apparently an altar of dedication, similar to those discovered in Crete. Many inscriptions were also found, as well as a large sculpture of an eagle standing on three lions.

In English archæology Dr. Auden described a series of objects, referable to the Viking age, recently discovered at York. Several of the objects have not previously been reported as occurring in England, and amongst these the brass chape of a sword scabbard, with an interlacing zoomorphic design, is of peculiar interest. The general consensus of opinion is that the finds may be referred to the first half of the tenth century, at which time Scandinavian influence in York was at its height.

The progress of the excavations at Caerwent, including the discovery of the Forum and Basilica, was described by Dr. Ashby, who also, in a paper on Sardinia, directed attention to the *nurhagi* or stone towers and their resemblance to the brochs of Caithness.

Another important archæological paper, dealing, however, with a very different area, was one in which Dr. Seligmann and Mr. Joyce described a series of prehistoric objects from New Guinea. The objects described consisted of stone weapons, engraved shells, and pottery, and are truly prehistoric, inasmuch as the present natives do not know who made them, and in some cases cannot even say for what purpose they were made. It is interesting to note that some of this prehistoric pottery is superior both in make and ornament to that now in use among the natives.

The most important papers on physical anthropology were those by Mr. Gray and Dr. Shrubsall, which opened the discussion on anthropometrics in schools. This discussion was held conjointly with Section L (Educational

Science), and will be found fully reported in the account of the proceedings of that section. Apart from these two papers, the most noteworthy contribution was one by Messrs. James and Fleure, giving an account of the progress of the University of Wales Ethnographical Survey. It is hoped to extend the survey to all the purely Welsh people, but at present only a limited area has been examined. Still, the results, although purely tentative, are very striking, and the population of the district examined may be said to fall into four distinct groups, of which two may be provisionally identified with *Homo mediterraneus* and the "Northern Race." The survey which has been so auspiciously started is one from which most important and valuable results may be expected, and it is to be hoped that the work will be energetically pushed forward, as the population is rapidly changing, and in a comparatively few years it may be too late.

In papers dealing more or less with ethnography, Mr. J. W. Crowfoot directed attention to the importance of the Anglo-Egyptian Sudan as a field for anthropological research. A great part of the district is virgin soil, and only waits the advent of the anthropologist to produce most important results, while in the northern Sudan the dervish rule has completely changed the conditions, whole tribes having been devastated, transplanted, or mixed with foreign blood. Still, the three main language groups remain, but the problem of the origin of the people using them still awaits solution. It is a matter for regret that Dr. Pirrie was unavoidably prevented from giving his promised account of the Buruns, as his observations would have had an important bearing on Mr. Crowfoot's paper.

Apart from the president's address, on "Religious Survivals," which has been reported in NATURE, the only paper dealing purely with religions was Dr. Farnell's criticisms of Dr. Usener's theories concerning Sonder-Götter and Augenblick-Götter. The divinities of which Dr. Usener treats are those which have no proper personal names, but mere appellatives, to express their functions. Such divinities are found in the Roman and Greek cults, and a few examples have been noted among savage peoples. The system may be regarded as a peculiar form of animism. Dr. Usener's theory assumes that these divinities are relics of a very primitive period, when imagination had not created concrete personal divinities, and that the Greek Pantheon was deeply indebted to this system. Dr. Farnell argued that the Greek evidence did not support these assumptions, and that many of these Greek appellative *numina* may be creations of personal polytheism, mere emanations of concrete divinities.

The subject of totemism was dealt with by Mr. G. L. Gomme in a paper on its origin. Mr. Gomme was of opinion that totemism must have arisen from conditions of human life which are universal, and which are probably supplied by migration. Sex cleavage was produced by the fact that woman was the stationary animal, and in this way became more closely associated with friendly animals, plants, &c., to which she looked for protection and food rather than to the male, who constituted a migratory element; women thus influenced the totem names. Mr. Gomme's conclusion was that totemism began as an artificial association of groups of people, and was not based on a kinship society.

Sociology was also dealt with in two papers by Dr. Rivers, one criticising Morgan's Malayan system of relationship, and the other offering some most valuable suggestions for the definition of the technical terms used by anthropologists, especially with regard to the divisions of society and marriage and descent. He urged the importance of the terms used being strictly defined, and also the necessity of some general agreement in their use being obtained.

A most suggestive technological paper was one by Prof. J. L. Myres on a terminology of decorative art. The necessity of arriving at a terminology was strongly emphasised, as persons would thus be enabled to describe by some recognised terms the arrangement and *motif* of any pattern in the same way as the herald is able to describe, without graphic illustration, the colours and component parts of any coat of arms, however complicated. The basis of any such system must be strictly technological; it must be a description of what the artist did, of the order in which he did it, and of the effect produced, and all minor elements in the design must be located by reference to the major element on which they are based. Such a terminology must, of course, be elaborated gradually, but Prof. Myres's valuable suggestions should serve as an admirable basis on which the work may be built up, and it is to be hoped that all persons interested in decorative art will assist him in his efforts to arrive at a sound scientific terminology, the practical value of which cannot be overestimated.

Attention was directed by Mr. Newbery and Dr. Bryce to what is practically an unworked field, namely, the so-called "door-step" art of the west of Scotland. The patterns, which are drawn solely by women, are of great variety, are purely geometrical and conventional, and are used to decorate doorsteps, hearths, &c. The drawings are very primitive, and represent an early stage of artistic evolution. Mr. Newbery was of the opinion that the designs were the expression of a primitive art instinct, but since they are traditional in character, being handed down from generation to generation, it seems more likely that they are a survival. However this may be, there can be no question as to their interest, both in themselves and as a field for research. Another paper of interest to which passing reference may be made was one in which Prof. Ridgeway sought to identify the origin of the crescent as a Mohammedan badge, not with the young moon, but with the well-known amulet of two boar's or other animal's claws or tusks set base to base in crescent form.

Amongst the reports of committees, reference should be made to that appointed to excavate the Lake Village at Glastonbury, which hopes to be able to complete its long work this month (August), and to the Stone Circles Committee. This committee was able to make the announcement that it had received permission to conduct excavations in the Avebury Stone Circle, from which important results cannot fail to be obtained, results which should go far towards accomplishing the object of the committee, namely, to ascertain the age of these structures.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—University College: In consequence of the removal of University College School to Hampstead, the south wing of the college buildings has been set free for university purposes, enabling the following developments to take place, beginning with the new session:—In the mechanical engineering department a new hydraulic laboratory will be provided in the basement, and also additional space for experimental work in mechanical engineering during the second and third years. A separate laboratory will be set aside for research work, thereby leaving the main laboratory entirely free for undergraduate work. In the department of electrical engineering, the present lecture-room will be replaced by a large new lecture-room with a small demonstration class-room adjoining it. The old lecture-room will be fitted up as an experimental room for advanced students. The electrical engineering department will also contain a research laboratory with apparatus and preparation rooms adjoining. The department of applied mathematics will also receive considerable extensions, providing two special research laboratories and ample accommodation for the work being carried on in the Galton Eugenics Laboratory. New accommodation will be provided for the department of geology, and include a museum, with a research room, and a lecture-room suitably equipped with lantern apparatus. Applications for the prospectus should be made to the secretary of the institution.

LORD KELVIN will open the new science buildings of Queen's College, Belfast, on September 20.

A COMMITTEE has been formed to promote the raising of a memorial to the late Major D. M. Moir, I.M.S., professor of anatomy at the Medical College, Calcutta, who died of septicæmia contracted in the execution of his public duties. It is hoped that sufficient money will be obtained to found a prize or to endow a bed, after providing for a tablet and portrait in the college hospital. The treasurer of the fund is Dr. Suresh P. Sarbadhicary, 79, 1 Amherst Street, Calcutta.

The Paris correspondent of the *Lancet* states that the Governor-General of Algeria has brought a proposal for the founding of an Algerian university before the financial delegates, who have adopted it. It will be remembered that the late M. Moissan and Prof. Bouchard, having inspected the secondary schools in Algiers, reported favourably on the founding of a university. They proposed the establishment of an institute of natural science, experimental botany, zoology, and hygiene, and pointed out the political and social effects of the foundation of a university which would form a powerful link between the various races which form the population of Algeria.

The secondary and agricultural school at Bigods Hall, Dunmow, which was established by Lady Warwick ten years ago to provide a scientific education in agricultural affairs for the boys and girls of the district, is to be closed. The Earl of Warwick, in a letter to the chairman of the Essex Education Committee, explains the reasons for the taking of this step. He states that, although the county committee has given the school a grant, it has intimated the possibility of a re-consideration of the educational necessities of the locality, and the headmaster has received the offer of another appointment; complaint is also made that the school has suffered from a lack of cordial support from the committee.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 19.—M. A. Chauveau in the chair.—Presentation of vol. xiii. of the *Annales de l'Observatoire de Bordeaux*: M. **Lœwy.** This volume contains an account of the work done at Burgos on the total eclipse of the sun of August 30, 1905, by MM. Rayet and Courty, also actinometric observations made by M. Esclangon at Bordeaux, from a balloon, on the same occasion. The observations made during 1899 and 1900, forming the contribution of the Bordeaux Observatory to the photographic catalogue of the sky, are also given.—Symmetrical dimethylethylene oxide, $CH_2—CH—CH—CH_3$:

O

Louis **Henry.** A study of the reaction between this oxide and methyl-magnesium bromide. The tertiary alcohol, $(CH_3)_2.C(OH).C_2H_5$, is formed exclusively, from which it follows that this substituted ethylene oxide behaves towards the magnesium compound as though it were first converted into the isomer $CH_3.CO.CH_2.CH_3$.—The comet 1907*d*: Ernest **Esclangon.** Observations with the large equatorial of the Observatory of Bordeaux on August 1, a specially clear night, brought out many details of the comet's structure. The nucleus was brilliant, sensibly circular, and appeared like a star of 5·5 magnitude. No scintillation was noticed, from which it may be concluded that the nucleus has a real sensible diameter, corresponding to the apparent diameter of the image of about 8″. Combining this with the known distance from the earth, the nebulosity forming the head would have a diameter about thirteen times that of the earth. The structure of the tail of the comet is shown in a figure.—The results of observations made at Cistierna, Spain, during the total eclipse of the sun on August 30, 1905: A. **Lebeuf** and P. **Chofardet.** Clouds interfered with observations during totality, but measurements were made of the first and fourth contacts, a reduction of these measurements being given.—The variations of the absorption bands of crystals of parisite and tysonite in a magnetic field at the temperature of liquid air: Jean **Becquerel.** The magneto-optical properties of two crystals of the same family present close resemblances, but with marked difference in details. From the behaviour of the bonds in parisite it is concluded that either there must be an inversion of the magnetic field in certain parts of the interior of the crystal, or positive and negative electrons must exist simultaneously.—The motion of electricity without action between the electric charges and without external forces: T. **Levi-Civita.**—Some modifications which produce the splitting up of the curve of rate of decay of induced radio-activity: Ed. **Sarasin** and Th. **Tommasina.**—The atomic weight of radium: Mme. **Curie.**—The disengagement of the emanation by radium salts at various temperatures: L. **Kolowrat.** It is known that the quantity of emanation produced in unit time is constant. When the salt is in solution, the whole of the emanation is evolved, but in the solid state a part remains in the salt. The author confirms the observation of J. Curie and J. Danysz, that when the radium salt is fused the whole of the emanation is given off. At a fixed temperature the quantity of emanation obtainable from a salt previously deprived of its emanation in a given time is a function of the temperature. It results from this work that, in the application of the method of heating to the estimation of radium in minerals or other solid substances by the disengagement of the emanation, it is absolutely necessary to fuse the material.—The dissociation of calcium carbonate: D. **Zavrieff.** A repetition of the work of H. Le Chatelier, especial care being taken to secure uniformity of temperature. The dissociation pressures are given for six temperatures ranging between 815° C. and 926° C.—The alloys of nickel and tin: Em. **Vigouroux.** Alloys containing between 57·65 per cent. and 66·76 per cent. of tin treated with hydrochloric acid leave residues richer in nickel, approximating to Ni_3Sn_2; treatment with nitric acid, on the contrary, gives alloys richer in tin, tending towards NiSn. All these alloys are brittle, brilliant, and non-magnetic.—Study of the alloys of cobalt and tin: F. **Ducelliez.** Alloys containing less than 50 per cent. of tin behave as mixtures of cobalt and Co_3Sn_2, the latter remaining when the alloys are subjected to the action of dilute nitric acid.—The action of some substances upon potassium iodide: B. **Szilard.**—A new and very sensitive method for the qualitative detection of nickel: Emm. **Pozzi-Escot.** The method is based on the fact that molybdate of nickel is insoluble in presence of an excess of alkaline molybdate, whilst cobalt molybdate is very soluble under the same conditions.—The preparation of unsymmetrical halohydrins and the properties of the corresponding ethylene oxides: MM. **Fourneau** and **Tiffeneau.**—Rhinanthin: Marcel **Mirande.**—The ichthyological fauna and the age of the shell marls of Pourcy (Marne): Maurice **Leriche.**

MARIGNAC'S COLLECTED PAPERS.

Œuvres complètes de Jean-Charles Galissard de Marignac. Edited by E. Ador. In two vols. Vol. i. (1840–1860), pp. lv+701, with a portrait; vol. ii. (1860–1887), pp. 839. (Geneva: Ch. Eggimann et Cie.; Paris: Masson et Cie.; Berlin: Friedländer und Sohn.)

AMONG the great chemists of the nineteenth century, and especially those engaged with inorganic chemistry, Jean-Charles Galissard de Marignac takes high rank, and in the notable advances which were made in chemical science during his lifetime he played a conspicuous part. The pride which his native city felt in his long and fruitful career has found expression in this sumptuous edition of his published papers, a worthy monument to the untiring energy that characterised him all his life so long as strength remained. It has been issued under the auspices of the Société de Physique et d'Histoire naturelle. The editing has been entrusted to the capable hands of his son-in-law and, for a time, colleague, Prof. E. Ador, who has executed what was evidently a labour of love with reverent care, and has contributed the interesting sketch of the life and works of Marignac which prefaces the first volume.

Marignac's personal life seems to have been singularly uneventful. Sprung from a French family which had settled in Geneva early in the eighteenth century, he was born in that city in 1817. With the view of entering the French service as a mining engineer, he underwent the course at the École polytechnique at Paris, and in accordance with the enlightened custom that prevailed in that country was dispatched at the end of his training on a scientific mission to foreign countries in order to study their methods. While at Stockholm he made the acquaintance of Berzelius, and there can be little doubt this meeting had a profound influence on the course of his life and turned his bent more definitely towards chemistry. At any rate, when, soon after his return to France, he was offered the chair of chemistry at the Academy of Geneva, he, despite the, from a worldly point of view, far better prospects that awaited him in France, accepted the offer without hesitation; and, as it turned out, he filled the post for thirty-eight years, until in 1878 failing health compelled him to tender his resignation.

It is pleasant to note the sympathetic consideration which Marignac experienced from the French Government. He was permitted to vacate his post and yet to retain the title of Ingénieur des Mines, and in the course of his letter the Minister of Public Works remarked:—

"Le gouvernement français ne peut voir qu'avec faveur que le gouvernement de Genève vienne chercher en France les hommes auxquels il confie le soin de répandre les lumières de la science, et, en remplissant avec distinction le poste qui vous est confié, ce sera encore un service indirect que vous rendrez à la France."

Shy and retiring by nature, he seemed to find happiness only in his laboratory; indeed, it was with considerable reluctance that he tore himself away for a few days at the time of his marriage. To quote Prof. Ador:—

"Marié en 1845, c'est à peine s'il consent à s'éloigner pendant quelques jours de son laboratoire; il emporte chaque matin un petit pain qu'il dévore à la hâte, ne pouvant se décider à interrompre ses travaux au milieu du jour";

a picture of a thinker, absorbed in his work and almost oblivious of every-day life. He shunned any position which brought him before the public gaze, and to the end found it irksome to lecture before a fresh generation of students.

The conditions under which most of Marignac's work was performed would be rather a shock to those accustomed to the greater luxury of these latter days. His laboratory is described by Prof. Ador thus:—

"Cette méchante cuisine enfouie dans le sous-sol, sombre en plein midi, avec ses cornues de grès ou de verre qui lui donnaient l'air d'une officine d'alchemiste."

Yet amid such forbidding surroundings were carried out elaborate researches with a care and completeness such as would be with difficulty surpassed at the present day even with the advantage of the improved apparatus now available. More commodious premises were eventually provided in 1873 when the academy was transformed into the university; but not long afterwards he was compelled to retire, and, although for a few years he continued work in his private laboratory, his strength at length failed so completely that he was practically confined to his couch. He died in 1894. The excellence of his work was recognised by the numerous honours conferred upon him; among them we may note that he was elected in 1881 a corresponding member of the Royal Society, and received in 1886 the Davy medal.

At the time when Marignac went to Geneva, the atomic weight of few of the elements had been at all accurately determined, and although some confidence might be felt in the numbers obtained by such a master as Berzelius, it was imperative that they should be confirmed by independent investigators and by other methods. There was at the time considerable speculation as to the question of the rigid application of Prout's law. Perceiving the pressing need for further trustworthy determinations of these fundamental data, on which the whole fabric of chemical science is based, Marignac resolved to devote his scientific energy to this important investigation. As was pointed out by Stokes, the president of the Royal Society, when bestowing on him the Davy medal, his work was the more important since he gave so much of his attention to the atomic weights of the more common elements on which the determination of new atomic weights is generally made to depend. In the whole of his researches he exercised the greatest care in considering the possibilities of error which might have occurred in the operations of previous workers, and displayed more than ordinary ingenuity in devising new methods to avoid such errors, and at the same time he paid particular attention to the necessity of employing the purest material in such work. He was never satisfied with even repeated experiments on different amounts by the same method, and always, whenever practicable, adopted two or more independent methods. If we include those elements which he did not completely study, he determined the atomic weights of no fewer than twenty-nine of the elements, and in nearly every case his numbers differ little from those now adopted —a remarkable feat for one man working without any assistance. In the course of his investigations he analysed certain of the minerals containing the rare earths, and succeeded in separating two new elements, ytterbium from gadolinite and gadolinium from samarskite.

The process of time has brought it about that much of his work begins to have mainly historical interest, and probably at the present day most chemists will feel more vivid interest in researches which were to some extent incidental to the principal investigation. Prominent among these is his elaborate work relating to the intricate and puzzling problem in analysis presented by titanium, niobium, and tantalum. So difficult is the separation of these three elements, when occurring together in the same substance, that many eminent chemists have imagined the existence of other elements; for instance, Hermann strongly insisted on the presence of ilmenium in samarskite, but Marignac showed it to be really a mixture of niobium and tantalum. Although it cannot be said that he solved the problem with complete success, yet Marignac was the first to devise a method—the differing solubilities in hydrofluoric acid of the double fluorides of the three elements with potassium—which effected any real separation, and which to this day has not been superseded by any more satisfactory. The problem is one that still awaits solution, and is occupying the attention of many chemists. It is of interest to note that, in recognition of the method devised by him, the name marignacite was recently assigned by Mr. Weidman and Mr. Lenher to a variety of pyrochlore from Wausau, Wisconsin. Of little less vivid interest is his comprehensive investigation relating to the formula of zirconia and the atomic weight of the element. He made use of the law of isomorphism propounded by Mitscherlich, of which he was early a keen advocate, and undertook a complete chemical and crystallographical examination of a large number of fluozirconates. None of his experiments lent any confirmation to the idea put forward by Svanberg that zirconia contains three distinct metallic oxides. Nevertheless, the question is one deserving of further consideration. Prof. Church and other observers have noted a remarkable range in the density of zircons, 4·0 to 4·7, and an even more remarkable alteration in the density effected in certain stones of low density by the application of heat, and the conclusion has been drawn that there are three varieties of zircon. Further, the crystallised native zirconia, baddeleyite, presents almost as wide a range of density, which is even more difficult to understand in the case of an apparently simple oxide. It is possible that zirconium has never been completely isolated; it is well known that a satisfactory method for separating it from titanium has yet to be found.

Marignac found time to examine the chemical and crystallographical characters of a large number of minerals, and also of artificial salts prepared by him in the laboratory. The sentence with which he opens one of his elaborate papers is indicative of the thoroughness characterising his work, and embodies a maxim which even now is by no means universally appreciated by chemists:—

"L'intérêt que présente l'étude des formes cristallines des divers composés chimiques, m'a engagé à ne jamais négliger de déterminer exactement les formes de ceux qui s'offraient à moi, en cristaux déterminables, dans le cours de mes travaux de laboratoire."

Towards the end of his career his attention was attracted to the physical side of chemistry, and he carried out with his customary skill and care a lengthy series of thermochemical determinations; unfortunately, the complete collapse of his physical vigour brought his work to a premature close. To his other investigations—for instance, on ozone—space will not permit us to allude.

As regards the appearance of the volumes, the quality of the paper and the style of the printing are beyond criticism, and care has been taken to indicate the original pagination. Most of the papers were published in the *Bibliothèque Universelle de Genève* or the *Annales de Chimie et de Physique*; those dealing with mineralogical subjects appeared in the *Annales des Mines*.

THE BLOOD-SUCKING GNATS.

A Monograph of the Culicidae or Mosquitoes. Mainly Compiled from Collections received at the British Museum. Vol. iv. By F. V. Theobald. Pp. xix+639; 16 plates. (London: Printed by order of the Trustees, 1907. Sold by Longmans and Co., B. Quaritch, Dulau and Co., and at the British Museum [Natural History].) Price 1*l*. 12*s*. 6*d*.

THIS work forms the second supplementary volume to Mr. Theobald's original monograph of the Culicidæ of the world, in two volumes, published by the trustees of the British Museum in 1901. The present volume deals very largely with the new species which have been added to the national collections, and besides these it also embodies the descriptions of one hundred and sixty species which have been described by various authors since the issue of the first supplementary volume in 1903.

It would be difficult to overestimate the great scientific value of Mr. Theobald's most exhaustive faunistic work on these insects. It is a model of painstaking scientific accuracy, and we congratulate him on its issue.

With the exception of the adoption of a few characters in an admirable scheme of general classification drawn up by Dr. Lutz, no changes have been made in this volume. The Corethrinæ have, however, been excluded from the Culicidæ and raised to family rank, partly on account of the asiphonate character of the larvæ, but mainly by the absence of piercing mouth-parts and of scales in the adults.

Felt's[1] new method of classification, based upon the genital armature of the males and the wing venation, is discussed at some length, but abandoned as unpractical on the grounds (1) that the majority of known mosquitoes are females only, and thus we should not be able to place many of our well-known species in any genus; and (2) that the cross-veins in the venation of the wings are subject to so great a variation that generic characters cannot be fixed by them. The author also points out that Messrs. Dyar and Knab's[2] unusual classification of the Culicidæ by larval characters only cannot be admitted. We need scarcely point out that any radical changes in the classification of these insects will result in endless confusion, especially so if based mainly upon local knowledge; and as practically all British, French and South American doctors and entomologists have adopted the Theobaldian classification, anything more than a modification of this system would be followed by somewhat disastrous results, especially among the students of the medical profession who are engaged in the study of the Culicidæ in connection with tropical diseases.

In the general notes we find a reference to Major Adie's evidence as to the benefit of *Lemma minor*, L., as a means of preventing mosquitoes from laying their eggs on water. He states that "tanks covered with this flat weed never contain larvæ of Culicidæ, whilst others at the same time of year are full of them." This genus of plants has apparently the same marked effect upon the frequency of both Anopheles and Culex in this country.

The natural reservoirs formed by the flowers of *Heliconia brasiliensis*, Hook., in Ceylon, the leaves of Nepenthes and various Bromeliaceous plants and the cut ends of bamboo in South America, are given as the breeding places of both Anophelines and Culicines. Mr. E. E. Green, of Ceylon, has contributed some notes on *Myzomyia rossii*, Giles, which he found breeding in the brackish lake at Batticaloa. There are also some interesting notes on the bionomics of *Nyssorhynchus fuliginosus*; but apart from these and a few other references to the habits of mosquitoes, very little is known of the earlier stages of a large proportion of the Culicidæ, so that those who have the opportunity of observing these insects have the pleasure of discovery before them.

In a work which has been so admirably performed, it is invidious, perhaps, to direct attention to any errors either of omission or commission, but we note that Patton's[3] important ~~~er in which he describes five new species of Anophelinæ has been quite overlooked, nor do we find any reference to Grünberg's[4] new Anophelines described in 1905.

[2] "The Larvæ of Culicidæ classified as Independent Organisms." Journ. New York Ent. Soc., vol. xiv., pp. 169–230. (1906.)
[3] Journ. Bombay Nat. Hist. Soc., 1905.
[4] Zool. Anzeiger, Bd. xxix., No. 12, September, 1905.

Myzomyia hebes, Dönitz (p. 42); *Cellia punctulata*, Dönitz (p. 109); and *Howardina chrysolineata*, Theob. (p. 218), are all omitted from the synoptical tables; while *Pyretophorus pitchfordi*, Power (p. 72), and *Nyssorhynchus indiensis*, Theob. (p. 98), are omitted both from the synoptical tables and the lists of species given under the respective genera.

Myzomyia listoni, Liston, is given priority on pp. 41, 43, but is sunk to the position of a synonym of *M. christophersi*, Theob., on p. 51. Under *Culicada fitchii*, Felt and Young (p. 321), Fig. 112 is described as *Grabhamia fitchii*; there are also some minor errors in the text, evidently printer's. R. N.

COMMERCIAL ORGANIC ANALYSIS.

Commercial Organic Analysis. By A. H. Allen. Vol. ii., part iii. Pp. xii + 547. Third edition, re-written and revised by the Author and A. R. Tankard. (London: J. and A. Churchill, 1907.) Price 20s.

WITH the publication of this volume, the whole of this standard work on the analysis of organic materials occurring in commerce is again available in a revised form. The preparation of this portion was undertaken by Mr. Allen so long ago as 1898, but, owing to his ill-health, little progress was made, and after his untimely death in 1904 the completion of the book was undertaken by Mr. Tankard.

The recent considerable additions to our knowledge of volatile oils, rubbers, gutta-perchas, and resins, the four principal groups of products now dealt with, have necessitated extension of the space devoted to these subjects in previous editions. As regards resins and volatile oils the author was assisted by Mr. E. J. Parry, and in the preparation of the article on oil of turpentine Mr. Archbutt was consulted, whilst Dr. Leffmann, of Philadelphia, contributed a portion of the section on aromatic acids and their hydroxy-derivatives.

The method of treatment adopted is to give a short critical *résumé* of the present position of the chemistry of each product, followed by a summary of the analytical methods available for its examination, one or more of these being finally recommended as giving trustworthy results in the author's own experience.

In spite of the care which has evidently been taken to secure accuracy in the information given, the specialist will be able to find here and there in the sections in which he is particularly interested statements requiring emendation or amplification. Thus the important matter of the botanical sources of rubber should not have been dismissed in the statement that it is "obtained from the latex of trees growing in S. America, Africa, India, &c.," supplemented by the inaccurate footnote, "A *new* source of caoutchouc has been recently discovered in the root-bark of *Landolphia thrallonii*, a plant growing in Lower Guinea and the French Congo." The statement that gutta-percha occurs in the latex of various trees belonging to the Sapotaceæ (*e.g. Palaquium pustulata* and other species) is all the information vouchsafed regarding the source of this important product, and is misleading since the best gutta is obtained from *Palaquium gutta*, *P. pustulata* yielding an inferior product of little commercial value. There is a reference on p. 384 to "Spanish oil of hops" or "Cretan oil of marjoram," described as obtained from *Origanum hirsutum* and *O. creticum*. This appears to refer to the material better known in this country as "Cretan origanum" or "red thyme" oil, which is generally believed to be obtained from *Origanum hirtum*. The tabular statement of the constituents of volatile oils is incomplete in some respects; thus, under "basil oil," there is no reference to the terpene ocimene isolated by van Romburgh from this source in 1901; and the information given under the head of "applications" in these tables is in some cases rather inadequate.

There is a reference in the list of "errata and addenda" to the recent confirmation by the Philippine Bureau of Science of Trimen and Bentley's statement that "elemi" is obtained from *Canarium luzonicum*, but, curiously enough, the generic name is wrongly given as Conarium.

The arrangement of the subject-matter adopted facilitates reference to the information given regarding most of the products described, but it would have been an advantage if a fuller index had been provided.

As a guide to the analysis of commercial vegetable products this book fully maintains the high standard set in previous editions, and those concerned in its revision are to be congratulated on the satisfactory way in which they have accomplished their work.

T. A. H.

SCIENTIFIC ASPECTS OF PHOTOGRAPHY.

Investigations on the Theory of the Photographic Process. By Dr. S. E. Sheppard and Dr. C. E. Kenneth Mees. Pp. x+342. (London: Longmans, Green and Co., 1907.) Price 6*s*. 6*d*. net.

DURING the last four years the authors have been working with the object of preparing theses for their degrees according to the regulations of the University of London, and in this volume they present in order the records of their work by republishing together their communications to several scientific societies. That particular branch of photography that the authors refer to as *the* photographic process is the exposure, development, fixation, and sensitometry of gelatino-bromide plates—in short, negative making as now understood, but without reference to the after-treatment of the fixed plate by such processes as intensification, or to such collateral matters as the production of developer stains.

As indicated by the title, the volume is theoretical rather than practical, though the results often have an important practical significance. The subjects are dealt with from the point of view of what is now understood as physical chemistry, and the work is described in the language of that branch of science. This will make the volume probably more acceptable to students interested in photography who have devoted themselves specifically to physical chemistry, but it imposes a serious difficulty in the way of those who have not. This difficulty is increased by the constant use of symbols instead of words in the text. We would suggest the addition of a glossary giving the exact meaning of each of the symbols used.

Some of the apparatus used appears to be disadvantageously complex. For measuring opacities a spectrophotometer is employed, though dispersion of the light is unnecessary, and appears to be undesirable, for it must add sources of error. The authors use the bright green part of the spectrum, but do not say why they throw away the rest. They recognise the fact that the light transmitted by the silver deposits in films is largely scattered, and that their instrument takes very little cognisance of scattered light. They apparently assume that the scattered light generally bears a constant proportion to the whole, but it is very doubtful whether such an assumption is well founded. On certain occasions the authors endeavour to obviate the error due to scattering by making the film itself the practical light-source by means of a diffusing medium, placed in contact with it. Opal glass, which they use, is probably the best diffusing medium available, but the present writer does not call to mind any proof that it is thoroughly effective for such a purpose. Other methods of measurement are well known that do not suffer from these drawbacks.

The authors deal with many questions that are of a very debatable character, and it in no sense belittles their work to say that they remain debatable. They adopt the "germ" theory of the developable image, but limit the effect of each germ to the grain or nodule of which it forms a part. The "suspicion of a vicious circle in the argument" that the authors refer to in connection with the "molecular strain" theory is, we fear, much more widely applicable than they appear to realise. The authors remark that "it may be said of the physical theories that they shirk a real explanation by treating the phenomena to be explained as a quality of the physical modification of the halide"; to which one might reply that those who advocate the chemical theories assume a decomposition of which there is no evidence. And so it remains a matter of opinion as to which is the safer and more useful hypothesis. We make only one other observation, namely, that it seems undesirable to speak of the *law* of constant density ratios, when, as the authors themselves admit, it is "frequently not followed." When this "law" was first propounded by Messrs. Hurter and Driffield they maintained that it was really a *law*, which it was very difficult, if possible, to get away from.

This volume will find a place, which it will worthily fill, in the libraries of all who are interested in the scientific aspects of photography, because it contains the record of a series of carefully conducted experiments under stated conditions, and gives copious references to the literature of the subject.

C. J.

OUR BOOK SHELF.

Surgical Instruments in Greek and Roman Times. By Dr. John Stewart Milne. Pp. xii+187; illustrated. (Oxford: The Clarendon Press, 1907.) Price 14*s*. net.

BOTH the author and the Clarendon Press are to be congratulated on the issue of this very valuable work—Dr. Milne because it represents work well done, and the Press on account of the successful manner in which the fifty-four plates of surgical instruments have been reproduced.

The book has grown out of a thesis written by Dr. Milne for the degree of doctor of medicine at the University of Aberdeen. It shows him to be a scholar of no mean capacity, and a fit member of a profession which used to be a great deal more learned and much less practical than it is at the present time. Knowledge about ancient surgical instruments is singularly scattered. There are descriptions of them in the medical and surgical writers of classical times, and there are remains of the instruments themselves in most of the national museums of Europe and America. But in modern times very little attention has been devoted either to the instruments or to their descriptions, and those who still read descriptions of the operations in the classical authors have either been contented to imagine the instruments with which they were performed or have had to draw upon their recollection of what they saw at Naples. Dr. Milne has now removed this reproach, and any intelligent surgeon, even though he be ignorant of Greek and should know but little Latin, can follow easily the manipulations of the older surgeons. Some day, perhaps, a surgeon with an archæological bias will do for Egyptian surgery what Dr. Milne has accomplished for Greece and Rome. Dr. Milne describes the instruments under the general headings of knives, probes, forceps, bleeding cups and clysters, cauteries, bone and tooth instruments, bladder and gynæcological instruments, sutures, and the portable outfit which was necessary for the surgery of so migratory a race as the Romans. In an appendix is an inventory of the chief instruments which Dr. Milne has seen in the various European museums, and a bibliography of the subject, short but apparently complete. There are no less than three indices, the first an index of subjects, the second a Latin index, and the third in Greek. Dr. Milne has done his work so well and so accurately that as this monograph is the first dealing with the subject it must remain for a long time the standard authority until further finds prove or disprove some of the disputable conclusions drawn by the author. The monograph presupposes a considerable amount of knowledge on the part of the reader. He must in the first place be skilled in the practice of his profession, he must be interested in its antiquities, and he must be a fair classic. These qualifications being granted, the book is most excellent reading, and throws abundant light, not only on the subject of which it treats, but also on many collateral points.

Diptera Danica. Genera and Species of Flies hitherto found in Denmark. Part I. By William Lundbeck. (Copenhagen: G. E. C. Gad; London: William Wesley and Son, 1907.) Price 4*s.* 6*d.* net.

This work is expected to be completed in about ten parts; and the first part is accompanied by a portrait of R. C. Stæger, an eminent Danish dipterist. The book is written in English, and as it appears to be very carefully done will prove very useful to English entomologists who take up the study of Diptera, which has been more neglected in England than any other order of insects, and respecting which we possess no complete work at present; though most European countries possess good monographs of Diptera in their own languages. The introduction relates chiefly to structure, illustrated by figures of structure and neuration. The other text-illustrations represent details of structure, such as heads, wings, palpi, &c. One term is new to us—the "yowls," which from the context seems to apply to the lower part of the face. The English is very good, but somewhat stilted, and occasionally rather unfamiliar words are used, such as "kinks" and "kneeformed."

There is no general table of families, which we regret; but detailed tables are given of subfamilies, genera and species. The descriptive part of the book appears to be very good, as well as the accounts of habits, transformations, and localities. There is even a table of the larvæ of the genera of Stratyomiidæ, the first family included in part i., the others being Xylophazidæ, Cœnomyiidæ, Tabanidæ, Leptididæ, and Acroceridæ.

It appears that the last estimate of the number of Danish Diptera was given by Zetterstedt in 1855 as 1439, to which Prof. Lundbeck will doubtless be able to add considerably by the time that his work is completed. The number of British species is probably somewhere between 2500 and 3000; and a considerable proportion of the Danish species probably also occur in the British islands, though the latter may be expected, when the Diptera of both countries are fully known, to possess a richer fauna than Denmark, owing to the greater extent and more varied character of the country.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Radiation of Meteors.

The shower of November Andromedids which occurred in 1885 exhibited a very large area of radiation, the flights being directed from a region variously estimated from 7° to 15° diameter. The Draconids of August, with a radiant near *o* Draconis and centre at about $290° + 60°$, appears to exhibit a similar feature, for the rich shower this system presented in 1879 had a very ill-defined radiant. An active shower of Taurids seen on November 2, 1886, also formed a very dispersed or scattered radiant.

The Draconids alluded to above returned rather plentifully this year between August 15 and 28, and they exhibited the same indefiniteness of radiation as in 1879. The feature is an interesting one, but it is very difficult to investigate it properly because of the errors of observation and mistakes in attributing meteors to their correct systems.

As a rule, it may be accepted as a general fact that showers of slow meteors have more diffused radiants than the swift meteors. I have often found the radiant points of the Perseids, Orionids, and Leonids very contracted and exact centres, while certain displays of slow meteors have proved rather puzzling to me in fixing their correct positions owing to the evident diffuseness in the intersections of the paths. W. F. Denning.

Bishopston, Bristol, August 30.

Experiment on the Rusting of Iron.

In view of recent work on the rusting of iron, the following simple experiment will be of interest. It is the result of a number of attempts to devise a simple method —for class-demonstration purposes—of showing that carbon dioxide is necessary for the rusting of iron.

A 500 c.c. flask was taken, and into it were put about 100 c.c. of 15 per cent. caustic potash solution. A partially bored sound cork was inserted in the neck, and the flask shaken occasionally for two days. Then a piece of bright iron wire (a long nail is suitable) was, after boiling in distilled water, pushed through the unbored portion of cork, leaving about an inch outside. After four months the iron inside shows no sign of rust, whilst that outside was rusted in as many days. Geo. A. Watson.

Grammar School, Cork.

THE EXPLOSION OF GASES.

THE earliest work on the explosion of gases was that of Humphry Davy, who in 1817 published those celebrated experiments on "the propagation of flame through small tubes and orifices" which led him to the construction of the miner's safety-lamp.

More than half a century later Bunsen devised the non-luminous gas burner, observing that unless the flow of the mixture of coal-gas and air exceeded a certain rate the flame became unsteady and passed down the tube. Bunsen believed that this rate represented the velocity with which an explosion would travel in the combustible gases in a closed tube, and he obtained definite values for a number of mixtures by leading the gases through an orifice at the end of a tube, igniting the jet, and determining the minimum speed at which the gases must be forced through the tube to prevent the flame passing back through the opening. The rates of explosion measured in this way were comparatively slow, the fastest observed being about thirty-seven yards a second.

FIG. 1.

But in 1881 Berthelot and Vieille discovered that when an explosive mixture is ignited at the end of a long pipe, the velocity of the explosion rapidly increases from its point of origin until it reaches a maximum velocity, which remains constant however long the column of gas may be, and which greatly exceeds the speeds of combustion measured by Bunsen; this discovery was confirmed by the independent investigations of Mallard and Le Chatelier, published at the same time. Berthelot gave the name "l'onde explosive" (detonation-wave) to the flame travelling with its maximum velocity, thus distinguishing it from the variable progressive combustion which precedes its development. The velocity of the explosion-wave constitutes a physical constant which has a specific value for each inflammable mixture; measurements by Berthelot and H. B. Dixon have shown that it is approximately equal to the velocity of sound in the burning gases at the temperature of the explosion. For a mixture of hydrogen and oxygen in equivalent proportions the velocity is about 3000 yards a second.

Mallard and Le Chatelier succeeded in recording the slow movements of the flame of progressive combustion by photographing the flash on a piece of sensitised paper fixed on a revolving cylinder. They found that when the gases are ignited at the open end of a long tube, the flame travels for some distance with a uniform slow velocity of the order measured by Bunsen; the flame next begins to vibrate, swinging backwards and forwards with oscillations of increasing amplitude; then it either dies down or sometimes the gas detonates. If the gas is fired near the closed end of the tube, the movement of the flame is uniformly accelerated until the detonation is set up. Le Chatelier's apparatus was not fast enough to analyse the wave of detonation itself.

The apparatus used by Prof. H. B. Dixon consists of a drum carrying a narrow strip of Eastman film, which can be rotated at the rate of 100 metres a second. The explosion tube is fixed horizontally, and the image of the flame is focussed on to the vertically moving film. The photographs show an inclined line of light compounded of the two motions. Fig. 1 is a photograph of the explosion of cyanogen with oxygen. The mixture was fired near the middle of a tube by an electric spark s. The flame moves slowly in both directions; to the left it passes out of the field of view, to the right its speed increases until at x the detonation-wave is set up. The detonation-wave, moving with constant velocity, is represented by a straight line (x, d), while the slower movement of the progressive combustion preceding it is shown as a curve (s, x), the steepness of which diminishes as the motion of the flame accelerates—the speed of the drum being uniform. The duration of the flash was less than 1/100 second. The period before the detonation is distinguished not only by the slow movement of the flame, but also by slow and incomplete combustion and feeble luminosity.

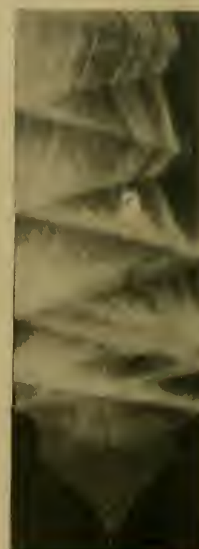

FIG. 2

The initiation of the detonation-wave is marked by certain characteristics—(1) a sudden increase in intensity of the flame, accompanied by an instantaneous rise in pressure; it is found that glass tubes are most often fractured at the point where the detonation originates; (2) rapid and complete combustion; (3) the setting up of a strongly luminous backward wave (x, r)—the so-called "retonation-wave"—which under certain conditions travels as rapidly as the detonation-wave itself. The sudden rise in pressure is due to the increase of chemical action, and this pressure not only produces the forward detonation, but also sends a backward wave of compression into the slowly-burning gases behind it; this compression-wave raises the temperature of the combining gases and increases the luminosity. It should be observed that the light produced by the explosion is chiefly due to particles knocked from the glass and raised to incandescence; the small particles suspended in the burning gases glow by the heat imparted to them by the hotter but invisible gaseous products of combustion.

The detonation-wave is set up only after the flame has run some distance, which depends on the nature of the mixture and on the size of the spark.

Fig. 2 shows the explosion of hydrogen and oxygen in a closed glass tube too short to allow of the detonation being set up. The gas is fired in the middle of the tube, and the flame spreads right and left with faint luminosity. The flame is preceded by an invisible compression-wave which travels with the velocity of sound through the unignited gas, and is reflected from the ends of the tube. The flame is checked while these two compression-waves pass through the burning gases, and is then helped forward by the waves moving in the same direction. The movement then becomes unsymmetrical; the flame to the left is checked a second time before it reaches its end of the tube, that to the right reaches the end of the tube and sends back a strong retonation-wave. The wave from the right is of greater intensity and moves more rapidly than that started a little later from the left, and, although the reflections of these waves at first run nearly parallel, the stronger gradually overtakes the weaker and coalesces with it, and the single wave continues to traverse the tube from end to end. As many as one hundred reflections have been counted in an explosion of this kind. Fig. 3 shows in outline the movements of the flame and compression-waves.

The flame in its initial stage is only very feebly luminous, a fact which has led to erroneous beliefs in regard to the mechanism of explosion. Von Oettingen and von Gernet, failing to photograph the flame itself, introduced finely-divided salts into the tube, and obtained brilliant pictures of the explosion showing a series of parallel waves. They believed that the explosion itself was *quite invisible*, the movements shown in the pictures being compression-waves rushing through the burning gases after the explosion was completed. These parallel waves, following each other in close succession, were supposed to be due to "successive partial explosions" proceeding from the spark, in accordance with Bunsen's theory of discontinuous step-like combustion.

Fig. 3.

The influence of water vapour on the combustion of hydrogen with oxygen has formed the subject of much recent research. Some years ago Dixon showed that an electric spark would fire ordinary electrolytic gas whether in the dried or moist condition, and that the velocity of detonation was practically unaffected by the presence of aqueous vapour. The experiments of Baker with very pure hydrogen and oxygen have, however, shown that the initiation of the flame is largely influenced by the purity of the mixture. It might be expected that the initial phase of the explosion (before detonation is set up) would be modified if the interaction of the gases depends on the presence of previously formed water molecules. Dixon and Bradshaw have shown by photographs that this is not the case; the flame, once it has been started by a spark, spreads with the same velocity in the dry as in the moist gases, and undergoes the same changes in intensity. So far as the development and movements of the flame are concerned, the presence of water-vapour appears to make no difference in the union of hydrogen and oxygen.

In a recent paper Dixon and Bradshaw have shown that the compression-wave which travels in front of the flame in the initial stage of the explosion may, under certain conditions, bring about the spontaneous inflammation of the gases in a region of the tube some distance from the spark. Fig. 4 shows the explosion of hydrogen and oxygen in a tube one end of which has been drawn off in the blowpipe flame in the manner of a Carius bomb-tube, so that the end has the form of a funnel followed by a short capillary. The explosion is started in the middle of the tube (*s*); almost simultaneously the gas inflames in the capillary (*c*). The flames meet midway between the fine dark vertical lines, which are reference marks produced by fastening narrow strips of black paper outside the explosion tube to eclipse the flame as it passes. The broad band is due to the clamp which held the tube in position. The firing of the gas in the capillary is caused by the sudden increase of pressure in the funnel, the heat of compression raising the gases to the temperature of ignition. The wave produced is analogous to the tidal "bore" in a funnel-shaped estuary. L. B.

Fig. 4.

THE SEVENTH INTERNATIONAL ZOOLOGICAL CONGRESS.

The meeting of zoologists at Boston was formally convened on Monday, August 19, in the Jordan Hall. Prof. Alexander Agassiz, as president, welcomed the members and delegates, and gave a short but vivid address on the recent progress of oceanographical research, especially in its zoological aspects. He directed attention, for instance, to the extremely interesting facts which he has discovered in regard to the relations of the deep-sea faunas on the two sides of the Isthmus of Panama. In a country where the stranger cannot but be impressed with the amount of public and private money which seems to be placed at the disposal of scientific institutions, it was interesting to hear Prof. Agassiz's complaint that the Government had not taken any steps to publish an account of the treasures of the *Albatross* expedition. It was one of those touches of nature which make the whole world kin.

Vice-presidents were appointed, such as Mr. Bateson (England), Prof. Hubrecht (Holland), Prof. H. F. Osborn (United States), Dr. Watase (Japan); and, on the report of Prof. Blanchard, the Czar Nicolas prize was awarded to Prof. Cuénot, of Paris, for his research on hybrids. Special mention was also made of theses by M. Loisel, of Paris, and M. Standfuss, of Zürich, which did not arrive in time to be considered in making the award. Prof. R. Hertwig, of Munich, gave a long address on the most recent researches on cytology. He spoke in German, and it was not always easy, in spite of his lucidity and illustrative charts, to follow his discussion of the intricate relations between the nucleoplasm and the cytoplasm. Of particular interest was the account of his observations on the influence of temperature on the size and rate of division of the chromosomes.

The meetings of the sections were held in the truly magnificent buildings of the Harvard Medical School, which stand like five marble temples on the three sides of a quadrangle, and are admirably designed for internal re-adjustment or for external extension outwards as future circumstances may demand. The internal equipment of the various departments, *e.g.* Prof. C. S. Minot's embryological laboratories, called forth universal admiration. Great praise is due to the organisers of the congress for the way in which they secured the orderly accomplishment of the scientific business and for the embarrassingly tempting arrangements for excursions. For creature comforts most thoughtful care was taken, from the providing of *al fresco* luncheons to the presence of a nurse!

The intellectual bill of fare—a metaphor which cannot be avoided amid so much hospitality—was all too full. Never can the zoologist of good appetite and digestion have wished more ardently that he could be, as Sir Boyle Roche's bird, "in two places at once." For in spite of clever arrangements, there was no avoiding the simultaneous occurrence of interesting events. This holds especially true in regard to the sectional addresses, which included the following:—The problem of the vertebrate head, by Prof. J. P. McMurrich; the chemical aspect of fertilisation, by Prof. Jacques Loeb; cytology and taxonomy, by Prof. C. E. McClung; facts limiting the theory of heredity, by Mr. William Bateson; fœtal membranes, by Prof. A. A. W. Hubrecht; operative factors in development, by Prof. W. Roux; economic entomology, by Dr. L. O. Howard; the relations between North American and European Hemiptera, by Dr. Geza Horvath; the problem of organic development, by Prof. C. O. Whitman; migrations of Tertiary faunas, by Prof. C. Depéret; the scope and promise of systematic zoology, by Dr. T. Gill; the evolution of continents as illustrated by the geographical distribution of animals, by Dr. R. F. Scharff.

One of the most striking of the sectional addresses delivered at the congress was that on the chemical character of fertilisation, by Prof. Jacques Loeb, of Chicago, delivered before an audience of about three hundred. He began by distinguishing between the function of the spermatozoon as a bearer of hereditary qualities and its function as an instigator of development. In connection with the latter the foremost effect is the enormous synthesis of nuclear matter. To attain to some understanding of the hydrolytic and other processes which the spermatozoon sets up in the egg, the most promising path at present is to study the phenomena of artificial parthenogenesis. By adding to "hypertonic" sea-water a small quantity of a monobasic fatty acid, Prof. Loeb has been able to induce in sea-urchin ova the formation of an egg membrane and perfectly normal development in the great majority of the eggs of a given female. The effects of the spermatozoon were thus more perfectly imitated than by the previous purely osmotic methods. Prof. Loeb's results lead him to the general conclusion that the membrane-formation is connected with the solution of a layer of fatty material underneath the surface-film of the egg. It seems that the essential feature of the process of fertilisation consists first in a liquefaction or hydrolysis, or both, of fatty compounds in the egg, and second, in starting the processes of oxidation in the right direction. The lecturer ended his discussion by making a very suggestive comparison between the chemical processes in the germination of oily seeds and those in the early development of the animal ovum. The general idea to which the experiments on the artificial parthenogenesis (of sea-urchins, Lottia, Polynöe, and Sipunculus) point is that the spermatozoon acts as a catalyser.

Sir John Murray gave a general afternoon address on the progress of oceanography, and another was given by that genial iconoclast, Prof. W. K. Brooks, who calmly asked, "Are Heredity and Variation facts?" If philosophy is a criticism of categories, the latter address was certainly philosophical, for its aim was to show that specialisation—none the less dangerous because often unconscious—necessarily leads to partial abstractions. Such, according to Prof. Brooks, are heredity and variation. The former means likeness between offspring and their parents; the latter means divergence of the offspring from the likeness of their parents. But these two aspects in isolation are not facts; they express our artificially abstracted realisation of *one* fact—kinship and individuality are inseparable. It might be suggested that heredity is more correctly definable as the relation of genetic continuity between successive generations—a relation which presents, on the one hand, the aspect of continuity, persistence, or hereditary resemblance, and, on the other, the aspect of divergence, novelty, or variation; but the lecturer would not accept this suggestion.

Much of the lecture, which was enlivened by a fine humour and by epigrams condensing much reflection, was in great part an apologia for the individuality of the living creature. "Like never does produce like, but only something like." "The sheep which the morphologist finds to be all alike, are all unlike, as the shepherd's dog knows. Each ewe knows its own lamb." (Is even this a fact?) "One never meets the average man, the normal man of the statistician." "Statistics of mortality are very useful, but they have no bearing on your death or mine." "We speak of *the* struggle for existence, but every struggle is private and particular in every respect."

If we follow Prof. Brooks's line of argument, we are led to the conclusion that since we cannot think of a living organism without an environment in which it lives, then the living organism is not a fact—it is only a scientific abstraction of one side of a fact; and so far as we understand, the Berkeleyan biologist did not hesitate to take this step. "The being is not in itself, but in its reciprocal relations." It is therefore illusory to speak of a material substratum of inheritance; the real creature is not in the idioplasm, or the chromosomes, or the determinants, or the vital units; it is to be sought and found in the reciprocal interaction between the organism and its environment. A luminous section of the lecture was devoted to showing that supposing one knew the pre-Cambrian Rhizopod from which all animals are descended, and knew it thoroughly, yet one would not be able to foresee from such knowledge all that was to follow. The history was not really in the pre-Cambrian ancestor, for living creatures, as they have evolved, have, so to speak, worked time into their being, and evolution is continual creation.

The last days of the formal meetings of the congress were overcrowded with remarkable communications, too numerous even to mention in a brief notice, but we cannot refrain from remarking on the addresses given by Mr. Bateson, on facts limiting our theories of inheritance; by Prof. C. O. Whitman, on orthogenesis in pigeons and on the relations of ontogeny and phylogeny; by Dr. L. O. Howard, on the recent progress of economic zoology; and by Prof. H. F. Osborn, on evolution from a palæontologist's point of view—all of them very remarkable and memorable expositions.

At the formal close of the congress it was announced that the 1910 meeting would be held at Graz under the presidency of Prof. von Graff. A welcome announcement was made that the committee on nomenclature had at last arrived unanimously at a code of rules which would cover 90 per cent. of all possible difficulties. Dr. Stiles further said that the committee would continue to sit in judgment on the remaining 10 per cent. of intricate difficulties, and that they had resolved to prepare a check-list of some thousands of common animals the names of which were not henceforth to be changed on any pretext whatsoever. As Prof. Agassiz remarked, the only difficulty remaining was the cheque. Prof. Blanchard announced that a third prize had been offered by Russia for adjudication by the congress and by representatives of the Zoological Society of St. Petersburg. It was offered to perpetuate the memory of the great Russian zoologist, Alexander Kowalewsky. In a very neat speech Prof. Hubrecht, of Amsterdam, thanked the local committee, the organisers, and the president for their indefatigable labours in making the congress a conspicuous success, and Prof. Blanchard, of Paris, eloquently expressed the gratitude of the ladies for the hospitality which had been shown them by the ladies of Boston.

NOTES.

THE weather conditions for the three summer months, June to August, have proved very disappointing, and the principal characteristic has been the entire absence of warm days. At Greenwich there have only been forty days during the whole period with a temperature of 70° and above. This is precisely the same number as in the phenomenally wet summer of 1903, but it is very greatly below the average. In 1860 there were only twenty-three days with a temperature of 70° or above, and in 1879 twenty-six such warm days, so that the past summer is not unique. There has not been, however, a single day this summer with a temperature of 80°, whilst in 1903 the thermometer touched that reading on six days. The aggregate rainfall at Greenwich for the three months was 5·29 inches, which is 1·37 inches less than the average of the past sixty years. In 1903 the aggregate for the corresponding three months was 16·17 inches, which is the wettest summer on record. At the London observing station of the Meteorological Office the aggregate rainfall for the three months was 4·76 inches, which is 2·13 inches below the normal, and the only month with an excess so far this year is April. June was generally wet over nearly the whole country, July was mostly dry, whilst in August the rainfall varied considerably in different parts of the kingdom. At Jersey the total measurement in August was 0·60 inch, whilst the average is 2·48 inches; at Valencia the measurement was 5·67 inches. The sunshine has not varied much from the average. In London there was a slight deficiency in each month, but in the aggregate for the three months it only amounts to thirty-eight hours. September has commenced with exceptionally cold weather, and the thermometer for the first four days has averaged about 30° lower than at the corresponding time last year.

A REUTER telegram from Rome states that it is expected that ratifications will be received by the end of the present year from all the Powers of the convention of June 7, 1905, for the establishment of the proposed International Agricultural Institute. If the expectations are realised the committee of the institute will be able to meet early in 1908, enabling the institute itself to assemble in the autumn of that year, and to be in working order in 1909. In connection with the new institute, the Italian Government is taking steps for the scientific organisation of a system of agricultural statistics which existed until about ten years ago, when it was abolished by Count Guicciardini, Minister of Agriculture, on the ground that it did not afford sufficient guarantees of correctness. By way of experiment, agricultural statistics will be collected this year in fifteen provinces of Italy, with the view of extending the new system to the whole of the country, with any reforms that may be suggested by the experiment. At the same time a count will be taken of the livestock in the country, which has not been done for a considerable time. In this way Italy will in 1909 appear before the International Institute with complete agricultural returns.

THE installation of the first electric irrigation system in southern British Columbia has just taken place. It is considered that by this means the problem of the irrigation of several thousand acres of fruit lands will in a great measure be solved.

AN organisation to be known as the Universal Society of the White Cross of Geneva has been formed at Geneva. It has for its object the coordination of the work being carried on throughout the world in combating tuberculosis, cancer, epidemic and infectious diseases, and social evils such as alcoholism, &c.

ACCORDING to the *Engineer*, an Inter-Ministerial Technical Commission has been appointed by the French Minister of Public Works to organise the whole system of wireless telegraphy in all its branches in the country, and it is expected that the commission will be able to arrive at results which will furnish France with a very complete and properly coordinated service of wireless telegraphy for land and sea service, both in peace and war.

IN 1859 Mr. U. A. Boyden, of Boston, deposited with the Franklin Institute the sum of 1000 dollars, to be awarded as a premium to any resident of North America who should show by experiment that light and other rays travel with the same velocity. According to the August number of the Journal of the Franklin Institute, the premium has just been awarded to Dr. P. R. Heyl, who has taken photographs in the blue and ultra-violet of the variable star Algol in the neighbourhood of its minima, and has shown that the time of minimum intensity of the blue photographs is so nearly identical with that of the ultra-violet that the speeds of the two radiations across the space between Algol and the earth cannot differ so much as one part in a quarter of a million.

THE following arrangements have been made for the opening of the winter session of certain of the London medical schools:—at the Guy's Hospital Physical Society, on October 4, Dr. G. A. Gibson will read a paper entitled "Past and Present"; at King's College, on October 1, Dr. W. H. Allchin will give "Some Observations on the Present State of Medical Education in London"; at the Middlesex Hospital Mr. A. G. R. Foulerton will, on the same date, speak on "The Development of Preventive

Medicine in Relation to the Welfare of the State"; at University College Hospital, on October 2, the inaugural address will be given by Sir R. Douglas Powell; and at the Seamen's Hospital Society, on October 21, Sir Lauder Brunton will give the inaugural address. The session of the Pharmaceutical Society will be opened on September 30, when Prof. R. Meldola will speak on "The Scientific Training of the Pharmacist."

PRELIMINARY particulars of the ninth International Geographical Congress, to be held at Geneva from July 27 to August 6, 1908, are given in the September number of the *Geographical Journal*. Ten scientific excursions, some of which will take place before, others after, the congress, have been arranged for, each being conducted by an expert. Dr. J. Früh, of Zürich, will lead a party, of not more than twenty, for the study of the morphological phenomena of the Alps and their foothills. Another party, conducted by Dr. Lugeon, will study the phenomena of inverted folding in various parts of the Alps. An excursion will be devoted to high-level forestry, and will be led by M. Ernest Muret. The structure of the Jura, the plateau, and the Alps will be studied under the direction of Dr. H. Schardt. A botanical excursion will be made under the direction of Dr. C. Schroeter, the well-known authority on the flora of the Alps. A study of vegetation contrasts and the technique of botanical distribution will be undertaken under the guidance of Dr. J. Briquet, and one of glacial morphology under the guidance of Prof. Brückner. Prof. J. Brunhes and others will direct attention to the contrasts between fluvial and glacial erosion, while Prof. Schardt will explain the structure of the southern portion of the crystalline Alps. Lastly, a party under the guidance of Prof. E. Chaix will study the phenomena of chemical erosion, especially as displayed in the surface forms known as *lapiés*, or *Karrenfelder*, and in the Karst. The place of meeting is particularly favourable for the arrangement of instructive excursions, and these may be expected to be one of the most prominent features of the congress.

THE *Philippine Journal of Science* for June (ii., No. 3) is entirely occupied with a paper by Dr. Richard Strong on studies in plague immunity. The author concludes that general vaccination in endemic centres would be a valuable means in accomplishing the extermination of this pestilence, an important pronouncement at the present juncture, when plague is rampant in India.

PREVENTIVE inoculations against hydrophobia were received at the Pasteur Institute of Paris in 1906 by 773 persons, only two of whom died from the disease, and as one of these may be excluded for statistical purposes, seeing that hydrophobia manifested itself in less than a fortnight after the conclusion of the treatment, the results show the low mortality of 0·13 per cent. Only one of the patients came from England. The person who died in less than fifteen days after treatment had received a severe penetrating wound on the face; the other fatal case had been severely bitten on the nose on August 3, was treated at the institute from August 5 to 26, and died from hydrophobia on October 12.

THE second report of the Natal Government Museum—covering the year 1905—has just been published by Messrs. Adlard and Son, and tells of progress in all departments. In the period under review the following additions to the specimens in the museum were made:—in ethnology, 145; mammals, 98; birds, 81; anatomy, 82; reptiles and fishes, 19; invertebrates, 425; palæontology, 4; geology and minerals, 1445. A native blacksmith's complete outfit, including a good specimen of skin-bellows, has been acquired by the ethnology department of the museum through the misbehaviour of its former owner, the police authorities of the colony having acted on the request made to them to forward to the museum all native articles which have been confiscated for wrongdoing.

IN a letter to the *Times* of August 28, Mr. James Brand states that intravenous injections of a mixture of aqueous solutions of methylene blue and corrosive sublimate cure trypanosome infections in horses, and suggests that this may be found to be a remedy for sleeping sickness, a Trypanosoma infection, in man. Prof. Moore and his co-workers have found that corrosive sublimate enhances the curative value of atoxyl, another anilin dye, in experimental infections with the human trypanosome, but it does not follow that methylene blue would be of service in sleeping sickness, since Nicolle and Wenyon have found that an anilin dye which is curative for an infection with one trypanosome is not necessarily curative for other trypanosome infections.

THE fifth annual report of the Imperial Cancer Research Fund, which has been recently issued, contains the reports of the executive committee, of the general superintendent, Dr. Bashford, and of the honorary treasurer. The fund now possesses a capital sum of 118,275*l*. for the purposes of the work, including the munificent gift of 40,000*l*. by Mr. and Mrs. Bischoffsheim on the occasion of their golden wedding. Dr. Bashford gives a *résumé* of the experimental and other researches carried out during the past year. Attention has been given to testing various alleged cancer cures; unfortunately, it is impossible to assign a curative value to any of them. The much-vaunted trypsin is incapable of curing inoculated cancer in mice, or even of influencing the progressive growth of the tumours. The only means capable of freeing the inoculated mice from cancer is the surgical removal of the tumours.

IN an illustrated pamphlet published at La Plata ("La Reforma" Press, 1907), under the title of "El Origen del Hombre," Dr. Florentino Ameghino reiterates his opinion that South America was the birthplace of the human race. Man is traced back to the supposed Cretaceous family Microbiotheriidæ—in other words, to Miocene opossums!

AMONG numerous articles in part i. of the fiftieth volume of Smithsonian Miscellaneous Collections, attention may be directed to a description, by Dr. Leo Walter, of Prague, of the structures by means of which the fore and hind wings of hymenopterous insects are linked together. After pointing out that homologous structures exist in the wings of certain other insects, such as many Lepidoptera, Cicadidæ, and Thricoptera, the author observes that in none of these is the development so full and so complicated as in the Hymenoptera. Strange to say, these structures in the latter group appear never to have been worked out in full detail—an omission which Dr. Walter has endeavoured to supply. Facts of considerable interest have been discovered during the investigation, and it has been found that these organs possess much importance from a systematic point of view. Their object is, of course, to enable the two wings to act during flight as a single unit, and, as might have been expected, it turns out that the strongest flyers among the Hymenoptera are those in which the connection between the wings attains its fullest development. The halting and uncertain flight not infrequently noticeable in individual humble-bees is attributed by the author to damaged wing-connections.

THE rapidly advancing study of spirochætes is at once of practical and scientific interest, of practical interest because these parasites occur in those "gustatory flashes of summer lightning," as Huxley said, which mortals call oysters, and because *Spirochaeta pallida* is believed to be the active cause of syphilis; of scientific interest, because it remains uncertain whether these protists are protozoa or bacteria. In a recent paper (Ann. Nat. Hist., xix., 1907, pp. 493–501), Mr. H. B. Fantham points out that the diffuse nuclei and transverse fission of spirochætes suggest bacteria, while, on the other hand, the presence of an undulating membrane, longitudinal fission, and even definite "chromosomes" suggest protozoa. It is to the latter interpretation that he inclines. Mr. Fantham has made a careful study of living spirochætes—*Spirochaeta balbiani* (Certes) from the oyster, and *S. anodontae* (Keysselitz) from the fresh-water mussel—and gives an interesting account of their puzzling movements. Their motion is resolvable into at least two components:—(1) a vibratory motion of flexion of the body, mainly for progression, and (2) a spiral or corkscrew movement of the body as a whole, due to the spirally wound membrane, which is composed of longitudinally arranged "myoneme" fibrillæ. The myonemes set up transverse movements on the surface of the body, manifested as waves passing down the body in a direction opposite to that in which the organism moves. The spirochætes seem to move more quickly than even trypanosomes, and with an added corkscrew motion. While flagella are present in the case of true Spirilla, they do not occur in spirochætes. What have been described as flagella or cilia by some investigators are really "myoneme" fibrils split off from the membrane during its rupture.

A DOUBLE number of *Le Bambou*, the first issue of this year, comprising Nos. 7 and 8, has been received. It contains a descriptive article on the aërial vegetative structures of bamboos, also notes on their cultivation and resistance to frost.

THE third number of vol. iii. of the Records of the Botanical Survey of India is appropriated to the determinations, by Dr. L. Radlkofer, of new species belonging to the order Sapindaceæ, based on material from India and Malaya.

THE results obtained by de Vries have led botanists to examine closely the so-called variable species, as from such species special modifications or new characters may most reasonably be expected. In the *New Phytologist* (February) Dr. L. Cockayne refers to a New Zealand plant of this type, *Leptospermum scoparium*, with regard to colour modification. Ordinarily the flowers are white, but a pink-flowered form was introduced to cultivation as *Leptospermum Chapmanni*, and recently another plant, bearing rich crimson flowers, has been discovered growing wild. Seedling plants of the latter have been raised, so that from the next generation some idea as to the origin of the plant, whether a mutant or hybrid, may be obtained. In *Science* (April 12) Dr. G. H. Shull notes that he can distinguish four elementary species in the numerous specimens of *Capsella bursa-pastoris* he has cultivated, all of which breed true, and that without geographical or complete physiological isolation they maintain themselves distinct.

AN account in the *Kew Bulletin* (No. 7) of the proceedings in connection with the Linnean bicentenary celebrations at Upsala, Lund, and Stockholm accords with other descriptions in testifying to the enthusiastic and impressive nature of the ceremonies. Correspondence connected with the award of the special Linnean gold medal to Sir Joseph Hooker is also published. An article on new or little-known algæ from eastern Asia is contributed by Mr. A. D. Cotton, in which a new alga from Ceylon, *Euptilota Fergusonii*, is described and figured. Dr. Otto Stapf communicates notes on two rubber plants, *Mascarenhasia elastica*, belonging to the order Apocynaceæ, that grows in British and German East Africa, and *Euphorbia fulva*, a tree known in Mexico as "Palo Amarillo." From the former balls of fair-quality rubber, known as "Mgoa," are prepared; the latex obtained from the latter contains a large percentage of resin, but a process of separation is said to have been devised. Mr. J. M. Hillier has collated information on Guayule rubber, the product of *Parthenium argentatum*, a shrubby composite of Mexico.

ACCORDING to the second part of the *Bergens Museum Aarbog* for the current year, Norway experienced an unusually small number of earthquake shocks in 1906, namely, thirteen, against twenty-three in 1905 and thirty-three in 1904. Mr. C. F. Kolderup, the author of the paper referred to, is of opinion that the comparative frequency of earthquakes in Norway is due to subsidence in the bed of the adjacent sea. In another article in the same issue Mr. J. Rekstad discusses ancient terraces and beach-lines in western Norway, illustrating his account with a number of reproductions from photographs.

IN the *Physikalische Zeitschrift* for August 15, Prof. F. Paschen gives the results of some careful measurements made by his pupil, Miss Stettenheimer, of the Zeeman effect in known magnetic fields for the lines Zn 4680 and Cd 4678 which behave normally. From the results he calculates by the theory of Lorentz the quotient of the electric charge on the ion by its mass, and obtains $1{\cdot}79\times10^7$. This agrees very well with the value $1{\cdot}77\times10^7$ given by Messrs. P. Weiss and A. Cotton in the June number of the *Journal de Physique* as the result of their measurements. The values which have been obtained by different experimenters for the above quotient in the case of the kathode rays differ so much from each other that it is difficult to fix on a representative one for comparison with the above numbers. Prof. Paschen takes the value $1{\cdot}88\times10^7$ given by Profs. Kaufmann and Simon, and is disposed to think that the difference between the values of the quotient in the two cases is due to some difference in the ions.

THE uncertainty as to the melting point of platinum, to which we referred a few weeks ago, is leading to corresponding uncertainties in all high-temperature determinations. Profs. C. E. Mendenhall and L. R. Ingersoll, in their paper on the melting points of rhodium and iridium in the July number of the *Physical Review*, are compelled to give two sets of values, one based on 1745° C., the other on 1789° C., as the melting point of platinum. They use the Nernst glower as a meldometer, place a very small particle of the metal on it, and observe through a microscope for what current through the glower the particle melts. The temperature of the glower is determined by measurement of the isochromatic radiation, assumed to follow a law similar to Wien's, with constants determined from the melting points 1065° C. and 1745° C. or 1789° C. of gold and platinum. With 1789° C. as basis, they give the following melting points:—silicon, 1452° C.; palladium, 1576° C.; rhodium, 1968° C.; indium, 2388° C.; the temperature of the glower at normal brilliancy 2480° C., the melting point of the glower material 2490° C.

THE atomic weight of radium was determined five years ago by Mme. Curie on about 0·09 gram of a highly purified radium chloride. Large quantities of Joachimsthal pitchblende residues have since then been worked up, and from these 0·4 gram of pure radium chloride has been obtained. The method of purification adopted was re-crystallisation from weak hydrochloric acid and fractional precipitation of the aqueous solution by alcohol, the progress of the purification from barium being followed by means of the spectroscope. It seemed desirable to repeat the determination of the atomic weight on the larger quantity now available, and Mme. Curie gives an account of the method adopted in the current number of the *Comptes rendus* (No. 8, August 19). Difficulties were encountered owing to the presence of traces of impurities in the reagents, leading to a gradual loss of radium during the purification, and a detailed account is given of the elaborate precautions found to be necessary for the preparation and preservation of the reagents used. The atomic weight deduced from the ratio radium chloride : silver chloride is 226·2 (Ag = 107·8, Cl = 35·4), or 1·2 units higher than the value found on 0·09 gram in 1902. It is shown that the slight increase of purity of the 1907 over the 1902 preparation is not sufficient to account for the rise of 1·2 units in the atomic weight, the difference being most probably due to the loss of accuracy on the determinations with the smaller quantity and the use of reagents not properly purified.

THE August number of the Journal of the Institution of Electrical Engineers (No. 185, vol. xxxix.) contains, amongst others, a paper on the technical training of electrical artisans, read by Mr. C. P. C. Cummings before the Dublin local section of the institution. The subject is one which is very rarely treated in papers read before the Institution of Electrical Engineers or the branch sections, but, at the same time, it is one which is very important to the future development of electrical work. The term electrical artisan, as referred to by Mr. Cummings in his paper, deals almost entirely with those electrical artisans who are generally classified as "wiremen," and the paper treats of the possibilities of improving the existing methods by which such men are trained at the present day, so that more efficient workmen may be obtainable. Mr. Cummings very rightly points out that there is a very large majority of the "so-called wiremen" obtaining the maximum rate of wages per hour which the highly trained and competent workman is fully entitled to, who cannot be placed in the same class with him, and can obtain this rate without any trouble. This in itself is evidence of the serious defect in the method by which electrical artisans are produced. So long as these methods continue, they will produce a considerable number of men who cannot be considered fully competent, but very few first-class artisans, and from this very fact the really competent men consider themselves so strong by virtue of their minority that their demands upon employers and their general independence greatly reduce their utility. Mr. Cummings describes the present method of training electrical artisans, and points out the faults of the system and propounds a scheme which is well worth the consideration of educational authorities and employers—especially the latter—for until the employers take a practical interest in this matter they cannot hope to obtain the man most suited to their requirements.

MESSRS. JOHN J. GRIFFIN AND SONS, LTD., of Kingsway, have just issued a new edition of "Chemical Handicraft," giving particulars (in many cases illustrated) of the chemical apparatus and reagents manufactured and sold by them. Science teachers will find the volume very handy for reference.

THE lectures delivered under the Silliman foundation at Yale University in March, 1905, by Prof. E. Rutherford, F.R.S., which were afterwards issued in book form under the title of "Radio-active Transformations," have now been translated into German by Dr. Max Levin, of Göttingen, and published by F. Vieweg and Son, Brunswick. Brief reference is made in the volume, in the form of footnotes, to the more important advances in the subject which have taken place since the first appearance of the work in English.

OUR ASTRONOMICAL COLUMN.

DANIEL'S COMET, 1907*d*.—The following is a continuation of the ephemeris for comet 1907*d* given in No. 4196 of the *Astronomische Nachrichten* (p. 337, August 23):—

Ephemeris 12h. (M.T. Berlin).

1907	α (true) h. m.	δ (true) ° ′	log *r*	log Δ	Brightness.
Sept. 9	9 41·5	+11 5·7	9·7250	0·1139	13·7
,, 11	9 53·3	+10 26·0			
,, 13	10 4·7	+ 9 45·9	9·7495	0·1408	10·8
,, 15	10 15·7	+ 9 5·5			
,, 17	10 26·3	+ 8 25·1	9·7818	0·1654	8·3
,, 19	10 36·5	+ 7 44·9			

It will be noticed that the brightness of this object is declining rapidly, and, as the comet rises nearer and nearer to sunrise, it is becoming increasingly difficult to observe. At present it rises about two hours before the sun, and on September 19 it will precede the sun by about 1½ hours, rising about 12° north of east.

Comptes rendus, No. 8 (August 19), contains the results of observations made by M. E. Esclangon at Bordeaux. The head of the comet was extraordinarily bright and of about 5′ diameter on August 1. Seven tails were seen, the extreme streamers being much shorter than the median. A reproduction of the observer's drawing shows the disposition of the tails.

SOLAR OBSERVATIONS AT CARTUJA, GRANADA.—In an extract from No. 3 (1907) of the *Bulletin de la Société belge d'Astronomie*, M. J. Mier y Terán, S.J., publishes an account of the solar observations and reductions now carried on at the Observatory of Cartuja-Granada (Spain).

Solar observations were commenced at the beginning of 1905 for obtaining statistics relating to sun-spots and faculæ. In January, 1906, photography was substituted for eye observations for the purpose of obtaining more precise measures, and photographs have since been secured on each clear day. A more suitable photoheliograph has recently been erected having an objective of 94 mm. (3·7 inches) aperture and 1·50 m. focal length, and fitted with a direct enlarger giving a solar image of about 10 cm. (4 inches) diameter. The areas and positions of the spots, &c., are measured with a Hilger micrometer, the positions afterwards being reduced to heliocentric coordinates in the usual manner, and it is hoped that the results will be found sufficiently precise to supplement the Greenwich measures. As it is proposed to publish these results in the tri-monthly numbers of the observatory bulletin, it may be expected that solar workers will find them available without having to wait for the Greenwich annual publications. Spectroscopic observations of the sun and the stars are also being carried on at Cartuja, and it is hoped that ere long the apparatus for spectrophotography with a large dispersion will be installed.

DISCOVERY OF SEVENTY-ONE NEW VARIABLE STARS.—The wholesale discovery of new variable stars from photographic plates is proceeding at Harvard, and in Harvard College Observatory Circular, No. 130, Prof. Pickering announces the discovery of a further batch of seventy-one new variables. These were found by Miss Leavitt on the Harvard maps Nos. 9, 12, 21, 48, and 51. Prof. Pickering gives a table showing the proportion of newly discovered variables to the total number now known to exist in each region examined, and arrives at the general deduction that about one-third of all the variables in the three northern regions examined, and about one-half of those in the two southern regions, yet remain to be found. The designations, positions, and magnitude ranges of the newly discovered variables are given, and the list includes thirteen probable Algol and seven long-period variables, the proportion of the former being remarkable, as in the case of Region 50 discussed in Circular No. 122.

THE ELECTRICAL ACTION OF THE SUN.—In these columns for March 14 we referred to a discussion, by Dr. Albert Nodon, of the nature and effects of the sun's electrical charge. The whole discussion is now published as an extract from the *Revue des Questions scientifiques* for April and July, and will be found to be of great interest by all workers on solar physics and the allied terrestrial phenomena. In the first part of the paper Dr. Nodon discusses the observations, the apparatus used in making them, and the theories deduced from them. The second part contains a discussion of the application of the results to the explanation of cometary, planetary, and terrestrial phenomena, whilst in the third part of the paper the author discusses the deductions relative to terrestrial physics. The paper is published by J. Polleunis, 45 rue Sans Souci, Brussels.

MICROMETER MEASURES OF DOUBLE STARS.—In No. 4193 of the *Astronomische Nachrichten* (p. 277, July 26) Dr. H. E. Lau publishes a further list of Struve double stars measured by himself, and discusses the mean probable errors of his measurements. In addition to the eighty measures made by Dr. Lau, the list also contains twenty-eight measures made by Herr Luplau-Jannsen.

THE MAY OR GORSEDD YEAR IN ENGLISH AND WELSH FAIRS.

SIR NORMAN LOCKYER has taught us to call the year indicated by alignments of stone monuments in Britain the May year. The quarter days of that year are astronomical, being the half-way stations of the sun between the solstices and equinoxes. In fixing these dates, of course, the solar quarter days were marked as well, which year is conveniently called the solstitial year. It will clear the way for the discussion of some figures bearing on the subject if the two series of quarter days are presented here side by side, as given in "Stonehenge Astronomically Considered," p. 23:—

MAY YEAR ...	Feb. 4	May 6	Aug. 8	Nov. 8
SOLSTITIAL YEAR ...	March 21	June 21	Sept. 23	Dec. 23

The quarter in both series is of the same length, ninety-one days, and the distance from a solstitial quarter day to a May-year one is roughly forty-five days.

Though the name May year is a very happy one, as the May festival was certainly the most popular, it is really the Gorsedd year, the very *raison d'être* for that institution which, in form, purpose, and ritual, is the temple-observatory brought up to date. We know now for what purpose the megalithic monuments were raised, and that knowledge has been acquired by working from the known to the unknown. By assuming that the Welsh Gorsedd is a much truer representation of ancient Druidism than the manifestly inaccurate, second-hand observations of Cæsar and other classical writers, we are able to see at the Welsh National Eisteddfod in this twentieth century the actual use to which the temple-observatory was put. If such a broad assertion causes surprise, that surprise is considerably lessened by what seems to me to be an incontrovertible fact, that, instead of having one Gorsedd, and that in Wales, a true survival from late Neolithic times (to fix an indubitable downward limit), we have in Britain more than one thousand Gorsedds the pedigrees of which are as unimpeachable as that of the Welsh institution. I refer to fairs still held on the quarter days of the May year. To a student of the Welsh Gorsedd this fact at once dispels any *a priori* doubt as to the antiquity of that institution. It is only one among a thousand, though, I would maintain, it is the only one that shows what all the others were at first.

The Gorsedd and the popular fair are one and the same, constituting a true monument as ancient as a temple-observatory in stone. A better way of putting it is, the temple-observatory has survived in (1) stone, in (2) tradition, and in (3) festival. The Welsh Gorsedd presents this triple evidence.

There is, I think, no need for a formal proof of the prevalence of the May year in Ireland, Scotland, and Wales, or the "Celtic fringes." It reigns supreme over still purely Celtic ground. It is when one comes to England proper that even one accustomed to mark time in May-year terms must confess to a feeling of surprise. The evidence from the Celtic fringes is, of course, indispensable to understand and explain the English May-year fairs, but a brief presentation of the English case may be helpful by way of enlisting the cooperation of English archæologists to make that case as strong as possible.

I take Owen's "New Book of Fairs" for 1824 as source. The book was published by Royal licence, but as regards Wales it is incomplete, and I would infer as much as regards England. The following figures, except those given by counties, include the Welsh fairs as given in the list. That inclusion cannot affect seriously the English case, as will be seen.

The relative popularity of the May and of the solstitial years may first be ascertained by comparing the number of all fairs in May with those in June. May fairs, 510; June fairs, 250; 2 to 1 for May.

There are two lists of fairs in Owen's book, one by counties and the other by dates. I take the latter first. The figures in every case are my own. As the book is incomplete, and all lists of fairs I have consulted are so, I have thought it sufficient for the present purpose to make only one rapid reckoning of the fairs. The chief fair days can be easily noted by large groups of fairs. The fairs corresponding to the May-year festivals are to be looked for under several dates. The astronomical day is in many cases observed eleven and twelve days later. Generally, that day has given way to the first of the calendar month. In both cases new and old style dates must be noted. Then there are fairs depending on such dates. All fairs held during the first twelve days of the month should be numbered. In the case of November, the inclusion of Martinmas fairs needs no comment, as November 11 is a Scottish quarter day, and the Scottish quarter days, with the fact that in Gaelic-speaking Scotland the months, as well as the seasons, are still reckoned in the true May-year order, is sufficient formal proof of the predominance of that year on Celtic ground.

February	Fairs	May	Fairs	August	Fairs	November	Fairs
2 ...	8	1 ...	32	1 ...	18	1 ...	10
5 ...	7	4 ...	42	2 ...	29	6 ...	13
13 ...	20	6 ...	38	5 ...	53	8 ...	43
14 ...	12	8 ...	14	10 ...	16	11 ...	17

—		18 ...	12	—		D. ...	57
—		D. ...	71	—		—	
	68		359		205		241

D. = Dependent fairs.

Thus we have 873 plain May-year fairs. I claim now the Church-year fairs, which are plainly the old May-year festivals. For February 4 I claim 28 fairs between Candlemas and the beginning of Lent; for May 6, 358 Whitsun and Ascension fairs; and for November 8, 53 fairs at Michaelmas, 71 on October 10 (Old Michaelmas), and 32 on December 11 (Old St. Andrew's Day). Though Michaelmas and St. Andrew's Day are both a month away from November 1, they constantly occur as half-year days corresponding to May Day. It is very likely, however, that some of the August fairs have been absorbed into Michaelmas. As that day occurs so near to the autumnal equinox, some concession must be made also to the solstitial year. There is no need, however, to decide these points at present.

We can now add 542 to our list of May-year fairs, altogether 1415 fairs which may reasonably be claimed as so many Gorsedds or prehistoric monuments, 96 in February, 717 in May, 205 in August, and 397 in November. It is curious to note that the number of plain May fairs and of Church-year May fairs is the same. The ratio for November seems to be too high, and the number for that month has grown evidently at the expense of August. Dividing the total for August and May, we get 301 for each of those months to match the figure for May, which is always at least twice as high as the corresponding figures. For obvious reasons February is a poor time for fairs, and the intrusion of Lent has very generally broken up that end of the May year. A more thorough scrutiny will be the means of recovering many February 4 fairs.

If the above estimate is considered too generous, my estimate of the solstitial-year fairs must err more in that pleasing direction, for I include, against strong reasons, all the Easter fairs in that estimate.

	Fairs		Fairs
March 21	2	June 22	29
April 5...	37	,, 24	35
		July 5	54
	39		118
Easter	231	Trinity	59
	270		177

	Fairs		Fairs
Sept. 19	31	December 21	7
,, 21	20	,, 25	8
Oct. 2	53		
	104		15

There are, then, 276 true solstitial fairs and 347 Church-year fairs to bring the total up to 623; but the figure for Easter shows evident borrowing from February, the vernal equinox, and May. A fair ratio would be obtained by counting sixty Easter fairs for the vernal equinox and the remainder for February.

In claiming the Easter fairs for the May year, I have a larger number of fairs to add to the solstitial estimate. Beside the May year, with the portions of the Church year which are evidently based on it, and the solstitial year as such, there are two other series of dates to consider. The one I would call the Roman year, being important dates in the old Roman year, which were early associated with the names of Christ, St. Mary, and at least six of the Apostles. I refer to groups of fairs on the 25th of the month. There are 25 fairs on March 25 and 43 on September 25, 68 fairs which I would add to the solstitial estimate.

The other series of dates I would call the Petrine year, with groups of fairs on the 29th of the month. When the old Celtic saints of Llandaff Cathedral, Teilo and Dyvrig, May-year saints, were superseded in Anglo-Norman times by SS. Peter and Paul, June 29 was fixed as the beginning of the year in that cathedral. The canons there still mark their time of residence as from that date. The Petrine year is fairly general, though it is altogether subsequent to the middle of the twelfth century A.D., at any rate in South Wales. There are 18 fairs on March 29, 35 on June 29, 45 on July 10 (O.S.), 53 on September 29, and 71 on October 10 (O.S.), in all 251 fairs which I would add to the solstitial estimate, which now stands at 948 fairs.

The May year is still 467 ahead, and the May-year figures are certainly much more satisfactory than the large figures I have juggled for the solstitial estimate. If the latter is fairly correct, I must now add it in a lump to that of the May year, and say that we have still in England and Wales 2363 fairs, relics of festivals held at the same spots or thereabouts when the dates were obtained by direct solar observations by means of aligned monuments. Several capable archæologists have expressed the opinion, anent the astronomical theory, that they admit the solstitial alignments, while doubting the very existence of the May year in connection with the monuments. Such admission is substantially complete. The solstices and equinoxes were of little direct practical use to the ancient farmer as dates to commence farming operations. The Welsh farmer of to-day is finely indifferent to the almanac statements that spring begins on March 21 and winter on December 23. He knows better. The solstitial quarter days were observed as points from which the infinitely more practically important May quarter days could be correctly marked.

So far I have made only a rough preliminary reconnaissance of the list of fairs. I now take up Owen's list of fairs by counties, not to learn more about the relative prevalence of the May and the solstitial year so much as to learn more concerning the May year itself. Except May 6 and November 8, I have counted all fairs in February, May, August, and November. From the Church year I have borrowed only some pre-Lenten fairs for February and the Whitsun fairs for May. The total is just the same, but the analysis is much more to the point. The Welsh fairs are included, though the list is very defective. The letters F.M.A.N., variously grouped, represent May-year quarters:—

It is curious to note that the total of fairs in February, May, August, and November, with pre-Lenten and Whitsun fairs, is 1425, just ten less than the total of true May-year fairs *plus* all the Church-year fairs which I would claim for that year. I can, therefore, add the Michaelmas and St. Andrew fairs to the last total obtained and make it 1571, or a round fifteen hundred May-year fairs, nearly two-thirds of the total number of solar, as distinguished from mere calendar, fairs.

Wales makes but a very poor show in Owen's list. Instead of five complete May-year series, I have noted ten in North Wales alone; but it serves the present purpose to keep Wales in the background.

It is satisfactory to find seventeen complete series. The case of Weldon, Northamptonshire, is eloquently put as follows :—" First Thursday in February, May, August, and November." There are, however, ten other combinations of May-year quarter days, each of which tells the same tale, and there are 277 places where the May-year seasons are observed by fairs, that is, where more than one May-year fair is held. The relative prevalence of the eleven combinations may be shown as follows :—

	Feb.	May	Aug.	Nov.
17	1	1	1	1
10	1	—	—	1
21	1	1	—	—
9	1	1	1	—
7	1	—	1	—
57	—	1	1	—
21	—	1	1	1
97	—	1	—	1
5	1	—	1	1
22	—	—	1	1
11	1	1	—	1
277	7	7	7	7

Each May-year quarter day enters into seven combinations, which reminds me of the story invented, I believe, to account for the popular name of the parish from which I write, *Yr Hên Blwyv*, the Old Parish. The story goes that a stone-cutter carved the figure 7777 on a gravestone intended to commemorate a man whose age was twenty-eight. By the way, multiplying the May-year sevens together would be a good way to remember the number of solar fairs we have made out, 2303 for 2363, leaving a margin of sixty for possible errors in such a large estimate.

No combination of figures affects the supremacy of May Day. February enters into combination with other quarters at 80 places, May at 230, August at 139, and November at 183. Generally, the ratio seems to be :— February = 1, May = 3, August = 2, November = 2.

But in the two most decisive factors there is not much to choose between May and November. These two factors are the prominence of the summer half of the May year and the fact that the astronomical dates are still observed at ninety-six places in remarkably even numbers—May, 55; November, 41. May 6 is associated with St. John the Evangelist. Such association may have helped to preserve the date; but no such Church sanction, favour, or support has been given to November 8. There are four places in England where both dates are still observed. In several instances where the astronomical dates have been preserved I note a startling parallelism between the dates and the prominence acquired by those places in tradition and archæology.

List of Places where Fairs are held on May 6 and November 8.

Bedfordshire ...	Nov. 8 ...	Biggleswade.
Berkshire	May 6 ..	Abingdon, Aldermaster.
	Nov. 8 ...	Newbury.
Buckinghamshire	May 6 ...	Buckingham, Ivinghoe, Risborough.

Middlesex ...	May 6 ...	Brentford.
Norfolk	May 6 ...	Rudham.
	Nov. 8 ...	Diss, Massingham.
Northumberland	Nov. 8 ...	Hexham.
Nottinghamshire	Nov. 8 ...	Bingham.
Oxfordshire ...	May 6 ...	Chipping Norton.
	Nov. 8 ...	,, ,,
Rutland	Nov. 8 ...	Oakham.
Shropshire ...	May 6 ...	Wem.
Somersetshire ...	May 6 ...	Pensford, Stoke-Gomer.
	Nov. 8 ...	Dulverton, Pensford, Somerton.
Staffordshire ...	May 6 ...	Uttoxeter, Wednesbury, Longnor.
Suffolk	Nov. 8 ...	Newmarket.
Sussex	May 6 ...	Lewes, Bolney.
	Nov. 8 ...	Billinghurst, Forest Row.
Warwickshire ...	May 6 ...	Coleshill.
	Nov. 8 ...	Sutton, Warwick.
Westmorland ...	Nov. 8 ...	Kendal.
Wiltshire	May 6 ...	Amesbury, Colne, Maiden Bradley, Chippenham, Mere, Purten.
Yorkshire	May 6 ...	Hunmanby, Knaresborough, Pocklington, Askrig, Burton in Bishopdale.
	Nov. 8 ...	Leeds, Keighley.
Wales	May 6 ...	Langharne, Llannerchymedd, Nantglyn, Hay, Penrice, Knighton.
	Nov. 8 ...	Aberconway, Llanedi, Llanrhaiadr.

From other sources I find six more May 6 fairs in Wales and three November 8 fairs, in all twelve of the former and six of the latter. Only in one place, Llanfynydd, Carm., I find both days observed.

Pensford, where both dates are retained, is near Stanton Drew, where Sir Norman Lockyer has made out a May alignment. At Lydney, Gloucestershire, a Roman inscription has been found to the Celtic Neptune, *Nudd* or *Lludd*. At Hexham a similar inscription equates Apollo with the Celtic god Maponos. Dunmow's flitch of bacon should be carefully studied.

I think all will admit that the phrase "startling parallelism" is no exaggeration when the case of Wiltshire is considered. When Sir Norman Lockyer ascertained the age of Stonehenge from the alignment of the avenue, he found evidence there of an earlier May-year temple. Geoffrey of Monmouth fixes the earliest festival he mentions as having been held at Stonehenge on the Kalends of May. That must have been against his liking as an ecclesiastic, and the next festival, held shortly after the first, he fixes at Pentecost, the Church equivalent of the May festival; but Geoffrey never fixes a Church festival where and when such a festival was an historical impossibility. Therefore it is practically certain Stonehenge was a May temple pure and simple in the fifth century A.D.

Now Wiltshire heads the record with six fairs on May 6 and its equivalent May 17. So the astronomical, historical, and ferial evidences point clearly to the preeminence of Stonehenge as a May temple. No wonder the Welsh bards claim it as one of the three chief Gorsedds.

But what of the manifestly solstitial character of the present ruins at Stonehenge? In Wiltshire seventeen out of thirty May-year fairs are held in May, but the May year as such is nearly *non est*. May and August combine in one place, that is all. On the other hand, the solstitial year in the county is a fairly well-balanced year. There are five fairs held on the vernal equinox, five on the summer solstice, eleven on the autumnal equinox, and three on the winter solstice, the last figure being quite significant, as definite winter solstice fairs are very rare, though, of course, as Christmas, it has no rival.

Now, the local fairs connect the two series of facts in the most striking manner. "Amesbury, May 17, June 22." So does Owen solve the riddle of Stonehenge. Chippenham, May 17, June 22. Maiden Bradley, May 6, October 2 (O.S. for September 21). Mere, May 17, October 10 (O.S. for September 29, here very likely September 21 at first). Ignoring the date May 6, we have many other like combinations, February 14—October 2, May 14—September 25, July 10—August 1, May 14—October 10, May 12—October 2, May 20—September 23—December 23, May 7—October 8. At Laycock we have only the two solstices July 7—December 21.

Since the foregoing tables were compiled, I have discovered that the estimates for both the May and the solstitial years are much too low, even on the incomplete showing in Owen's list. The astronomical date is to be looked for not only eleven days later, as, for instance, May 17 at Amesbury for May 6, but also eleven days earlier. When immediately before 1752 A.D. the solstice was the eleventh, the date corresponding to our May 6 would be April 26. In 1824 there was a remarkable series of fairs eleven days before the May-year quarter-days proper. This came out while I was searching for some explanation of the strange fact that there is not a single fair on February 4. I find them under January 25. August 5 is the most popular survival of the old August quarter day, and the equivalent of that date is July 25, and that of November 8 is October 29. As the tables given above are sufficient to show the distribution and relative prevalence of May-year fairs, it may suffice to add only the places where the overlooked series of fairs is found.

January 25 (February 4).—Bentham, Bingley, Bodmin, Chesterfield, Churchingford, Derby, Kington (Warwickshire), Weasenham, Whittlesea in the Isle of Ely. (Nine fairs.)

April 23 (May 4).—Bewdley, Billesden, Bruton, Campden, Downton, Finchampstead, Great Bedwin, Hatfield, Hinton St. George, Holywell, Manhineot, Methwould, Norlease, Oakingham, Sawbridgeworth, Stanaway, Tenbury, Yetminster. (Eighteen fairs.)

April 25 (May 6). Ashover, Bracknell, Brigstock, Burnham (Essex), Crowborough, Dronfield, Great Oakley, Holt (Norfolk), Iron-Acton, Llandegla, Llannerchymedd, Llanrwst, Limpsham, Loughborough, Medhurst, Methwould, Parkgate, Stoke-under-Hampden, Toddington, Warkworth. (Twenty fairs.)

April 25 and 26 (May 6).—Kendal, Penrith. (Two fairs.)

April 26 (May 6). King's Norton, Ovingham, Settle. (Three fairs.)

April 27 (May 6).—Axminster, Boroughbridge, Cerrig y Druidion, Dorston (Heref. There is a cromlech there), Holdsworthy, Keynsham, Mortimer, Spalding, South Molton. (Nine fairs.)

April 28 (May 6). Boroughbridge, Cerne-Abbas, Keynsham, Malmesbury, Soham. (Five fairs.)

I claim April 23 because of the popularity of May 4. The two-days' fairs at Kendal and Penrith connect April 25 and 26 with May 5 and 6. I claim April 27 and 28 for a similar reason, namely, that both at Boroughbridge and Keynsham there are two-days' fairs held, which must have been old May festivals. We have the first and the last day of the three-days' festival in the fairs at Methwould on April 23 and 25.

There are only two fairs on August 8, Rhuthin and Shepton Mallet, and there are only two fairs on the equivalent date, July 29, Mountsorrel and Wivelsfield. Mountsorrel is an interesting name, as, I believe, some authorities hold that the wood-sorrel was the original shamrock, which we have reason to claim as a May-year emblematic plant. The great August fair day is the fifth, which we are sure was one day of the August festival because it is coupled with the sixth in two-days' fairs at Ewhurst, Goldsithnay, Louth, and Trowbridge.

July 25 (August 5).—Acle, Alresford, Ashton-under-Lyne, Barnard Castle, Billesdon, Blackboys, Castle-Acre, Little Clacton, Derby, Dunwich, Earith, Gissing, Great Wakering, Hockwold, Ipswich, Leigh (Kent), Lindsey, Liverpool, Middlewich, Milverton, North Down, Reading, Saltash, Seaford, Shoreham (Sussex), Southrepps, Staple, Tiptree Place, Totnes, Tregony, Trew, Wisbech (Isle of Ely), Wells, Yarmouth (Isle of Wight). (Thirty-four fairs.)

July 26 (August 8). Bewdley, Clare, Great Bedwin, Hastings, Horsemonden, Kirby, Lewes, Llanelian, Llansawel, Leighton Buzzard, Malpas, Mattingley, Newnham (Kent), Portsdown, Sherborne, Tamworth (Staff.), Twyford. (Seventeen fairs.)

July 28 (August 8).—St. Kenelm's, Leek, Manhineot, Week St. Mary, Winchcomb. (Five fairs.) (I claim this date on the strength of the correspondence of the Manhineot July fair with that on April 23.)

The fairs in October are very numerous. From the 20th to the 29th I recognise familiar May-year places, such as Cerrig y Druidion, Sawbridgeworth, and Wells on the 20th; Boroughbridge and Llansawel on the 23rd; Leighton Buzzard on the 24th; Bentham and Wells on the 25th.

October 26 (November 8).—Appletreewick (an excellent name), Grantham, Edwinstone, Llandegla, Llansannan, Ovingham, Pen y Bont (Radnor), Spalding, Warminster, Whittlesea in the Isle of Ely. (Ten fairs.)

October 27 (November 8).—Abergwili, Appletreewick, Caergwrle, Cleobury-Mortimer, Darley-Flash, Daventry, March in the Isle of Ely, Nantglyn. (Eight fairs.)

October 28 (November 8).—Alnwick, Askrig, Bangor, East Dean, Llanidloes, Lifton, Linfield, Milbourne-Port, Needham, Plympton, Radnor, South Harting, Thirsk, Totnes, Warminster, Whitchurch (Salop), Wigan. (Seventeen fairs.)

October 29 (November 8 strictly).—Abbey-Holm, Ambleside, Askrig, Bourn, Little Brickhill, Bridgenorth, Broadwater, Burton, Chaford, Charing, Chippenham, Clay, Ely, Ewell, Farringdon, Halstead, Hampton (Gloucestershire), Henley-in-Arden, Highworth, Hindon, Holt (Denbighshire), Horncastle, Hunmanby, Kidwelly, King's Cliff, Kirkby Stephen, Saint Lawrence (Cornwall), Marlow, Midhurst, Mongham, Newcastle-upon-Tyne (nine days), Pamphill, Pleasley, Radnor, Sedburgh, Tenby, Thirsk, Tidswell, Towcester, Tunbridge, Uphaven, Usk, Wellingborough Wigan. (Forty-four fairs.)

Without making any further attempt at estimating the number of May quarter-day fairs, we must count nine fairs on January 25 as February 4 festivals; add 57 to the 38 on May 6, in all 95 fairs which are strictly May 6 fairs; add 56 to the 53 on August 5, and regard them all as strictly August 8 fairs; and add 79 to the 43 on November 8, though there are more fairs in October claiming such recognition.

Our lowest possible estimate of true May-year fairs is now as follows:—

	Feb.	May	Aug.	Nov.	
	77 ...	416 ...	261 ...	321 ..	Total 1074
Astronomical	35 ...	96 ...	109 ..	122 ...	,, 362

The table of the quarter-day groups must likewise be corrected, only to strengthen materially the whole case for the May-year. (Only in a few cases have I been able to correct Owen's spelling of place-names.)

The Bardic Mystic Sign. (Reproduced from "Barddas." "Morien" quotes Payne Knight's "Symbolical Language of Art and Mythology," pp. 69, 70, where it is stated that the same sign, with a small circle or ring at the converging point of the three lines, is a very ancient emblem in Asia Minor. The angles in Knight's sketch, as reproduced by "Morien," are also exactly 28° each.)

George Meredith makes one of his Welsh characters "think in triads." Here is a new triad:—"The three interpreters of the riddle of the stones: the Sun, the Gorsedd, and the Popular Fair." I have already shown (NATURE, May 2) that the May year is the true basis of the Gorsedd. The bardic *Nôd Cyvrin*, Mystic Sign, which Mr. A. L. Lewis (NATURE, June 6) associates very naturally with the "broad arrow," is really a miniature Gorsedd. I have tested several printed cuts of the sign and find the angles to be 28°, that is, regarding the middle line as an east-west line, the right line points to N. 62° E. and the left to S. 62° E., the only possible emblematic representation, in the simplest form, of the May year in the Gorsedd country.

JOHN GRIFFITH.

KATHODE RAYS AND THE AURORA.[1]

THE idea that kathode rays play a part in aurora has been advanced by several physicists. Prof. Kr. Birkeland ("Expedition Norvegienne," 1899–1900, Christiania, 1901) has described a number of phenomena produced by kathode rays in the neighbourhood of a magnetised sphere, which resemble various types of aurora. He supposed the sun to be a primary source for kathode rays, which might set up secondary rays in the earth's atmosphere. Mr. C. Stormer has carried out elaborate calculations as to the possible ways in which electrified particles coming from a great distance can approach a magnetised "earth"; his

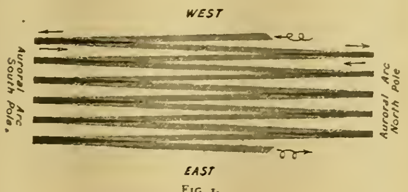

FIG. 1.

results tend to limit the approaching particles to the space near the magnetic poles. Prof. S. Arrhenius has supposed electrified particles to be driven from the sun by the repulsion of light and to reach the earth's atmosphere in about two days, originating aurora and magnetic storms.

M. Villard refers to Arrhenius's theory, but seems somewhat sceptical as to the supposed solar origin of the electrified particles. His own views appear to be a combination of theory and observation as to what happens to ions or electrified bodies of any kind moving in a magnetic field. In a uniform field the ion, when travelling with uniform velocity, describes a regular helix on a cylinder the axis of which is parallel to the lines of magnetic force. The radius of the cylinder varies directly as the component of the velocity perpendicular to the lines of magnetic force, and inversely as the intensity of the field. Suppose, however, that the magnetic field is not uniform, but increases in intensity in the direction in which the ion travels; then, as has been shown by Poincaré, the path forms a curve with diminishing spirals on a cone, and before actually reaching the summit of the cone the particle ceases to advance, and retires, the spirals gradually opening out. If, for instance, the field is that due to two elongated parallel poles, then if the particle gets under weigh between the poles, travelling obliquely to the lines of force, there is a regular game of battledore and shuttlecock, the particle zigzagging to and fro slantwise, reversing its direction whenever it gets within a certain distance of either pole.

M. Villard supposes ions to get in motion somewhere in the earth's atmosphere. As to exactly how this comes about he is not prepared to dogmatise. He is inclined to think that cirrus clouds—which he believes to consist of ice particles negatively electrified—under the influence of ultra-violet light, or less probably under a solar bombardment such as Arrhenius postulates, are probable sources. He also thinks that not improbably a part is played by cosmical dust encountered in the earth's movement through space. Ions starting, say, from a cirrus cloud, and moving obliquely to the lines of magnetic force in the earth's atmosphere, will travel each in a spiral, the whole together forming a sort of luminous spindle, which on getting within a certain distance of, say, the south magnetic pole, turns as if reflected, makes for the north pole, suffers a second reflection there, and so on. Fig. 1, copied from M. Villard's paper, represents the idea diagrammatically. The particles are supposed to come in at the top (answering to the west) and first to travel south. The movement may be supposed to be set up by ultra-violet light from the sun falling on cirrus. The first band or two will thus be in the still illuminated hemisphere, and so invisible; succeeding bands will be overhead in the unlighted hemisphere, and will be visible. Passing further to the east, the energy will be gradually dissipated and the aurora cease to be visible, thus explaining why the late evening, and not the morning, is normally the time of most brilliant aurora.

To fit the theory, the charge carried by the particles must be negative. If it were positive, the motion would be from the east, and the principal aurora would be in the early morning. Fig. 2 reproduces a photograph showing the actual appearance near a magnetic pole from one point of view, in one of M. Villard's experiments. He regards the intensifications of brightness, due to the superposition

FIG. 2.

of the direct and return paths, as answering to an auroral arc. Below the arc there would, he says, be total darkness—answering to the "dark segment" of the ordinary aurora—but for a special form of discharge which he terms "magneto-kathodic" rays; these rays require, he says, a very steep potential gradient, and do not exist in the earth's atmosphere. Changes in the magnetic field or

[1] "Les Rayons cathodiques et l'Aurore boréale." By M. P. Villard. (*Bulletin de la Société d'Encouragement pour l'Industrie nationale*, May, 1907.)

in the velocity of the particles alter the distance between the bright patches in Fig. 2, giving the effect of changes of luminosity running round a circle, a well-known auroral phenomenon. Other phenomena analogous to the "dancing" of auroral rays are easily produced by advancing or withdrawing a bar magnet. M. Villard seems to regard magnetic disturbances rather as agents causing auroral phenomena than the converse, but his theory seems still in a somewhat uncrystallised state. Those actually familiar with auroral phenomena will think of a number of points requiring explanation to which M. Villard does not refer; but his researches, like those of Prof. Birkeland, are at all events highly interesting and suggestive.

C. CHREE.

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE proceedings of this year's meeting were largely influenced by the number of foreign visitors, most of whom made lengthy communications to the section. The latter part of the president's address in particular elicited the warmest approval; it was felt that his warning against the danger we now run into of neglecting to cultivate manipulative skill in the young chemist was most timely. The discussions ranged over an unusually wide field; that on valency came first in importance; in its course the new doctrine of Barlow and Pope was subjected to searching criticism, although the general tone was far from hostile. Of deep significance, as illustrating the importance of maintaining the very closest connection between science and industry, was the discussion on the quality "strength" in flour; it was felt by those concerned in the debate that this did much towards establishing clear ideas on this controversial subject.

Prof. Pope opened the discussion on valency with an account of the theory put forward by Mr. W. M. Barlow and himself. Combining chemical with crystallographic data, it is possible to show that the fundamental valency of an element represents, very approximately, the number of units of volume contained in the polyhedral cell which constitutes the domain of its atom in any molecular assemblage. Valency, from this point of view, is primarily a simple volume relation. If the atoms are regarded as centres of attraction and repulsion, a crystalline structure may be considered to be an equilibrium arrangement of such centres. If each atom be allotted its own polyhedral cell or sphere of influence, the simplest assumption that can be made as to the shape of these spaces is that they depart as little as possible from sphericity. The polyhedral cells must fill space without leaving interstices, and the centres of the identical polyhedral cells will be those of the centres of a closest packed assemblage of equal spheres. There are two varieties of homogeneous arrangement of equal spheres in closest packing, distinguished as the cubical and the hexagonal closest packed arrangements.

A crystalline element, in which no molecular aggregation of the single atoms occurs, should thus exhibit holohedral cubic or hexagonal symmetry. Of the forty known crystalline forms of the elements, only six are neither cubic nor hexagonal; in the rest the axial ratios all approximate to the theoretical values calculated on the above hypothesis. The binary compounds can be constructed from spheres of two kinds, but of approximately equal size, present in equal numbers.

This hypothesis has been worked out in detail in the case of the alkali haloid salts and of silver iodide. The assemblages thus constructed present geometrical properties which are entirely in harmony with corresponding physical properties of the crystalline material. The cleavage, twinning, and gliding of the cubic alkali haloid salts and the dimorphism of silver iodide are precisely paralleled by corresponding properties of the assemblages suggested as representing the crystalline structures of these salts.

Each crystalline substance is to be regarded as a close-packed homogeneous assemblage of the spheres of atomic influence.

Prof. Sollas criticised the form of close packing put forward by Messrs. Barlow and Pope, and objected to the structure suggested for silver iodide on the grounds that it did not explain the sudden contraction in volume of this substance when heated to a certain temperature. He described and showed models to illustrate an alternative system. Prof. Miers agreed that the fact that more than 80 per cent. of the elements and binary compounds crystallise in the cubic system was a strong argument in favour of closest packing, yet this principle must be tested by all the physical properties as well as the geometric form of the crystals. Dr. Tutton also criticised the idea of closest packing; he suggested that the topic axial ratios should be taken as an index and measure of the relative closeness of the packing.

Prof. Abegg pointed out that, according to van der Waals, in the liquid state three-eighths of the volume are occupied by matter and five-eighths are free space, and that as substances changing from liquid to solid do not vary essentially in volume, this would seem opposed to the idea of close packing. In answer to the above, Mr. Barlow explained that the spheres were only in reality centres of influence and attraction, and thus there was no real distinction between loose and tight packing. Prof. Tilden remarked that the authors in their explanation of what happens when a change of valency occurs did not appear to recognise that there are two kinds of valency, the one corresponding to the electric charges and the other an extra valency developed under special conditions.

Prof. Larmor thought that the views of the authors seemed to carry weight in their application to the forms of crystals. The approximation that is exhibited by actual crystalline forms to those calculated for dyad molecules consisting each of two equal spheres or nearly spherical domains of influence seemed noteworthy; it gained even more weight when it was remembered that considerable difference in size of the spheres would produce but little difference in the ratios, so that the restriction to equality of the domain of influence could be largely dispensed with and yet the results remain substantially as they are. He hazarded the suggestion that the direct operations of the chemist can grasp only those molecules which have pronounced architectural features, but that there may be whole regions of incipient combinations which do not submit to architectural modification, though they may be recognisable indirectly, as by the spectroscope.

The electrochemical aspect of valency was to associate it with the number of loose and displaceable electrons in the atom. The essential physical features of a metallic atom being generally that a certain number of its negative electrons are thus relatively free, we may imagine that when it is in combination to form a molecule of a salt these electrons are attracted across into the domain of the radicle thus united with it, and when accidental separation occurs in the appropriate way they may remain there. But while something like this is a fact, the mechanism remains largely a mystery, as it has been ever since valency was first connected in this way with electric displacement by Faraday eighty years ago.

Prof. Werner (Zurich) and Prof. Abegg (Breslau) gave descriptions of their views on the broader questions of valency. Prof. Kauffmann (Stuttgart) spoke on the divisibility of valency, and dealt briefly with his own investigations on the colour and fluorescence of organic compounds in connection with structure.

The second morning was entirely given up to a joint discussion with Section G on explosion temperatures, in which Profs. Boudouard, Haber, Smithells, and H. B. Dixon spoke on the chemical side. In the afternoon Prof. Dixon described his observations on the ignition point of various gases and mixtures. In the discussion which followed Mr. Dugald Clerk dwelt on the trouble arising from pre-ignition in large gas engines, and showed that it was important to be able to predict the ignition temperature from the nature of a mixture of gases, and so to allow proper compression space in designing the engine.

Dr. H. O. Jones gave a concise account of work carried out with Sir James Dewar on iron carbonyls. The pentacarbonyl is a yellow liquid, which resembles nickel tetracarbonyl in its properties, but is more stable towards chemical reagents. When decomposed it always gives rise to ferrous salts. On exposure to light it yields carbon monoxide and an orange crystalline solid—diferrononacarbonyl, $Fe_2(CO)_9$. This, when heated alone, gives a dark green liquid consisting chiefly of iron pentacarbonyl, but when hydrocarbons or ether are present in excess and the temperature is maintained below 100° C., an intensely green-coloured solution is obtained, which deposits dark green lustrous crystals of iron tetracarbonyl, $Fe(CO)_4$. This is stable towards reagents, and its dark green solution in organic solvents exhibits a characteristic absorption band in the yellow.

Dr. K. S. Caldwell described his investigations on the conductivity of electrolytes in pyridine carried out in Leipzig in Prof. Hantzsch's laboratory. With the exception of the pyridonium halides, the true acids, compared among themselves, follow approximately the same order in pyridine as in water, and the same applies to the pseudo-acids, which, however, yield much better conducting solutions than do true acids having the same or even greater affinity constants. He further dealt with the influence of temperature on the conductivity of electrolytes in pyridine solution. The temperature of maximum conductivity is well marked, but it is not higher the greater the conductivity as in the case of solutions in liquid sulphur dioxide. Pyridonium salts in pyridine show an abnormally high conductivity.

On Monday Dr. Alex. McKenzie presented a valuable report on the applications of Grignard's interaction. Since the discovery in 1900 that a vigorous action ensues when magnesium powder is added to a mixture of methyl iodide and anhydrous ether, and that this product is extremely active, the Grignard method has been applied with important results in almost every branch of organic chemistry, and the progress made with its help in so short a time as six years is little short of amazing.

By means of it, secondary alcohols are obtained from aldehydes, tertiary alcohols from ketones, acid chlorides or acid anhydrides. Unsaturated hydrocarbons are also obtained from aldehydes, ketones, &c., under suitable conditions. It is also applicable to the preparation of carboxylic, sulphinic and other sulphur acids, of ketones, aldehydes, ethers and esters, and also of alkyl and aryl metallic compounds. Dr. McKenzie dealt at length with the preparation of the agent, and this part of the report should prove of the utmost value to future workers in this field.

Prof. Tschitschibabin, of Moscow, read a valuable paper on triphenylmethyl, in which he discussed the formula of this remarkable substance. Dr. Chattaway described his copper mirrors discovered in the course of an investigation on the oxidation of aromatic hydrazines. When solutions of cupric salts are reduced by these compounds the metal is deposited on the glass in the form of a brilliant coherent film. A number of such mirrors were exhibited; they showed the lustrous red colour of burnished copper, and were perfect in reflecting surface and uniformity. Dr. Boudouard contributed an account in French of the suboxides of carbon.

Dr. Jaeger, of Amsterdam, described the colour changes which occur on melting cholesterol esters, and dealt with the theory of these from the point of view of the phase rule. The colours are due to the formation of doubly refracting layers of liquid crystals and occur at, or a few degrees below, the transition temperatures whilst the two liquid layers are separating from each other. The author gave a striking demonstration of these liquid crystals.

Prof. Phillips Bedson described and exhibited an apparatus for studying the inflammability of mixtures of coal dust and air, consisting of an arrangement whereby the dust was projected by a blast of air through a gap between two platinum wires, and there subjected to a series of electric sparks. A number of interesting experiments were shown with this apparatus; in one instance the flame produced by the ignition of dust at one point was made to ignite a cloud of dust at a point 2 feet or 3 feet distant from the point of inflammation.

Another experimental paper was contributed by Mr. Pratt, who described some properties of metallic calcium, which seems to have industrial possibilities as a reducing agent. In discussing the paper, Dr. F. M. Perkin mentioned his own experiments with turnings of metallic calcium, which has a more powerful reducing action on oxides than aluminium.

The reports of the research committees were as usual of considerable interest. Dr. Lowry, in the report on dynamic isomerism, brought forward very definite evidence in favour of his view that the isomeric change, which usually takes place when nitrocamphor is dissolved in chloroform or benzene, does not occur spontaneously, but is conditioned by the presence of minute traces of alkaline impurities. So sensitive is this change to piperidine that it is complete in ten hours under the influence of so small a quantity as N/1,000,000.

Dr. Orton's report on the transformation of aromatic nitroamines also laid stress on the important part played by the transforming agent in intramolecular changes which, accepting Armstrong's view, is regarded as forming an additive compound with the nitroamine. Dr. Crossley's report on hydroaromatic substances, besides giving an account of the researches made by the committee, included the usual valuable summary of recent work done in this field.

The discussion on the chemistry of flour was opened by Mr. A. E. Humphries with a short paper entitled "The Causes of the Quality Strength in Wheaten Flour." To make bread of the quality required in this country today what are known as strong flours are required, that is, flours which have the capacity of making big, shapely loaves. Most English-grown wheats are deficient in this quality of strength, and give what are known as weak flours. When attempts are made to grow a foreign strong wheat in this country, the yield of grain and straw is, as a rule, too low to make the culture pay. It has been the object of the Home-grown Wheat Committee of the National Association of British and Irish Millers to produce such wheats in England as shall combine strength with maximum crops of grain and straw. In addition to botanical and field work, this problem has demanded the solution of the question, What is the ultimate cause of strength and the nature and source of those constituents which confer on some varieties of wheat the inherent quality of strength and the power of transmitting it?

It has been proved that though climate and soil influence quality, they are not the determining factors in the production of strength, for though the strongest wheats are ordinarily produced in districts where the winters are cold, the summers hot, and the summer rainfall high, certain varieties possess and retain the inherent quality of strength when grown in England. Manuring or early cutting at harvest time has no beneficial effect on quality. Quick growth or rapid maturation is not correlated with strength, nor does the percentage of natural moisture in well-harvested wheat indicate it; indeed, in certain cases the addition of water to wheat materially increases its effective baking strength.

The term "strength" has been loosely applied to cover several characteristics. In the view of the committee it should not be measured by the quantity of water required to make doughs of a standard consistency, nor by the quantity of bread produced per sack of flour used, nor by the way a flour behaves in the dough, but by its capacity for making big, shapely, and therefore well-aërated loaves. This definition covers two characteristics; one, a flour's capacity for making gas in yeast fermentation; the other, its capacity when made into dough for retaining the gas so generated.

The gas-making power will depend largely on the percentage of natural sugar any given wheat contains and its diastatic capacity. These characteristics vary substantially in different wheats. The baker can, and does, influence the quantity of gas generated in baking. The retention of gas when made involves complex problems.

Mr. A. D. Hall pointed out that the old idea that the wheat plant takes definite materials out of the soil to give it strength is incorrect, and emphasised the view that each type of wheat elaborates a mixture of starch, proteins, &c., of definite proportions right from the very beginning, so that the plant as an individual affords a characteristic product. Strength on this assumption is a congenital factor, and probably a "character" in the Mendelian sense.

Prof. T. B. Wood described in detail experimental investigations from which he concludes that two factors are involved in the term *strength*, that of *size*, which is a function of the gas evolved by the flour due to its diastatic capacity, and that of *shape*, which is a function of the proportion of acid and salts present in the flour. Mr. Julian Baker mentioned some determinations of the diastatic power of flours from which he infers that diastase is always present in excess, so that the determination of diastatic power will not be of much value in judging a flour. Dr. E. F. Armstrong alluded to the importance of the gas formed during the early stages of fermentation in distending and affecting the gluten, and pointed out, as also did Mr. Baker, that the enzymes of flour other than diastase should receive the closest attention.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE papers on local geology which followed the president's address were of more than ordinary interest. Mr. Fox Strangways dealt with the district round Leicester as a whole, dwelling specially on those points which are obscure and require further elucidation. Prof. Watts gave an account of his researches in the rocks of the Charnwood Forest. Dr. F. Bennett and Dr. B. Stacey, in describing the felsitic agglomerates occurring at Bardon Hill and in other parts of Charnwood, gave a new reading of some of the features described by Prof. Watts. These questions raised an interesting discussion, which was carried on, not only in the sectional meetings, but also in the field, when the localities were visited in the course of the admirable series of afternoon excursions which had been arranged by the local secretary of the section.

A full day was given to papers dealing with the Triassic rocks. Mr. H. T. Ferrar led off with a description of the features and activities of the desert regions of eastern and western Egypt, and he dealt more particularly with those which have a bearing on the origin of the British Trias. The Libyan Desert presents broad, featureless plains, with no very definite drainage system, and the veneer of waste is protected from removal by wind by layers of pebbles. The Etbai, on the other hand, displays bare hillsides free from débris, aggrading wadis, no sand dunes, and an integrated drainage system.

The origin of the Trias about Leicester was very ably discussed by Mr. T. O. Bosworth. He showed that the Charnian rocks beneath the Keuper were fresh right up to the surface, and when the marl had been denuded, the igneous rocks of Mount Sorrel, Croft, Scapcote, Groby, &c., were smoothed, fretted, and carved by wind action. The beds themselves dip in the direction of the slope of the underlying rocks, and catenary bedding is seen at Croft and Groby. At the base of the marls, too, there are breccias with chemically unaltered stones, and these he considered to be desert screes. Such evidence of subaqueous deposition as there is points to the existence of occasional streams and salt pools rather than the deep waters of one great Keuper lake.

Messrs. Keay and Gimson discussed the relation of the Keuper marls to the pre-Cambrian rocks at Bardon Hill. They showed that the Keuper fills in joints of the pre-Cambrian rocks to a height of 880 feet, which is the greatest altitude yet reached in Britain for any rocks of the Triassic system.

Dr. Cullis, in dealing with the mineralogical constitution of the Keuper marls in the west of England, announced the discovery of minute crystals of dolomite, which he contended were precipitated from the waters of an inland sea. In the discussion which followed, Mr. Lomas showed that dolomite was absent from the Keuper marls of the north of England, and their occurrence in the sands now being laid down by the River Mersey showed that other modes of origin are possible. The exact manner in which limestones become dolomitised and crystals of dolomite are produced in sands is still a matter of great uncertainty, and no satisfactory explanation has yet been offered.

Messrs. Bolton and Waterfall communicated a paper on the occurrence of boulders of strontia in the Upper Triassic marls of Abbots Leigh, near Bristol. This remarkable deposit contains boulders of all sizes from a pea to 100 tons in weight; the yield is about 2000 tons per acre, and it has become the principal world's supply of this mineral.

The fifth report of the committee appointed to investigate the fauna and flora of the Trias was presented by the secretary. To this report Dr. A. Smith Woodward contributed an important paper on a mandible of *Labyrinthodon leptognathus*, Owen, recently obtained from the Keuper sandstone of Cubbington Heath, near Leamington. Its structure confirms the recent conclusions as to the complex nature of the mandibular ramus of Labyrinthodonts, and helps to connect these early amphibians with the Palæozoic Crossopterygian fishes.

Mr. H. C. Beasley has taken advantage of the great find of footprints at Storeton, in Cheshire, last year to re-describe some of the forms hitherto imperfectly known, and Mr. Lomas gave a detailed account of a large slab recently presented to the Liverpool University. This slab gives a track containing fifteen impressions made by the same individual, and the markings are so perfect that the minutest detail of the skin, claws, and movements of the animal which made them, can be observed. It is suggested that Cheirotherium walked erect, and only used the manus to steady itself when bending down to drink or feed. The rocks containing the footprints have been found to contain, besides quartz, felspars, zircon, tourmaline, anatase, rutile, kyanite, staurolite, chert, and numerous black grains not identified.

Mr. A. R. Horwood also contributed to the report an account of the plants and animal remains found in the Leicestershire Trias, and a bibliography of works referring to the flora and fauna of the Keuper of the district.

Mr. L. J. Wills gave an account of a very rich assemblage of fossils he recently obtained from the Lower Keuper of Bromsgrove, in Worcestershire.

Prof. Seeley, in describing the structure of the mandible of a South African Labyrinthodont, pointed out the grea resemblance between the British Triassic fauna and th of the Karroo in South Africa.

A discussion on iron-ore supplies was opened by M Bennett Brough and Prof. Sjögren. Mr. Brough c tended that as the production and consumption of per head of population is increasing year by year, a the world's production in 1905 attained the enormo total of 56,000,000 tons, the outlook for the future disquieting, though not necessarily depressing. The futu of the home demand is likely to be affected by the develc ment of the basic open-hearth process of steel makir which enables phosphoric ores to be utilised. The devel ment of magnetic concentration and of the briquetti of pulverulent ores for furnace use will render possi greater utilisation of poorer ores, and the electric furna will doubtless render it possible to use black sands a other titaniferous iron ores, which cannot be treated pro ably in the blast furnace.

Prof. Sjögren took a more hopeful outlook in deal with the Scandinavian iron ores. These are distributed "ore-provinces" characterised by special geological str tures. While the view that the iron-ore supply is limited is not well founded, the professor estimated t the total supply for the different provinces in Scandina is 1105 millions of tons of ore, equivalent to 582 millis of tons of pig iron. Of these, 60 millions contain a percentage of phosphorus and are suitable for reduc by the Bessemer process, 545 millions are richer in ph phorus and can be worked by the basic-hearth proc, and 500 millions are lean ores only profitable to sm after magnetic concentration.

Continuing the dicussion, Prof. Lapworth congratulated the association upon the importance of the communica tions. He referred to the great changes in the positio of the centre of gravity of the iron industry. Years ag the native forests served for the working of the ore when the Weald was the great centre of output. Whe coal came to be used, the coalfields became the centres, and in later days the ores of the Lias and Oo had come to the front, and probably for some time t would be the chief British sources of supply.

Mr. G. W. Lamplugh said that an important aspect the question was one of cost, and as the first-class ores became exhausted and prices rose, the second-class ores would prove remunerative.

Colonel Parrett took an optimistic view, and referred to the vast quantities of rich ore in Australia and the Transvaal.

The president, in closing the discussion, looked forward to Australia, with its vast coalfields and easy transport, becoming the great centre of iron production.

Mr. W. G. Fearnsides, in describing the pisolitic iron ores of North Wales, showed that they were not, as formerly supposed, characteristic of certain geological horizons.

A paper by Prof. J. Joly, on the distribution of radium in the rocks of the Simplon Tunnel, raised many questions of great interest. From the examination of thirty-six typical samples taken from various points in the tunnel, he showed them to contain varying amounts of radium, and, taken together, they were sufficient to disturb any forecast of the temperature which under normal conditions would be encountered at the level of the tunnel. The presence of radium in the sediments, in hitherto unsuspected quantities, raises the question whether its presence may not be a factor in the events attending mountain building. The shifting of radium and its parent elements by denudation must be regarded as a convection of thermal energy, and result in the shifting of areas of high temperature and crust-weakness from age to age as the site of sedimentary accumulation changes.

The chief papers dealing with palæontology were by Mr. F. Raw, on the trilobite fauna of the Shineton shales and on the development of *Olenus salteri*; the palæontology of the North Derbyshire coalfield, by Mr. A. R. Horwood; and reports from various research committees.

The Carboniferous Zones Committee, after several years of useful work, presented its final report, but the work, which has been carried on with so much vigour and success by Dr. Wheelton Hind and others, will be continued by another committee of which Dr. A. Vaughan is secretary.

The committee appointed to investigate the fossiliferous drift deposits at Kirmington and at various localities in the East Riding of Yorkshire has devoted its energies to a careful examination of the mammaliferous gravels at Bielsbeck, in the Vale of York. The deposits occupy a depression in the Keuper marls, and have accumulated in a boggy hollow on an old land surface. None of the material excavated can be assigned to the direct agency of ice, and there is no evidence available which will definitely fix its age relatively to the Glacial period.

A new section of glacial gravels in Holderness was described by Messrs. Sheppard and Stather. They are considered by the authors to represent part of the terminal moraine of the North Sea ice sheet.

The pre-Devonian beds of the Mendip Hills were reported on by a committee appointed to examine their fossil contents and their relations to a peculiar coarse, ashy conglomerate found in the neighbourhood.

Mr. Lomas described the occurrence of a remarkable bed of peat found during excavations in the Union Dock, Liverpool. The chief interest of the deposit lies in the fact that the peat is composed of marine plants encrusted with polyzoa, hydrozoa, serpulæ, and other marine organisms.

Mr. A. R. Horwood read a paper on a hitherto unnoticed section of the *Amaltheus spinatus* zone in the Middle Lias at Billesdon Coplow, Leicestershire, and some notes on the ancient volcanoes of Basutoland were sent by the Rev. S. S. Dornan.

A catalogue of destructive earthquakes was submitted by Prof. J. Milne. Taking only those which have done structural damage, he finds that between the years 1150 and 1250 A.D. large earthquakes were very frequent, and another great increase commenced about the year 1650, and is still in progress.

Prof. Frech in a subsequent paper showed the part which earthquakes have played in mountain building.

Reports on the Anglesey rocks, by Mr. E. Greenly, and on erratic blocks, by Prof. P. F. Kendall, completed the papers read before the section.

J. L.

ENGINEERING AT THE BRITISH ASSOCIATION.

In accordance with its usual custom, the section did not meet on the opening day until 11.15 a.m., in order that members might have an opportunity of attending the presidential address in Section A.

The proceedings of Section G began with the delivery of his presidential address by Prof. Silvanus Thompson, which dealt mainly with the subjects of the history and development of electric motive power, and the education and training of engineers. After the vote of thanks to the president, Mr. Dugald Clerk read a paper on the present position of gas and petrol engines. The author pointed out that experience in the construction and design of large gas engines is gradually accumulating, but that the conditions of work in this country differ in one important respect from those on the Continent. Practically all the large Continental gas engines are operated with blast-furnace gas, while in this country producer gas has been almost exclusively used, and he was of opinion that until the problem of the bituminous fuel producer was solved, it would be difficult to continue to increase the dimensions of gas engines. Mr. Clerk himself has been working for some years now at the problem of reducing maximum pressures as well as temperatures, without reducing mean pressures, in order that the thickness of the cylinder castings, &c., might be reduced, and that the weight of the engine itself might be made more reasonable for moderate powers; he has been experimenting with a 50 horse-power engine in order to obtain definite data as to the rates of cooling of the working fluid in the actual engine at different temperatures and pressures, and he showed a very interesting diagram illustrating his results, and a table of apparent specific heats of the working fluid at varying degrees of temperature which he had worked out from these experiments. This table showed conclusively a rapid increase of apparent specific heat with increase of temperature. From the values of the specific heat thus obtained, Mr. Clerk was able to obtain a curve of heat loss to the sides of the cylinder both for complete double strokes and for partial double strokes at the inner end of the stroke. The paper concluded with a brief discussion of some interesting points in connection with the petrol engine, and especially with the problem of the exhaust gases. The author showed by results of experiments on his own motor-car that by adjusting the carburetter he was able to reduce the percentage of CO in the exhaust gases very considerably.

In the afternoon the members of the section had an opportunity of visiting the works of Messrs. N. Corah and Sons, hosiery manufacturers, where they saw many examples of the most efficient and up-to-date machinery now used in the manufacture of hosiery. The works are extremely well planned, and reflect the greatest credit upon the proprietors, not only for the skill with which the machinery has been arranged and working costs kept down, but for the great attention paid to ventilation in the workrooms and to the comfort and general well-being of the employees.

Friday morning, with the exception of a short paper by Prof. B. Hopkinson and Mr. L. G. E. Morse on the gases exhausted from a petrol motor, was entirely devoted to a joint discussion with Section B on gaseous explosions with special reference to temperature. Prof. Hopkinson and Mr. Morse in their paper gave an account of experiments which had recently been carried out in the engineering laboratory of Cambridge University on a four-cylinder Daimler engine in order to determine the conditions under which carbon monoxide is formed in an internal-combustion motor, and the relation between the composition of the exhaust gases, the strength of the mixture, the power developed by the engine, and the thermal efficiency. These experiments showed that the curve obtained by plotting the thermal efficiency reckoned on the indicated horse-power to a base of petrol consumption had a sharply defined maximum near the point where the consumption was about 2/10th lb. of petrol per 1000 revolutions, or at the point at which the petrol is just sufficient to be burnt by the available oxygen. The rapid increase in the percentage of carbon monoxide in the exhaust gases as the petrol consumption was increased was shown very strikingly by another curve, and it was apparent that if the carburetter was set in the usual manner in order that the engine might give its maximum power, no attention being paid to petrol consumption, the exhaust was almost certain to contain large quantities of carbon monoxide.

The discussion on gaseous explosions was opened by Mr. Dugald Clerk, who showed a part of the original apparatus used by Bunsen in his classic experiments. Mr. Dugald Clerk then briefly described his own important work in this field of research, beginning with his earlier experiments, in which the pressures reached were recorded by means of a Richard's indicator, down to his latest researches, some of which have been recently described in papers read before the Royal Society in March, 1906, and before the Institution of Civil Engineers at the beginning of the present year, in which optical methods have been used for obtaining records of the variation of pressure with changes of volume and temperature in the cylinder. Dr. Boudouard, of Paris, followed Mr. Dugald Clerk, and described, with the help of blackboard sketches, the apparatus which is being employed by the committee which has been appointed by the French Government to carry out a fresh series of experiments on gaseous explosions, with the object of determining whether the numerical results obtained in the earlier experiments are trustworthy. Prof. Haber, of Carlsruhe, another well-known worker in this subject, dealt very fully in his remarks with the subject of the variation of the specific heat of gases as the temperature of the gas is raised, and Prof. Dixon and Prof. Hopkinson, who also spoke, took up the same point. Prof. Dixon showed by a table of results obtained in his own experiments that, at any rate up to the limit of temperature to which he had at present worked, the specific heat of CO_2 rose very markedly as the temperature of the gas was increased, while, on the other hand, there was very little apparent variation in the specific heat of nitrogen.

During the afternoon the section paid a visit to the British United Shoe Machinery Co.'s works; a very excellent descriptive pamphlet had been prepared in connection with this visit, which was a most enjoyable one, and enabled members to see to what an extent self-acting machinery is now used in connection with the manufacture of boots.

The section did not meet on Saturday, but many of the members spent the day in a visit to the Leicester and Swannington Railway, one of the oldest railways in the kingdom, constructed by George and Robert Stephenson; Mr. Clement Stretton acted as conductor of the party.

Monday, as usual, was devoted to electrical papers, and the first paper taken was by Sir William Preece, on the Pupin mode of working trunk telephone lines. The author stated that he himself had pointed out in 1896 that the effect of electromagnetic induction in telephone wires was in one sense beneficial, and that Prof. Pupin had made it more beneficial in another sense, and had thus been able to reduce the weight of copper used on trunk lines and also to extend the distance to which ordinary speech is practicable. Sir William Preece inspected in April last the very successful work which has been done by the New York Telephone Co. in connection with the adoption of Prof. Pupin's methods. The Pupin coil stores up a portion of the energy, which, like a spring under pressure, is ready to react on the release of the forced condition. The size of the coils and their distance apart on the circuit is a question of experiment; Sir John Gavey has found the best results with coils at every two miles; Mr. Carty, on the other hand, employs them at every $1\frac{1}{4}$ mile on a long line, and at every $\frac{3}{4}$ mile on a short line. The author termed the addition of these inductance coils "loading" the line, and he stated that the use of loaded lines is increasing rapidly. In underground cables the range of a loaded line is found in this country to be 2·4 times that of an unloaded one. The application of this principle to submarine cables is now under investigation, though it has not yet reached a practical stage. In concluding his paper, the author pointed out that telephone troubles in this country often arise from the fact that the subscriber is entirely ignorant of the system of working, and will not take the trouble to make himself familiar with it.

Sir Oliver Lodge read a short paper on tuning in wireless telegraphy, and described the system adopted in the Lodge and Muirhead wireless telegraphy stations.

Mr. J. T. Morris then read a note on an oscillographic study of low-frequency oscillating arcs. The paper collected together a number of observations which had been made both with direct and alternating current arcs, mainly with the object of studying the effect of a change in the medium in which the arc is burning, and also to examine the effect, if any, produced on the arc by the application of a transverse magnetic field. No frequencies of more than 1000 were investigated. The paper was fully illustrated by curves representing the results of the experimental investigations.

The next paper was by Mr. Leon Gaster, on developments in electric incandescent lamps. The author stated that at the York meeting last year he had been able to show a few sample 110-volt metallic filament lamps consuming 1 watt per candle-power; to-day such lamps were ordinary commercial articles. A number of types of metallic lamps were shown by the author, including tantalum lamps, "Osram" lamps, in which tungsten is employed, and a lamp known as the Helion lamp. In the discussion Sir William Preece stated that he had lately equipped his own house with Osram lamps of 105 voltage, and, in order to reduce the pressure from 220 volts to the necessary 105, he had put in an alternating-current transformer, but the cost of this had been more than met by the saving in the payment for current within a year, and that though he had put the lamps in in January, 1906, none of them had so far needed replacement.

The business of the day concluded with a short paper by Prof. E. G. Coker descriptive of the new engineering laboratory at the City and Guilds of London Institute, Finsbury. A new wing has been added to the college, in which accommodation has been provided for an engineering laboratory, drawing offices, lecture rooms, &c. The hydraulic section of the engineering laboratory contains a long cast-iron channel, and all the necessary measuring tanks and other appliances; a number of hydraulic machines have been installed. The engines in the heat laboratory are all of moderate size, and in many cases have been designed with special reference to research work. This new laboratory will bring the teaching equipment at Finsbury well up to date.

Tuesday opened with two papers on ferro-concrete, one by Mr. J. S. E. De Vesian and the other by Mr. W. Noble Twelvetrees. Both authors made extensive use of the lantern, and showed a large number of slides illustrating the kind of work for which ferro-concrete has been so far generally employed. It was interesting to find that this method of construction is now rapidly making its way in this country; Mr. De Vesian showed in his lantern-slides a number of big mills, granaries, &c., which have recently been built in Great Britain on the Hennebique system of ferro-concrete. In the first portion of his paper this author went fully into the specifications which he uses in connection with the materials required in ferro-concrete construction, and explained the tests he carries out in connection with the Portland cement.

Mr. Noble Twelvetrees showed a series of slides to illustrate the use of reinforced concrete for such types of construction as railway sleepers, standards for overhead electric cables, &c., and he advocated the use of concrete for preserving existing steel bridges, especially where they are liable to the corrosive effect of locomotive fumes.

Mr. Worby Beaumont followed with a paper on the origin and production of corrugation of tramway rails; he suggested various causes in explanation of this peculiar phenomenon, but, though the paper led to an interesting discussion, no speaker was able to throw any light upon the real origin of this troublesome problem, which so often worries the tramway engineer.

Two other papers were dealt with by the section on this day, one, by Mr. H. I. Brackenbury, on modern machinery and its future developments, and the other, by Mr. C. V. Drysdale, on resistance coils and their comparison. The latter author exhibited his ingenious apparatus, not only at the sectional meeting, but later on in the evening at the conversazione which was held in the Leicester Museum.

Owing to the very full programme of papers, the section was forced to meet again on Wednesday, August 7, when four papers were discussed. The first, a short paper by Mr. J. F. Brooks, described a machine for weighing the forces on a cutting tool; the author exhibited and explained one of his machines, and the values of the forces on tools with cutting angles of 65° and 70° when cutting cast-iron and mild steel with small cuts at moderate speed were shown by means of diagrams.

Mr. R. S. Ball, in his paper on the governing of hydraulic turbines, dealt with the problems involved in the speed control of hydraulic turbines for a wide range of head. He showed that such regulators may be divided into two classes:—(1) disengagement governors (mechanical), which come into action when an assigned departure from the normal speed is attained, being otherwise out of gear; (2) continuous governors (mechanical and hydraulic), which are always connected to the gate-controlling mechanism, and which begin to operate at the moment the speed rises or falls from the normal. The action of various types of governors was described by figures and diagrams plotted from the results of tests.

Prof. H. T. Barnes, of McGill University, Montreal, then read a paper on the ice problem in engineering work in Canada. He showed that in Canada there is always great steadiness of the temperature of the water throughout the ice season, and that there are three varieties of ice to be distinguished—surface or sheet ice, spicular or frazil ice, and anchor or ground ice. Prof. Barnes explained that by an intelligent use of artificial heat, especially at night time, when super-cooling is most common, the interference of ice with the normal operation of a power-house may be largely prevented. The most favourable condition for a power-house is when it is situated on a river normally frozen over on its surface and with no stretches of open water above.

The section concluded its business with the reading of some notes by Mr. J. Smyth on the application of water-power and how to secure the greatest efficiency in working same.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The sum of 250,000 dollars has been appropriated by the Kansas Legislature for the erection of engineering buildings in connection with the State university.

The Sunderland Technical College is to be extended by the addition of a day training college and engineering laboratories at a proposed cost of 10,000*l*.

Dr. James E. Talmage has resigned the professorship of geology in the University of Utah in order to devote himself to investigation work in mining geology. Dr. F. J. Pack has been appointed to succeed him.

This year's scholarship of the Institution of Naval Architects has been awarded to Mr. A. M. Robb, Glasgow. The scholarship is of the annual value of 50*l*., and, subject to the regulations, is tenable for three years.

Mr. Simon Flexner has been made a member of the Rockefeller Institute for Medical Research, New York, and director of the pathological laboratories; and the following have been appointed members of the institute:—Mr. S. J. Meltzer (physiology and pharmacology), Mr. E. L. Opie (pathology), and Mr. P. A. Levene (biological chemistry).

The calendar of the Manchester School of Technology and Municipal School of Art for the session 1907–8 has just been issued by the firm of John Heywood, Ltd. In it are to be found full particulars of the courses of instruction, and the scholarships, prizes, &c., at the institution. Many of the laboratories and workshops are pictorially represented in the volume.

The following appointments abroad have recently been made:—at the Rush Medical College, Chicago, Dr. Robert R. Bensley to be professor of anatomy, and Dr. Edwin O. Jordan professor of pathological anatomy and bacteriology; Dr. Francis Huber has been elected to the chair of medicine at the New York College of Physicians and Surgeons, and Dr. Frederick Peterson to that of psychiatry in the same institution; at Yale University, Dr. J. M. Flint has been appointed professor of surgery; at Würzburg, Dr. Faust has been made professor of pharmacology.

The remarkable progress accomplished by the Japanese during the last thirty-two years in the field of public education is brought out very clearly in the thirty-second annual report of the Japanese Minister of Public Instruction, which has been published recently. This report deals with the year 1904–5, the date of the war with Russia. It is instructive to note that this time of stress was allowed to interfere in no way with educational activity. The Emperor, indeed, proclaimed it to be a national duty that the zeal and efforts of educational administrators and teachers should be redoubled. Despite the financial difficulties to which a great war gave rise, the expenditure on education was not diminished. While in 1873 only twenty-eight out of every 100 children were under instruction in public schools, the ratio had risen in the year under review to the remarkable one of 97 boys and 91·5 girls out of every hundred, and the number of children in the schools had reached 7,551,445. Higher education, too, was in an equally flourishing condition. For example, the number of students in the University of Tokyo had reached 3500, and in Kioto 1300. Numerous special schools, technical schools for engineers and for agricultural specialists, medical schools, and schools for the study of modern languages, were all in a high state of efficiency. Moreover, a point of special interest in our country to-day, the hygiene of schools, is scrupulously watched, and medical officers are charged specially with the duty of keeping the pupils under examination. Altogether the report provides abundant evidence of the success with which Japan is educating her people.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 6.—"The Osmotic Pressure of Compressible Solutions of any Degree of Concentration." By Alfred W. **Porter.**

An exact equation is obtained connecting osmotic pressure with the vapour pressures of solvent and solution, viz.:—

$$\int_{\pi_\pi}^{p} s\,dp + \int_{p-P_p}^{\pi_{00}} u\,dp = \int_{\pi_\pi}^{\pi_{00}} v\,dp,$$

where

P_p is the osmotic pressure when the hydrostatic pressure of solution is p;

π_{00} is the vapour pressure of the solvent when under the hydrostatic pressure of its vapour alone;

π_π is the vapour pressure of the solution when under the hydrostatic pressure of its vapour alone.

v and u are the specific volumes of vapour and solvent;

s is the diminution of a very large volume of the solution when 1 gram of solvent is removed.

The equations given by van 't Hoff and the Earl of Berkeley can at once be derived from this general one by taking the liquids as incompressible and considering respectively the cases in which (1) the solvent, (2) the solution, is under the pressure of its own vapour alone.

It is shown that if two solutions in the same solvent have the same osmotic pressure, they have also the same vapour pressure provided the values of these pressures be measured for the same hydrostatic pressure of the solution. They have also the same freezing point.

It is shown that when a solution is in equilibrium with the pure solvent across a semi-permeable membrane the vapour pressure of the solution is necessarily equal to the vapour pressure of the solvent, *each being measured for the actual hydrostatic pressure of the fluid to which it refers.*

The above involves a recognition of the variation of vapour pressure with the hydrostatic pressure of the fluid to which it relates; an equation giving the mode of variation is derived.

A graphical solution of the osmotic-pressure equation is given.

June 13.—"Some Points in the Development of *Ophiothrix fragilis*." By Prof. E. W. **MacBride**, F.R.S.

The paper contained a preliminary report on the result of researches on the development of the British Ophiurid *Ophiothrix fragilis*. The eggs of this species are small (0·1 mm. in diameter) and opaque, and the development until the completion of the metamorphosis occupied twenty-six days. The full account of the research, which will shortly appear in the *Quarterly Journal of Microscopical Science*, will contain the first complete description of the formation of all the organs of an adult Ophiurid from their rudiments in the Ophiopluteus larva. In the preliminary account two points of special interest are emphasised:—(1) the varying character of the early development according to the conditions under which the egg was fertilised; and (2) the indications of metamerism in the cœlomic sacs of the larva. With reference to (1), if the eggs were artificially fertilised, *i.e.* if the ovary were removed from the body and the eggs shaken out and then mixed with sperm, a larva resulted in which there was a precocious formation of mesenchyme, so that the blastula stage was practically solid; this was succeeded by an invagination in which the endodermic plate was many layered. As a result, the gastrula had a wedge of cells projecting into the gut which was slowly absorbed. A similar wedge seems to be a normal feature of the development of *Ophiura brevis*, according to Dr. Caswell Grave. If the animals were allowed to spawn naturally, a hollow blastula was formed, and invagination was normal; in addition, at the anterior end of the larva a vacuolated crest of cells was formed, which later disappeared. With regard to (2), the cœlom on both sides of the larva became divided into three somites. Of these, the middle one on the left side gave rise to the hydrocœle, or rudiment of the water-vascular system; its fellow on the right is the homologue of the "dorsal sac" or "madreporic vesicle" of Asteroidea and Echinoidea, but in *Ophiothrix fragilis* it sometimes assumes a form similar to that of its left antimere, showing that the water-vascular system was originally paired.

PARIS.

Academy of Sciences, August 26.—M. A. Chauveau in the chair.—Study of the spectrum of the comet 1907*d*. Peculiarities of the tail: H. **Deslandres** and A. **Bernard**. The spectrum of this comet has been studied by two methods, with and without a slit. The present note gives an account of the results obtained working without a slit. The spectrum shows bands in the yellow, green and blue corresponding to hydrocarbons, and, in addition, the characteristic ultra-violet band of cyanogen. Differences were observed between the spectrum of the tail and that of the head, but further observations are required to elucidate the exact meaning of these differences.—Parthenogenetic developments in solutions isotonic with sea water: Yves **Delage**. All the principal salts of sea water, employed separately, including the chlorides of sodium, potassium, magnesium, calcium, the sulphates of sodium and magnesium, and magnesium bromide, can determine parthenogenesis of the eggs of sea urchins; these vary greatly in their effects, and the best solutions for each are given in detail. One unexpected result is noted: a pure solution of saccharose sometimes allows of strong development of the egg. As regards the stage to which it is possible to raise the eggs, the author has at last been able to obtain true sea urchins furnished with all the characteristic organs by a purely chemical action.—Propylene oxide: Louis **Henry**. It is known that primary alcohols arise from the action of alkyl magnesium compounds upon ethylene oxide, and in a previous paper the author has shown that the symmetrical dimethylethylene oxide behaves differently. In the present communication it is shown that methylethylene oxide, or propylene oxide, resembles ethylene oxide in its reaction with ethyl-magnesium-bromide, normal methylpropylcarbinol being formed.—The ephemeris for the search for the comet 1907*d* on photographic negatives: P. **Stroobant**.—The root of the least modulus of an algebraic equation: Léopold **Fejér**.—The theory of the radiation of incandescent mantles: M. **Foix**. The conclusion is drawn from the mathematical investigation given that the yield of light may be increased either by diluting the cerium oxide in thorium oxide or by reducing the thickness of the cerium oxide. The latter result has been confirmed by experiment.—The probable formation of thorianite and uraninite: B. **Szilàrd**. The amounts of uranium and thorium in these two minerals are in practically inverse ratios; the proportion of uranium in thorianite is the same as the proportion of thorium in uraninite, and inversely. From this fact hypotheses are deduced as to the mode of formation of these two minerals.—The action of cold in the treatment of coffee trees against the Indian borer (*Xylotrechus quadrupes*): Louis **Boutan**. The momentary cooling of the stem of the tree by such a substance as ethyl chloride presents no inconveniences from the point of view of the life of the plant, and is sufficient to kill all the larvæ in the interior of the wood. The price of ethyl chloride, however, is too high for any practical use to be made of these results.—A newly born hippopotamus at the menagerie of the Natural History Museum, fed by goats: E. L. **Trouessart**. The mother of the infant hippotamus had always on previous occasions refused to feed her young. In the present case the young animal was removed, and has been successfully reared for eleven days by goats, eight of whom serve as foster-mothers.—The mechanism of the closing of the appendicular canal: R. **Robinson**.

CONTENTS.

THURSDAY, SEPTEMBER 12, 1907.

THE PHYSICAL LIFE OF BIRDS.

The Bird, its Form and Functions. By C. William Beebe. Pp. xii + 496; illustrated. (London: Archibald Constable and Co., Ltd., 1907.) Price 14s. net.

MR. BEEBE'S handsome and beautifully illustrated book on the bird forms as charming and interesting an introduction to physical ornithology as the general reader, or the unscientific bird lover, can desire. In his preface, the author points out that too many students of ornithology stop short at the classification of birds, the naming of new species, and the observation of the habits of those that are known; and that not one of an audience of teachers to whom he had lectured, though they could identify fifty birds or more, knew the significance of the scales on a bird's foot. His book is intended to bridge this gap. It is an untechnical study of the bird in the abstract. His aim has been to take a few dead facts and clothe them with the living interest which will make them memorable and full of meaning to any lover of birds, and at the same time to keep them acceptable in tenor and truth to the most critical man of science. Wherever possible, a fact has been illustrated with a photograph from a preparation, or from a living bird, the author's belief being that when verbal exposition fails, pictorial interest will often fix a fact in the memory. How successful he has been in this a glance at the wealth of exquisite illustrations will show. Beginning at the root of all things avian, his first chapter deals with the birds' ancestors, the Ichthyornis, Archæopteryx, &c., both the remains and a "restoration" of the latter being illustrated.

We cannot follow in detail the seventeen chapters in which he deals with the entire structure of birds (treating each part in relation to the various functions it has to perform), their senses, their eggs, and the young in the egg. But we will turn to that on "beaks and bills," as a fair example of the treatment of the subjects. It is illustrated with thirty-three figures, and all the various forms of beak are described with their special adaptation to the wants and habits of the different birds. The beak is all-important to the bird.

"Tie a man's hands and arms tightly behind his back, stand him on his feet, and tell him that he must hereafter find and prepare his food, build his house, defend himself from his enemies and perform all the business of life in such a position, and what a pitiable object he would present! Yet this is not unlike what birds have to do. As we have seen, almost every form of vegetable and animal life is used as food by one or another of the species. Birds have most intricately built homes, and their methods of defence are to be numbered by the score; the care of their delicate plumage alone would seem to necessitate many and varied instruments; yet all this is made possible, and chiefly executed, by one small portion of the bird—its bill or beak."

This picture is hardly overdrawn if we allow a little for feet and spurs and wings, which some birds use for getting food and making homes and fighting. In feeding alone, so many different kinds of beaks are wanted. To pick up small seeds, to probe the deepest calyxes of flowers, catch insects on the wing, and fish in the sea in various ways on or below the surface; to sift the mud and ooze, and skim the surface of the water, to chisel away wood and tear flesh; all these ways of feeding require different beaks, and they are all described in a delightful manner that anyone can understand. So wonderful is their variety and the variety of their functions that this one chapter, like the others, as the author observes, could easily be elaborated into one or more volumes. "A collection of bills of the various wading-birds would look like a complete set of surgical tools."

In the same way the rest of the subject is treated, the chapters on feathers (in which are some most interesting pictures of pelicans in their breeding haunts) and eggs being perhaps the most attractive. The book will take and hold a distinct place in the literature of the subject, for it is quite original and stands alone. Not only is it a most readable and interesting book, but a valuable one to teachers. A short list of books in the appendix indicates sources where much more detailed information may be obtained by those who desire it. They relate chiefly to North American birds, for the author writes from the New York Zoological Park. Nevertheless, his book is of world-wide interest. The wealth of illustration is one of its chief features, and the index is very full and elaborate.

ANIMAL MECHANICS.

Kinematik organischer Gelenke. By Prof. Dr. Otto Fischer. Pp. xii + 261. (Brunswick: Friedr. Vieweg and Son, 1907.) Price 8 marks.

ENGLISH anatomists appear to have taken up the study of the joints and the movements performed by means of them almost entirely from the standpoint of descriptive anatomy, leaving the mathematical and more precise study somewhat severely alone. Proof of this statement is amply afforded by reference to the excellent bibliography which Prof. Fischer has appended to his handbook, the work under review, on the kinematics of living joints. No less than 127 references are given to German or French text-books or papers on the subject, whilst English or American authors are responsible for only nine. Of these, eight are papers to be found in various journals. The only extended mathematical treatment in English is that by Prof. Haycraft, entitled "Animal Mechanics," to be found in the second volume of Schäfer's "Physiology." The combination of a sufficient knowledge of mechanics with the necessary anatomy would therefore appear to be somewhat rare in this country. The subject, however, is one of great interest, and it is treated in a learned and at the same time lucid manner by Prof. Fischer, who has made for himself a considerable reputation in connection with it.

In the first section of this work, a more or less general investigation is made into the mechanical principles which govern the movements of organic joints. This is done by considering first a machine joint, such as an ordinary hinge, and then the points of difference between such a joint and an organic joint. In a hinge the form of the surfaces in contact is practically constant, as the joint moves between its extreme positions. This is rarely the case, of course, in a living joint. The variations introduced by these changes are carefully considered, the diagrams aiding very materially in the treatment. The mathematics employed requires some knowledge of differential and integral calculus, and also of coordinate geometry, but presents no very serious difficulties.

The succeeding part of the book is of great interest, as it contains a description of Prof. Fischer's own methods of showing graphically the movements of single joints and of combinations of joints. There have been many advances in this direction since the Webers, so far back as 1830, investigated the variation in the position of the centre of gravity of the body in walking and running. M. Marey introduced photographic methods, somewhat resembling modern kinematograph work. The method described in the present work is the best yet devised. A man is clothed from neck to feet in black, and a series of Geissler tubes, eleven in number, are arranged symmetrically on his head and limbs. These are joined to the secondary of a Ruhmkorff coil, the primary of which is interrupted about twenty-five times per second. The man's movements are then recorded photographically by means of cameras placed on either side and in front and behind. In this way records in three directions in space were obtained, and these were coordinated by means of networks of squares photographed at the same time. The phases of movement, either of the whole body or of a single joint-system such as the arm, are thus illustrated.

Prof. Fischer brings much originality into his treatment of a by no means easy subject. The publication of this handbook may well direct the attention of English students to a branch of anatomy which has been somewhat neglected, but in which there remains much to be done.

GAS ANALYSIS.

Traité pratique de l'Analyse des Gaz. By M. Berthelot. Pp. ix+483. (Paris: Gauthier Villars, 1906.) Price 17 francs.

IN that branch of chemical analysis dealing with gases there is by no means the superabundance of text-books characteristic of other branches of analytical work, and it is noteworthy that such works as we possess are nearly all memoirs of original work by the author, or have been developed from that form. The names of Bunsen, Winkler, Hempel, and Travers occur in this connection, and the present work is no exception. In some of his earliest researches, M. Berthelot was met with the necessity of devising methods for the analysis of gases, and many of the methods described in this book were used by him as early as 1858. After an introduction, the work is divided into five sections dealing with the collection and storage of gases, methods of qualitative analysis, general methods of quantitative analysis, monographs, and the recognition and estimation of single gases and mixtures.

The whole book is strongly impressed with the author's individuality, and a considerable proportion of the section dealing with qualitative analysis is original, especially the chapters on the pyrogenic analysis of gases and spectroscopy. In the latter connection, a simple apparatus is described by means of which a spectroscopic examination of a gas at the ordinary atmospheric pressure can be rapidly made, and in the section dealing with the properties of each gas in detail a table of the chief lines observed by this method is given. The actions of the electric spark and the silent discharge are also special to the author, and his methods are expounded in detail. The remarks on the use of absorbents are worthy of close attention, it being rightly pointed out that the reduction of volume by treating with a given absorbent cannot be taken as a proof that a particular gas is present: a gas must be isolated in a pure state before its presence in a gas mixture can be taken as proved. On the quantitative side more exception can be taken to the methods expounded, which, indeed, leave much to be desired, both on the score of rapidity and precision. Water jackets are not used for the measuring vessels, the temperature being controlled by immersion in a large mercury trough holding from 16 to 20 litres, and this is described as "the essential instrument in all exact manipulations relating to gases and their analysis." As this trough requires about 600 lb. of mercury to fill it to its working level, exact gas analysis would of necessity be confined to a very limited number of laboratories if this dictum were to be accepted. The sections on mercury pumps, calibration of measuring vessels, and determination of gaseous densities are also entirely out of accord with present-day standards of accuracy. References to other workers in the same field are rare, and the description of their apparatus and methods not always accurate. The account given of Hempel's gas burette and its use on p. 269 is an example of this. The commencement of the description is that of the Hempel burette, but the figure and manipulation correspond to a modified Winkler gas burette, and Prof. Hempel would hardly recognise the description of his pipette as "formed of two bulbs connected by a fine tube and each furnished with a recurved capillary tube."

In the fourth section a monograph is given of each gas, and this section will perhaps be found to be the most valuable part of the work. It is a drawback that no references to original memoirs are given in this section, and for this reason it is difficult to make out whether the densities given are experimental or calculated, or whether such a figure as $-93°$ C. for the boiling point of propylene is the result of a misprint or an inaccurate observation.

The book is one which everyone interested in gases should have on their bookshelves, but, like the classical work of Bunsen on the same subject, it cannot be regarded as of practical service as a text-book at the present day. Its value will be historical and personal as the last published work of a great French chemist.

MOTOR ENGINEERING.

A Manual of Petrol Motors and Motor-Cars, comprising the Designing, Construction, and Working of Petrol Motors. By F. Strickland. Pp. ix+376. (London: C. Griffin and Co., Ltd.) Price 18*s.* net.

Mr. Strickland has produced a very original and useful work on the modern motor-car. There is no padding; the book is filled from cover to cover with the practical remarks of a man who knows his subject. The matter is conveniently arranged, and the reader, whether he be manufacturer, designer, or user, is able to follow the author, and in almost every case to obtain his very decided opinions on many of the controversial points which have arisen during the development of the car of to-day.

First we have a short but very readable chapter on the power required, and a second chapter on the general arrangements of an up-to-date car. Then follow nine chapters on the details of the engine, and the remainder of the book is devoted to the other details taken seriatim.

It is refreshing to find the author in his chapter on general arrangements taking the bold line of prophesying that the present type of motor-car will not long endure. Most thoughtful engineers will agree with him that this is the right view to take, and in spite of the repeated assurances of those who have the car of to-day to sell, that finality of design has already been reached, and that little remains to be done to pleasure cars beyond perfecting details and cheapening modes of manufacture, it is probable that Mr. Strickland is right in saying that the present design, with its long engine sticking out in front necessitating a long wheel base, has been made necessary by the requirements of the engines, which up to the present are found in practice to need frequent attention on the road. He points out that when the engines become more trustworthy they will be relegated to their proper position underneath and nearer to the centre of the car. He gives strong reasons for showing that this position, although it does not give such facilities as at present for the chauffeur to make his repairs in public, will undoubtedly improve the car in many important respects, not least being that of the comfort and ease of the occupier.

The chapters devoted to the consideration in detail of the various parts of both pleasure and commercial motor vehicles are very complete; every important organ is considered and discussed separately, the various modes of construction are clearly explained, the drawings are real drawings and not process blocks, and are consequently far clearer than is unfortunately now too often the case.

The important features of the book are the tables of the principal dimensions of the best known cars of the day. These tables are accompanied by very full notes, which make them additionally valuable. It is the first time that anyone has attempted to collect together such a mass of useful information as is contained in these tables with their accompanying notes.

While there is so much to praise in this book, it is curious to note the peculiar error that the author falls into on p. 309 when he discusses the comparative flexibility of the steam engine and the internal-combustion engine. He seems entirely to ignore the extraordinary range of power without change of gear that has been rendered possible in the steam engine by the use of flash boilers. When with such boilers it is possible to give effective mean pressures varying from 100 lb. up to 1000 lb., it is evident that even for heavy commercial vehicles the use of change gearing is no longer necessary when steam is employed as motive power.

A few other dicta laid down by the author may be challenged in a similar manner to the above, but on the whole his work contains, in addition to the valuable tables and data above mentioned, an unusually large number of carefully reasoned and valuable conclusions which will render it almost a necessity for everyone who is closely interested in the modern motor-car to keep this book in his library.

THE FAMILY AND THE FUTURE.

Population and Progress. By Montague Crackanthorpe, K.C. Pp. viii+131. (London: Chapman and Hall, Ltd., 1907.) Price 2*s.* 6*d.* net.

This volume contains a series of five essays, of which the first three were published originally in the *Fortnightly Review*, the earliest in 1872 and the two later ones in 1906 and 1907. As is stated in the preface, the thread that binds them is the "Voluntary Principle," that is to say, the principle that married people should for the good of society exercise voluntary control over the size of their families. Together they form a connected and forcible argument in support of this principle. The author sees in it, if not a panacea for all social ills, at any rate the most effective of prophylactic measures. Some space is occupied in reasoning, probably without avail, with those who would oppose it on religious grounds; but this we will pass by, mentioning only the very pertinent reminder to those who urge the biblical precept "be fruitful and multiply" that there were at the time at which this injunction was given, according to the very record on which its authenticity is based, only eight persons living on the face of the earth.

Dealing with masses, one may recognise two kinds of limitation of family, the one general or non-selective, the other eugenic or selective; each is regarded by the author as conducive to social sanitation, but the class of disease which may be prevented by the former is somewhat different from that on which the latter puts a check. The possibility and desirability of eugenic limitation of families has been much discussed recently, and most people recognise that society suffers if epileptics, degenerate and feeble-minded persons, or those suffering from inheritable disease are allowed freely to propagate their kind. In this connection Mr. Crackanthorpe does not rely on the "Voluntary Principle" only, but advocates that anti-eugenic marriages should be prohibited by law, and he gives instances, quoted from the writings of Dr. Rentoul, of Liverpool, of laws of this nature in force at the present time in Austria, Servia, and some American States.

The range of evils, which, according to the author, may be met by general limitation of families, is large—embracing prostitution on the one hand, and war on the other. The chief excuse for the former is that many men are prevented by prudential consideration from contracting early marriages; and this he suggests might be removed if it were universally recognised that prudence might be exercised after marriage, and if popular opinion shifted so as to condemn the raising of larger families than could be adequately provided for. With regard to war, we find on p. 128 the following passage:—

"The wars of brutal conquest and plunder, of religion, and of dynastic succession, which have from time to time devastated Europe, are now things of the past. But there remain commercial and colonial laws—wars to procure in old countries fresh markets for manufactures, and to provide in new countries an outlet for their superfluous inhabitants. These are the wars that the future has in store for us, unless we can remove the causes of them."

Of the causes referred to, the most predominant is the numerical increase of the population of the older countries in a ratio disproportionate to their food supply or to the territory at their disposal.

E. H. J. S.

OUR BOOK SHELF.

Temperatur und Zustand des Erdinnern. Eine Zusammenstellung und kritische Beleuchtung aller Hypothesen. By Hermann Thiene. Pp. iv+100. (Jena: Gustav Fischer, 1907.) Price 2.50 marks.

THIS memoir, which was written as a prize essay in connection with the University of Jena, is an admirable *résumé* of the various memoirs dealing with the nature of the earth's interior. The first twenty-eight pages contain a slight sketch of the literature of the subject from the earliest times down to the year 1870, beginning with Plato's "Phaedon" and ending with Delaunay and Sterry Hunt. The work done since 1870 is treated in somewhat greater detail in the second part of the memoir. For the chemical composition of the earth's crust the author adopts the average calculated by Clarke from the analyses of American rocks. He then discusses the determinations of the mean density of the earth, concluding that it must lie between 5·4 and 5·7, while for the density of the crust he argues that the specific gravity of diorite (2·8) may be accepted as an average. On the problem of the distribution of density within the globe, the author cites the views of Lipschitz, Sir George Darwin, Stieltjes, Callandreau, and Radau, and proceeds to consider the very problematic views that have been enunciated concerning the chemical constitution of the earth's interior.

On the question of the temperature of the earth's crust the author finds himself on safer ground, and he gives a summary of the evidence derived from the observations carried on in tunnels, mines, wells, and bore-holes, which is fairly complete and up-to-date. With speculations on the limits of temperature in the earth's interior, the author returns to more debatable problems, and in the absence of exact knowledge concerning the effect of enormous pressures on materials at high temperature can only cite the guesses that have been made upon the subject. The discussion of the question of the condition of the earth's interior, to which the latter part of the memoir is devoted, contains a very useful *résumé* of the views of various authors upon the subject, the important bearing of recent discoveries concerning radio-activity upon the question of the source of the internal heat of the globe and upon the age of the earth being kept in view. No fewer than one hundred and fifty-eight authors are cited, and the catalogue of works and memoirs numbers one hundred and seventy-seven. A few, not very important, omissions may be noted, but the summary, on the whole, is fairly complete and judicious, and it can scarcely fail to be of great service to those interested in the important questions with which the author deals.

The Garden Anthology. Edited by Rose Gardner. Pp. xiv+313. Price 2s. 6d. net.
The Voice of the Sea. Edited by Ingram Swale. Pp. x+163. Price 2s. 6d. net.
The Wayfarer. Edited by Claude E. Benson. Pp. xv+252. Price 2s. 6d. net. (London: George Routledge and Sons, Ltd.; New York: E. P. Dutton and Co.)

THESE three volumes contain good selections of prose and verse. In each case the respective editor has brought together a very interesting collection. Those fond of flowers and gardening will be attracted to the first book named. The poems have been classified, so that it is possible to refer to gardens of various kinds and to their aspect at the different seasons of the year. Some of the references to plant-life exhibit a very accurate knowledge of the less obvious changes it undergoes.

"The Voice of the Sea" is chiefly of interest as a collection of poems dealing with the sea in its many changes and phases; objects of marine interest are in some cases referred to, but in few instances is expression given to more technical thought in connection with them.

"The Wayfarer" is a miscellaneous collection referring to the seasons, the times of day, and touching on many things dealing with wild life and nature. The poems are brought together under various headings, and the book should be of interest to many readers.

The Relation of Man to the Animal World. By Sir Samuel Wilks, Bart. Pp. 34. (Hampstead: The Priory Press, 1907.) Price 1s. net.

WE find ourselves somewhat at a loss to discover the object and aim of this "booklet," which is based on an address by the author delivered some few years ago before the Church Congress at Folkestone. The subjects discussed, or rather, perhaps, mentioned, include the killing of animals for food, clothing, &c., and sport, their maltreatment for the sake of fashion, the use of eggs and milk as nutriment, castration and vivisection, and the rearing of animals in domestication. Although incidentally recording his objection to some of our methods of treating animals, the author (who is an eminent medical man) is in no sense a fanatic or a faddist, taking up for the most part what may be best described as the equivalent of an "agnostic" position. He remarks, for instance, on the concluding page that "if anyone should ask what position I adopt myself towards the animal world, I can say no more than that I submit tacitly with others to the present arrangement, which our forefathers have made for us." Such a very tame conclusion seems to cut away the whole *raison d'être* of the book, which is neither a stalwart defence of present conditions such as can be used against the ultra-humanitarian school, nor an advocacy for reform. On the whole, it seems to us likely to do more harm than good.

R. L.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Regnault's Experiments on the Joule-Thomson Effect.

THAT Regnault made a number of experiments similar to some of those described by Joule and Kelvin in their papers on the thermal effects of fluids in motion does not seem to be commonly known; at all events, the numerical results of his work on this subject are not often mentioned. After experimenting on the flow of gases through small holes in thin plates, and through long capillary tubes, he followed the example of Joule and Kelvin in using porous bodies, especially discs and tubes of soft, unglazed porcelain. He found great difficulty in getting definite results, especially in the regard that the temperature observed in the stream of gas issuing from the porous wall depended on the position of the thermometer. He concludes the account of his experiments in the following words:—"Après ces tentatives infructueuses et beaucoup d'autres dont je ne parlerai pas, j'ai renoncé à l'espoir d'obtenir quelque chose de précis, d'expériences fondées sur la mesure de températures dans les courants gazeux, et il ne m'est resté que le regret d'avoir consacré beaucoup de temps à des recherches stériles" (Regnault, "Relation des Experiences," vol. iv., p. 707, 1870).

At the present day we can see that Regnault's experimental method was not in this case the best that might have been devised, but in spite of his dissatisfaction with the results of the work, his most definite numerical values are not very different from those of Joule and Kelvin. Air under pressure was forced through the wall of a porous porcelain tube from the outside. The tube was 20 cm. long and 2·8 cm. in diameter, the thickness of the wall not being stated. The fall of temperature Δt was found in two ways. In the first method, one mercury thermometer was placed in the axis of the porous tube, while a second thermometer was immersed in the large water bath containing the worm for leading in the compressed air. In the second method an iron-copper thermocouple was used, one junction being in the axis of the porous tube and the other in the compressed air just outside. The results of the thermoelectric measurements are somewhat irregular, and it seems probable that the fault was mainly with the imperfect electrical instruments of the time. The two series with the mercury thermometers are more satisfactory.

In one of these, the mean of eleven measurements in which the fall of pressure, Δp, at the porous wall was between 4·9 metres and 3·9 metres of mercury, gave $\Delta t/\Delta p=0{\cdot}293$, the separate values ranging from 0·285 to 0·303. Nine subsequent measurements in the same series gave values ranging from $\Delta t/\Delta p=0{\cdot}407$ for $\Delta p=3{\cdot}1$ metres up to 0·685 for $\Delta p=0{\cdot}65$ metre and then down to 0·312 for $\Delta p=0{\cdot}30$ metre. In the other series, made with a somewhat thinner-walled tube, the mean of the twenty-two measurements, in which the fall of pressure was between 6·6 metres and 3·4 metres, gave $\Delta t/\Delta p=0{\cdot}255$, the extreme values being 0·234 and 0·313, while twelve of the twenty-two values are between 0·250 and 0·260.

It is interesting to compare the mean of these values, $\Delta t/\Delta p=0{\cdot}27°$ C. per metre of mercury, with the value obtained by Joule and Kelvin. Their results may be represented sufficiently well, in the same units, by the equation

$$\Delta t/\Delta p=0{\cdot}36-0{\cdot}0017t,$$

which gives for $t=20°$ C. $\Delta t/\Delta p=0{\cdot}33$. Regnault does not state the temperature at which his experiments were made, but it was probably not far from 20°, so that in reality his work agreed fairly well with that of Joule and Kelvin.

EDGAR BUCKINGHAM.

Bureau of Standards, Washington, August 27.

Genetics.

IN a recent review of the report of the third International Conference, 1906, on Genetics (NATURE, August 22, p. 417), the following sentence occurs:—"Mendel's peas have already been called classical; and it is a very remarkable fact that no one has repeated Mendel's experiments with the deliberate intention of testing the Mendelian interpretation of the results." This statement is misleading, for in the following five instances many of Mendel's experiments on the pea have been repeated and confirmed:—

Correns, C., *Deutsch. Bot. Gesellsch.*, 1900.

Tschermak, E., *Zts. f. d. landw. Versuchsw. in Osterr.*, 1900 (and later).

Hurst, C. C., Journ. R. Hort. Soc., 1904.

Lock, R. H., Ann. R. Bot. Gard., Peradeniya, 1904.

Bateson, W., and Miss Killby, Rep. II. to Evolution Committee of Roy. Soc., 1905.

In each case the experimental results have led the author to accept Mendel's interpretation of the phenomena.

R. C. PUNNETT.

Gonville and Caius College, Cambridge, August 30.

THE sentence which Mr. Punnett quotes from my review is not in the least misleading. I did not say that Mendel's experiments had not been "repeated and confirmed"; I said that they had not been repeated with the deliberate intention of testing the interpretation which Mendel put upon them. This statement I repeat, and shall shortly prove to be correct. I am familiar with the work of the five authors in Mr. Punnett's list (which surely should have included a reference to de Vries's papers), and, what is more, I have a first-hand acquaintance with the facts themselves.

I do not doubt for one moment the correctness of Mendel's results, as my critic implies in his sentence which follows the quotation from my review. I do not doubt, as Weldon did, the validity of the generalisation that yellowness of cotyledons in peas is dominant over greenness, or that these characters segregate in Mendelian fashion in F_2. I do not doubt the reality of the phenomena in any of the cases described by the authors whom Mr. Punnett cites any more than I doubt the reality of the results which I have myself obtained; but does that mean that I must accept the Mendelian interpretation of them? Certainly not. The Mendelian phenomenon is a fact; but the Mendelian interpretation is an inference, and it is dangerously misleading not to lay stress on the distinction between the two.

What I mean by "testing the interpretation" is the carrying out, by one who is actively sceptical of Mendel's hypothesis, of an experiment of such a kind that the result can leave no doubt in the mind of the experimenter as to the validity, or otherwise, of the hypothesis tested. I will suggest an experiment. The proportion 75 per cent. yellow, 25 per cent. green, holds good for F_2 from crosses between pure strains of yellow-seeded and pure strains of green-seeded peas; but does it hold good for F_2 from crosses between a pure yellow *and an extracted green in* F_5, *i.e.* a green with all its parents yellow, and with all its grandparents yellow, and with all its great-grandparents yellow, and with all its great-great-grandparents yellow, and with half its great-great-great-grandparents yellow? If Mendel's interpretation of the proportion he obtained in F_2 (75 per cent. yellow, 25 per cent. green) is correct, that proportion must hold good for F_2 from such a cross as I have suggested.

When I say that "no one has repeated Mendel's experiments with the deliberate intention of testing the Mendelian interpretation," I mean that crucial experiments on the lines of that which I have suggested have not been carried out by sceptical observers. I know perfectly well that Mendel's experiments have been repeated on a large scale, that alleged exceptions have been satisfactorily disposed of, and that a number of new Mendelian characters have been discovered, not only in peas themselves, but in a host of other plants and animals. But that is not testing the interpretation; it is witnessing the phenomenon. "In each case," says Mr. Punnett, "the experimental results have led the author to accept Mendel's interpretation of the phenomena." Surely he must follow willingly who can be led by so slender a thread.

THE REVIEWER.

ARCHÆOLOGICAL DISCOVERIES IN EGYPT.

THE progress of archæological discovery in the Near East goes forward steadily without halt. Every year more is added to our knowledge of the ancient peoples of Greece, Egypt, and western Asia; with each year we have only to await the surprises that the excavators have in store for us. Egypt has contributed some very important results this season, in two remarkable discoveries at Thebes. One of these is a find of the highest interest which will appeal to the minds of all, even those entirely ignorant of archæological science; this is the discovery of the actual body of Tii, one of "the most famous of Egyptian queens," lying in her tomb, with her funeral pomp around her. The other is a discovery which will appeal more to the architect and the student of Egyptian religion than to the layman—the uncovering of the subterranean "tomb-shrine" of King Mentuhetep, and the pillared halls above it, at the western end of his funerary temple, the excavation of which has been brought to a close by this final discovery.

Both these discoveries were announced in the *Times* some time ago, but readers of NATURE may like to hear further details.

Thirty years ago nobody would have thought it possible that we should eventually recover and place in one central museum the actual bodies of all the most powerful Pharaohs of Egypt, the actual mummies of three whole dynasties of kings. But this is now the case. With but few exceptions, the mummies of all the monarchs of the eighteenth, nineteenth, and twentieth dynasties, the most imperial period of Egyptian history, now rest within the walls of the Cairo Museum. Some have been unrolled, others have not. It seems doubtful whether the actual features of these dead princes should be exposed to the gaze of every vulgar tourist, who very often has no appreciation whatever of the wonder of the sight which he is beholding; and very probably a more reverent taste will eventually withhold these august bodies from the indignity of public exhibition in glass cases. But at present those that have been unrolled may be seen by all for a shilling.

The chief discovery of royal mummies was the well-known one of 1881. In 1898 a further series was discovered in the tomb of Amenhetep II. (the only king who rests, as all should do, still in his own sepulchre). Of late years the systematic exploration of the Valley of the Tombs of the Kings has been undertaken by an American, Mr. Theodore M. Davis, who has each year made some discovery of importance. To him is due the opening of the tombs of Thothmes IV., with its interesting funerary furniture, of Hatshepsu, of Siptah, of Iuaa and Tuaa, the parents of Queen Tii, and, lastly, of Queen Tii herself. In the discovery of the first two tombs mentioned above, Mr. Davis was assisted by Mr. Howard Carter, then chief inspector of antiquities at Thebes; the discovery of the tomb of Iuaa and Tuaa was effected with the cooperation of Mr. J. E. Quibell, Mr. Carter's successor at Thebes; while in the discovery of the tombs of Siptah and Tii Mr. Davis had the help of Mr. Edward R. Ayrton, who had previously assisted Prof. Petrie at Abydos and Ehnasya and Prof. Naville at Deir el-Bahari.

Of all Mr. Davis's discoveries, that of the tomb of Iuaa and Tuaa, the parents of the queen whose grave was found this year, is the most important from the scientific standpoint. Not only were the mummies in absolutely perfect condition, but the tomb was found full of an incredible treasure of funerary furniture and other work in wood, ivory, and gold, which has become well known from various popular publications during the last two years, and has already provided many new models to our cabinet-makers. But a greater personal interest attaches to the tomb of their daughter, the Queen Tii, and more general attention has been directed to this discovery than to the former one, although, alas! the body of the queen has decayed, and nothing but the grinning skull remains which once was clothed with the most beautiful features and contained the cleverest brain in Egypt about 1400 B.C. The furniture, too, of the tomb is not in such good preservation, and, indeed, never was so fine, as that in the tomb of Iuaa and Tuaa. But personal interest is great nowadays, and Tii is more interesting than her parents.

Like the rest of the royal tombs, that of Tii was found in the Valley of the Tombs of the Kings at Thebes, "the Place of Eternity" as the Egyptians called it, where, in his "August Habitation of the West," a deceased king was laid to rest, "no man seeing, no man knowing," that tomb-robbers might not find the position of the grave and despoil it of

FIG. 1.—The Valley of the Tombs of the Kings, taken by moonlight.

its treasures (Fig. 1; photograph taken by moonlight).

But neither Tii nor, possibly, her parents had originally been buried in the Theban valley. Tii belonged, as is well known, to the heresy of the Disk-worshippers, of which her son Khuenaten was so vigorous an adherent. To her more than to any other person was probably due the introduction of this heresy as the fashionable religion of the royal court, and she instilled the principles of her peculiar belief into the mind of her son, who became a fanatical persecutor of the national orthodox religion, so much so that he removed his court from Thebes, the headquarters of the orthodox priests of Amon, to a far distant spot, the modern Tell el-Amarna. Here Tii lived and died, and was first buried. But after the fall of the Disk-worship and the re-migration of the court to Thebes under King Tutankhamon, these royal bodies were taken from their tombs and re-interred in the King's Valley at Thebes. Queen Tii, like her parents, was placed in a small private tomb of older date, hardly consonant with her royal state, and contrasting greatly with the magnificent royal hypogæa close by (Fig. 2). Here she was hurriedly laid in some confusion, her funerary furniture being incomplete and its parts improperly fitted together. Before leaving the mummy, thus transferred to its final abode, careful erasure was made of every occurrence of the name and figure of the heretic Khuenaten, who had laid his mother to rest at Tell el-Amarna, and had dedicated in her tomb funerary furniture bearing the record of his filial piety. That the transference took place in the reign of Tutankhamon is shown by the discovery in the tomb of seals bearing his name.

Such are the conclusions to which Mr. Ayrton has been drawn by the study of the condition of the tomb, and there is little doubt that they are correct.

The funeral pomp of the queen had been of great splendour and unusual design, but has most unhappily been damaged by water, which at some period unknown has penetrated into the tomb. The result is that most of the woodwork will not bear handling; much, however, including the skull and bones of the queen, has been preserved by means of boiling paraffin wax, which soaks into the porous substance to which it is applied and solidifies it. Of great splendour must undoubtedly have been the

FIG. 2.—The Tomb of Tii.

great catafalque, in the form of a shrine, which covered the coffin of the queen instead of a sarcophagus. This, on which are delicate reliefs, was entirely overspread with thick gold, the remnants of which filled the tomb, so that everywhere the excavators trod upon gold when they entered. Of unusual design was the actual coffin, the woodwork of which was covered by a frame of gold, inlaid with carnelian and with blue and green glass in scale patterns and the forms of hieroglyphs recording that Khuenaten had had it made for his mother. The mummy itself, the lamentable condition of which contrasts so strongly with the splendid preservation of the mummies of Iuaa and Tuaa, was wrapped in sheets of gold. On the head of the mummy was a golden diadem in the form of a vulture with wings spread round to embrace the head. The workmanship of this diadem shows that it is merely a funerary object, and was not an actual crown worn by the queen in life.

Of the other objects found in the tomb, the most important are the "canopic jars," which contained the mummified viscera of the deceased. Usually the lids of these jars are formed in the shape of the heads of the "four genii of Amenti" (the underworld); but in this case the heads are those of the dead queen herself, beautiful portraits in alabaster, with the eyes and brows represented in lapis-lazuli and obsidian. As portraits, these heads are remarkable, and evidently are accurate likenesses of the queen.

Of other funerary furniture there was little, the reason being that it had been left behind at Tell el-Amarna.

Such is the most remarkable discovery of the year in Egypt. The completion of the excavation of the funerary temple of King Mentuhetep at Deir el-Bahari, not far off, naturally makes a bad second in point of view of general interest, but is of much greater scientific importance to the student of Egyptian architecture and religion.

The explorations which have been carried out during ten seasons at Deir el-Bahari by Prof. Naville for the Egypt Exploration Fund have now been brought to an end with the completion of the excavation of the Eleventh Dynasty temple (see NATURE, vols. lxx., 1904, p. 155; lxxiii., 1906, p. 468). Four seasons have been occupied with this work since the discovery of this temple by Prof. Naville and Mr. H. R. Hall, of the British Museum, in 1903. For part of each season Mr. Hall has been associated with Prof. Naville as his principal assistant and coadjutor, while Mr. C. T. Currelly has also assisted during the whole of the last two seasons' work, taking the place of Mr. E. R. Ayrton, who assisted during the second season, but has since transferred his energies to the work of excavating the royal tombs, as we have seen above. During the fourth season Mr. M. D. Dalison also worked as a regular member of the Fund's staff, having in the preceding year worked as a volunteer. In the second season Mr. H. Garnett-Orme, and in the third and fourth Mr. J. T. Dennis, also volunteered their assistance. The preparation of the plans has been carried out by Messrs. C. R. Peers and Fatio, under the supervision of Mr. Somers Clarke; and Madame Naville has specially undertaken the work of piecing together the fragments of sculpture, a task which demands much study.

The work of the third season (1905–6) was chiefly notable for the discovery of the remarkable Cow of Hathor in her shrine, now in the Museum of Cairo. This was the most sensational archæological discovery in Egypt last year, as the find of Tii's tomb is the most sensational discovery this year. Nothing so sensational has been discovered in Mentuhetep's temple this year, though the results of the work are archæologically important. At the extreme western end of the temple, immediately beneath the cliffs of Deir el-Bahari, is a pillared hall, of ten rows of eight columns each, at a slightly higher level than the rest of the temple. Within this is a small *cella* or *sekos*, which contains a white limestone altar, of unusual form—square, with a circular depression on its surface, on to which libations were poured. This altar is placed in front of a niche in the rock, which formerly contained a stone shrine.

The whole of this Western Pillar Court, with the *cella*, is placed above the most remarkable feature of this part of the temple—the Tomb-sanctuary of the *ka* of King Mentuhetep. This is to all appearance a rock-cut royal tomb, like those of the Valley of the Kings. It descends in the regular way at a gentle slope for a distance of 450 feet until a chamber is reached, faced with splendid granite blocks like those of the Pyramids, and containing an alabaster shrine in which once stood a statue of the king. In M. Naville's view the monarch himself was not buried here; this was a sort of imitation tomb, made for the statue of his *ka*, and perhaps commemorating his deification at the time of his jubilee, the "Festival of the End," or *heb-sed*; when, before he could be regarded as a god, the king had to be temporarily regarded as dead, in which case a funerary chamber might be built, and

FIG. 3.—West End of the XIth Dynasty Temple, Deir el-Bahari, showing descent to tomb-sanctuary.

even an elaborate tomb constructed, long before his real death, when the real tomb would be built. The real tomb of King Mentuhetep seems to have been within the bounds of the temple. In the south-west corner of the western hall was excavated a small tomb containing a great alabaster sarcophagus which probably once contained the body of King Mentuhetep. This may have been the real tomb, in an in-

FIG. 4.—The two Temples of Deir el-Bahari, from the south.

conspicuous spot. The imitation tomb descended with a great open dromos in the sight of all men in an open court between the Western Hall and the Pyramid (Fig. 3).

All this constitutes a considerable addition to our knowledge of Egyptian architecture and archæology, and the authorities of the Egypt Exploration Fund are to be congratulated on having brought their great work at Deir el-Bahari (Fig. 4) to a successful conclusion.

Of other work in Egypt, the most successful seems to have been that of the Oxford archæologist, Mr. Randall-Maciver, for the University of Pennsylvania. Mr. Maciver has been excavating town-ruins of the XVIIIth and XXVIth Dynasties near Amada, in Nubia, and in the XXVIth Dynasty town has found remains of a peculiar art, very un-Egyptian in type, and showing points of contact with that of Greece. The painted pottery is especially remarkable. This art would seem to be of native Nubian origin, influenced perhaps by Naukratis; Naukratite wares could easily be sent up the Nile into Nubia. We await further details of this discovery with interest.

Excavations at Alexandria have resulted in the discovery, near Pompey's pillar, of some fine sphinxes; one, headless, of the reign of Horemheb (XVIIIth Dynasty), and two others, made of fine white limestone, of the Ptolemaic period (Fig. 5).

At Asyût Mr. D. G. Hogarth has discovered and excavated many new tombs of the XIth and XIIth

FIG. 5.—Sphinx discovered at Alexandria.

Dynasties, with the usual funeral furniture, of model boats, granaries, and so forth, like those found by Prof. Garstang a few years ago at Beni Hasan.

Prof. Garstang and Mr. Harold Jones have been exploring cemeteries of the XIIth Dynasty and the Roman period at Abydos with success.

Outside Egypt, the chief discovery of the past year of interest to Egyptologists has been Prof. Winckler's find at Boghaz Köi, the ancient Pterion, on the Halys, of cuneiform tablets containing the records of diplomatic intercourse between the kings of the Khattê or Hittites, whose capital Pterion was, and King Rameses II. of Egypt. We already knew from the Egyptian records that Khetasil of the Hittites and Rameses of Egypt made an extradition treaty according to which criminals of either country were to be given up by the other, but now we have some of the correspondence between the two courts, found on the Hittite side. In these tablets the Egyptian king is spoken of as "*Ramases mai-Amana satep-ni-riya.*" This transcription of the Egyptian name is interesting, as giving us an approximate idea of how the Egyptians pronounced the name which we conventionally write "Rameses meri-Amen setep-en-Rā." This find is a second discovery of Tell el-Amarna letters, and may prove equally important!

In connection with the relations between Rameses II. and the Hittites, an interesting little discovery may be chronicled. Last year Prof. Breasted, copying the inscriptions of the temple of Abu Simbel in Nubia, read through again the inscription which records the marriage of Rameses with the daughter of the Hittite king, contracted in order to cement their alliance. In the course of reading he came across a new word, which he identified as the Egyptian expression for *snow*; this word reads *selg*, which is evidently the Semitic *telg*, "snow" or "ice," which we have adopted to express the substance *talc*. Rameses is speeding the Hittites on their homeward way, and hopes that they will not be troubled by snow in the Lebanon passes. Hot Nubia was a curious place in which to find and first identify the hieroglyphic word for "snow"!

SCIENCE AND GOVERNMENT.

THEORETICALLY at least most observers admit that the adoption of the scientific method in the management of the affairs of State is a preliminary necessity if national efficiency is to be secured. The Secretary of State for War notably has urged again and again that we cannot expect as a people to compete successfully with other nations, whether in peace or war, unless like them we learn to take advantage of the assistance which science and men of science are able to offer.

It is only in recent years that it has begun to be understood in how many directions the methods of science are applicable. No longer is it imagined that the plan of inquiry which has proved so successful in probing the mysteries of the material universe is suitable only in the laboratory and observatory. The adoption of similar lines of approach in the study of history, language, economics, education, and other subjects at one time thought to have nothing in common with science has resulted, indeed, in unprecedented progress in all of them. So, too, in recent times industry and commerce have come under the same influence with beneficial results. The spirit of scientific research, in fact, is beginning to dominate most forms of intellectual activity.

There is growing evidence, also, that politicians in most countries are beginning to realise that statesmanship is no exception to this rule, but, like other skilled labour, is most satisfactory when conducted on scientific principles. But whether British statesmen appreciate this truth to the same extent as those of other great nations is a matter of grave doubt. Their education generally has been of such a character as to leave them with a colossal ignorance of science and scientific methods; and it is only by overcoming the bias received at the public school and university that most of them come to understand the modern outlook. One of the results of the regard in which science is held by legislators is to be found in the amount of money they vote from the public funds for scientific purposes, and it is consequently possible to institute a comparison between the importance attached to scientific investigation by statesmen in the United States on one hand, and in the United Kingdom on the other.

"The Digest of Appropriations for the Support of the Government of the United States for the Service of the Fiscal Year ending June 30, 1908," recently published in Washington, provides detailed information as to the amounts voted by Congress to enable American statesmen to secure the best scientific assistance in the different Government departments. Similarly, the various estimates—for the Army, Navy, Civil Services, &c.—ordered to be printed by the House of Commons, and procurable from Messrs. Wyman and Sons, Ltd., give full particulars as to the provision made by the House of Commons, at the suggestion of the Chancellor of the Exchequer, for similar help during 1907–8 for the British Government.

In the following comparison no reference is made to educational establishments for the technical training of soldiers and sailors or to the grants made to colleges and universities. This subject has been exhaustively treated in these columns on more than one occasion. The intention here is to compare the amounts set aside in the two countries for scientific investigation with a view to the application of the results to matters of national importance. Some amounts may have been overlooked, but it is believed that every sum of importance, so far as the comparison is concerned, has been included.

To begin with the United States, it will be best first to state simply, under the headings as they occur in the official volume from Washington, the amounts voted for various purposes, and then to explain more fully the specific purpose of the grant in cases where it seems necessary.

Table I.—United States.

Office of Experiment Stations:	
Agricultural Experiments...	213,400
Nutrition Investigations	1,000
Irrigation Investigations	30,000
Weather Bureau	280,710
Department of Commerce and Labour.	
Coast and Geodetic Survey	198,000
Bureau of Fisheries	134,000
Total	2,740,360

Most of the items included under the Smithsonian Institution explain themselves, but it is worth while to say that the grant to American ethnology is "for continuing ethnological researches among the American Indians and the natives of Hawaii." The grant of a quarter of a million pounds sterling to the National Museum is stated to be for the completion of the construction of the building.

As regards the last two items under "Surveying Public Lands," the first is explained to be for "the analysing and testing of the coals, lignites, and other mineral fuel substance belonging to the United States, in order to determine their fuel value," and "for the purpose of increasing the general efficiency or available supply of fuel resources in the United States." The grant for testing structural materials is similarly "for the investigation of structural materials belonging to and for the use of the United States, such as stone, clays, cement, and so forth."

The Bureau of Animal Industry was instituted "to enable the Secretary of Agriculture more effectually to suppress and prevent the spread of contagious and infectious diseases of live stock, and for other purposes." The duties of the Bureau of Plant Industry cover every part of scientific agriculture so far as plant life is concerned. In the same way, the Forest Service includes every aspect of scientific and economic forestry; and each of the departments under the heading agriculture deals in a like comprehensive spirit with the branch of science with which it is identified. The other items are sufficiently explained by their titles.

Chronometers	2,393
Contributions to Scientific Institutions...	625
Total	242,863

The second table will explain itself to most readers of NATURE, but one or two variations in the amounts which have been introduced during the year deserve a few words of comment. The Royal Society grant is 425*l.* less than in 1906–7, and the reason is chiefly that the grant in aid of new buildings and equipment for the National Physical Laboratory was this year reduced by 5000*l.* The grant-in-aid of salaries and other expenses of the laboratory was increased by 750*l.* The grants to the society for scientific investigations undertaken with the sanction of a committee appointed for the purpose and for scientific publications has undergone no change, and remains at 5000*l.*

The grant towards the expenses of the Meteorological Office shows an increase of 200*l.*; that towards the expenses of the Royal Society of Edinburgh an increase of 300*l.*, or, in other words, the grant was doubled this year; that to the Royal Irish Academy an increase of 400*l.*, the increase being intended to provide for the cataloguing of Celtic MSS. now in the custody of the Academy; that to the International Geodetic Association an increase of 119*l.* to pay the expenses of the British delegate in respect of his attendance at the conference of the association held in 1906. The contribution to the International Seismic Association, however, shows a decrease of 40*l.*

As regards the grants enumerated under the heading "Temporary Commissions," the detailed estimates show that the amount received on behalf of the Commission on Sewage Disposal shows an increase for the year of 250*l.*, and that the total sum of 3750*l.* is expended in the remuneration and expenses of bacteriological and chemical experts and their assistants, apparatus, and so on. The amount voted for the Tuberculosis Commission represents a decrease of 675*l.* on the amount of the grant for the previous year, though why the "expenses of experimental farms, buildings, and laboratories, the remuneration of scientific experts, &c., should be less this year is not made clear. The Committee on Epizootic Abortion received an increased grant of 260*l.* this year towards its work of inquiring, "by means of experimental investigation and otherwise, into the pathology and etiology of epizootic abortion," and this year's grant of 1110*l.* covers the expenses of the experimental farm, buildings, and laboratory. The Mines Commission, which was appointed on June 6, 1906, receives its grant of 1000*l.* for experimental work.

To sum up, the State grant for the current year towards scientific research in the United States amounts approximately to two and three-quarter millions sterling, that in the United Kingdom—allowing generously for items which may have been missed in examining the estimates—reaches a quarter of a million sterling. The revenue of the United States for 1906 reached the total of 152,477,381*l.*, and that of the United Kingdom 143,977,575*l.* In broad terms, therefore, it may be stated that with approximately the same revenue the United States attaches eleven times as much importance to scientific assistance as the mother country of Newton, Darwin, Maxwell, Kelvin, and a great host of other scientific pioneers. Who shall say that there is to-day no need for missionary enterprise on the part of the British man of science?

A. T. S.

NOTES.

Successful trials were made with the British military airship at Farnborough on Tuesday. The airship is cylindrical in shape, its length being about 100 feet and diameter 30 feet. Four bands which encircle the cylinder support a light framework under which the car of the balloon is suspended. The motor driving the propellers is fixed in the forepart of the car, and in the stern of the framework there is a large six-sided rudder, which is controlled by rudder lines from the car. Above the car are six aëroplanes, three over the bow and three over the stern. The trials on Tuesday demonstrated that the airship could be controlled and steered in a very satisfactory manner; and the success attained shows that real advance has been made in aëronautics during the past few years.

Official announcement is made that on and after September 26, the colony of New Zealand and the territory belonging thereto will be called and known by the title of the Dominion of New Zealand.

Science states that Prof. J. J. Stevenson, of New York University, and Prof. W. M. Davis, of Harvard University, are among the Americans who will attend the celebration of the centenary of the foundation of the Geological Society of London at the end of this month.

It is stated in the *Engineer* of September 6 that the deepest bore-hole put down for coal in Great Britain has just been completed at Cameronbridge, Fifeshire. The bore-hole attained a depth of 4534 feet before the mountain limestone was reached. At the instigation of the Scottish Geographical Society, steps are to be taken to ascertain the earth temperature at the bottom of the bore.

A Reuter message to Winnipeg from Athabasca Landing reports the loss near Fort Anxious of the *Duchess of Bedford*, the vessel of the Anglo-American Polar Expedition under Captain Ejnar Mikkelsen. The expedition sailed from Victoria on May 20, 1906, with the object of exploring the unknown regions lying to the west of the Parry Archipelago, and of discovering whether there was land to the north of the Beaufort Sea. Though the vessel is lost, a message received on September 7 from Mr. V. Stefansson, the ethnologist of the expedition, reports "Expedition all safe." The telegram was sent to the U.S. National Geographic Society from Eagle City, Alaska, on the Upper Yukon River.

A committee to inquire into and report upon certain matters relating to the improvement of forestry in Ireland has been appointed by the Vice-President of the Department of Agriculture and Technical Instruction. The committee consists of the following members:—Mr. T. P. Gill (chairman), Lord Castletown, Mr. W. Redmond, M.P., Rev. D. Kelly, Lord Bishop of Ross; Mr. H. de Fellenburg Montgomery, Mr. W. F. Bailey, Mr. W. R. Fisher, and Prof. J. R. Campbell. The terms of reference are to inquire into and report upon the following matters relating to the improvement of forestry in Ireland, viz.:—(1) the present provision for State aid to forestry in Ireland; (2) the means whereby in connection with the operation of the Land Purchase Acts existing woods may be preserved, and land suitable for forestry acquired for public purposes; and (3) the financial and other provisions necessary for a comprehensive scheme of afforestation in Ireland.

The Rome correspondent of the *Times* states that the palace which is being erected for the International Agricultural Institute in the gardens of the Villa Borghese is rapidly approaching completion, and before the end of September will be roofed in. Invitations for the meeting of the permanent committee and for the inauguration of the institute will probably be issued in the course of November next, and with the first meeting of the committee in the spring of next year the institute will enter upon its career of activity. The Italian Royal Commission has appointed Prof. M. Pantaleoni to superintend an inquiry for the purpose of ascertaining exactly the extent of the information which the different countries that have adhered to the convention are in a position to supply with regard to their agricultural production. Prof. Bodio, of the General Bureau of Statistics, has been entrusted with a mission to Germany and Austria to study on the spot the systems pursued by those countries for the collection of agricultural reports.

The latest example of the close connection between science and industry in Germany is afforded by the foundation of an institute for milling research in the Seestrasse, Berlin, adjoining the two already well-known institutes for research in the sugar and fermentation industries. The new institute was formally opened on July 30; it consists of a main building containing the administrative offices and laboratories, together with an experimental granary, a wheat and rye mill, and a bakery. The granary has a storage capacity of more than one million kilos., and the dimensions of the elevators, conveyors, and other apparatus and machinery are such that 17,500 kilos. of grain per hour can be dealt with. The mill is electrically driven throughout, and fitted with the most modern machinery; it contains two complete separate plants, each capable of milling two tons of grain every ten hours. The bakery is similarly fitted with the latest improvements of bakehouse machinery, and contains a laboratory. The institute was built out of a grant of nearly 30,000*l.* from the Minister of Agriculture, who also gives a yearly subsidy; it is carried on and maintained jointly by the Prussian Chamber of Agriculture, the German Millers' Union, and the Central Bakery Union of Berlin. The objects of this research institute as set forth in the contract with the Minister of Agriculture are of interest. It is proposed to carry out practical research and scientific investigation on grain during storing, milling, working up and baking; to experiment with the baking of home and imported grain; to conduct research work for the Government, and to carry out official and private analyses of grain, flour, fodder stuffs, &c., thereby supplementing the income. Everything has been done to ensure a proper and complete investigation of the many problems which the milling and baking industries present. It is of interest to contrast this new sign of German thoroughness with the state of things in this country, where it is left to private enterprise to initiate research. Thanks, however, to the work of the Home-grown Wheat Committee of the National Association of British and Irish millers, in cooperation with the Rothamsted Experimental Station and the Agricultural Department of the University at Cambridge, much valuable work on problems connected with wheat and flour has been and is being carried out in this country.

We have received the report of the meeting of inspectors of apiaries (U.S. Department of Agriculture, Bureau of Entomology, Bulletin No. 70). It contains much information respecting the diseases of bees; in particular, the American and European foul broods are discussed as regards ætiology and prevention.

FROM the Economic Proceedings of the Royal Dublin Society (vol. i., part ii., August) has been reprinted, as in previous years, a very valuable report on some of the injurious insects and other animals observed last year in Ireland, and reported on by Prof. Carpenter. The report consists of only thirty-one pages, and yet is full of new, interesting, and important matter, and such that one can thoroughly rely upon. Amongst the thirty pests reported on, the most interesting is the cabbage stem-borer (*Psylliodes chrysocephala*, Linn.), of which an excellent account of the larva is given, of scientific as well as practical value. Another new pest is dealt with, the long-horned barley-fly (*Elachyptera cornuta*, Fallen) attacking barley in Ireland. A willow beetle (*Phyllodecta vulgatissima*, Linn.), as yet unrecorded as a pest in England, where its place is taken by *P. vitellinae*, is also dealt with, owing to the harm caused by it in Lurgan. Amongst the parasites of domesticated animals, notes are given on the sheep louse (*Trichodectes sphaerocephalus*), known also as the red louse. Prof. Carpenter wisely recommends dipping twice at an interval of ten days to clear the sheep of these pests. We hope he will insist on this necessary treatment also in sheep scab, for just as in red lice so in the sheep Acarus, eggs hatch out some days after dipping, not having been affected by it, and thus the disease is carried on, and dipping "orders" lose much of their value. Amongst other pests mentioned we note the lackey moth in the south of Ireland, small ermine moths in Waterford County, mussel scale attack, the turnip moth (*Agrotis segetum*) feeding on mangolds in Queen's County, the beet carrion beetle in County Wicklow, and the pine bark beetle in County Dublin. There are eleven figures in the text, three being original, and six plates, two excellent ones giving details of the larval *Psylliodes chrysocephala* and damage caused by it. A plate (xli.) showing the life-history of the lackey moth is given, photographed from a museum preparation; this does not seem to us to give a natural representation of the larvæ feeding, &c.

ACTING on the instructions of M. Maspero, Directeur général du Service des Antiquités, Prof. Elliot Smith removed the wrappings from the mummy of Ménephtah—the Pharaoh engulfed in the Red Sea while in hot pursuit of the Egyptians. From the writing on the shroud, the process of embalming, the resemblance to Rameses II. (Ménephtah's father) and to Seti the Great (his grandfather), there is every reason to believe that M. Maspero is right in the identification of this as the mummy of Ménephtah. From a very thorough examination of the mummy, Prof. Smith infers that Ménephtah at the time of his death was "a somewhat corpulent old man of rather more than medium height (1·714 m.), almost completely bald, with only a narrow fringe of white hairs," with calcareous patches in the walls of his arteries, calcified costal cartilages, and with few remaining teeth. The mummy had suffered much at the hands of plunderers, while there is also evidence that the embalmers had taken liberties with the Pharaoh of the Exodus. Prof. Smith's report appears in the *Annales des Antiquités de l'Egypte*, 1907.

THE first Bulletin for the current year of the Société d'Anthropologie de Paris contains the annual address of the president, M. Zaborowsky, which is mainly devoted to a review of the work in recent years, and to an appeal for the recognition of anthropology as an exact science by "the official hierarchy" of the Académie des Sciences. The most important contribution is that of M. E. T. Hamy, on representations of the human figure in the monuments of ancient Egypt, supplementary to other studies by the author on the same subject. He discusses the influence of the system of hierographs on the attitudes of the figures, which usually face the right, and he reviews the characteristics of the persons depicted by comparison with existing races. Incidentally, he criticises the classification adopted by Prof. Flinders Petrie in his communication on the same subject published in vol. xxxi. of the Journal of the Royal Anthropological Institute. The committee appointed to allot the Broca prizes has conferred the first on M. A. M. Lapique, for his researches on Negro races, and awarded medals and honourable mention to M. A. M. Choquet, for his contribution on teeth with reference to sex and race, and to M. A. M. Fischer, for his investigation of the variations of the radius and ulna.

THE Linnean bicentenary was celebrated in Washington, U.S.A., by a joint meeting of scientific societies, at which Mr. E. S. Greene delivered a Linnean memorial address. In the address, published in the Proceedings of the Washington Academy of Sciences, vol. ix., the author presents a description of Linnæus's chequered career and his associations with contemporaneous European botanists and physicians.

As a method of stocking forest land in dry districts of the Deccan, Mr. L. S. Osmaston recommends a combined system of agriculture and tree planting, which he describes in the June number of the *Indian Forester*. The land is let out to cultivators for two years; after the preliminary clearing, the lessee is allowed to plant the whole area with his crops during the first year, but in the following year is required to sow a proportion of seed for trees. In the case of the experiments quoted, the trees planted were *Melia azadirachta*, *Hardwickia binata*, *Albizzia Lebbek*, and *Tamarindus indica*; the crops cultivated were sesamum, cotton, and Indian hemp. An interesting experiment of planting live teak stakes is recorded by Mr. T. R. Singh. Shoots from the buds developed favourably for two or three months, but subsequently died, as the stakes became rotten before roots were developed.

DR. J. C. WILLIS takes the opportunity afforded by the completion of ten years' service as director of the Royal Botanic Gardens in Ceylon to review the work of that period in his annual report for 1906. In 1897 he discovered the "wound response" of Para rubber trees, that the first tapping leads to an increased yield of latex, and Mr. J. Parkin introduced the system of preparing rubber in biscuit form. Impetus was given to camphor cultivation by Mr. K. Bamber's work on the distillation of camphor. Green manuring and treatment of cacao canker have been profitable subjects of investigation at the experiment station. Cotton cultivation has been tried with some measure of success in the north of the island since 1903. The advances made in these subjects and in the exploitation of numerous minor products, the preparation of practical leaflets, and a considerable amount of scientific research furnish a remarkable record of material progress.

THE methods and objects of keeping land in good tilth are explained in *Irish Gardening* (August), to which Mr. A. D. Hall contributes a practical article, and Prof. J. Wilson also writes on the same subject. The editorial article refers to the passing of the Destructive Insects and Pests Act, and the speedy issue of an order applying to the counties of Gloucestershire and Worcestershire compelling growers to take measures against the gooseberry mildew disease.

In the *Agricultural News* (July 27) particulars are given regarding the efforts that are being made to establish an industry in Sea Island cotton in Tobago; with this object in view seed has been distributed, and a ginnery is in course of erection at Scarborough. In connection with the disinfection of cotton seed with corrosive sublimate in wooden vessels, experiments have shown that the mercury salt is absorbed, so that it is recommended to give the vessels a preliminary soaking before disinfecting the seed with a fresh solution. A note on the exhibition of limes from Dominica records the award of a gold medal at a recent show of the Royal Horticultural Society.

The Engineering Standards Committee has issued the British standard specification for steel castings for marine purposes (No. 30, price 2*s*. 6*d*. net). The present specifications of the Admiralty, the Board of Trade, and the three leading registry societies were carefully compared, and from these the specification has been prepared.

A special number of the *Far Eastern Review* (vol. iv., No. 1) has been published devoted to the mining industries of the Philippine Islands. The important part played by the mineral industry in the American development of the Philippines is clearly shown. In at least one district gold has been taken out in payable quantities, and the development of the coal deposits is making satisfactory progress.

A lengthy paper on the origin of the gold in the Witwatersrand banket, by Prof. J. W. Gregory, is published in the Bulletin of the Institution of Mining and Metallurgy (No. 35). He considers that the theory in best agreement with the facts appears to be that which regards the banket as a marine placer in which gold and black sand (magnetite with some titaniferous iron) were laid down in a series of shore deposits. The gold was in minute particles, and it was concentrated by the wash to and fro of the tide, sweeping away the light sand and silt, while the gold collected in the sheltered places between the larger pebbles. The black sand deposited with the gold has been converted into pyrites, and at the same time the gold was dissolved and re-deposited *in situ*. The absence of conclusive evidence of any considerable impoverishment in depth is an argument in favour of the alluvial origin of the gold, and is favourable to the further extension of the banket in depth.

The facilities provided by liquid air are leading to a rapid extension of our knowledge of the properties of substances at low temperatures. Mr. H. G. Dorsey, of Cornell University, is at present engaged in investigating the coefficients of expansion of solids, and gives in the August number of the *Physical Review* an account of the results obtained for quartz glass, ordinary glass, and several pure metals and alloys. For quartz glass the coefficient is negative below and positive above 190° absolute, remaining very small throughout, while for all the other substances tested it is positive, and increases with rise of temperature. In the case of gold, the curve connecting temperature and coefficient is undulating. The method used by Mr. Dorsey is a modification of Fizeau's, the interference taking place between rays reflected at the top surface of a sheet of black glass, on which a hollow cylinder of the material to be tested stands, and those reflected from the under surface of a sheet of clear glass supported on the cylinder. Temperature corrections are obviated by placing the apparatus in an exhausted chamber.

The merits of aluminium conductors are likely to be freely discussed, owing to the fact that insulated aluminium cables have recently been placed on the market by one of the well-known cable companies. Bare aluminium conductors have been used already in this country and largely used in America, but insulated aluminium cables have up to the present been practically unknown. The difficulty of making sound joints has been the trouble which has prevented a larger use of aluminium for commercial purposes, but this difficulty, it is stated, has been overcome, and both mechanical and "sweated" joints can be made as desired, and the makers claim that the electrical and mechanical properties of the joints are superior to those of the wire itself. Owing to the conductivity of aluminium being only 60 per cent. that of copper, the diameter of the cable carrying the same current is, of course, greater. How this will affect the cost when insulated aluminium conductors are employed still remains to be seen, as no figures are given as yet as to the price as compared with insulated copper cables. A 50 per cent. saving in weight is claimed over copper conductors of the same capacity, with an increase in diameter of 28 per cent. The insulation used is vulcanised bitumen, as being lighter than paper, for the same degree of insulation. Doubtless practical experiments in the use of these cables will now be made, since the jointing difficulties have been overcome, and the commercial utility of insulated aluminium cables will be tested.

The *Electrician* for August 30 contains a note on a new system of wireless telephony described by the inventor, Prof. Majorana, at a recent meeting of the Associazione Elettrotecnia Italiana, which is based on the use of a spark gap. For generating the spark a special rotating arrangement is used, and it is claimed that 10,000 single sparks per second can be obtained. These conditions entailed a special microphone, and the Majorana hydraulic microphone, which depends on the capillary action of fluid jets, answers this purpose. With this microphone Prof. Majorana has obtained telephonic currents of very great clearness and strength. The microphone consists of the usual mouthpiece and of a membrane fixed to a glass tube which moves freely under the oscillations of the membrane, and through which slightly acidulated water flows. A special opening in the tube allows the liquid to pass out and strike the upper surface of two cylindrical pieces of platinum which are insulated from each other. This is called the "collector." On striking the middle of the "collector" the fluid spreads over the surface, making contact permanently between the two halves. If a battery is connected in circuit with a telephone and the "collector," so long as the membrane is not disturbed by sound waves, a constant current will flow. As soon, however, as the membrane vibrates the aperture oscillates and varies the flow of drops, so that the thickness of the fluid on the collector is always altering. Prof. Majorana conducted his experiments with a spark gap, and got some satisfactory results, but at the same time he found that by using the Poulsen arc in nitrogen certain advantages accrued.

The report of the Meteorological Committee for the year ended March 31, 1907, recently presented to Parliament, records great activity in all branches of the useful work of the office, and is more than usually interesting from various points of view. Both the daily and weekly weather reports have been improved; the maps of the former now include *in situ* observations from Iceland and the Azores, and the statistical portion contains observations by wireless telegraphy from commanders of His Majesty's ships. The Icelandic reports are of the greatest value for weather prediction, and the successful inauguration of the service is due in a great measure to the exertions of the Danish Government and the Copenhagen Meteorological Office. The most important change in the weekly report is the inclusion of a table in which the week's warmth, rainfall, &c., for districts are characterised verbally; to obtain this result the weekly values of the various elements for the years 1881–1905 have been re-examined from the point of view of their frequency distribution. The committee notices with satisfaction that the weather forecasts for the year show a considerable increase of accuracy; the percentage of complete and partial success for the whole of the British Isles of the forecasts published in the morning newspapers was ninety-one, or 3 per cent. higher than in any year since they were first issued in 1879. The operations of the marine branch are carried on with great vigour; we have before us the monthly pilot charts of the North Atlantic and of the Indian Oceans for September, 1907, both issued about the middle of August. These charts afford an amazing amount of useful information brought down to the latest time, and although they represent but a small part of the work of that department, their publication monthly at a regular date is of itself a very onerous piece of work. The committee, recognising the importance of observations made in British colonies and dependencies, fully supports a proposal, emanating, we believe, from correspondence between Dr. Shaw and Mr. R. F. Stupart, of Canada, for holding a meeting of colonial meteorologists at Ottawa in 1908, with the view of promoting mutual cooperation in dealing with meteorological questions generally.

THE third volume (pp. x+528), which deals with linguistics, of the Reports of the Cambridge Anthropological Expedition to Torres Straits has now been published by the Cambridge University Press. The volume is by Mr. Sidney H. Ray, and consists of four parts, dealing respectively with the languages of Torres Straits, the languages of Cape York Peninsula, North Queensland, the languages of British New Guinea, and the linguistic position of the languages of Torres Straits, Australia, and British New Guinea. These reports will occupy six volumes, of which the fifth—the first to be completed—dealing with sociology, magic, and religion of the western islands, was noticed in NATURE of June 23, 1904 (vol. lxx., p. 179). The following general linguistic summary gives the results of Mr. Ray's work on the material collected by himself and Dr. A. C. Haddon with the assistance of numerous other workers:—(1) The western language of Torres Straits is Australian. (2) The eastern language of the Straits is morphologically related to the Papuan of New Guinea. (3) There is no genealogical connection between the two languages of the Straits. (4) There is no evidence of an African, Andaman, Papuan, or Malay connection with the Australian languages. There are reasons for regarding the Australian as in a similar morphological stage to the Dravidian, but there is no genealogical relationship proved. (5) The Papuan languages are distinct from the Melanesian. They are in some respects similar to the Australian, but their exact positions are not yet proved. (6) Languages of the Papuan type are found in German New Guinea. There is no direct evidence of their existence in Netherlands New Guinea. (7) There is insufficient evidence to connect the Papuan with the Andaman or Halmaheran languages. (8) In the northern Melanesian Islands a few languages are found which have Papuan characteristics. (9) Differences of grammar and vocabulary which appear in other island languages appear to be remains of an archaic Melanesian speech. There is no grammatical evidence to connect them with the Papuan, but they show the Papuan diversity of vacabulary. (10) The Melanesian languages of New Guinea and those of the islands are closely (genealogically) related in grammar and vocabulary. (11) The Melanesian languages of New Guinea and the islands stand in the same position with regard to the Polynesian. Both the former represent an older and fuller form of speech of which the Polynesian is a later and more simplified descendant.

WITH reference to a note in NATURE of August 29 (p. 449), Prof. B. Brauner asks us to say that the penultimate sentence should read:—"The atomic weight of nitrogen cannot be higher than 14·01 (*not* 14·10) and lower than 14·008 (*not* 14·08), and so the atomic weight of silver must lie between Ag=107·880 and 107·883."

FROM the author, Mr. Angel Gallardo, we have received a copy of a paper from the *Revista de la Universidad de Buenos Aires* devoted to a discussion of the methods of zoological teaching in that University.

WE have received a copy of vol. v., parts xvii. and xviii., of Prof. G. O. Sars's "Account of the Crustacea of Norway," dealing with a section of the copepod family Canthocamptidæ.

THE July number of the *Trinidad Bulletin* contains several notes on cacao, in which varieties, diseases, and pruning are discussed. On the subject of varieties, Mr. J. H. Hart affirms that clear distinctions exist between Venezuelan and Trinidad Criollo, both in the matter of shape and toughness of skin, and refers to the inconstancy of colour inheritance in cacao pods. With regard to the raising of new seedling varieties of sugar canes, the opinion is expressed that it is more advantageous and quite suitable to make a first selection according to the results of cultivation, and subsequently to test the canes so selected for sugar content, thereby saving extensive chemical investigations.

WE have received from Messrs. R. and J. Beck their illustrated catalogue of microscopical apparatus. It should be useful to microscopists, as hints are given on the use of the apparatus figured.

STUDENTS of the mollusca will be interested in the description, by Dr. W. Gadzikiewicz, of the biological station at Sevastopol, in *Biologisches Centralblatt* of August 1, of a new species of doris (*Staurodoris bobretzkii*) from Sevastopol Bay.

THE ovaries of Hemiptera (by Mr. A. Köhler), the nervous and excretory systems of various fresh-water planarians (by Mr. H. Micoletzky), and the tracheal muscles of ephemerids (by Mr. E. Dürken), constitute the contents of vol. lxxxvii., part iii., of *Zeitschrift für wissenschaftliche Zoologie.*

IN vol. lxiii., part ii., of *Verhandlungen des naturhistorischen Vereins der preussischen Rheinlande und Westfalens*, Dr. O. le Roi completes his synopsis of the birds of the Rhine province.

AMONG others, the *Bio-Chemical Journal* for August (ii., No. 9) contains a paper by Dr. MacLean on safranin as a test for carbohydrates. It is concluded that this is one of the most suitable reagents for determining the presence of traces of carbohydrates in liquids.

OUR ASTRONOMICAL COLUMN.

SEPTEMBER METEORS.—September has long been known for the abundance of fireballs which it supplies, and apparently the present month will justify this reputation. On September 3 a large meteor was observed from Redruth and Falmouth, in Cornwall, falling among the stars in the south-east region of Pegasus. On September 7 two fireballs were seen from near Bishop's Stortford. The first of these was observed at 8h. 56m. descending almost vertically a little to the right of the planet Saturn. The other made its appearance at 11h. 22m., but details are wanting.

DANIEL'S COMET, 1907*d*.—Numerous reports of observations and photographs of Daniel's comet are now coming to hand, and show this object to be one of unusual interest.

The *Comptes rendus* for August 26 (No. 9) contains a preliminary description of spectrograms obtained by MM. Deslandres and Bernard. The chief bands shown are those typical of the hydrocarbons and of cyanogen, but there are other, fainter bands which are unfamiliar. An as yet inexplicable difference is noted between the spectrum of the comet's head and that of its tail. A multiple tail 6° in length was shown on a photograph obtained by Mr. Plaskett at the Dominion Observatory, Ottawa, on July 20.

As reported in the *Observatory* for September (p. 364, No. 387), Mr. Melotte photographed the comet with the Greenwich 30-inch reflector on August 10, 11, 12, and 13, and the photographs show a tail some 100′ long with fifteen to twenty streamers. On a small-scale photograph secured with the Dallmeyer R.R. lens on August 13, the tail can be traced for about 7° from the head, its general direction being west. The streamers curve to the south and spread out in a fan-like form.

In No. 4198 of the *Astronomische Nachrichten*, Herr H. H. Kritzinger points out that the earth will, on September 12, pass through the straggling portions, if there be any so far behind the main body of the comet, and that any meteors occasioned by the collision will have as their apparent radiant $\alpha = 23h.\ 8m.$, $\delta = +3°$.

COMET 1881 V.—A note by Mr. Denning, published in No. 387 (p. 363, September) of the *Observatory*, recalls the fact that the return of the periodical comet discovered by him on October 4, 1881, is due this year.

According to Dr. Matthiessen's elements, the period is 8·68 years, and it therefore returned in 1890 and 1899, but its position rendered it invisible. This year its position indicates the same favourable conditions as obtained in 1881, when it was calculated to have been visible to the naked eye in August, before its discovery. The comet is of interest from the fact that at one point in its orbit it approaches to within 3½ million miles of the earth. The following is from a search-ephemeris calculated by Dr. Smart on the assumption that perihelion passage will take place on October 6 next:—

Ephemeris 12h. (G.M.T.)

1907	R.A. h. m.	Dec. ° ′	log Δ	Brightness.
Sept. 12	7 44·7	+17 50	9·897	1·71
,, 16	8 13·6	+17 28	9·912	1·74
,, 20	8 40·8	+16 50	9·930	1·72
,, 24	9 6·6	+15 59	9·951	1·67
,, 28	9 30·9	+14 58	9·973	1·58
Oct. 2	9 53·7	+13 49	9·995	1·47
,, 6	10 15·3	+12 33	0·017	1·34

From this it will be seen that the comet should now (September 12) be about 21m. west of ζ Cancri, and should rise, about 30° north of east, some 5 hours before the sun. On October 3 it will pass a little to the north of Regulus.

THE PARIS OBSERVATORY.—The annual report, for 1906, of Prof. Lœwy, the director of the Paris Observatory, is full of interesting items, of which only a few may be given here. After outlining the present state of the Eros work, the director mentions some instrumental alterations and improvements, and states how satisfactorily a registering micrometer has been found to work used in connection with the Cercle meridien du Jardin. Five hundred and eighty plates of the moon were obtained with the large equatorial *coudé*, and a number of enlargements of other plates have been made for the tenth section of the *Atlas photographique de la Lune*. A number of photometric observations and experiments on atmospheric absorption were carried on by M. Nordmann with interesting and important results, whilst M. Bigourdan continued his researches on the nebulæ. The work on the *Carte du Ciel* proceeds steadily, and 116 enlargements for the chart were prepared during the year; forty-one of these were from Paris, the others from Algiers, Bordeaux, and Toulouse.

THE LATE PROF. S. P. LANGLEY.—No. 1720 (vol. xlix.) of the Smithsonian Miscellaneous Collections is devoted to three interesting addresses delivered, respectively, by Messrs. White, Pickering, and Chanute, at the memorial meeting held on December 3, 1906, "to commemorate the life and services of Samuel Pierpont Langley, secretary of the Smithsonian Institution from 1887 to 1906." Dr. White's address dealt with Langley's work in general, dwelling especially upon his invaluable services to the institution and his ever-readiness to promote the cause of scientific research in every direction. In Prof. E. C. Pickering's address one finds a brief *résumé* of Langley's contributions to astronomy and astrophysics; whilst Mr. Chanute dealt with his work on aërial navigation. An apparently complete bibliography of Langley's published works from 1869 to 1905 is also included in the publication.

THE DISTRIBUTION AND CONTROL OF STANDARD TIME.—A paper of general interest on the subject of time-control is reproduced as an extract from the *Bulletin astronomique* (vol. xxiv.) for May. In it M. Jean Mascart describes the apparatus and method employed for this purpose at the Paris Observatory, discussing each operation separately, and illustrating the text by diagrams of various parts of the system. The causes of accidents and the special artifices adopted for eliminating their possibility form an important part of the paper.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

THE geographical section of the association met at Leicester under particularly favourable conditions, the quarters provided being the airy and spacious assembly rooms in Hotel Street. The meetings were generally well attended, and only in a few cases was any serious falling off in the audience noticeable. The papers were, so far as possible, grouped under the broad subdivisions of the subject, but as some deviations from this arrangement were necessary, in order to suit the convenience of the readers, it will be well here to disregard the strict order, and bring together the subjects of a more or less similar character.

Besides the opening address of the president, Mr. G. G. Chisholm, which has already been printed in full in these pages, several papers dealt with the specially human and economic aspects of geography, which it had been felt desirable to emphasise as suiting well with the industrial activities of the place of meeting. Communications had been received from distinguished exponents of this side of geography both in France and Germany. Prof. Vidal de la Blache, of Paris, whose writings are noteworthy for the admirable way in which they apply the geographical method to the consideration of human relations, was unfortunately unable to be present in person, but his paper, on the geographical evolution of communications, was read in his absence. Starting from the earliest devices evolved by primitive man as aids in the movement of loads, it traced their gradual improvement under varying conditions of local environment, and especially through the adaptation of animal power to purposes of transport; showing how the vast open plains of Central Eurasia, with the peculiar facilities they offered for the employment of the horse and wheeled vehicle, encouraged the movements of peoples, and brought about the development of long-distance traffic, in which the internal commerce of modern States may be said to have itself originated. While the early beginnings of commercial activity were especially dealt with in this paper, the most recent developments of economic geography were the subject of the communication by Prof. Max Eckert, the author of one of the best treatises on that subject which has appeared in Germany. Prof. Eckert pointed out that the geography of mankind, understood as the study of the relations of man to his environment, had really only come into existence within the last few decades. While supplying the one adequate bond of union between the natural and moral sciences, it bases all its considerations on the physical conditions of the earth, and evolves general laws regarding the influence of the soil on man and of man on the soil. Commercial or economic geography, which was more specially considered in the latter part of the paper, was defined as a study in which the earth is viewed as the theatre of human production and commerce, one of its most important tasks being the determination of the factors which govern the occurrence of industrial products, though the methods and apparatus of traffic fall also within its purview.

A third paper on the economic side supplied an example of the application of such general principles to a special problem. It was by Mr. J. McFarlane, of Manchester, who set himself the task of determining the limits of the area served by the Port of Manchester, and the character of the trade so carried on. The inquiry had involved much laborious research, the necessary data being obtainable, if at all, only through correspondence with a large number of individuals or bodies engaged in such trade. The material collected, while not permitting a complete answer to the question, was enough to give some indication of the influence exercised by the ship canal as a factor in the commercial relations of the region behind Manchester—an influence which the reader considered likely to increase with time.

One of the afternoon lectures, that by Mr. Mark Sykes, also dealt with the human side of the subject. The attendance was, unfortunately, somewhat small, owing to the counter-attraction of a social gathering, but those who were present listened to a most graphic account of the Kurdish tribes of Asiatic Turkey, among whom Mr. Sykes has travelled very extensively, and whose intricate subdivisions and varying characters he has studied with great care. The number of the separate tribes is astonishingly great, and they differ, not only in religion and language, but in physique, character, and mode of life. The lecturer traced the regional distribution of the principal main groups, and brought home to the audience the physical characteristics of the people by a striking series of photographs. One other short lecture, by Mr. J. D. Rogers, should be mentioned here. It was entitled "Explorers and Colonists," and traced in an instructive way the various motives which have led men to explore—exploration for exploration's sake being, as the lecturer pointed out, a thing of quite modern growth, unless we go back to the first beginnings of travel, and place men like Ulysses in the category of explorers pure and simple. Mr. Rogers spoke of the influence exercised by the imagination in sending the early explorers into remote corners of the world, and traced the connection which in later times grew up between exploration and colonisation.

The mathematical side of geography, which had received attention, outside Section E, both in the address of Sir David Gill and in that of the president of Section A on the figure of the earth, was represented within the section by two papers, both dealing with survey work in Africa. Major Close, R.E., gave a lucid outline of the present state of the official surveys in the several British possessions, showing what a large amount of excellent work is being carried out, often under great difficulties. Captain Behrens, R.E., spoke more especially of the methods of survey adopted, illustrating his subject by instances from special surveys, particularly that of the southern frontier of Uganda, in which he had himself taken part. He also showed upon the screen a number of views in the Ruwenzori range, taken during the expedition of the Duke of the Abruzzi.

Three papers only were concerned with physical geography pure and simple, which it is the modern tendency to leave more and more to the geologist, so far as studied independently of its bearing on man's activities. Prof. J. W. Spencer, who for many years has devoted his attention to the recession of Niagara, put before the meeting the results of his latest survey, carried out some two years ago on behalf of the Geological Survey of Canada. This has permitted conclusions as to the rate of recession since the date of earlier surveys, and Prof. Spencer finds that this rate is more variable than has been supposed, much depending on the shape of the crest at the time and the varying manner in which the rock is worn away. He has endeavoured to trace the state of affairs in the days of the early visitors to the falls, such as Hennepin, and has found what he considers must have been an old channel of the river in their time. He also spoke of the results of his soundings of the river below the falls. The physical geography of the Etbai desert of Egypt was spoken of by Mr. H. T. Ferrar, of the Geological Survey of that country, who exhibited a large-scale map specially drawn to bring out the physical characters of the country. He discussed various morphological features in regard to their mode of origin, and explained the meanings and mode of use of a number of Arabic geographical terms. Lastly, Mr. M. Allorge described the recently discovered cave of Atoyac, in Mexico, paying special attention to the relation borne by the passages and chambers to the structural planes of the limestone formation in which the cave occurs.

An afternoon lecture by Dr. Vaughan Cornish, on the Jamaica earthquake and its effects as witnessed by himself and Mrs. Cornish, dealt with a physical phenomenon, though much of its interest lay in the vivid way in which the effects of such a catastrophe on the life of the people were pourtrayed. A thrilling account was given of the personal experiences and sensations of the lecturer and his wife during the earthquake, and the effects on the buildings of Kingston were well illustrated by photographs. Dr. Cornish investigated the place of origin of the earthquake, the character of the shock, and the effects on buildings of different kinds, and he briefly described the methods by which these researches were carried out.

An interesting paper by Mr. R. B. Woosnam described briefly the recent British Museum expedition to Ruwenzori, giving a general account of the features of the range, and especially of the life-zones upon it. The differences between the east and west sides, due to the greater humidity of the latter, were explained, and the question of the modifications or variations of type with change of altitude was briefly touched upon. Nothing very remarkable in the way of special adaptation to the wet and cold of the mountain slopes was noticed, and it was pointed out that the bird most commonly met with in the wettest and coldest zone is a sun-bird of brilliant colour. On the other hand, a species of sun-bird which occurs below 7000 feet is represented above 10,000 feet by another twice the size, though otherwise an exact facsimile; and a similar case occurs among the plants.

Two papers presented detailed studies of special regions from the all-round point of view. Mr. O. J. R. Howarth described the district of Jæderen, in southern Norway, which he showed to possess special characteristics separating it entirely from the typical scenery of that country. The hills rise in partially isolated groups, the whole forming a practically unbroken tract of naked rock, which reveals, to an extent dominating every other feature, the work of the glacier which once covered it. The coast presents exceptionally clear evidences of the upward movement of the land, in the form of old fjords and islands, as well as an old beach, dating from a period of subsidence following that of glaciation, in which last the land stood even higher than at present. The paper indicated briefly some ways in which the distribution of the population had been influenced by the diverse physical characters. The other paper, by Mr. A. W. Andrews, described the Land's End peninsula, an isolated area of old rock separated from the rest of Cornwall by a neck of low land, and thus presenting characteristic features of its own. This granite plateau forms in its higher parts a bare and wind-swept moorland, with undulating hills rising above it. The coast is, as a rule, lofty, with striking granite and greenstone cliffs, and is almost harbourless. The whole area is but little inhabited, though mining was once more actively prosecuted, and there are some signs of a resumption of activity in this direction.

Mr. Andrews showed a number of views illustrating the structure and other features of the district and its coastline.

On one afternoon the section joined with Sections C and K to listen to an illustrated lecture by Prof. Conwentz on the need of preserving what may be called "natural monuments" (typical scenery, flora and fauna, &c.), and the measures adopted or to be recommended to this end. Another lecture, by Mrs. Leonidas Hubbard, presented a graphic account of a journey in Labrador, during which the lecturer completed the work begun by her late husband in the survey of two previously unexplored rivers, the navigation of which is rendered difficult and dangerous by the many falls and rapids. Lastly, a short extempore account of the general and economic characters of British New Guinea was given by Dr. W. M. Strong, a Government official who had just arrived in England on furlough.

Reports were presented by the committees for investigations in the Indian Ocean (Mr. J. S. Gardiner); for the study of the relations between rainfall and river discharge (Prof. McCallum and Dr. Herbertson); and for that of oscillations of land-level in the Mediterranean (Mr. R. T. Günther); and grants were obtained for the further prosecution of the work of the two first.

EDUCATION AT THE BRITISH ASSOCIATION.

TWO joint conferences were held, the first with Section H, on *Anthropometrics in Schools.* The report of a committee of Section H on anthropometric investigation in the British Isles was presented by Mr. J. Gray (secretary). The anatomical subcommittee reported on methods of taking chest measurements, on hair colours, and on iris colours. A series of schedules of proposed anthropometric measurements for the use of schools has been drawn up, suggestive as to what could be done with limited opportunities. A psychological subcommittee has drawn up a list of thirty-four mental characters, on which they suggest observations on a scale indicating average or more or less marked over or under development of each character. The educational subcommittee (Mr. E. N. Fallaize, convener) states some of the aims of anthropometric observations in schools as the determination of averages and standard deviations, the correlation of physical and mental growth, the detection of the unfit, and the testing of the efficiency of different systems of education. Mr. J. Gray recommended that measurements and observations in all schools should be made in accordance with the scheme of the Anthropometric Committee of the British Association, that the data obtained should be entered on the card schedules, and each subject's dossier kept in an envelope as recommended by the committee. Dr. F. C. Shrubsall showed some lantern-slides of the results already obtained by anthropometric methods, including a comparison of the relative statures of Jewish and British children, the Jews leading at first, but both alike at age twenty-two; the heights of the professional, commercial, and artisan classes, the professional always leading: the percentage distribution of stature in Scotland, Liguria, and Sardinia, showing the Scottish stature as taller than the Sardinian; a map showing the average statures in different counties of the British Isles; the range of variation at different ages in schoolboys, showing that the tallest aged five was taller than the smallest aged ten. This demonstration was most impressive, indicating both the importance of the results already obtained and the risks of generalising from imperfect statistics or with inadequate knowledge.

The discussion thus begun was adjourned and continued throughout the afternoon. Sir Victor Horsley read a resolution already accepted in the committee of Section L:—"Resolved that, in view of the national importance of obtaining data on the question of physical deterioration, this association urges upon the Government the pressing necessity of instituting, in connection with the medical inspection of school children, a system of periodic measurement which will provide definite information on their physical condition and development." This resolution was afterwards adopted by the general committee of the association, and, pending further consideration by the council in November, it was agreed that it should be communicated to persons interested without delay.

Prof. M. E. Sadler hoped that a medical bureau would be instituted, preferably by the Board of Education, but with the cooperation of the medical staff of the Local Government Board and of the Home Office. It was desirable that the central authority should give supervision in order that observations may be made on a uniform basis. Mr. J. Ramsay Macdonald, M.P., regarded anthropometrics in schools as a necessary scientific basis for social legislation and educational policy. Mr. E. Meyrick, F.R.S., of Marlborough College, spoke on the practical difficulties in obtaining measurements of growth in schoolboys, perturbations and inaccuracies being so considerable that the final results were nearly valueless. Subsequent speakers, thinking perhaps of height rather than of growth (or difference of consecutive heights), freely declared that the accuracy of the measurements did not much matter so long as there were plenty of measurements used in the average, but no one indicated exactly what standards of accuracy were possible or desirable. Mr. Cecil Hawkins, of Haileybury, read a paper on types of physical development in schools. A series of diagrams was distributed having in each case age as the abscissa, and for ordinate either height, weight or girth. Across each of these a series of nearly equidistant curves was drawn to show the progressive development of twenty different grades of boys (each equally probable). This system makes it easy to plot the course of any individual boy and to compare him, not merely with the average, but also with his own type, and to see how his height, weight, and girth are losing or gaining relatively to each other. Prof. Findlay referred to the suggestions of Prof. Armstrong that more might be done to interest the scholars themselves in these measurements and in the necessary calculation of results.

The discussion on *The Scholarship System* afforded a full day's work, the morning being devoted to the transition from the primary school to the secondary day school, and the afternoon to the preparatory school, public school, and university. The opening paper, by Prof. M. E. Sadler and Mr. H. Bompas Smith, greatly assisted the discussion by focusing attention on points raised by their recent inquiry, the results of which will be most welcome on fuller publication. New sections of the community are demanding access to secondary schools, and it has become necessary either to extend the scholarship system or to embark upon a policy of free, or nearly free, secondary education under public control. Maintenance allowances are also necessary. The demand for secondary education has been accelerated by new regulations for the training of pupil-teachers. A scholarship system must give the opportunity of long training for individuals of unusual capacity, and not merely brief but widespread encouragement to average ability. The records kept of the later careers of scholarship holders are at present inadequate, but the evidence points to an overwhelming majority passing into literary, clerical, and other non-industrial callings. The scholarship question should be looked at from a national point of view, not only from the standpoint of the personal advantage and preferment of the individual scholar. Ability should be directed towards those callings in which the individual, by natural aptitude and by physical stamina, can best render valuable service to the nation. Hitherto preferential treatment has been given to the recruiting of the more literary professions. At present special advantage is given to urban districts. The fixed values of the scholarships at public schools and universities might well be reduced, but ample supplementary allowances should be given to those scholars who need them, after private inquiry into the circumstances of each case. The best examinations now conducted for junior scholarships are confined, so far as written tests are concerned, to papers in English and arithmetic. A simple oral test is desirable. The examiners should also have access to the pupil's school record. Stress should always be laid upon physical fitness; this would be an incentive to the healthy up-bringing of children and discourage neglect of the candidate's health. Mr. R. Blair, executive officer L.C.C., reported that the 2000 scholars selected annually were about the number who were fit to take advantage of secondary education, but this number was much less than the 25 per cent. of free places which secondary schools, aided by the Board of Education, were required to provide. He agreed to the principle of an oral examination and to making a fair standard of physical development a condition of eligibility, but he warned the audience as to the difficulties in applying such tests; for instance, a missing limb was an obvious defect, but doctors might differ as to disqualifying for anæmia. Mr. H. Bompas Smith said that we needed scholarships to train girls for callings other than that of primary teaching, and a greater variety of secondary schools to meet different needs.

In the afternoon Mr. G. Gidley Robinson spoke on the scholarship system as affecting preparatory schools. The Rev. A. A. David, headmaster of Clifton College, thought that the money value of all scholarships might be reduced to something quite nominal, but sufficient to serve as a symbol of the intellectual distinction; the remainder of scholarship revenue might then be converted into augmentation funds. Dr. H. B. Baker, F.R.S., reported that at Cambridge about 17 per cent. of scholars could have resided at the University without their scholarships, while at Oxford the proportion was only 6 per cent. There might be a voluntary relinquishment of the emoluments of a scholarship by a wealthy parent, the other privileges of the scholar being retained. Not infrequently a former scholar, on attaining to fatter fortune, has paid back in some way the money that was the foundation of his fortune. Prof. H. A. Miers, F.R.S., thought that scholarships should be awarded by examinations of a less special character, and should be administered by the university. The present system of grouped colleges is a step in this direction. Any exhibitions given otherwise than by examination should be administered by the colleges. Scholarships are required for advanced and post-graduate work. The whole discussion indicated a marked advance of thought on the scholarship question. The difficulties were clear, especially the poverty question. Suggestions were numerous and helpful. The general agreement on the proposals made was very clear, and was emphasised by other speakers.

Sir Oliver Lodge read the report of the committee, consisting of Sir Oliver Lodge (chairman), Mr. C. M. Stuart (secretary), Mr. T. E. Page, Profs. M. E. Sadler, H. E. Armstrong, and J. Perry, Sir Philip Magnus, Principal Griffiths, Dr. H. B. Gray, Prof. H. A. Miers, Mr. A. E. Shipley, Prof. J. Findlay, and Sir William Huggins, appointed to consider and to advise as to the *Curricula of Secondary Schools*; in the first instance, the curricula of boys' schools. "The committee submit for consideration the following conclusions which they have reached as the result of their debates:—(1) There is need for secondary schools of different types, with different curricula or combinations of curricula, because (*a*) all boys are not suited to the same course of study; (*b*) the requirements of the various callings upon which the boys will subsequently enter differ considerably; (*c*) the needs of the schools differ in a considerable degree according to the economic conditions of the districts in which they are situated. . . . (2) The committee consider that one modern foreign language should in all cases be begun at an early age, but are of opinion that it would be a wise educational experiment to postpone the *systematic* teaching of Latin as an ordinary school subject until twelve years of age, and that such a change will prove sufficiently successful to warrant its adoption. . . . The committee also desire to record their opinion that the continued teaching of either of the two dead languages to boys who after serious trial have shown little or no progress in, or capacity for, such linguistic study, has little or no educational value; and that, though the mental training afforded by such study is of great value in the case of many boys, yet in the case of others such study not only produces no good results, but does positive harm to their mental and moral progress by reason of their incapacity to grapple with its difficulties. The committee go further, and express their doubt whether the authorities in some secondary schools have sufficiently recognised this fact or have provided sufficient alternatives to such linguistic study. (3) The committee deprecate any form of early specialisation in the education of children, and therefore regard with grave concern the fact that the entrance examinations at the great English public schools give undue prominence to the study of Latin (and Greek) in the course of education at the preparatory schools, the result being that too little time is available for (*a*) the teaching of the mother tongue, (*b*) manual training, (*c*) science and mathematics. (4) The committee would deprecate anything like State-imposed rigidity in the organisation and studies of secondary schools. . . . (5) The committee are of opinion that the curriculum in secondary schools suffers gravely from the number of subjects which have been crowded into it. . . . (6) The committee desire to see a great simplification in the arrangement of examinations for secondary schools, and they strongly recommend that examination and teaching should go hand in hand, the examiners cooperating with the teachers and acting in conjunction with them in order to further the interests of real education. The committee would urge upon the universities and professions to accept as qualifying for entrance the leaving certificates granted by each university to the schools which submit to its inspection. . . . The committee particularly deprecate any uniform or centrally administered examination applied to all the schools of the country. . . . (7) The committee feel that no scheme of secondary education can be satisfactory unless it is carried out by teachers of learning and force of character, and they would urge that every effort should be made, by conditions of appointment, by scale of salaries, and by retiring allowances, to attract a high class to the teaching profession, which should be regarded as a very laborious, but very honourable, form of public service. . . ."

In this and other discussions there was much keen criticism of the Board of Education. The burden of it was distrust in matters which could be put on a scientific foundation. A subcommittee of the curriculum committee has been appointed at the request of Mr. G. F. Daniell to report on the sequence of scientific studies. Prof. Armstrong directed attention to the dangers of State control, to the importance of manual training as a branch of intellectual education, and to the administration of the examination system, not with altruistic motives, but as a lucrative business. A committee of Section L has been appointed to watch legislative and administrative action. Dr. Anderssen, of Christiania, reported the gymnasium for boys of fifteen to eighteen years as divided into three branches, one with mathematics and science as the centre, one with modern languages, chiefly English and history, as the centre, and one with Latin as the centre. Prof. L. Morel, of Paris, spoke of France as a field for experiments. For the years fourteen to seventeen, boys are grouped in four sections. Section A is characterised by Latin and Greek, B by Latin and foreign languages, C by Latin and sciences, and D by sciences and foreign languages. The last is the normal course for those who learnt no Latin before fourteen or who choose to abandon it.

Mr. R. E. Thwaites reported the results of his inquiry into the *Conditions of Science Work in Secondary Schools*. The average number of boys in a class is twenty-one or twenty-two, but twenty should be the maximum for a laboratory class. The average expenditure per boy on apparatus and chemicals is about *1l.* per annum in public schools and *8s. 6d.* in secondary day schools. From two-thirds to three-quarters of the schools are satisfied with the number of the science staff, the laboratory accommodation, and the equipment of apparatus, but little more than half have any laboratory assistant, the more expensive time of the science master being spent on details which could be performed less expensively by an assistant.

A joint meeting was held with Sections D and K on *The Teaching of Biology in Schools*, introduced by a paper from Mr. O. H. Latter, of Charterhouse. In the preparatory school and lower forms of public schools the standard indicated as "nature-study" seems the best form of science training. Common animals involving direct personal observation were more suitable in the next stage than the "type-method" with its underlying idea of evolution. A year of chemistry and physics might be interpolated before physiology. With older and cleverer pupils pure nature-study methods become insufficient. As the mind matures it must have more solid matter to digest. The theory of evolution was beyond the grasp of any but the best class. Prof. Hickson agreed that the ordinary course of biology was unsuitable for schools, but possibly best for the teachers. Prof. Marcus Hartog advocated accurate detailed descriptive and systematic work in botany as the remedy for a certain fluffiness of observation and description in nature-study.

The report on curricula deals in the first instance with boys' schools. The girls' schools had their turn when Prof. H. E. Armstrong addressed the section on *The Need of a Scientific Basis to Girls' Education from a Domestic Point of View.* Women should cease from competing with men to the neglect of their own interests and natural duties. A scheme of scientific education for girls might radiate from the household. Instead of chalk and salt, the common materials of the household, flour, starch, coal, meat, sugar, &c., might be used as starting points for a girl's study of science. The science of bread-making would lead to a general cooperation of all studies helpful to that end. The committee of Section L would like Prof. Armstrong's paper to have been published in full. It was a powerful enforcement of ideas advocated by Prof. Smithells in York.

The remaining hours were devoted to a discussion on *Types of Specialised Teaching.* Mr. J. H. Hawthorn, of Leicester, spoke on the teaching and the teacher in evening technical schools. The type of evening student has been changing, there are fewer adult workmen, and the average age is lower than ten years ago. No student should take a trade class until he has laid a foundation of pure science. Good results were obtained by a science teacher with a competent artisan demonstrator. The teacher keeps abreast of the trade when he is known to local factory owners, appreciated by them, and encouraged to visit factories. Mr. C. T. Millis, of the Borough Polytechnic spoke on problems of trade education considered in relation to our school system. Reforms are needed in our elementary-school education to make it an effective preparation for the battle of life, especially for those children who will take up industrial work. Too much attention has hitherto been given to those going into clerical occupations. The types of schools required are specialised trade schools for boys and girls of fourteen to sixteen years of age teaching definite trades, and also preparatory trade schools teaching practical mathematics, drawing, and science. The course must be planned to fit the elementary school at one end, and also to fit the system of apprenticeship followed in each trade. The labour market must be watched to guard against mistaken specialisation. The teacher of trades must have had trade experience in the factory. Cooperation of parents, teachers, employers, and trade-union leaders was necessary. Mrs. J. Ramsay Macdonald described the day trade schools for girls in greater detail. Women's work is double, wage-earning in factory and responsibility at home. To look upon the former as unimportant is disastrous to women wage-earners. There are now day classes in waistcoat-making, dressmaking, corset-making, and ladies' tailoring. The pupils mostly hold scholarships with maintenance grants. Six half-days are devoted to trade teaching, four half-days to general instruction. The trade teachers have come straight from good positions in the workroom. The pupils' development, not customers' convenience, is the first consideration.

An excellent paper on technical training of the rank and file, by Mr. J. C. Legge, of Liverpool, was in reserve, but under pressure of time and in his regretted absence it was distributed in abstract and taken as read.

It was most gratifying to have so good a discussion on these matters of technical and industrial training, which have been a special interest to the president, Sir Philip Magnus. Although not referred to in Section L, no account of technical education at the British Association would be complete without mention of Prof. S. P. Thompson's suggestions in Section G for the abolition of premium apprenticeship, and the opening of the best opportunities in engineering works to merit and not to wealth. From Section D we cull another pregnant idea. The little procession of blue-eyed and brown-eyed school children brought by Mr. Hurst from Burbage inevitably suggests the possibility of our pupils having Mendelian minds as well as Mendelian eyes.

The brief interim report on the conditions of health essential to the carrying on of the work of instruction in schools, presented by Sir Edward Brabrook, may seem inadequate to represent the interest of the association in such matters. But papers on school hygiene were deliberately avoided this year as the most effective method of supporting the simultaneous congress in London.

Two exhibitions were organised, one an exhibition of work representing practical and observational studies collected from the Leicester Council Schools by Mr. Charles Bird. The exhibition of school-science apparatus collected from several important schools by Mr. R. E. Thwaites was conveniently adjacent to the section room.

H. R.

LOCAL SOCIETIES AT THE BRITISH ASSOCIATION.

THE number of delegates from the local scientific societies which are in correspondence with the British Association was exceptionally large at the conference held during the Leicester meeting. Mr. H. J. Mackinder opened the session, in the council chamber of the municipal buildings, by an address on the advancement of geographical science by local scientific societies. He pointed out that in France there are about twenty local societies devoted to geographical study, each taking a region nearly corresponding with one of the old provinces, whilst in Germany there are many societies working specially for the furtherance of local geography. In this country each provincial scientific society should seek to correlate, from a geographical point of view, all the facts obtained by specialists in its own locality, taking as a basis a natural area rather than a county boundary. From such correlation, if undertaken by a person of special training, deductions could be drawn which would be of great value to specialists in the future. Until systematic work of this kind is accomplished on uniform principles throughout the country, no complete geographical conception of our land is possible. Captain Dubois Phillips, representing the Liverpool Geographical Society, referred to the stimulus which should be given to the rational study of geography by local societies through the influence of the British Association; and Dr. H. R. Mill bore testimony to the inspiriting character of the discourse, but feared that the complete realisation of Mr. Mackinder's scheme must be far distant.

At last year's conference of delegates it was suggested that the British Association should be asked to appoint a committee to organise a general photographic survey of the country, county by county. The suggestion was carefully considered by the Corresponding Societies Committee, but it was felt that the scheme was too vast to be taken up by the British Association. At the same time, it was considered that some section of the suggested work, such as archæology, might perhaps be advantageously undertaken. A discussion was therefore initiated by the Rev. R. Ashington Bullen, who read a paper at the Leicester conference on the advisability of appointing a committee for the photographic survey of ancient remains in the British Islands. The anthropological section held, however, that such work might be fairly undertaken by the committee which already exists for the collection and registration of anthropological photographs. As the result of much discussion the following resolutions, on the motion of Mr. W. Jerome Harrison, of Birmingham, were sent up to the Committee of Recommendations and ultimately referred to the Council:—That it is advisable to obtain information as to the present state of things in Britain, in connection with photo-survey work; to publish instructions, or give advice, for the execution of a scientific photographic survey; and to endeavour to found or promote a photo-record of the town and district in which the British Association holds its annual meetings.

At the second meeting, presided over by the Rev. J. O. Bevan, the local societies were urged to give greater attention to the study of the fungi occurring in their districts. The subject was introduced by Mr. Carleton Rea, of Worcester, at the instance of the British Mycological Society. It was pointed out by Mr. Rea that British botanists generally omit fungi from the county floras, or give lists that are compiled without the necessary local knowledge. Yet the group ill deserves neglect, for it is one of great economic importance. It is said that the cereal rusts cost Prussia in one year 20,000,000*l*. To encourage the study of British fungi, the Woolhope Naturalists' Club in 1868 instituted a series of autumnal forays, and some other natural-history clubs, like the Essex Field Club, have followed the example; but this occasional study is insufficient. The fungi should be studied throughout the year, and specimens displayed for exhibition at all times in the society's rooms or in the local museum. In the course of the discussion, Prof. J. W. Carr, of Nottingham, and some other naturalists, dwelt on the difficulty of working out the fungi of a given district in consequence of the general lack of expert knowledge. Mr. Rea, however, considered it the duty of each society to be able to determine the fungi of its own area, without submitting them, except in difficult cases, to a mycological referee. A large collection of hand-coloured photographs of fungi, taken by Mr. A. Wallis, of Kettering, was exhibited by Mr. H. N. Dixon.

Several delegates from the sections explained in what way the local scientific societies might aid the sectional committees. Mr. Wilfrid Mark Webb appealed for specimens of centipedes in illustration of a work on which he was engaged, but the Rev. Thomas Stebbing explained that his repeated request for well-shrimps had met with no response from any of the local societies through their delegates.

HEALTH AND EDUCATION.

THE Health Education League of Boston, Massachusetts, U.S.A., has issued a series of small pamphlets dealing with the common aspects of our daily life from a health point of view. Mrs. Ellen H. Richards appears to be the moving spirit in this useful sanitary campaign, and with her are associated as writers of pamphlets and directors of the league several medical men. The usefulness of the hints contained in these tiny publications is undoubted, all the more so because they are tiny, and because the facts they set forth are stated in terms readily to be understood by everyone.

The first of the series gives "Hints for Health in Hot Weather." In it we find sensible remarks, under the heading of "Rules for Children," "Cleanliness," &c., concerning the general bringing up of children, but, except the benefits of sunshine and the use of wire screens to keep out mosquitoes, we are told all too little about bodily protection in hot weather.

No. 2 of the series deals with milk. The story of milk as a food and as a vehicle of disease is admirably told. The meaning of unwholesome milk, how it is brought about, and how prevented by chilling and sterilising, is described and fully explained; the information contained in this pamphlet is an education to the public in the very best sense.

"Colds and their Prevention" is dealt with in series No. 3. Under this heading the subject of ventilation is skilfully introduced. The care of the skin and of the feet is also incorporated in the text.

No. 4 of the series is concerned with "Meat and Drink." Good nutrition is held to be of vital importance to our courage, cheerfulness, and physical efficiency, and the meaning of cooking and the effects of boiling, roasting, frying, &c., scientifically yet simply explained.

"Healthful Homes" is the subject of No. 5. The moral atmosphere of family life is dwelt upon as an important factor in national life, and the practical details of elementary hygiene and sanitation are here collected and set forth in admirable fashion.

"The Successful Woman" (series No. 6) pamphlet tells the business woman how to keep well, and good and sensible rules and suggestions are laid down for her guidance. Most of us would hesitate to stamp a business woman, that is, one whose chief ideal is to keep well, so "that she may earn a full salary," as one of nature's successful productions. That women should be compelled to, or by choice, take to business cannot but be regarded as one of the blots of our civilisation of which we ought to be heartily ashamed. To stamp a woman so engaged as a successful woman is rather encouraging woman along a side-path of doubtful benefit to the race.

"The Boy and the Cigarette" (series No. 7) should be read by everyone, and the recommendations against this poisonous and harmful practice should be stringently enforced by law in the case of boys. Women are warned that neither their brothers nor their admirers think better of them for smoking cigarettes. A woman who smokes is spoken of in a ribald manner, did women but know it, by men in private, and their morality made a subject of question and banter.

"The Care of Little Children" (series No. 8) is replete with good advice, and can be heartily commended; and the fact that the future health and welfare of the individual is mostly determined by the wisdom or folly bestowed upon the infant during the first few weeks of life pointedly brought home.

"The Plague of Mosquitoes and Flies" constitutes the subject of series No. 9. It is a timely contribution, and contains the most recent lessons we have learned concerning the spread of disease. We know within recent years that our household pests and pets, the flies, fleas, bugs, and other vermin which inhabit our houses, and our dogs, cats, fowls, mice, rats, &c., are frequent media of the transmission of diseases. It is a great advance in knowledge, one of the greatest hygienic advances since Parker first brought the subject systematically before the world. This pamphlet should be distributed broadcast, and the subject it deals with taught in every school.

No. 11 of the series points out, under the title of "Tonics and Stimulants," the necessity for temperance in the use of alcohol, tea and coffee, and drugs. The lessons in this short pamphlet are well taught, and the advice wise and wholesome.

The series as a whole is an unfortunate necessity. It implies that mankind, in modern days, has so lost touch with nature and nature's ways that the instinct of the care of the young, which belongs in common to all animals, is a lost attribute of modern men and women. Perhaps it is wise to recognise the fact; and being recognised, we can conceive no better method of repairing the loss than by the publication and wide distribution of information such as we find in the series before us.

THE INSTITUTION OF MINING ENGINEERS.

THE annual meeting of the Institution of Mining Engineers, held at Sheffield on September 4, 5, and 6, was attended by a large number of members. Cordial addresses of welcome were delivered by Mr. J. R. R. Wilson, president of the Midland Institute of Mining Engineers, by the Lord Mayor of Sheffield, and by Mr. A. J. Hobson, speaking on behalf of the Chamber of Commerce and of Sheffield University, who kindly lent the Firth Hall for the occasion. Mr. C. E. Rhodes was elected president for the ensuing year, and the report of the council, read by the secretary, Mr. M. Walton Brown, recorded a year of satisfactory progress. The institution is a federation of seven local mining societies, and its membership has grown from 1239 since the foundation in 1889 to 3100 at the present time. During the past year sixty-eight papers of a varied nature were published in the Transactions. Mention was made of the efforts being made, in conjunction with the British Science Guild, to secure a reduction of postage on the publications of scientific societies, and of the reports submitted by Mr. J. A. Longden, representative of the institution at the British Association, and by Mr. Bennett H. Brough, representative of the institution at the testing congress in Brussels. It was also noted that Mr. Arthur Sopwith, senior past-president, represented the institution on the governing body of the Imperial College of Science and Technology.

Three papers were read and discussed. The first, by Mr. J. W. Fryar and Mr. Robert Clive, described the sinking of two shafts through 100 feet of quicksand at Bentley Colliery. In the second Mr. H. T. Foster dealt with the subject of roof weights in mines, his views being deduced from observations in long-wall workings. Lastly, Mr. H. St. John Durnford described a deep boring put down on the Earl of Londesborough's estate, near Selby, in the hope of finding a workable seam. Although some 1060 feet of Middle Coal-measures strata were proved, boring was continued to a depth of 2371 feet without any good seam being encountered. It is probable that the bore-hole passed down through the limb of a fold where the seams had either thinned or pinched out altogether. In the afternoon of September 4 the members visited the Tinsley steel, iron, and rope works, and the East Hecla works of Hadfield's Steel Foundry Company, Ltd. At the dinner in the evening Sir William Clegg, in proposing the toast of the Institution of Mining Engineers, incidentally referred to the new Imperial College of Science and Technology, and stated that a deputation from Sheffield had waited upon Lord Crewe to urge that mining and metallurgy should be taught at Sheffield in the centre of mining and metallurgy, rather than centralised in London.

On September 5 the members visited the Clyde Steel Milling Works, Bentley Colliery, and Silverwood Colliery; and the meeting concluded with a drive, on September 6, to the Derwent Valley waterworks.

METEOROLOGICAL OBSERVATIONS.

SEVERAL reports of meteorological observatories have recently been received, and four of them are of noteworthy interest. The report of the observatory department of the National Physical Laboratory for 1906 shows that the value of the instrumental certificates is very generally appreciated; the increase in the number of instruments verified during the year amounted to more than 2900, the total being 29,567. There was a marked increase in the number of marine chronometers submitted to trial, more than 20 per cent. of which failed to pass the test. In the magnetic department the curves were free from any large disturbances. The largest movements of the seismographs occurred on January 31, April 18, and August 17, the dates of the Colombian, Californian, and Chilian earthquakes. The meteorological observations show that shade temperatures exceeding 80° were recorded in each of the four months June–September, the extreme reading being 91°.8 on September 1. Rainfall amounted to 23·68 inches (nearly half an inch below the average for Greenwich for the sixty-five years 1841–1905); the greatest daily fall was 2·36 inches on June 28, and was within half an inch of the total amount for that month.

The report of the director of the Bombay Government Observatory for 1906 gives room for little comment, excepting that the operations, which deal especially with terrestrial magnetism, meteorology, and seismology, were carried out with the usual care and punctuality. The maximum temperature was 94° on October 23, being only about 2° higher than the extreme reading recorded at the Kew Observatory. Owing to concussion from exceptionally heavy gun-firing at Colába the dry-bulb thermograph was broken in June. The yearly rainfall amounted only to 56·3 inches, being nearly 19 inches below the normal of twenty-four years (1873–96). Milne's seismograph registered fifty-nine earthquakes during the year; of these three were very great disturbances, viz. January 31, August 17, and October 24; the two first mentioned correspond to the dates of the Colombian and Chilian earthquakes.

The fiftieth year-book of the Austrian Central Meteorological Office, for 1905, contains hourly and daily observations at some selected stations, as before; the results at other stations are arranged either according to the international scheme or in tables showing monthly and yearly means and extremes. The stations number 412, of which fifty are more than 1000 metres (3280 feet) above sea level; this number in no way represents the whole of the valuable Austrian meteorological work, as there are several independent organisations dealing more particularly with rainfall and temperature, the principal of which is the hydrographic department, with more than 1000 stations, for eighty of which the observations are printed *in extenso*. The Hungarian and other meteorological services also issue separate year-books. The Vienna Meteorological Office deals specially with earthquake phenomena and with the collection and discussion of thunderstorm observations, the results of which are printed separately; it also publishes a daily weather report, and takes an active part in the investigation of the upper air by means of balloons.

In the annual report of the meteorological department of the Transvaal for the year ended June 30, 1906, the results of observations are well arranged in appendices, as before; the hourly readings at Johannesburg are not now printed *in extenso*, but MS. copies are available, on loan, for special inquiries. The stations have increased in number to 376, most of which record rainfall only; all the observers are volunteers, or are attached to other departments. The rainfall was considerably below the average in all parts except in the S.W., where the defect was only slight; no snowfall was reported during the year. A forecast of the weather for the ensuing twenty-four hours is now exhibited at every postal telegraph station in the Transvaal. The director (Mr. R. T. A. Innes) seems dissatisfied with the Campbell-Stokes sunshine recorder, which only shows the time during which the sun is sufficiently powerful to burn the cards; in future reports both the duration and burning times will be given.

RUSSIAN SCIENTIFIC WORKS.

THE Imperial University of Kazan, with its society of naturalists, is noted for excellent work in many departments, and we are greatly impressed with the magnitude of Mr. M. Ruszky's volume "The Ants of Russia" (*Formicariae Imperii Rossici*), of which the first part lies before us. It consists of 800 pages, with 176 sketches, comprising an introduction, bibliography, systematic examination of Russian ants, list of collectors to whom the author is indebted, and indexes. Mr. Ruszky began the study of Russian myrmecological fauna in 1892, when he undertook a zoological excursion in the Kazan and Simbirsk governments on behalf of the Society of Naturalists. He was induced to take up this investigation partly because Russian ants had been very little studied, and partly for the collection of materials for the solution of biological and zoo-geographical questions. This work is to be understood as a preliminary array of results, being an attempt at a description of Russian ants in systematic geographical and biological respects. The author anticipates criticism for omission of questions of internal morphology and embryology, and observes that such exhaustive treatment of the Formicidæ by a single investigator would occupy, not one, but many decades. In the important bibliography of writings on ants, occupying with addenda about seventy pages, very few works are devoted to Russia, chief among the number being twelve by the author. Mr. Ruszky estimates the approximate total of species and subspecies known at the time of writing at 3500, and groups Russian ants under the subfamilies Camponotinæ, Dolichoderinæ, Myrmecinæ, and Ponerinæ. Representatives of Dorylinæ, principally found in the tropics, have not been seen in Russia, though one species (*Dorylus juvenculus*) is European, being found in southern Italy, Sicily, &c. After some useful preliminary notes and tables of species of Russian ants, the author proceeds to detailed descriptions of smaller groups. In all, 258 forms are described (155 species and races, 103 varieties), of which sixty are new and treated for the first time (subfamilies, Camponotinæ, 109; Dolichoderinæ, 7; Myrmecinæ, 138; and Ponerinæ, 4). The regions richest in myrmecological fauna are the Caucasus, with 130 forms; Russian Central Asia, about 112; European Russia, 92; Siberia, 71; Crimea, 43; and Finland, 32. All these figures are approximate, and it is probable that since this work appeared more results have been recorded. This first part gives geographical distribution, locality, and biological information, and in the second Mr. Ruszky proposes to deal with this fauna from the bio-geographical point of view.

Vol. xxxiv. of the Transactions of the St. Petersburg

Society of Naturalists, edited by Mr. J. Borodine, is devoted to botany. Mr. Y. N. Voronoff describes his botanical excursion in the summer of 1902 in Abhasia (Caucasus). The whole region is rich in Alpine flora, of which the writer collected thousands of specimens and hundreds of species. Mr. Voronoff supplements Alboff's work on the flora of Colchis, and gives a list of 129 plants, of which four are newly described. Mr. E. Ispolatoff's article on the vegetation of the eastern portion of the Novgorod government contains descriptions and lists of that found in forest, marsh, and meadow land respectively, with observations on the influence of man upon local vegetation. He notes that localities suitable for human habitation are also favourable to vegetation. The presence of primitive Siberian flora in certain districts is accounted for by the wild, sparsely populated nature of the country, as contrasted with the more cultivated areas of western Russia. Mr. Ispolatoff gives a list of local names of plants, *e.g. Cypripedium calceolus* (Adam's head), *Aegropodium podagraria* (bear's paw), Ranunculus (jaundice, hen's blindness). The bulk of the journal is occupied with Mr. Leonid Ivanoff's papers on phosphorus and its relations to plant life, with results of experiments. Mr. J. L. Serbinoff furnishes preliminary notes on water plants and fungi of the Crimea, a field scarcely studied. The mountain districts are poor in water plants, while there are more in the south, but on account of their comparative rarity considerable time must elapse before a complete list can be compiled.

There is a wealth of interest for the geologist in part v. of vol. xxxiii. of the Transactions of the St. Petersburg Society of Naturalists, devoted to geology and mineralogy. Mr. W. Lemann writes on the Jurassic deposits of Orlovka, and furnishes a plate of fossils. Mr. B. Popoff describes a new method of investigating spherolithic formations, with diagrams. Besides notes on diabasic rocks on the shores of Lake Onega, by Mr. S. A. Jakovleff, and on the island of Pargas, by Mr. Sustchinsky, Mme. Jeremina and Mr. Loewinson-Lessing describe expeditions in the Mugodjaren (Ural) mountains, and the former writes on the spherolithic formations in this range, with numerous illustrations. *Résumés* of the articles appear, mostly in German.

In part ix. of vol. xxxvii. of the Journal of the Physicochemical Society of St. Petersburg University appears a list of minutes and papers, the volume containing more than 1300 pages. Mr. V. Menschutkin writes on the action of water on etherates and combinations with ether-salts, and Mr. A. Gorboff on the static character of the equilibrium of physicochemical systems. Mr. E. Orloff furnishes a new synthesis of benzylideneimides, and a lengthy paper on the phosphorescence of some organic compounds between $+100^\circ$ and -190° appears from the pen of Mr. P. Borissoff. The purpose of Mr. Borissoff's work was to examine the influence of temperature on the phosphorescence of certain organic compounds, and to determine the relation of fluorescence to phosphorescence. A memoir of Mr. V. A. Mokievsky, a promising laboratory worker cut off all too soon, is given by Mr. S. Lebedeff.

In part ii. of vol. xxxv. of the Transactions of the St. Petersburg Society of Naturalists, Mr. V. N. Tonkoff describes experiments in embryology in connection with dual formations, and gives a bibliography of works on embryology, development, abnormal formations, &c. The writer appears to be of opinion, judging by results of experiments by pressure and osmosis on the eggs of frogs, fish, and medusæ, that similar results would be produced in the case of other ova. This article is illustrated by two plates. Mr. A. V. Zhuravsky contributes notes of a zoological journey in the Siberian tundra. This region, largely volcanic, has been summed up as "dead land (*i.e.* clay) and lakes." For the naturalist there is abundant material for study in the lakes and on the sloping shores. Of the fauna, *Mus amphibius* is very prevalent, and finds its way on board steamers and other craft as an emigrant. A list of mollusca occupies several pages. A short *résumé* in German follows each article.

Vol. xxxv., part iv., of the Transactions of the St. Petersburg Society of Naturalists, devoted to zoology, is chiefly taken up with articles by Mr. W. M. Schimkevitch, one of the editors. He is responsible for notes on the development of Thelyponus, experimental observations of the eggs of *Philine aperta*, and a preliminary article on the theory of mutation. His paper of more general interest is that on the instincts of domestic animals, in which certain well-known habits of the dog are discussed, as burying of bones, &c., without apparent reason. Most of these are followed by a German *résumé*. The concluding article, by Mr. S. Susloff, treats of phagocytes in relation to insects, with diagrams and a bibliography.

Mr. N. Andrussoff has issued part i. of his material for the geology of the Aralo-Caspian region (Transaction of the Aralo-Caspian Expedition), which he has studied for twenty years at intervals. The places covered in this part include the Krasnovodsk peninsula, Great and Little Balchan, Djanak, and Ustiurt. Notwithstanding its proximity to Krasnovodsk and the railway, the geological features of the Kubadagh have been very little studied. In his first chapter Mr. Andrussoff summarises the work of previous explorers since Eichwald visited the neighbourhood in 1825. The work is illustrated with plans, sections, and views.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE professor of mechanical engineering at the City and Guilds Technical College, Finsbury, is about to appoint a chief assistant to take charge of the new engineering laboratory. Particulars of the appointment will appear in our advertising columns.

THE question of the extent of the training in science, and especially in physics, which one who intends ultimately to become a physics teacher should receive at the high-school stage of his career, is treated with great insight by Dr. K. T. Fischer, of Munich, in a recent article in *Natur und Schule*. It will be remembered that Dr. Fischer spent some time in this country investigating our methods of teaching science, and that his observations are embodied in his book "Der naturwissenschaftliche Unterricht in England." His present article is largely a plea that even at this stage the future teacher should be brought into close contact with physical apparatus, and should be taught to handle simple tools and fit together apparatus. Dr. Fischer's ideal of a teacher is one who by the end of his training has not only learnt to read with understanding the original work of the great masters, but has carried out a piece of research himself. He recognises, however, the difficulty of his last demand even in his own country, and we in this country must, we fear, look on it as a counsel of perfection for many years to come.

THE new syllabus of classes at the Sir John Cass Technical Institute, Aldgate, shows that the work of the various departments has been considerably re-organised since last year. Apart from systematic courses in physics, mathematics, and chemistry, special courses of instruction are now given in physical chemistry, brewing and malting, and in several branches of advanced physics, including radio-activity. The course in physical chemistry includes general physical chemistry, electrochemistry, and a laboratory course of practical work; the instruction in brewing and malting also includes laboratory work of a technical character in addition to a course of lectures designed for those engaged in the brewing and malting industries. The teaching in metallurgy, which for the past four years has formed a distinctive part of the work of the institute, has now been established as a separate department, and a full graded curriculum extending over three years is provided.

THE London County Council desires to direct attention to the facilities offered for evening instruction in the various institutions maintained by it or under its control. In the various polytechnics, technical institutes, and schools of art situated in the county, classes in science, art and technology, music, artistic handicrafts, &c., will be re-opened towards the end of the present month. These institutions provide instruction of an advanced or technical character. The council offers annually scholarships and exhibitions to the total value of 1500*l.* for competition among students of polytechnics, technical institutes, and art schools. In thirty-six London County Council schools, centres for instruction in commercial and science and art subjects will be opened. These centres are in a degree contributory to the polytechnics and technical institutes mentioned above and are primarily intended for students not sufficiently advanced for the polytechnic classes. Advanced work, however, is taken in many of the subjects. In 237 London County Council school buildings situated in every part of London, ordinary evening schools will be opened this session. The instruction will, as a rule, be of a character preparatory to that given in the centres.

THE educational demands of the organised workers of this country are expressed in the following points of a resolution adopted at the Trade Union Congress at Bath last week:—(1) The State maintenance of school children. (2) Scientific physical education with individual medical inspection, and records of the physical development of all children attending State schools, and skilled medical attendance for any requiring it, and in order to secure this:—(*a*) The formation of a properly staffed medical department at the Board of Education, the head of which shall be directly responsible to the Minister of Education, to whom he shall report annually. (*b*) The payment of an adequate grant from the Imperial Exchequer for purposes of medical inspection. (*c*) The establishment under every education authority of scientifically organised open-air recovery schools, the cost to be borne by the community as a whole, and not in any part by charitable contributions. (3) The complete dissociation of reforms (1) and (2) from Poor Law administration. (4) A national system of education under full popular control, free and secular from the primary school to the university. (5) That secondary and technical education be an essential part of every child's education, and secured by such a reform and extension of the scholarship system as will place a maintenance scholarship within the reach of every child, and thus make it possible for all children to be full-time day pupils up to the age of sixteen. (6) That the best intellectual and technical training be provided for the teachers of the children, that each educational district shall be required to train the number of pupil teachers demanded by local needs, and to establish training colleges, preferably in connection with universities or university colleges. (7) That the provision of educational buildings and facilities be obligatory upon the local authority, who shall always retain administrative control of the buildings and facilities so provided. (8) That the cost of education shall be met by grants from the Imperial Exchequer, and by the restoration of misappropriated educational endowments. (9) That it be an instruction to the Parliamentary Committee of the Trade Union Congress to formulate these proposals in a Bill to be laid before Parliament during the forthcoming session.

FROM tables published in *Science* of August 30, it appears that the total number of degrees of doctor of philosophy and doctor of science conferred by the universities of the United States this year was 327, which is almost exactly the same as in 1905 and 1906, when the numbers were, respectively, 325 and 326. The average number for the past ten years is 271. Of 2715 doctorate degrees conferred during the past ten years, 1232, somewhat less than half, have been in the natural and exact sciences. The relative proportion of degrees in the humanities and in the sciences has not altered appreciably in the ten years covered by the statistics. The Johns Hopkins has conferred more degrees in the sciences than any other institution, but is closely followed by Chicago, and at a not very considerable distance by Harvard, Columbia, and Yale. Fifty-five per cent. of the degrees conferred at the Johns Hopkins have been in the sciences, and 57 per cent. at Cornell, whereas in the other leading institutions the percentage is decidedly less—46 at Chicago, 42 at Harvard and Columbia, and 40 at Yale and Pennsylvania. Of the 1232 degrees conferred in the sciences during the past ten years, chemistry leads with 320 doctorates; then follow in order of numbers, physics, 155, zoology, 147; psychology 134; botany 126; and mathematics 121. The remainder of the degrees are divided among fourteen other sciences, meteorology and geography being at the bottom of the list with one doctorate each.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 27.—"On the Force required to Stop a Moving Electrified Sphere." By G. F. C. **Searle,** F.R.S.

If F be the force which must be applied to the sphere at any time t, after it has been brought to rest at $t=o$, the positive direction of F being opposite to that of u, the initial velocity, the momentum given up by the electromagnetic field from $t=o$ to $t=t$ is

$$\int_0^t \mathrm{F}dt.$$

During this period the force F does no work, since the sphere is at rest, and hence the energy is unchanged during this period.

At the time t let the sphere be restarted with the same velocity u without change of direction, and let G be the force which must be applied to the sphere at any subsequent time in the direction of u in order to maintain the velocity u. This force lasts from $t=t$ to $t=t'$, where $t'-t$ is determined by the condition that in the time $t'-t$ the pulse formed on restarting the system has completely passed over the sphere. During the interval $t'-t$, the momentum is increased by

$$\int_t^{t'} \mathrm{G}dt,$$

and hence the total gain of momentum is

$$\int_t^{t'} \mathrm{G}dt + \int_0^t \mathrm{F}dt.$$

During the interval $t'-t$, the energy has been increased by

$$u\int_t^{t'} \mathrm{G}dt.$$

The stopping and the restarting of the sphere each give rise to a pulse, and the compound pulse so formed carries off energy W′ and momentum P′. Before the system was stopped the energy of the electromagnetic field was U+T and its momentum was M, and at an infinite time after the stopping and restarting the energy is U+T+W′ and the momentum is M+P′, since the energy and momentum in the parts of the field outside the compound pulse ultimately vanish.

Equating the two expressions for the gain of momentum, we have

$$\int_t^{t'} \mathrm{G}dt + \int_0^t \mathrm{F}dt = \mathrm{P}'.$$

Similarly,

$$u\int_t^{t'} \mathrm{G}dt = \mathrm{W}'.$$

Hence

$$\int_0^t \mathrm{F}dt = \mathrm{W}'/u - \mathrm{P}', \qquad (1)$$

and thus we find that the force required to stop the system is given by

$$\mathrm{F} = \frac{d}{dt}\left(\frac{\mathrm{W}'}{u} - \mathrm{P}'\right). \qquad (2)$$

This force will become zero as soon as $\mathrm{W}'/u - \mathrm{P}'$ becomes constant, which will occur as soon as t is so great that the two pulses due to the stopping and restarting do not overlap.

It follows from (2) that, if F_0 be the force required to stop a sphere of radius a with a uniform surface charge Q,

$$\mathrm{F}_0 = \frac{\mathrm{Q}^2}{2\mathrm{K}a^2}\left(\frac{v}{u} - \frac{v^2-u^2}{2u^2}\log\frac{v+u}{v-u}\right),$$

where v is the velocity of light. When the sphere has a uniform volume-charge

$$\mathrm{F} = \tfrac{3}{8}a^{-4}(16a^3vt - 12a^2v^2t^2 + v^4t^4)\mathrm{F}_0.$$

PARIS.

Academy of Sciences, September 2.—M. A. Chauveau in the chair.—Caryolysis in the nidorian glands of *Genetta senegalensis*: Joannes **Chatin.** A study of nuclear degeneration in the perineal glands. It is shown that this is a case of true caryolysis, exactly corresponding to the disappearance of the nucleus in the true sebaceous cell.—Physically similar fluids: M. **Jouguet.** The action of gravity on the deposit of induced radio-activity: Mme. **Curie.** Metallic plates were submitted to the action of a fixed amount of emanation for a fixed time, and the induced radio-activity measured. The results obtained were as if the induced radio-activity suspended in the gas surrounding the plates behaved as solid particles, possessing weight, and falling through the gas. The activity of plates turned towards the top of the vessel was always greater (two to five times) than that of those turned towards the bottom or hanging vertically. The presence of a gas was found to be indispensable to this phenomenon, the effects not being observed when the pressure was reduced below 2 cm. of mercury. The presence of water vapour was also a necessary condition.—The radio-activity of uranyl molybdate: B. **Szilárd.** In a recent note M. Lancien stated that he had prepared a uranyl molybdate the activity of which was much higher than that of the original uranyl nitrate. In all previous researches on the subject the activity of uranium preparations has always been found proportional to the amount of uranium present in the salt, and less than that of pure uranium. The author has therefore repeated the experiment of M. Lancien, preparing the molybdate in the same manner, but with opposite results. The activity found was about 0·3 that of metallic uranium, a normal figure for the amount of uranium present in the salt.—The effect of metallic wire screens on the secondary radiation of induced radio-activity: Ed. **Sarasin** and Th. **Tommasina.**—*Cyperus tuberosus* in the auriferous strata of Madagascar: H. **Jumelle** and H. Perrier **de la Bathie.**—Intra-organic oxidation and the electric charge of leucocytes as important agents of immunisation: Alexandre **de Poehl.**—The relation which exists between the distribution of petroleum-bearing regions and the distribution of seismic zones: L. C. **Tassart.** A comparison of the seismic maps of M. de Montessus de Ballore and the map of the petroleum-bearing regions of B. Redwood shows that all the petroleum deposits which are found in relatively recent strata are situated in the maximum seismic zones or in their immediate vicinity. In these seismic zones there may be petroleum deposits in relatively ancient strata, but this is exceptional. Petroleum deposits which are found outside the seismic zones are situated in ancient strata, and in regions which at some time or other have been the seat of important seismic disturbances.

New South Wales.

Royal Society, June 5.—Mr. H. Deane, president, in the chair.—Some peculiarities in our coastal winds and their influence upon the abundance of fish in inshore waters: H. C. **Dannevig.** Careful comparison between the catches of fish in certain coastal waters and the number of men employed has shown that the average catch per man in each locality is greater in some years than others. Also it is apparent that this fluctuation in abundance of fish is uniform all along the coast; thus in 1898 there was a general scarcity of fish; each man then captured less than during previous and succeeding years. This was followed by a gradual increase until 1901, when a climax was reached; a gradual decrease in the catches followed, until in 1905, when the results were as poor as in 1898. Last year shows a tendency to improvement. These periodic increases and decreases in the abundance of fish all along the coast at the same time are not traceable to the action of the fishermen, but can alone be due to certain climatic changes. A careful examination of the wind records from this coast for the last twenty-four years has furnished important evidence in explanation; it is this: by measuring the winds' influence by the number of *inches* they blow from each point during a twelvemonth, it is found that almost every year the atmosphere is on this coast pushed *northwards* to the extent of many thousands of miles, and not in the opposite direction as usually thought. But this northerly movement—or the yearly dominating wind—as the resultant may be called, does not invariably follow the same direction; it has an easterly or westerly tendency or direction from the normal in different years. This difference in the direction of the yearly wind-force has a corresponding influence upon the coastal current; the latter flows normally along the coast in a southerly direction, and is pushed *on* to the land or *away* from it according to circumstances. The current carries the bulk of our floating fish eggs, and these, therefore, are some years kept close inshore and at other times carried out to sea, in which case they are lost to us. Year after year there are good hatching seasons and bad ones, and in a number of years afterwards there ought to be correspondingly plenty of fish or scarcity. This is the case: most of our market supplies consist of four years old fish—the average of maturity—and by comparing the periodic deviations of the winds on to the coast and away from it with the richness of the catch of fish per man four years afterwards, a very striking correspondence is found. This comparison has been made over a period of ten years, and in no case is there any important discord, so it would seem that a very interesting and also important answer has been found to the otherwise inexplicable fluctuation in abundance of fish. It follows that as this year's winds control the abundance of fish four years hence, it may be possible some day to make a fairly accurate forecast as to what the next succeeding years will bring.

July 3.—Prof. Liversidge, F.R.S., in the chair.—Note on action of nitric acid in neutralising alkaline soil: R. S. **Symmonds.** Culture-pots were filled with alkaline soil and treated with various proportions of nitric acid. Seeds of wheat were sown in these and in pots containing untreated soil. Photographs of the plants were taken, and show an enormously increased growth, due to the neutralisation of the sodium carbonate and its conversion into sodium nitrate. A further series of experiments is being carried out on a large scale, which will form the subject of a future communication. The author discusses the possibility of the manufacture of the required nitric acid on the spot from the atmosphere by utilising the power derivable from the pressure given in the outflow from the artesian bores.

IRRIGATION ENGINEERING.

Irrigation: its Principles and Practice as a Branch of Engineering. By Sir Hanbury Brown, K.C.M.G. Pp. xv+301. (London: Archibald Constable and Co., Ltd., 1907.) Price 16s. net.

IRRIGATION is of such paramount importance to extensive tracts in India, and to the whole of Egypt, that it is in these countries that irrigation works have been carried out on the largest scale, and therefore the author, who has gained his experience in this branch of engineering in both these countries, is particularly well qualified for dealing with this subject; and by drawing his examples of works in illustration from both sources, and especially from Egypt, he has been able to present the principles and practice of irrigation in their grandest and most modern aspects. The whole object of irrigation is to supply water for agriculture to lands which are either devoid of adequate rainfall or on which the rain does not fall at a suitable period for the crops; and owing to the very unequal and irregular distribution of the rainfall in certain warm, and especially tropical, countries, large and extensive engineering works are often required to store and convey the abundant rainfall to arid regions at a distance. The simplest sources of water for irrigation are rivers which overflow their banks in the flood season, and inundate the adjacent low-lying lands, such as the Nile in Egypt, the Tigris and Euphrates in Mesopotamia, and the Indus in Sind. As, however, the land near the river bank is higher than the plains at the back, owing to the chief deposit of silt from the muddy flood-waters occurring when the overflow from the river loses its velocity on overtopping the banks, inundations would only occur with high floods, and would spread irregularly over the land according to variations in level.

To provide against these natural defects, and to obtain a uniform distribution of the fertilising silt as well as of the water, the basin system of irrigation was introduced, in which the land is divided by banks into a series of basins, and the water is admitted into the large low-lying basins at the back through sluices at the side of an embanked canal drawing its supply from the river above the highest up-stream basin of the set; whilst the smaller basins at a higher level adjoining the river are fed from a high-level canal deriving its water from the river further up-stream. By these arrangements the filling of the several basins in each set can be regulated with uniformity, and advantage is taken of a high flood to secure a large deposit of mud serving as manure. The mud is gradually deposited from the still water in the basins, and when the river falls the clear water is discharged, and the seed is laid in the damp mud. The basin system has been very extensively developed in Egypt; whereas in India canals draw the water from the rivers in flood-time, and irrigate the land by means of branch canals leading the water into field channels. Irrigation by inundation, however, only provides for winter crops; whilst the more valuable summer crops, such as sugar-cane, cotton, and rice, need water at definite intervals when the rivers are low, and protection from inundation during the flood season. This perennial irrigation enables two crops to be raised in the year, and more than doubles the value of the land; and the water stored by the Assuan dam has provided for the conversion of 450,000 acres from basin irrigation into perennially irrigated land. Besides rivers, wells, lakes, and artificial reservoirs afford sources for the supply of water for irrigation.

In India, wells irrigating 13 million acres are second only in importance to canals from rivers, which irrigate 17 million acres; whilst tanks enclosed by embankments, serving as primitive storage reservoirs collecting the rainfall and local drainage, irrigate 8 million acres; and the high concrete reservoir dam across the River Periyar, in the very rainy district of Travancore, stores up water which is discharged by a tunnel through the Ghats for irrigating the arid district of Madura, on the eastern side of the mountain range. Wells are used for irrigation in Egypt, but do not occupy at all the same important position as in India; though in olden times Lake Mœris provided a natural reservoir filled with water in flood-time, and supplementing the discharge of the Nile at its low stage, for which also the equatorial lakes act as regulators at the present time; whilst the reservoir formed by the Assuan dam supplies water for summer irrigation when the flow of the Nile is deficient. In the chapter on sources of supply it is stated that the storage required to secure the volume of water needed for the irrigation of summer crops for the whole of Egypt, during the hundred days in the year during which the flow of the Nile is at its minimum, is six thousand million cubic metres, of which one-sixth has been provided by the existing Assuan reservoir. The author enumerates five methods of increasing the storage, the first of which, namely, the raising of the Assuan dam, has been decided upon, since the book was written, for doubling the present supply; whilst the second proposal of building a second dam higher up the Nile has been rejected as impracticable. Little attention has been bestowed on the third project of forming a reservoir in the Wadi Rayan depression near the site of Lake Mœris; and a reservoir of this kind at the side of the river, when periodically filled up with muddy Nile water, would appear destined to be filled up before long with deposit.

The two last schemes for increasing the supply, advocated by Sir William Garstin, consist in effecting a great reduction in the loss from evaporation of the flow of the White Nile in passing through the swamps of the Sudd region, by diverting the discharge from the swamps into a straight cut, not less than 210 miles long, from Bor to the confluence of the River Sobat at Taufikia below the Sudd region, and combining this increased discharge with the utilisation of the Albert Nyanza for storage, during the four months of flood discharge, by regulating its outflow, so as to make up the deficiency during the remaining eight months. The new cut would have the great value of permanently increasing the flow of the Nile throughout the year below the confluence of the Sobat, but its construction would involve a very great expenditure, and occupy a long time; and it is very unfortunate that the fact of Lake Tsana, near the headwaters of the Blue Nile, being in Abyssinia is considered as precluding its utilisation as a storage reservoir for the irrigation of the Sudan and Egypt, with its great natural advantages of extensive area and commanding position. Several sections of reservoir dams are given in a chapter on dams and reservoirs, which, being drawn to various scales, are not readily compared, though forming an interesting series; but the foundations of the new Croton dam have had to be carried down more than forty feet deeper than shown on the section; and the Salt River dam, constructed for the irrigation of an arid district in Arizona, only about seventeen feet less in maximum height than the Croton dam, has the crest of its waste weirs raised the unprecedented height of 225 feet above the deepest part of the river-bed at the dam.

Interesting descriptions are given of the diversion weirs across rivers in India to raise their water-level for supplying inundation canals, and of the Zifta, Delta, and Assiout barrages for regulating the supply of irrigation water from the Nile, worked by Stoney's sluice-gates sliding on free rollers. The important function, however, performed by the Assiout barrage in raising the water-level of the river in August, 1902, during so low a flood of the Nile that the water could not flow into the great canals, until, by the prompt action of Mr. Webb in closing the gates, a sufficient head was obtained, for which the barrage had not been designed, should not be overlooked, as it preserved a large tract from a loss in non-irrigated crops of more than 600,000*l*. Moreover, the Esna barrage, in course of construction across the Nile between Assuan and Assiout, has been designed of sufficient strength to perform a similar duty when needed in perfect safety. Standard books, indeed, have been previously issued dealing with irrigation works on their grandest scale, in "The Irrigation Works of India," by Mr. Buckley, and "Egyptian Irrigation," by Sir William Willcocks; but the book under review will be very valuable for all persons interested in irrigation, by dealing in a single volume with and contrasting the principal works and systems of irrigation in these two great countries, and thus presenting a very comprehensive view of that most important subject of irrigation for the development of arid regions.

GEOLOGICAL EXPLORATIONS IN SINAI.

The Topography and Geology of the Peninsula of Sinai (South-eastern Portion). By W. F. Hume. Pp. 280+plates. (Cairo: National Printing Department, 1906.)

THE interesting region described in this memoir by the superintendent of the Geological Survey of Egypt extends from near Dahab along the western borders of the Gulf of Akaba to the promontory of Ras Mohammed. It lies east of Mount Sinai proper, or Gebel Musa, which is not, however, the highest of the Sinai mountains.

Attractive as the region is from an historical point of view, and interesting as it is to the naturalist, it offers few temptations for the ordinary tourist; and this not merely because it is an arid country. The Arab inhabitants are honest and obliging, but their dwellings consist simply of cloth stretched on a few poles, and placed under the protection of a rocky ridge. Keen as sportsmen, they use flint-lock guns, often of great length, serviceable for small game, as well as for the leopard, hyæna and ibex, which are the more abundant of the larger mammals. The country itself has been spoken of as "one of the most mountainous and intricate regions on the face of the earth," and Dr. Hume admits that much of it is a veritable wilderness with a bewildering complex of topographical structure. To the mountaineer it will hardly appeal, as there are no inaccessible peaks, but to the botanist and zoologist, who will find chapters specially devoted to them, and to the geologist, there are many attractions, not the least of which may be the absence of any extensive literature on their subjects.

The main portions of the area are composed of igneous and metamorphic rocks of ancient date—pre-Carboniferous at any rate. They rise in a mountain system trending north-east and south-west with a transverse chain that parts the region into two districts. The rocks include gneiss and sundry schists, granites, andesites, felsites, &c. The earliest sedimentary and volcanic rocks were penetrated by masses of granite, and some of the later intrusions have been arranged in strikingly symmetrical lines. The northern portion of this region is largely plateau, an old plain of marine denudation that appears only recently to have lost its capping of Nubian Sandstone. It has an average level of 1220 metres, except where cut by narrow gorges. In the southern portion, which comprises a multitude of ranges and peaks, the valleys are more deeply excavated, and in consequence the mountains, though lower, appear relatively higher than those in the north.

Still further north there is an area composed of barren Nubian Sandstone with overlying fossiliferous limestones of Cenomanian age, where the succession is greatly disturbed by trough-faults that have led to the production of rift valleys.

The structure, in a broad sense, is comparatively simple, as Dr. Hume observes, the main features having been produced by upheaval and dislocation rather than by erosion. Thus the principal mountain chain is due to a fault with a westerly downthrow of more than 5000 metres. Nevertheless, the influence of the rocks on the configuration of the land is well marked. The summits of many peaks are formed by felsite dykes; elsewhere parallel dykes of felsite and dolerite form the remarkable "dyke country," while the granite, which wears away in shells, presents curious rounded knobs and pillars. The coastal plain exhibits many features of interest in the presence of Miocene strata, and also of raised coral-reefs of Pleistocene age. Moreover, there are terraces of roughly stratified gravel in the principal valleys, as well as countless loose boulders. These were probably of torrential origin, distributed during the Glacial period, when, as Dr. Hume remarks, a small amount of *névé* might have accumulated on the Sinai mountains. Of still later date are some curious calcareous sandstones that contain oolitic grains, and are perhaps of marine origin. No economic products of great importance are known, though ores of copper, iron, and manganese have been found, and it is suggested that gold should be sought for.

It only remains to add that the work is well printed and illustrated. If the geological maps are exceptionally ruddy in tint, this arises from the extent of igneous rocks. For the topographical details the author expresses his indebtedness to Mr. H. G. Skill, who contributes also an appendix on meteorology. The photographic views enable the reader to gain a good idea of the scenery and rock-features, as well as of a hyæna-den, of certain stone-circles, and of the Sinai convent. H. B. W.

ELECTROCHEMISTRY.

A Text-book of Electro-chemistry. By M. Le Blanc; translated by W. R. Whitney and J. W. Brown. Pp. xiv+338. (London: Macmillan and Co., Ltd., 1907.) Price 10*s.* 6*d.* net.

THE new English edition of Le Blanc's "Electrochemistry" has followed very closely upon the publication of the fourth German edition. One is at once struck by the great increase in size of the book and by the large increase in the number of diagrams. From the translators' preface we notice that twenty-five of the diagrams have been added by themselves, and the book has certainly been improved by the additions.

Although the scheme of the book is much the same as it originally was, the additions are so numerous that it is almost a new work. By studying this edition and the first edition, which appeared in 1895, one is struck by the large amount of work which has been done in the domain of electrochemistry, albeit the fundamental laws have undergone very little change, the chief being one of degree rather than of principle. The ionic theory has been assailed from all sides, but although certain modifications have been made, such, for example, as the conception of the hydration of the ions, it must be conceded that it has rather gained strength than lost by the attacks. If those who assail the theory would give an alternative hypothesis which would as satisfactorily explain the phenomena of solution as does the ionic hypothesis, then the arguments would assume a more tangible form, and the ionic theory might be consigned to the limbo of history.

Prof. Le Blanc deals almost entirely with the theoretical aspects of electrochemistry, but at certain points he indicates the bearing of theory on practice. For example, on p. 18, when referring to the conversion of heat into electrical energy and of electrical energy into heat, a digression upon the "Electrical Furnace and its Industrial Importance" is made, the application of Ohm's law being given. Brief reference is here made to calcium carbide, cyanamide, carborundum, phosphorus, and the preparation of nitrates from atmospheric nitrogen, but the book, as already mentioned, does not deal with technical processes.

Chapter ii. deals with the development of electrochemistry up to the present time, and treats in the main with the development of the ionic theory.

More notice might have been taken of the difficult subject of the electrolysis of fused salts, the author having contented himself with a footnote on p. 316 referring the reader to Lorenz's "Die Elektrolyse geschmolzener Salze," and a remark that the phenomena are entirely analogous to those of aqueous solutions. The interesting phenomenon of electrolysis without electrodes is referred to on p. 317, and it is pointed out that in this case, as in electrolysis where both electrodes dip into the solution, Faraday's law is obeyed.

The translators, Drs. Whitney and Brown, have paid particular attention to nomenclature, and have endeavoured to be consistent throughout. The method adopted is set out in full in an appendix. The adoption of F instead of E for electromotive force is hardly happy; according to this rendering we get Ohm's law

$$C = \frac{F}{R}.$$

F is more generally used to denote a Faraday, or 96,540 coulombs of electricity. The translators employ the symbol Q for quantity of electricity. These are, of course, minor points, but they are inclined to muddle the student. It would perhaps be a good thing to convene an international committee so that electrical and electrochemical nomenclature might be standardised; at present it must be admitted that it is more or less chaotic.

From a theoretical standpoint we do not think it possible to meet with a better book than the one before us, and there is little doubt that it will be highly appreciated and widely studied. F. M. P.

AUSTRALIAN INSECTS.

Australian Insects. By Walter W. Froggatt, Government Entomologist, New South Wales. Pp. xiv+449; with 37 plates, containing 270 figures, also 180 text-blocks. (Sydney: William Brooks and Co., Ltd., 1907.) Price 12*s.* 6*d.*

THIS is the first general introductory work published on the insects of Australia, and it will be very useful to residents commencing the study of entomology, as well as to any European or American entomologists who wish for a general view of the Australian insect fauna, which contains a large number of highly interesting forms not met with in other parts of the world, though some species found in the extreme north appear to be only an offshoot from the rich tropical fauna of New Guinea.

The classification adopted is mainly that employed by Dr. D. Sharp in the "Cambridge Natural History." Mr. Froggatt commences his work with an introduction, tables of contents, and chapters on classification, distribution, structure, and fossil insects; after a detailed account of the principal groups of insects represented in Australia, including much interesting information about habits, &c., he concludes the book with chapters on the collection and preservation of insects, museum collections and types, publications dealing with Australian entomology, and an alphabetical index of Latin and English names.

We have, fortunately, no representative of the termites, or white ants, in Britain, though one species is found as far north as Bordeaux; but the author figures the huge nests of several Australian species, one of which, *Termes meridionalis*, Froggatt, builds what is called a "magnetic nest," like a brick wall, about 10 feet high and long (judging from the figure of the man standing in front), always pointing north and south, with the wall facing east and west. Another species, *Eutermes pyriformis*, builds a towering pillar-shaped nest, often 18 feet high.

Among the more remarkable specially Australian insects of various orders figured in this book, we may mention the curious apterous desert cockroaches (genus Polyzosteria, p. 19); the great Phasmidæ (of which *Podacanthus wilkinsoni*, Macleay, is figured as an example on plate v.); various strange grasshoppers, &c. (on plates vi. and vii.), and neuropterous insects (pp. 60, 61, plate ix.); the curious sawflies belonging to the genus Perga, &c. (pp. 71–73, plates x. and xi.); various handsome Buprestidæ (plate xviii.); the gaudy day-flying moths of the family Agaristidæ (p. 233) and the "whistling (stridulating) moths" of the genus Hecatesia, which emit sounds like the call of a Cicada (pp. 234, 235), of which latter group there are also many large and remarkable Australian species. We may also note that while the butterflies of Australia are not specially numerous or remarkable, the moths are extremely numerous and interesting, many being very remarkable either for their size, their structure, or their beauty. Of course, we do not meet with many British species, but among them we may mention forms of the painted lady butterfly and the convolvulus hawkmoth, hardly distinct from the ordinary European insects, and the well-known meal moth or flour moth (*Asopia farinalis*, L.) figured on p. 269.

Occasionally we note a trifling error; thus, on p. 41, the names *Locusta danica* and *Œdaleus senegalensis* appear to have been transposed by some accident.

We congratulate Mr. Froggatt on the publication of this useful and interesting book. W. F. K.

OUR BOOK SHELF.

Nature's Craftsmen: Popular Studies of Ants and other Insects. By Henry Christopher McCook. Illustrated from Nature. Pp. xi+317. (London and New York: Harper and Brothers, 1907.) Price 7*s*. 6*d*. net.

DR. McCOOK has long been known as one of the most painstaking and successful of the investigators of insect life in America, and the publication of a selection of his researches in a more popular form will, we hope, bring them under the notice of a far wider public than his former works have appealed to. There is no want of variety in the volume before us, and, in addition to ants and spiders, which are perhaps the author's favourites, he discusses bees, wasps, ant-lions, cicadas, caddises, &c. Still, nearly one-third of the book is taken up with the most interesting subject of the whole insect world, ants; probably the most highly organised of all known animals, born, not only in complete armour, like some of the ancient gods and heroes, but provided with all the tools and requisites necessary for their busy and industrious lives, even to brushes and combs, &c. Their wonderfully organised communities, where each works for all, and all for each, make our most advanced civilisations appear almost as barbarism in comparison, and our grandest architectural and engineering triumphs little better than mud-pies.

Among the most curious developments of ant-life are the so-called "honey-ants," where the nests contain a certain class of ants in which the abdomen becomes enormously distended with a sweet substance derived from a kind of oak-gall. When they have attained this condition, they pass their lives in the nests, hanging to the uneven roofs of the vaulted chambers, and they dispense food to the workers, by whom they are tended like the other dependent classes of the community, such as the queens and larvæ. An excellent illustration of one of these internal chambers is given on p. 99. This was taken from a nest eight feet long, three feet high, and a foot and a half wide, formed of galleries and chambers honeycombed in the solid rock.

The book is written in a very pleasing style throughout, with the exception of the last few pages, which bear signs of haste. The illustrations are also numerous and spirited, and many readers will be pleased to see the frontispiece, which gives us a portrait of the amiable author sitting on a lawn in a garden chair.

In conclusion, we may perhaps venture to express a regret that the word "instinct" is still used, as it appears to us to be an obsolete expression which is philosophically untenable at the present day, and which it would be just as well to avoid.

Concrete Steel Buildings. By W. Noble Twelvetrees. Pp. xii+408. (London: Whittaker and Co., 1907.) Price 10*s*. net.

THIS is a companion volume to the author's work on concrete steel, in which the distinctive characteristics of reinforced concrete were dealt with, and the theory underlying the design of structures in this material was discussed fully and in detail. In the present volume the author gives particulars of a number of typical pieces of constructional work in ferro-concrete which have been carried out in this country and abroad during the past few years. Mr. Twelvetrees has selected with great care the various examples of this method of building construction which he describes, and architects and engineers who consult this book will have little trouble in finding full descriptions of buildings similar to any they may be called upon to design. Examples of transit sheds for docks, railway goods stations, warehouses, factory buildings, business premises, villas, flour mills, hotels, theatres, &c., are all in turn fully described, and excellent illustrations are given of all important details, with copious notes as to the methods of making the concrete, the nature and disposition of the reinforcing steel, and of the results of proof tests of the structures. In the illustrations, which form a very important feature of a book of this nature, the author has wisely contented himself with giving the chief overall dimensions. When a radical departure from ordinary practice, such as the use of ferro-concrete, is made in constructional works, much can be learnt from the inevitable failures; and the last chapter of the book is devoted to a brief account of a few noteworthy collapses and of the probable causes of these failures, whether due to faulty design, or to bad workmanship, or to both causes. In the appendix a list is given of concrete-steel buildings and other structures in the United Kingdom, which will be found useful by those who are anxious to have the chance of inspecting such works before deciding to adopt this type of construction in any given case. An excellent index adds much to the value of this book for reference purposes, which will prove a welcome addition to the library of every architect and civil engineer. T. H. B.

Waterworks Management and Maintenance. By W. D. Hubbard and Wynkoop Kiersted. Pp. vi+429. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1907.) Price 17s. net.

THIS book is divided into three parts, the first dealing with the methods and principles of developing, improving, and storing water supplies; the second with the maintenance and operation of waterworks; and the third with water rates, and depreciation and valuation of waterworks property.

Although this book treats of American practice, and cannot be regarded as a text-book for experts, yet it contains a great deal of information useful to those having the designing and management of waterworks for urban districts.

The authors point out that in selecting a source from which a supply can be obtained a knowledge of the physical characteristics of the territory from which the water is to be obtained is the first consideration; a chemical analysis is necessary to detect impurities; and as drinking water is a medium through which the bacilli of certain diseases may be imbibed, and infection thus widely disseminated, a rigid bacterial examination has now become a recognised necessity.

Chapter i. treats of ground water supply and wells, the percolating capacity of soils, rate of filtration through sand, and purification works. The second chapter deals with water supply from rivers, and the means of fitting it for domestic use. The third chapter describes the class of engines in use for pumping, the other chapters treating of plans and records, service connections, meters and fittings, fire protection, financial management and accounts, water rates, and depreciation.

Attention is directed to the subject of electrolysis, or the effect that the introduction of street railways worked by electricity has had on the water mains; and illustrations are given showing the effect of electrolysis on the cast-iron mains. As a result of electrolytic action the metal of the pipes becomes in some cases so softened that it can be cut with a knife. Cast-iron is affected the least, wrought-iron next, mild steel the next, then high carbon steel, and lead the most. The salts in the ground also have a varying effect, the order of activity being chlorides, nitrates, and sulphates. The drier the soil the more resistance it offers to the passage of the current. Wasting of the lead in the joints also leads to leakage and eventual failure of the pipe by the blowing out of the lead.

Pictures from Nature's Garden; Stories from Life in Wood and Field. By H. W. Shepheard Walwyn. Pp. 311; illustrated. (London: John Long.) Price 6s.

To the naturalist the chief point of interest in this little volume is undoubtedly centred on the illustrations, which are reproductions from photographs by the author. Among these we may specially refer to one of a dormouse asleep (p. 34), which, so far as we know, is unique, and certainly of great interest. The photograph of a sleeping bat, apparently a pipistrelle (p. 27), is likewise excellent, as is also one of a Japanese or Manchurian sika-deer, with the white "chrysanthemums" on the buttocks fully expanded (p. 306). In both these instances it is a pity that the names of the species depicted are not given. As to the text, we venture to think even the author himself would admit that it is scarcely of a nature demanding detailed notice in the columns of this journal.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

On Correlation and the Methods of Modern Statistics.

IN NATURE of August 29 (p. 461) appeared some account of a discussion at the British Association on modern methods of treating statistics. The following paragraph occurs:—

"Mr. A. R. Hinks, who was somewhat sceptical as to the general applicability of the new methods, inquired what meaning could be attached to the value 0·3 of the correlation coefficient in such cases as $y = \log x$. He also gave an example in which questionable conclusions had been arrived at by the method, the reason being that certain groups of stars had been studied for special purposes, while others had been neglected."

The obvious answer to the first part of Mr. Hinks's inquiry is that no meaning could be attached to the particular value 0·3 unless we were told what part of the relation $y = \log x$ it referred to, and then it would have a quite definite but limited meaning. Every statistician trained in modern methods in the case of statistics belonging to new material plots his regression lines and tests the approach to linearity in his material. When he finds any orderly system, but no approach to linearity, he naturally tests the dependence of his characters by the correlation ratio. That test applied to Mr. Hinks's case of two absolutely correlated variables $y = \log x$ gives unity or perfect correlation, as we might anticipate.

Writing to Mr. Hinks for further information as to the bearing of the second part of his criticism, he tells me that the report is too brief to be intelligible, and owing to his courtesy I have been provided with a fuller report of his speech, in proof, for the Journal of the Royal Statistical Society. The "questionable conclusions" reached by the method of correlation to which he refers occur in "a recent paper published under the auspices of Prof. Karl Pearson" (Winifred Gibson, Monthly Notices R.A.S., vol. lxvi., p. 445), and the special point to which Mr. Hinks refers is the result reached by Miss Gibson for the relationship between parallax and photometric magnitude. The point is an extremely interesting one, and that must be my excuse for ventilating the matter in the pages of NATURE. Mr. Hinks makes two criticisms, the first as to method and the second as to matter.

First, as to Method.—Mr. Hinks says that if the stars were uniform in size and brilliancy, the parallax and magnitude relation would be logarithmic, and consequently the coefficient of correlation would not be unity. "He understood that in such a case it was proper to use correlation ratios, but not correlation coefficients. If this was so, he would ask the exponents of modern methods to erect a very large and conspicuous danger signal to keep astronomical statisticians from falling into such a trap."

Now Miss Gibson's paper was, I believe, the first to place modern statistical methods before astronomers, and the statistician may well make slips in a new field. But as to *method*; what does she actually do? She calculates (1) the correlation coefficient between magnitude and parallax, (2) the correlation coefficient between parallax and amount of light, and finding both small, she plots (3) the regression line, and calculates the correlation ratio, and as this takes a value of 0·4, she points out that the correlation coefficient is not the suitable measure in this case. In other words, she puts up the very danger signal which Mr. Hinks requires! I fail entirely to see how Mr. Hinks's remarks as to the logarithmic relation apply to Miss Gibson's work. She has treated the matter correctly from the statistical standpoint, and her paper shows that she was fully aware of the possibilities attached to a logarithmic relationship, which she more than once cites.

Secondly, as to Matter.—Here Mr. Hinks is on safer ground, but one in which I fancy astronomers have been guilty of a considerable amount of circular reasoning.

They start from the hypothesis that magnitude is very closely related to parallax, and when the statistician shows that the best determined parallaxes show no continuous relationship between parallax and magnitude, they turn round and say: "Yes, but our stars were selected because they had big proper motions." They thereby screen entirely the fact that the fundamental hypothesis that the brighter stars are much the nearer as yet awaits statistical demonstration. Miss Gibson worked on the seventy-two stars given by Newcomb, as of fairly well-ascertained parallax. Mr. Hinks says that the peaks in Miss Gibson's parallax-magnitude curve are in two out of three cases due to selection of certain stars because of their exceptional proper motion. Now this naturally leads us to inquire why the stars with magnitudes about 2 and again about 6 were not selected by their proper motions, but those about 4 and 5 and again those about 7 to 9 were. Further, there is a fundamental point which Mr. Hinks has to meet. Statistically to produce large effect on the correlation of two quantities by selection, the character used for selection must have high correlation with both. In other words, if the selection of stars by proper motion is to pull down the assumed high relationship between magnitude and parallax to a low value, not only must magnitude and proper motion be highly correlated, but proper motion and parallax. Now these correlations have been carefully investigated, and we know what they are—they are such as to influence, but not very much influence, any relation between parallax and magnitude. Now I think the circular process of the reasoning I have referred to will be visible. It runs as follows:—

There is a high relationship between parallax and magnitude; it is not statistically evident, because the parallax stars have been chosen on account of proper motion; this involves a very high correlation between proper motion and magnitude; a very moderate correlation, but not a high correlation, does exist. Shall we say that these stars have been selected by reason of something else?

Surely the hypotheses of high relationships between magnitude and parallax and proper motion are of sufficient importance to deserve *proof*, rather than to be taken as axiomatic? If the reader will examine Table III. of vol. ii. of the Yale Observatory Memoirs (p. 202), which has reached me since Miss Gibson's memoir appeared, he will find the parallaxes of 163 stars, differing widely from Newcomb's series, dealt with, but the correlation ratio (0·28) is even less than that (0·40) found for Newcomb's material. The specious appearance of descending magnitude with the parallax groups is almost wholly due to the first group of large negative parallaxes, which seems merely to signify that large errors of parallax are more common with faint stars. I take it that 0·35 is an excessive value for the relationship between proper motion and magnitude.[1] Against these merely moderate relationships I would place those connecting spectral class and magnitude, which can be as high as 0·69, and, again, the fact that colour and magnitude are related at least as closely as parallax or proper motion and magnitude; and I would venture to ask whether it may not be that the mass, the chemical constitution, and the life-history of a star, as evidenced in its spectroscopic character, have sensibly more to do with the magnitude than its mere distance? After all, almost any theory of distribution of stellar mass, position, and motion would lead us to expect a relatively small correlation between proper motion and distance, sensible, indeed, on the average of great numbers, but as ineffectual for the purpose of selecting an individual as choosing an able assistant by a preliminary measurement of his head.

KARL PEARSON.

Biometric Laboratory, University College, London.

Plague Prevention in India.

HIS MAJESTY'S recent letter on this subject to the Government of India was well designed to stimulate the Government to more active efforts against the disease, but has been followed by pronouncements from it which do not suggest any strong hope that that object will be attained. In these pronouncements the Government of India issues advice to the heads of local administrations regarding the methods of dealing with plague—a familiar matter; but, as the *Pioneer Mail* of August 23 remarks:—"Nothing is said about finding the money for the proper carrying out of these recommendations." There is, moreover, another defect which suggests further doubts. The whole of the edict is filled with injunctions to avoid "any action which excites the opposition of the people." Now as almost every sanitary action, from cleansing the backyard upwards, does excite the opposition of a large percentage of the people, this policy means, I fear, not the advancement, but the abandonment of any large-scale operations against plague in India.

Obviously, in epidemics as in war, the superstitions, fancies, and trifling objections of the individual must give way to the public interest. The only alternative is widespread death. To use compulsion may be unpleasant to a Government, but it is a duty to use it. If a Government does not use compulsion it must be held responsible for the fatal results. In my experience, popular opposition to sanitary measures is not really a serious matter. The strength of it is in inverse proportion to the capacity and resolution of the authorities. What opposition has occurred in this case has, I think, been created largely by the original weakness which gave in to it. It is useful to compare the despotic and successful sanitary methods of the Americans with the feeble and futile system adopted in India.

It is difficult to see the object of this pronouncement of the Government of India, which will apparently tend only to hamper executive officers in the performance of their duties. We must infer that the recommendations were made chiefly with a view to please the numerous pseudo-philanthropists who exert so much evil influence in the councils of the great empire of Letspretendia.

Those who wish to ascertain what is really being done against plague in India, compared with statements in Parliament, should consult Prof. Simpson's recent lecture in the *Lancet*, especially that of July 27. According to him, the Government has spent only about 1,500,000*l.* on plague prevention, against 17,000,000*l.* on famine relief, and this in spite of the fact that 20,000,000*l.* surplus revenue has been collected during the same period (since 1896).

I have not seen any complete discussion of the actual measures which should now be taken against plague in India, but think that the following will be approved of by most hygienists who have considered the matter:—

(1) The whole of the plague administration should be centralised, removed from the hands of the civilians who have hitherto obtained such poor results, and put in those of experts, on the American system. This administration should allot the expenditure, indicate the researches, direct the practical measures, publish monthly reports showing exactly what it is doing, and be held responsible for the results of its work.

(2) The expenditure on plague research should be increased ten-fold. The present commission is doing excellent work, but the investigations can be obviously enlarged so as to include many new fields, such, for instance, as the search for a specific therapeutic agent, on the lines of work now being done in connection with sleeping sickness.

In the message of the Government of India there is no sufficient statement on either of these important points. We may rest assured that if they are not included the plague measures will remain as ineffective as before.

RONALD ROSS.

The University, Liverpool, September 16.

Root-action and Bacteria.

IN NATURE of July 18 (p. 270) I mentioned that I had proved the excretion from plant roots of a toxic substance. This substance proves to be alkaloidal in nature, and is precipitated, in addition to the usual alkaloidal reagents, by most of the substances in use as artificial manure. Potassium sulphate and chloride appear to be the most complete precipitants of all the reagents so far tried. They appear to precipitate the substance in the form of a base—a white amorphous powder. The amount excreted is by no means negligible, and *Sesamum indicum*, indeed, in its early stages at least, appears to excrete more solid matter than it builds up in its own substance.

Details are given in a Memoir of the Agricultural Department of India.

F. FLETCHER.

Ghizeh, Egypt, August 22.

[1] Dr. A. Lee has worked out for me the correlation ratio for more than 300 northern and 300 southern stars in Boss's catalogue. For the southern stars the correlation of magnitude and proper motion is insignificant, for the northern stars it is much less than in the above cases, and would be insignificant but for a group of four stars with magnitude less than 1·5. These points will he brought out in a forthcoming memoir.

SOME SCIENTIFIC CENTRES.

X.—The Liverpool School of Tropical Medicine.

On July 9, 1898, Major Ronald Ross completed the proof that the malaria of birds was transferred by the bite of mosquitoes from infected to healthy birds. In December, 1898, a commission was dispatched by the Colonial Office to British Central Africa to study blackwater fever, to inquire into the truth of Ross's discoveries, and to study the whole question further.

About this time, Sir Patrick Manson had been urging the formation of schools of tropical medicine, and the subject had received energetic support from Mr. Chamberlain. In Liverpool, also, the subject was warmly taken up, and with such practical result that the first tropical school was founded by Sir Alfred Jones, K.C.M.G., in November, 1898. Major Ross was appointed the first lecturer of the Liverpool School of Tropical Medicine, and the school was formally opened by Lord Lister on April 21, 1899, and on July 1 Major Ross delivered his inaugural lecture, directing attention to his scheme for extirpating malaria by attacking the pool-breeding mosquitoes. The further result of this was that at the end of July, 1899, the first (malarial) expedition of the school was dispatched to Sierra Leone, West Africa. This was the first of those expeditions to the tropics which have made the school famous. Since 1899 there has not been a year in which some expedition has not been carrying out research in the tropics, and at the present moment there are at work one in Brazil at yellow fever, another in Africa on trypanosomiasis; and a third is on the point of starting to study blackwater fever in Central Africa.

The educative effect of these expeditions has been immense, and we hardly think it can be doubted that every person interested, not only in West Africa, but in the tropics generally, owes a deep debt to the school. Not only has the direct practical outcome in the saving of life been great, but indirectly also a powerful effect is exercised on the young generation, so that now those going to the tropics do so with a knowledge of what risks they run in respect of malaria, and how to avoid them.

But, further, the influence of these expeditions and of the reports furnished by them has given an immense impetus to anti-mosquito measures all over the world. The most successful instance and the best known of these measures has been the extinction of malaria at Ismailia, and perhaps it is not too much to claim that the influence of the Liverpool School of Tropical Medicine has determined the magnificent success of anti-mosquito measures under Col. Gorgas against yellow fever at Havana.

In this connection it is of interest to point out that Major Ross will read a paper at Berlin this autumn summing up the progress of anti-malarial measures in British Possessions all over the world. The gain to the public is, then, we believe, a great one. That the scientific results have been not inconsiderable is evident from the publications of the well-known memoirs of the school. Since 1899, when the first memoir was published, twenty-one memoirs had been published up to 1906, together with a text-book, "The Practical Study of Malaria and Other Blood Parasites."

Perhaps the two most striking discoveries recorded in these memoirs were, firstly, that of Dutton, of a human trypanosome in man, *T. gambiense*, the finding of which was the forerunner of that of the same trypanosome as the causative agent of sleeping sickness; and, secondly, Dutton and Todd discovered, independently of Milne and Ross, the spirochæte, *S. duttoni*, of African tick fever, and they showed that it was transmitted by the tick *Ornithodorus moubata*.

Thus the school can claim a worthy, if not exclusive, share in the elucidation of three of the great diseases of Africa, viz. malaria, sleeping sickness (trypanosomiasis, and African tick fever. Thomas's successful experiment in Manaos in infecting chimpanzees with yellow fever by means of mosquitoes is also worthy of mention.

These expeditions have cost the school large sums of money, and have also involved the loss of two valuable lives, viz. those of Dr. Walter Myers and Dr. J. E. Dutton. Myers, who gave promise at Cambridge of a distinguished career, died of yellow fever at Para shortly after the commencement of his work. Dutton's brilliant career was cut short by death while working in the Congo. Two recent developments show that the school is still in vigorous youth, and is not content with its past achievements. We have above alluded to the publication of the memoirs. These memoirs were exclusively devoted to the publications of the results of the various expeditions of the school, and from this cause and from their somewhat expensive price it was thought advisable to change their form and to enlarge their scope. A journal of high standard devoted to tropical medicine and parasitology has long been needed, and it was resolved to admit publications from others than those who were connected with the school. The result has been to establish the "Annals of Tropical Medicine and Parasitology," which promises to have a successful and useful career before it.

Prof. Ronald Ross, F.R.S.

The expeditions, as we have already stated, have become a marked feature of the school's activity. They have necessitated the establishment of special research laboratories. For although underlying these expeditions is the idea that research into tropical disease is best carried out in the area where the disease is endemic, yet much material is accumulated during these expeditions which can only be worked out subsequently. As the laboratory accommodation is insufficient to accommodate all this material, a research department under a special director has been established at Runcorn, where ample room for animals and laboratory experiments exists. These laboratories also supply parasites in a living condition for the purposes of study in the teaching laboratories. Here numerous experiments have been and are being carried out in the treatment of sleeping sickness (trypanosomiasis). It was Thomas who first suggested atoxyl in the treatment of trypanosomiasis. This, followed by mercury, is probably the most hopeful treatment now in existence.

We may finally briefly refer to the laboratories, where the public, no less than by the expeditions, benefits by the training of medical men, already stationed in or about to proceed to the tropics. In fact, it is stated in its prospectus that the first of the objects of the school is to give a practical training to medical men proceeding to the tropics. In connection with this training, which is as thorough as the too-brief period of three months will allow, about thirty medical men pass through the school in the year, a number which is not too great for the staff successfully to cope with.

THE YEAR'S PHOTOGRAPHY.

THE annual exhibition of the Royal Photographic Society is now open at the New Gallery in Regent Street, and will remain open until September 26. Artistic, professional, and commercial photography are well represented, but we are concerned chiefly with the scientific and technical sections. The exhibition aims at showing the year's progress, and as the item that has aroused the most interest since last October is the commercial introduction of the Lumière "autochrome" plate, which serves for the copying of coloured objects in colour on a single plate, photographs by this method form the most conspicuous group in the exhibition. The results are transparencies on glass, and are conveniently arranged for viewing them in a darkened portion of the balcony. The character of the new plates has already been described in these columns, therefore it is sufficient to say here that they depend upon the usual principles of three-colour work, and that their novelty consists in having each plate complete in itself, and needing no instrument, taking or viewing screen, or other special accessory for their use or examination. Messrs. Lumière are to be congratulated on their success, and well deserve the medal that has been awarded them. As to the results, some appear to be excellent, while others must be faulty from the predominance of one of the three colours; but, as we have so often said before in connection with colour work, it is impossible to judge of the results as one would like to be able to unless the original is side by side with the copy. No exhibitor seems to have cared to submit any of his pictures to this test. This remark also applies to the other colour photographs, which demonstrate that the multiple-plate methods still hold their own, and that the standard of perfection has, perhaps, a tendency to rise. Photomicrographs of the grain of the "autochrome" plates and spectra taken on them are on view, and serve to show the limitations of three-colour processes when dealing with the comparatively unmixed colours of the spectrum.

Some of the photographs of Mars, taken two months ago at the Lowell Observatory, are shown by Profs. Lowell and Lampland. Several canals are visible, and one has been photographed double. Drawings of the planet made under high magnification are added for the sake of comparison. The Greenwich Observatory send four frames of work done during the year, which include the recent comet, Saturn and its satellite Phœbe, and Jupiter and its satellites VI. and VII. These astronomical exhibits will prove of great interest, not only to those who are students of the subject, but also to those whose chief source of information is their daily paper.

Of the considerable collection of photographs of living creatures it is possible to refer to only a few. Mr. Douglas English contributes a series of photographs illustrating the life and history of the British mud-wasp, but his most striking exhibits are those in which he has obtained a very close imitation of the colour of the original by locally modifying the image with reagents, and in one case backing it with "metallic powders." He is bold enough to send the actual skin in one case to show how very nearly he has reproduced the colour. Notwithstanding Mr. English's success, we are inclined to discourage work of this kind, because by such manipulation the examples lose much of their value as photographs, and it is very doubtful as to how long the colours produced in this way will remain without change; but it must be admitted that at present they convey an excellent idea of the originals. Among the other exhibits of special interest may perhaps be mentioned Mrs. Veley's "Lemur Studies," Mr. W. Bickerton's three photographs of the common tern alighting at its nest after flight, and Mr. Alfred Taylor's ten photographs of the "Long-eared Owl from the Egg to Maturity." Mr. Daniel Finlayson's three frames are of a kind that must be exceedingly useful for teaching purposes. He shows the leaves of four common plants "awake and asleep," five photographs illustrating "Red Clover strangled by Dodder," and ten distinct examples of "Seed Dispersal by Hooks, Parachutes, and Wings."

Pathological work is not much in evidence, but the majority of visitors will doubtless find a personal interest in Dr. G. H. Rodman's radiograph of the two hands of a young lady, one of which was severely affected by rheumatism. The small bones of the diseased wrist are apparently matted together. Mr. Martin Duncan's photomicrographs of living bacteria are noteworthy, though for practical purposes of identification microscopists will probably continue to prefer to deal with dead "preparations." Mr. Duncan gives no hint of his method which he "has now perfected."

There are numerous other exhibits of many various subjects, for the collection of this year surpasses that of any previous year that we recollect in interest, variety, and general technical excellence; but we must refer to Mr. Frederick E. Ives's diffraction gratings, though they are not strictly photographic. These replicas are made with fish-glue instead of gelatin, and, by the means described in the catalogue, he has obtained, in addition to normal results, "freak gratings" of many different kinds. Not only can most of the light be thrown into the first-order spectrum on one side, but vigorous copies can be made from weak originals. A considerable variation of colour effects is shown in the "freaks," and may serve to indicate some of the possibilities of variations that may occur to a greater or less extent in gratings intended to give normal results. These gratings can be seen on application to the attendant by anyone interested in the subject.

Those who wish to see the results of the practical application of photographic methods to pictorial purposes will find a collection of excellent examples in the west room which is devoted to this section, and a choice selection at the Gallery of the Royal Society of Painters in Water Colours, 5a Pall Mall East, this latter being the fifteenth annual exhibition of the Photographic Salon. In neither case is the method of production stated, so that it is not possible to know how much is pure photography nor whether any given example is likely to be reasonably permanent. It is, however, a noteworthy fact that, besides the platinum and carbon processes in their numerous variations, this year there are many "oil prints," that is, prints in which the image is produced in pigments prepared in oil, by the process introduced by Mr. G. C. H. Rawlins a year or two ago. It is satisfactory to note that as these processes that yield results of undoubted trustworthiness increase in number, there is a tendency for them to oust those that are less desirable.

C. J.

INTERNATIONAL SEISMOLOGICAL CONGRESS.

THE second conference of the International Seismological Association will be held at the Hague on September 21–25. The first two days will be occupied by the permanent commission, which will discuss the financial reports from the secretary and the director, election of officers, and other matters relating to general administration. The meetings of the general assembly will take place on September 24 and 25. Amongst matters of immediate seismological interest to be discussed we notice the question of establishing a station at Kashgar, seismological bibliography, the annual publication of a catalogue of earthquakes for the entire world, and the geographical distribution of sound phenomena which have had hypogenic origin. Other scientific questions which will receive consideration relate to the rapid publication of data relating to large earthquakes, the reduction of seismic elements to absolute values, and the reproduction of seismograms. Discourses and conferences relate to a catalogue of microseisms for the year 1904, and the earthquakes in that year which have been recorded throughout the world, together with the analysis of seismograms, the publication of seismograms obtained on August 16 and 17, 1906, and the new work now in progress at Strassburg Observatory. To carry out the above programme evidently means a full four days' continuous work.

From what we read in daily papers and magazines, it is clear that much haziness exists in the public mind as to how earthquakes came to have an international importance. The first successful attempt to treat earthquake phenomena in a scientific manner was undoubtedly due to the late Robert Mallett. Strange as it may sound, his work practically remained in abeyance until Japan, desiring to acquire some of the material civilisation of the west, invited to her shores people from all quarters of the globe. Although none of these was asked to give instruction relating to earthquake phenomena, none of them could refrain from giving serious attention to movements which were frequently, and we may even say rudely, brought to their notice. In 1880 a seismological society was established. The first important work accomplished by this society was to devise instruments which would measure earthquakes, the result of which was that constructors for the first time learned that earthquake forces could be expressed in definite mechanical units. This led to new types of structures, and these experience has shown will stand severe shakings whilst ordinary European structures seriously suffer. This issue of seismological investigation, inasmuch as it bears upon the safety of life and property, indicates that the study of earthquake phenomena is of more practical importance than is generally supposed. Among other outcomes of the study we may mention the determination of suboceanic sites where it would be fatal to lay a cable, the indication where certain cables have failed, and the collection of materials which enable those who insure to adjust rates to risks.

Whether the information bearing upon what may be called the "by-products" of seismological investigation will attract the attention of the International Association remains to be seen. Should it do so, then the British Government and the British investor may be compelled to go abroad to supply their wants. At present the work of the association is chiefly directed to that which is purely scientific, teleseismic records and their interpretation receiving the most attention. Since 1755 it has been recognised that a very large earthquake occurring in one country might give evidence of its existence in very distant regions by causing water in lakes or ponds to oscillate. In 1877 the oscillations of a bubble in a level at Pulkova were traced to an earthquake which destroyed Iquique. In 1884 cryptoseismic movement was frequently recorded in Japan. The late Dr. E. von Rebeur-Paschwitz also recorded these unfelt movements, which he traced to definite seismic centres.

In connection with the history of international seismological cooperation, it may be here mentioned that one of the first attempts to obtain the same was made in 1883 through his Excellency the late Sir Harry Parks and the Foreign Office of Japan. In 1895 attempts to repeat the same came from Japan and from Germany; the first successful attempt was that undertaken by the British Association in 1897, which now enjoys the cooperation of about fifty similarly equipped stations fairly evenly distributed over the land surfaces of the globe. This is an asset of considerable importance which we hope may continue to exist, and at the same time be able to assist the congress now sitting at The Hague.

THE IMMIGRATION OF SUMMER BIRDS.[1]

THIS second report is very similar to that first issued, which was noticed in NATURE for September 6, 1906. It has been prepared on the same lines, and is open, to a large extent, to the same criticism, though we are glad to observe that the various immigratory movements are now associated with the weather conditions prevailing in countries south of the shores of the Channel.

In the best interests of the inquiry, and at the risk of again being considered "somewhat hostile," the writer would once more urge the committee to confine its labours for several years to come to the publication of the observations received, and to refrain from drawing conclusions of any kind from its present limited knowledge. It serves no useful purpose to mention that particular species arrived on certain sections of the coast only, for in all but a few cases their supposed absence merely indicates that they escaped the notice of the observers, and nothing more; they have long been known as immigrants on the sections of the coast from which the committee has not, as yet, received information concerning them. The publication of observations of this nature has already misled some who have but little knowledge on the subject; and so also has the statement that the few species which arrived on the south-east coast held a north-westerly course and so reached Wales! No proof is offered in support of this very remarkable speculation, nor is any worthy the name

[1] Report on the Immigrations of Summer Residents in the Spring of 1906. By a Committee appointed by the British Ornithologists' Club. (London: Witherby and Co., 1907.) Price 6s.

afforded by the published data. In fact, the report generally bears evidence of having been drawn up on the supposition that the data are practically complete, whereas such perfection, or anything like it, is an absolute impossibility. The committee, and others interested in bird migration, would do well to remember that not one bird in a thousand that arrives on our shores, or which proceeds inland or coastwise, comes under the notice of competent observers, numerous though they be. This important consideration makes it imperative that some years must be devoted to the amassing and testing of materials ere the foundations of a trustworthy report can be laid.

The records collected by the committee are numerous, and, as interim reports seem to be desired, may be considered of sufficient interest and value to render them worthy of publication. There are a number of unfortunate slips in the report, some of which are so palpable that it seems strange that Mr. Bonhote's—the preparer's—colleagues on the committee did not detect them. W. E. C.

PRESERVATION OF MEMORIALS IN AMERICA.

As an outcome of an article which appeared in these columns on June 6 (p. 130), entitled "Landscape Protection in Germany," the American Scenic and Historic Preservation Society has sent us some of its literature. This society was incorporated in 1895 by a special act of the Legislature of the State of New York, and holds, therefore, a semi-official position in that State. It has to report annually to the Legislature, and has a right to make recommendations regarding improvements to any of the municipalities.

The society's aims are summed up to a large extent in its name. It endeavours "to protect beautiful features of the natural landscape from disfigurement, either by physical alterations or by the erection of unsightly signs and structures, and to preserve from destruction remarkable geological formations or organic growths possessing an artistic or scientific value"; and it also endeavours "to save from obliteration names, places, and objects identified with local, State and national history; to erect suitable historical memorials where none exist."

In towns and villages it aims at procuring parks and open spaces, where necessary for the health and comfort of the inhabitants; it makes every effort to prevent the destruction of trees, and stimulates as much as possible a desire for local beautification in the minds of the public.

The funds depend on the members' subscriptions and voluntary contributions. The Government gives no financial support, but public money is occasionally placed at its disposal for acquiring or keeping in order properties for the public benefit. It is also empowered, according to its charter, "to receive real or personal property, in fee, or trust . . . and to administer it as a public trustee."

By means of meetings, free lectures, circulating historical pamphlets, and various educational means, the society endeavours to engrain in the people an appreciation of the beauties of nature, and also a patriotic interest in historical localities. Its efforts are becoming fully appreciated all over America, for its services are requisitioned in many different parts and in many different ways, the verifying of historical sites and putting up of tablets to commemorate noteworthy events being the most usual. America is much to be congratulated on having such a society, and especially one that is so active.

NOTES.

PROF. J. B. FARMER, F.R.S., has accepted the editorship of the *Gardeners' Chronicle* in succession to the late Dr. M. T. Masters, F.R.S.

THE inaugural address of the coming session of the Royal Scottish Geographical Society will be delivered by Lord Milner in the Synod Hall, Edinburgh, on Wednesday, November 13.

WE regret to see the announcement that Prof. L. F. Vernon Harcourt, emeritus professor of civil engineering at University College, London, died on Saturday, September 14, at sixty-eight years of age.

THE managers of the Metropolitan Asylums Board have approved of the erection at Belmont, Surrey, of new laboratories for the preparation of diphtheria anti-toxin and for bacteriological work. The total expenditure on the laboratories is not to exceed 6500*l*.

Symons's Monthly Magazine, the present issue of which is the five hundredth number of that interesting organ of meteorological opinion, announces that Dr. G. Hellmann has been appointed professor of meteorology in the University of Berlin and director of the Prussian Meteorological Service, in succession to the late Prof. von Bezold.

A TELEGRAM from Seattle states that a volcano in the Aleutian Islands became active on September 1 and 2, and that ash ejected from it fell upon twenty villages. A disturbance recorded by a seismograph at Washington on September 2 appears to have been due to this eruption.

THE Royal Geographical Society has received the following telegram referring to the Anglo-American Polar Expedition, signed by Captain Mikkelsen and Mr. Leffingwell:—"Sledge trip covering 500 miles crossed edge continental shelf twice soundings 50 miles off coast and beyond 630 metres no bottom ship lost next year continuation geology ethnography surveying and exploration Beaufort Sea."

THE Royal Commission on Mines has appointed Dr. A. E. Boycott to make an investigation with a view to determine whether there are any indications of the disease known as ankylostomiasis (miner's worm) in coal mines in Great Britain. Mr. John Cadman has also been appointed to make a series of observations and tests of mine air in connection with the question referred to the commission whether any steps should be taken to lay down a standard of ventilation in mines.

PROF. E. HECKEL, director of the Colonial Institute at Marseilles, has been awarded the gold medal founded by Dr. F. A. Flückiger, of Strassburg, in 1893, and awarded every five years, in recognition of steps taken to promote the advancement of scientific pharmacy, irrespective of nationality. Mr. E. M. Holmes, the curator of the museums of the Pharmaceutical Society of Great Britain, received the first medal, and the second was presented to Dr. C. Schmidt, of Marburg.

THE discovery of an interesting dene-hole on the south side of Windmill Hill, Gravesend, was described in the *Times* of September 14. It appears that a workman engaged in making excavations for building purposes discovered a shaft, rather less than 3 feet wide, which descended vertically to a depth of 55 feet from the surface, when it entered the chalk, and after piercing 3 feet of this rock opened out into a large artificial cavern. This cave was divided into two chambers by a roughly hewn wall of solid chalk, a western chamber measuring about 30 feet by 24 feet, and an eastern one about 24 feet by 20 feet. The excavation consequently presented the exceptional character of a twin chamber. The roof showed numerous holes, apparently made by picks of horn used in excavating the chalk, whilst the walls had been smoothed, perhaps by means of flints. A curious smoothness on part of the roof of the eastern chamber, clearly due to long-continued but gentle friction, led to the suggestion that some substance like corn in the ear had been pitched into the chambers from the top of the wall, which formed a platform under the shaft, thus apparently lending some support to the view that the dene-hole may have been used as a subterranean store-house for grain.

Owing to the development of wireless telegraphy in the Navy, the Admiralty has decided to establish a separate branch of the Service for this work, and this branch will be kept quite distinct from the ordinary signalling branch. In order to place the new section on a proper basis, about three hundred men will be turned over to it as volunteers, taken from the leading signalmen as well as able seamen and marines. Ultimately the telegraphists will be recruited from boys entered in the training ships in the usual way. The Admiralty has also decided to erect a wireless telegraph station for the use of the Royal Naval Service at Corkbeg, near the mouth of Cork Harbour. This station is to supersede Roche Point station, the situation of which is not considered safe.

The President of the Local Government Board has authorised the following researches under the grant voted by Parliament in aid of scientific investigation concerning the causes and processes of disease:—(1) Further study by Dr. Sidney Martin, F.R.S., of the chemical products of pathogenic bacteria. (2) Bacteriological investigation by Dr. F. W. Andrewes of the air of sewers and drains. (3) Observation by Dr. W. G. Savage of the bacteriology of "garget" and maladies of the udder or teats of milch cows, and of possible relation of sore throat in the human subject to pathological conditions of the udder and teats of these animals; also investigation by him of paratyphoid fever and its microbic cause. (4) Joint investigation by Drs. M. H. Gordon and T. J. Horder of the life-processes of the Meningococcus, with a view to means of combating cerebro-spinal fever.

The Permanent International Commission of Aëronauts and the International Federation of Aëronauts held conferences at Brussels last week, under the presidency of Prince Roland Bonaparte. An address on the advantages of the universal adoption of the metric system in aëronautics was read by Dr. Guillaume, and a resolution in favour of its adoption by all affiliated aëro clubs was carried unanimously. Papers were also read on air currents, dynamics of the atmosphere, wind velocity, temperatures at high altitudes, aëronautic observatories for practical meteorology, the history of dirigible balloons, progress of the problem of flying and aërial navigation, and the economical manufacture of hydrogen for balloons. On Sunday, thirty-four balloons started from the Parc Cinquantenaire in competition for the valuable cup to be presented to the aëro club of the country the balloon of which covers the greatest distance. The contest was won by a German balloon, which descended at Bayonne, having covered a distance of 1000 kilometres. The second place is shared by a Swiss balloon, which covered 900 kilometres, and a British balloon, which travelled 890 kilometres. The international conference will be held next year in London.

The *Frithjof*, with the Wellman expedition on board, arrived at Tromsö on September 13, the attempt to reach the North Pole by airship having been abandoned for this year. On September 2 Mr. Wellman's balloon, the *America*, was towed about two miles in a northerly direction to Vogel Bay Island. Off this island the airship was set free, but the wind, coupled with a driving snowstorm, finally beat it back over the mainland of Spitsbergen. The gas being allowed to escape, the airship descended and landed on a glacier about half a mile inland. No damage was sustained, except that a few tubes and wires were broken and bent. The scientific instruments on board were uninjured. The *America* was in the air three hours. In the one hour and a quarter during which she was travelling by her own power she made about fifteen miles, including some beats to windward, demonstrating the power of the motor and the dirigibility of the airship. In three days the entire ship, including even part of the gasoline, was conveyed back to camp in good order. The balloon-house and the entire plant were put into condition for the winter. Three men were left to guard it until next summer.

On September 13 the *Lusitania*, the world's greatest and fastest ship, reached New York, having covered the distance between Queenstown and Sandy Hook, 2782 miles, in five days fifty-four minutes, at an average speed of 23·01 knots. Although the *Lusitania* has not lowered the Atlantic record, she has crossed at a greater pace than any boat on a maiden voyage ever did before her. The slight difference existing between the *Lusitania's* average and the *Deutschland's* record of 23·15 knots in 1903 is attributed to fog. The progress marked in steamship construction since the advent of the *Umbria* twenty-three years ago is instructive. The length has been increased 50 per cent., and the displacement is more than three times what it was. The power of the machinery has been multiplied by five, but so great is the difficulty of increasing the speed that the *Lusitania*, notwithstanding its enormous advance in size and power, has not added more than 25 per cent. to the speed. The *Lusitania* has a length of 760 feet, a breadth of 88 feet, and a depth of 60 feet 4½ inches. Its draught is 33 feet 6 inches, its displacement 38,000 tons, and its gross tonnage 32,500. It requires about 5000 tons of coal to steam to New York, and carries a cargo of 1500 tons and 2198 passengers. The indicated horse-power of the steam turbines is 68,000, and the steam pressure 200 lb. The full complement of the ship is 827 persons, the navigating staff numbering sixty-nine, the engineering staff 369, and the personal 389.

Two papers read at a conference of the Catholic Truth Society on September 11 dealt with the question of the bearing of scientific progress upon religious belief. The Rev. J. Gerard, S.J., in a paper entitled "Science and her Counterfeit," pointed out that the true man of science, that is, the investigator actively engaged in scientific research, must be distinguished from purely popular writers and lecturers on scientific subjects. "It is the first principle of science," he remarked, "that nothing should be taken on faith, that we should prove all things, and take no step forward until we have made quite sure of our ground." Many writers, however, who undertake to supply the demand for popular scientific instruction, contradict in their practice the principles which men of science insist upon as necessary for the attainment of real knowledge, and encourage the habit of hasty conclusion instead of the spirit of scientific caution. Hypothesis is an essential part of scientific progress, but, as Dr. B. C. A. Windle explained in a subsequent paper on scientific facts and scientific hypotheses, it is necessary to distinguish clearly between hypothesis or theory and scientific observation. Let facts be accumulated in as great a measure as possible, and theories too, in reasonable number, but let us be quite clear as to what are facts and what are theories, and quite definite in our ideas as to the relative value of the two categories. Father Gerard and Dr. Windle are justified in their remarks as to the unscientific character of much that is put forward in the name of science, but without the authority of careful and accurate observation. One reason for this is the attempt made to instruct people in scientific progress who will not take the trouble to understand the alphabet of nature. To the general public a sensational assertion is much more interesting than a plain statement of fact, and a personal opinion is confused with the established truth to which it refers. It is, however, a sign of progress that the road to the present position of science is strewn with the wreck of hypotheses and theories. No true philosopher regards a hypothesis or theory as a Procrustean bed upon which all new knowledge must be placed, but only as a working or suggestive explanation of observed facts. In this respect the scientific type of mind differs from that which is content to accept mediæval scholastic philosophy as a final court of appeal for new learning.

Biologisches Centralblatt for August 15 and September 1 contains an article by Mr. A. Mordwilko, of St. Petersburg University, on the biology of the Aphididæ, being a summary of a larger work on the same subject. The reproduction of these insects is discussed in the first portion of the article.

IN *British Birds*, No. 4, Messrs. Witherby and Ticehurst continue their account of important additions to the list of species recorded from our islands since 1899. Attention may also be directed to a note by the first-named writer on the nesting of a pair of herons in a pool on Dungeness beach.

THE greater portion of the August issue of the *Museums Journal* is devoted to the conference held at Dundee in July last, where the presidential address was delivered by Mr. J. Maclauchlan. The majority of the papers read was devoted to subjects connected with art and manufactures rather than to natural science.

TWO papers in part iii. of vol. li. of the Memoirs and Proceedings of the Manchester Literary and Philosophical Society are devoted to zoological collections made by Mr. S. A. Neave in N.E. Rhodesia. In the first, which is illustrated by a coloured plate of two new species, the collector discusses the birds, while in the second Mr. G. A. Boulenger, who describes one new fish, records the cold-blooded vertebrates obtained.

THE habits of the North American short-tailed shrew-mouse (*Blarina brevicauda*) form the subject of an article by Mr. A. F. Shull in the August number of the *American Naturalist*. In winter, at any rate, the species feeds largely on snails of the genus Polygyra. These snails are hoarded by the shrews for future use, the emptied shells being either left on the surface of the ground or deposited in various parts of the nests or burrows. Short-tailed field-mice and vesper-mice are also attacked and killed for food, while numbers of insects and earthworms are likewise consumed. The shrews are therefore highly beneficial to the agriculturist.

To the August number of the *Zoologist* Mr. Graham Renshaw contributes some notes on the Californian condor (*Gymnogyps californianus*), a species in imminent danger of extermination. Although in former days ranging so far north as British Columbia, this condor—the largest bird-of-prey in the United States—is now represented only by a small remnant in south-west California. A flock of twenty-six was, however, seen so lately as 1894, and it is hoped that the species may still be holding its own in the more remote mountains. A specimen is now living in the Zoological Park, New York.

WHAT amounts to little less than a revolution in the taxonomy of invertebrates is proposed by Mr. R. T. Günther in the August issue (vol. li., part iii.) of the *Quarterly Journal of Microscopical Science*. Although their molluscan affinities were suggested by d'Orbigny in 1834, the arrow-worms (Sagitta, &c.) have been definitely classed by nearly all modern zoologists among the annelids, in which they constitute the group Chætognatha. Mr. Günther is, however, convinced that they are in reality primitive molluscs. "No organ of importance," he remarks, "has been described in chætognath anatomy which is not paralleled by similar and, we believe, homologous organs among the Mollusca. Indeed, we believe, we can go further and demonstrate that the divergences of structure between the Chætognatha and the Mollusca are slighter than those known to exist between different orders belonging to the latter phylum." The Mollusca, according to the author, typically pass through a free-swimming ("veliger") stage, and while in creeping and sessile forms the foot and shell attain high development, in pelagic types the shell tends to disappear, and the foot may either likewise atrophy or become modified into a swimming organ. On this view the class may be divided into Nectomalacia and Herpetomalacia, the former including the shell-less Chætognatha and the shelled Cephalopoda, and the latter all the rest.

IN *Nature Notes* for September, Mr. O. C. Silverlock records the results of experiments conducted by himself during the last two years with the view of testing the sensibility of ants to changes of temperature and to the ultra-violet rays of the spectrum. As regards the first point, the experiments indicate that very small changes of temperature are perceived by these insects, the sensations of heat in which must be much more delicate than in human beings. Many ants, for instance, perceive so small a rise of temperature as 0°·3 C., while a very large percentage take cognisance of a rise of 0°·5 C. In respect to the ultra-violet rays, it has been already shown by Lord Avebury that these affect ants like true light-rays, and this being so, the author is of opinion that these rays probably appear to them as a colour of which the human mind cannot form a conception. The ants do not appear to be chemically affected by these rays, but they change their positions when placed in the spectrum by reason of their dislike to the colour of these rays, and also on account of the smaller heating effect produced by this end of the spectrum.

IN the report for the year 1906–7 of the industrial section of the Indian Museum, Calcutta, Mr. I. H. Burkill enumerates the additions to the collections received during the year; among the art specimens is a sword and silver scabbard presented by the Tashi Lama. Of the products examined by Mr. D. Hooper in the laboratory, the oleo-resin of *Hardwickia binata*, the gum-resin of *Mangifera indica*, and the oil of *Cochlospermum gossypium* are interesting; also the sample of Kashmir hops.

IT was a happy inspiration to bring together in the Natural History Museum at South Kensington a collection of Linnean mementoes in commemoration of the bicentenary of the great Swedish naturalist. The collection, consisting of portraits, autographs, manuscripts, specimens and books, is arranged in one of the bays of the great hall, and a small pamphlet, prepared by Dr. A. B. Rendle, explaining the different exhibits has been issued as the third of the special guides of the museum.

AN ingenious but difficult hypothesis, tracing the origin and evolution of angiosperms to aposporous developments from a type allied to the thallose liverworts, is offered by Mr. O. F. Cook in vol. ix. of the Proceedings of the Washington Academy of Sciences. It is suggested that as aposporous prothalli arise from the sporophyte in certain varieties of *Nephrodium pseudo-mas*, so the gametophyte of the primitive angiosperm may have had its origin; the proposition requires the elimination of the macrospore, and leads to the comparison of the nucellus with an aposporous prothallus, thus running counter to accepted homologies. It cannot be said that the arguments advanced are sufficiently weighty to warrant a reversal of existing opinion.

THE third part of the botanical series of the *Philippine Journal of Science* (vol. ii.) contains determinations of new or little-known indigenous ferns, and a collation of species of Dryopteris, both prepared by Dr. H. Christ, and the diagnoses of new Philippine palms, by Dr. O. Beccari; also Mr. E. D. Merrill contributes a first list of Philippine botanical literature. Dr. Christ notes that there is a tendency to the production of insular reduced types among the ferns, instancing the irregularity and reduction of fronds in *Dryopteris canescens*, and the peculiar stunted forms grouped under *Leptochilus heteroclitus* and *Pteris heteromorpha*. A new species of Christensenia, more recognisable under the generic name Kaulfassia, is described. Dr. Beccari's communication includes three species of Areca, one as robust as *Areca catechu*, also species of Pinanga, Arenga, Livistona, and Calamus.

MR. R. N. HALL, in his "Notes on the Traditions of South African Races, especially of the Makalanga of Mashonaland," reprinted from the *African Monthly*, and published by the African Book Co., Ltd., Grahamstown, has revived his controversy with Mr. R. MacIver regarding the date of the Zimbabwe temple. In his reply to the theory that the ruins cannot be dated earlier than the fourteenth or fifteenth century A.D., he lays special stress on the statement of De Barros that, on the arrival of the Portuguese at Sofala, about 1505, the Moors informed them that the temple was then ancient, and that the Makalanga possessed no tradition of its erection. It is obvious that on such a question the oral traditions of savages are of little value. But Mr. Hall discusses at length various lines of evidence, which, he believes, establish the permanence of such traditions among the Bantu races—their veneration of ancestors, their genealogies of royal families, their belief that their forefathers migrated from the north, their tales of the early Portuguese occupation, of cannibalism, the slave trade, and so on. He further asserts that the Makalanga have been less migratory than their Bantu kinsfolk, and hence their belief in the extreme antiquity of the Zimbabwe is deserving of credit. On the other hand, he admits that these traditions were not recorded at the time when Europeans first came in contact with them. On the whole, the Makalanga traditions in the versions now accessible do not command perfect confidence, and they do not furnish conclusive evidence in disproof of the archæological facts on which the conclusions of Mr. MacIver were based.

THE third part (the second in order of issue) of the Eugenics Laboratory Memoirs has just been issued by Messrs. Dulau and Co. It is entitled "The Promise of Youth and the Performance of Manhood," and contains the results of an inquiry, by Mr. Edgar Schuster, into the question how far success in the examination for the B.A. degree at Oxford is followed by success in after-life. Apart from the Oxford class lists, the investigation is based on "Crockford" and Foster's "Men at the Bar." The results show a striking relation between the earlier and later success. Thus among those who took their degree in 1859 or previously, and subsequently entered the Church, 68 per cent. of the first-class honours men obtained some clerical distinction or first-class scholastic appointment, whilst the percentage falls to 37 per cent. for the second-class men, 32 per cent. for the third class, 29 per cent. for the fourth, 21 per cent. for those who took pass degrees, and 9 per cent. only for those who took no degrees. The results in the case of those subsequently called to the Bar are similar. Taking a rougher division, 32 per cent. of those who obtained first to fourth-class honours subsequently obtained some form of office or appointment that was reckoned as distinction, whilst only 16 per cent. of those who obtained pass degrees or no degrees did so. It would seem from these figures that the degree examinations are a better test of general ability, and not of a merely special type of ability, than is generally believed. It seems a pity that these memoirs cannot be issued at a lower price, or, preferably, published in some recognised journal.

DR. GUSTAV VON ZAHN contributes to Nos. 5 and 6 of the current volume of the *Zeitschrift der Gesellschaft für Erdkunde* a paper on the physical and economic geography of the isthmus of Tehuantepec. The author visited the isthmus in October, 1906, and devoted special attention to existing and possible routes across it as means of interoceanic communication. His conclusions are strongly in favour of a new Transpacific route from Salina Cruz.

A LECTURE delivered before the Versammlung deutscher Naturforscher und Ärzte at Stuttgart by Prof. Dr. E. Hammer in September last is reprinted in *Petermann's Mitteilungen* (vol. liii., p. 97). Prof. Hammer discusses the scales of maps most useful for geological and general economic purposes, favouring 1 : 25,000 for ordinary publication. He lays great stress on the need for such maps bearing some indication of the degree of accuracy of the contour lines shown, as well as of the actual determinations of height upon which the contours depend.

THE *Mitteilungen* of the Vienna Geographical Society contains (vol. l., p. 139) an interesting paper on the "zonal" distribution of rainfall, by Dr. Fritz von Kerner. The author has repeated and extended the measurements of Loomis's rainfall maps made by Sir John Murray, using the more recent maps of Supan, and gives the rainfall in belts of latitude, first for all longitudes and also for the eastern and western old world and the new world separately. Detailed comparisons are given with Murray's results, and also with the measurements of Bezdek published in 1904. Supan's maps for the four seasons are treated in a similar way, the accuracy of the work being tested by comparing the sums of the four seasonal values with those obtained independently from the map for the whole year.

THE most noteworthy feature in the report of the Mauritius Observatory for 1906 is the shortage of rainfall; the annual amount for the island (mean of fifty-seven stations) was 72·4 inches, as compared with the average, 79·5 inches. Notice is directed to an apparent connection between droughts in Natal and Mauritius, well-marked winter droughts at the coast stations of the former place being followed by summer droughts in Mauritius at intervals of from three to seven months.

WE have received from the Deutsche Seewarte its monthly meteorological chart for the North Atlantic Ocean for September, which, like the corresponding chart published in this country, is replete both on face and back with information of value to seamen, and includes notes on ice, fog, &c., brought down to the latest possible date. A comparison of the face of the English and German charts naturally exhibits slight differences in the results; this is unavoidable when compilation is made from data received from different sources. The back of the German publication contains, *inter alia*, charts showing the weather conditions between Ushant and Gibraltar, and sudden changes observed in the sea-surface temperature south of the Newfoundland Bank, each chart being accompanied with useful explanatory text.

THE Publications of the Japanese Earthquake Investigation Committee, Nos. 23 and 24, are devoted to an account and study of the seismograms of what is called the "Great Indian Earthquake of 1905." The preface states that these are issued as a systematised account of the instrumental observations of the earthquake, to be laid, for discussion, before the International Seismological Association at its next general conference. The data yielded by the seismograms are discussed with a wealth of elaboration and tabulation which tends to obscure the conclusions drawn; some of these are diametrically opposed to those generally held in this country, and the data on which they are based seem more consistent with the view that this earthquake was not so very "great," and that the distant records are imperfect. The value of the series of reproductions of forty-one seismograms taken at twenty-nine different stations would have been increased had the reproductions of Milne seismograms been less coarse in texture, but even with this drawback they form a collection which will be extremely useful to students of seismology, and we have only to regret that it should have been left to the Japanese Government to produce an adequate report of a British earthquake.

A NEW microphone for wireless telephony, the invention of Prof. Majorana, is described in the *Electrician* of August 30. The microphone consists of a jet of water falling on a collector made of two cylindrical pieces of platinum. The two pieces of platinum are connected to a battery, and a current passes depending on the thickness of the water film connecting the two surfaces; this thickness is varied by passing the stream of water before it falls on the collector through a receptacle, one side of which is formed by a membrane actuated in the ordinary manner of a telephone transmitter. It is stated that the vibrations produce corresponding fluctuations in the water jet, and the secondary current reproduces in consequence the sound waves. The collector circuit is connected to the spark-gap in the wireless transmitter, a Poulsen arc in nitrogen being the most suitable spark-gap to employ. No particulars are given of distances over which transmission has been accomplished.

THE *Halbmonatliches Literaturverzeichnis* of the *Fortschritte der Physik* continues to fulfil its function of bringing the titles of papers published in the various departments of physics promptly before its readers. It is interesting to notice that nearly 40 per cent. of the papers published fall within the section cosmical physics.

THE general characteristics of the treatment of elementary geometry adopted by Messrs. Barnard and Child in their "New Geometry for Schools" (Messrs. Macmillan and Co., Ltd.) and similar volumes have been described in these columns on more than one occasion (vol. lxix., pp. 97 and 391; vol. lxxi., p. 174). To meet the requirements of teachers and students who wish only to follow the subject up to particular standards, the course of work has been subdivided, and three new volumes containing various sections have recently been published. Part iii. of "A New Geometry" contains the equivalent Euclid, Books ii., iii. (35–7), and the harder parts of Book iv.; parts iii. and iv. (in one volume) include, in addition, Euclid, Book vi., and the algebraical treatment of ratio and proportion for commensurable quantities; and "A New Geometry for Middle Forms" contains the substance of Euclid, Books i.–iv., together with additional matter. The six volumes, which now form Messrs. Barnard and Child's series on practical and theoretical geometry for schools, provide students in any part of the Empire with courses of study which cover satisfactorily the revised syllabuses of examining bodies, and follow the reformed methods of geometrical teaching brought about by the reports of committees of the British Association and the Mathematical Association.

OUR ASTRONOMICAL COLUMN.

DANIEL'S COMET (1907*d*).—An excellent reproduction from a photograph, and a description of comet 1907*d*, are published in the September number (p. 385) of the *Bullétin de la Société astronomique de France* by M. F. Quénisset, of the Juvisy Observatory. With a clear sky, the comet appeared incomparably brighter than the Andromeda nebula, and gave the impression of being about the brightness of a second-magnitude star; the tail could be seen, by the naked eye, extending to a distance of 8° or 10°. Between July 12 and August 15 twenty-six photographs were obtained, three portrait lenses of 16·0, 13·5, and 3·8 cm. aperture, and 0·740, 0·565, and 0·130 metre focal length, respectively, being chiefly employed. On these photographs the structure of the tail is very sharply defined, and on one obtained with the last-named objective the tail can be traced for not less than 17°. From the photographs obtained with this instrument on August 7 and 8 there is evidence of a rotatory motion of the comet about a line joining the nucleus and the sun.

As seen in the 24-cm. (10-inch) equatorial and on the photographs taken with a Viennet objective, the structure of the tail near the head was fan-like, the colour being a fine green, and the brightest part was directed towards the sun. A visual examination of the comet with a spectroscope revealed the three strong hydrocarbon bands on a brilliant background of continuous spectrum. These bands were sharply defined on the red side, and faded away gently towards the violet, and, on replacing the spectroscope slit, they, with others, were seen resolved into lines; the order of their brightness was green, blue, orange.

From Mr. G. Gillman, of Aguilas (Spain), we have received a drawing showing the observed path of the comet from August 13 to 21. On the former date Mr. Gillman, as shown on his drawing, was able to trace the tail for a distance of 25° in a W.S.W. direction.

Owing to its decreasing brightness and to the fact that it does not rise until about 1½ hours before sunrise, the comet is becoming a difficult object, but we give below a further extract from the ephemeris published in No. 4196 (p. 337, August 23) of the *Astronomische Nachrichten*:—

Ephemeris 12h. (Berlin M.T.).

1907	α (true) h. m.	δ (true) ° ′	log r	log Δ	Brightness
Sept. 21	10 46·3	+7 5·1	9·8179	0·1879	6·4
23	10 55·7	+6 25·8			
25	11 4·8	+5 47·1	9·8550	0·2085	4·9

As mentioned last week (p. 503), Herr Kritzinger, of Berlin, recently pointed out (*Astronomische Nachrichten*, No. 4198) that the radiant point of this comet was in $346° + 1°$ on September 12. Mr. W. F. Denning informs us that he watched the sky on September 10, 12, and 14, the weather being very clear, but did not notice any meteoric shower from the point mentioned. There was an active radiant at $355° + 5°$, however, about ten degrees E.N.E. from the position given by Herr Kritzinger. This display is often seen in September, and there is another at $346° + 1°$ (exactly agreeing with the cometary radiant), often noticed both in August and September. The correspondence in the apparent places is probably accidental.

Mr. A. J. Hawkes writes from Bournemouth to suggest that the fine sunsets seen on Monday, and also at the end of last week, may be due to meteoritic dust in the track of the comet recently crossed by the earth.

THE LOWELL EXPEDITION TO THE ANDES.—In a recent communication to Dr. W. J. S. Lockyer, Prof. David Todd briefly describes the location and work of the Lowell expedition to the Andes for the purpose of observing Mars under the best conditions during the last opposition. Prof. Todd states that he selected Oficina Alianza, in northern Chili, for the location of the Amherst College 18-inch telescope, one of the instruments sent out by Prof. Lowell, and has found the atmospheric condition most favourable. Cloudless skies obtained day and night, and a windless and steady atmosphere produced an average "seeing" of 4 on a scale of 5. More than 5000 photographs, covering all regions of the planet, were obtained by Mr. E. C. Slipher, and many of them exhibit clearly the much discussed double canals. The telescope is the last one, of large size, erected by Messrs. Alvan Clark and Sons, and their chief mechanician, Mr. A. G. Ilse, is a member of the expedition. Photographs of the annular eclipse on July 10 were also secured, and the ringless phase of Saturn was much observed and photographed. Prof. Todd removed the station to a point in the higher Andes above Limas during the first week in August.

MARKINGS ON THE THIRD SATELLITE OF JUPITER.—In No. 4199 of the *Astronomische Nachrichten* (p. 381, September 6) Senor J. Comas Solá continues his description of the markings he has observed on Jupiter's third satellite, and gives position angles determining the positions of the same, at stated times, with regard to the direction of the axis of rotation of the planet. From the discussion of his results he concludes, provisionally, that (1) the visibility of the northern white cap is independent of the satellite's position in regard to the planet, and is incomparably greater than that of the other cap; its brightness is comparable to the snow-caps of Mars. (2) As on Mars, the northern cap of satellite III. is always bordered by a dark area, which appears darker nearer to the cap. (3) The northern cap appears to be turned towards us, and, if it is situated at the extremity of the axis of rotation of the satellite, the inclination of the equatorial plane to the orbit of the satellite must be considerable. (4) The dark spots and areas are difficult to observe, and appear to be variable in a very short time. (5) As yet nothing can be said of the rotation period of the satellite.

A plate of twelve drawings accompanies the paper, and shows very markedly the different features referred to, and their variations from time to time, as observed during the period November 24, 1906, to March 25, 1907.

ASTROPHYSICAL OBSERVATIONS AND ANOMALOUS DISPERSION.—In Nos. 4197–8 (p. 341, September 2) of the *Astronomische Nachrichten*, Prof. Hartmann discusses at length the possible explanation of several observed astrophysical phenomena by the theory of anomalous dispersion. He first discusses the general problem, and then its effect in the observed phenomena of the chromosphere, sun-spots, prominences, faculæ and flocculi, and the fixed stars. The results of the discussion are not universally conclusive, but Prof. Hartmann points out that, with stated conditions, the question may be decided by special observations. A bibliography of fifty-six papers on this subject is given at the end of the discussion.

FORTY YEARS OF CORNISH MINING.

MY connection with Cornish mining began in the year 1867, when I succeeded the late Sir Clement (then Dr.) Le Neve Foster as lecturer and assistant secretary to Mr. Robert Hunt's Miners' Association of Cornwall and Devon. It was a time of transition, for copper-mining after a brilliant career of a century or more was rapidly declining, and tin-mining, which though far more ancient had become second in importance, was once more in the ascendant. The man-engine, the employment of which had been greatly assisted a quarter of a century earlier by substantial prizes offered by the Royal Cornwall Polytechnic Society, was in use in a dozen of the principal mines, wire-rope and skip were gradually replacing chain and kibble, and rock-boring machines, thanks to the initiation of my predecessor, had already been practically tested in several parts of the county. These were real advances, but kibble-winding was still common even in the deepest mines; the cobbing hammer, the bucking iron, the hand-jigger, and the wooden shafted stamp were still at work to a large extent; while the stonebreaker, the California and pneumatic stamp, the various forms of pulveriser, the Frue and Luhrig vanners, the Wilfley and Buss tables, the self-acting and round slime frames, the air-compressor, and many other contrivances which are now looked upon as essentials in well-provided mines were only beginning to appear. When one compares the present condition of Cornish mining with its condition forty years ago, it is obvious that a sort of revolution has taken place.

In mining proper there has been no great advancement during the forty years. Somewhat greater depths have been attained in a few instances, and notably at Dolcoath, but Cornwall is still far behind several other mining regions in this respect. We are now more impressed than heretofore with the advantages afforded by good shafts, good underground roads, and good surface transport; the tramroad and tram-wagon have largely displaced the wheelbarrow; underground ore-bins, once so rare, are now becoming common; but in the main our system of underground mining was so good even a century ago that there was not very much room for improvement. Still, I will venture to predict that during the next forty years more vertical shafts will be sunk, that levels will be driven farther apart, that there will be a great deal more cross-cutting, and that our underground tramroads will be better constructed, so that "three men at a wagon" will be no more heard of.

As to the methods employed for breaking the ground, the chief changes have resulted from the use of boring machines and high explosives. In 1868 I first saw Doering's machine at work in Tincroft Mine. It was not a success, for, being operated by steam, the workings were rendered almost unbearable; in fact, while steam was the motive power, the use of the machine drill made very little progress either at home or abroad, and it is certain that if compressed air had not been introduced boring machines would to-day play a very small part in mining or tunnelling. Once introduced, however, the immense value of the system was at once recognised.

The difference between "to-day" and "yesterday" is seen in the fact that no rock-drill or air-compressor has ever been employed in the great mining parish of Gwennap, several of whose mines were still at work a generation ago, while at present all the great mines of the neighbouring parishes of Camborne and Illogan depend very largely upon these machines, not because they break the ground more cheaply, for it is well known that such is not the case (and, moreover, in narrow lodes they do not even break the ground more advantageously, for the "pay-streak" inevitably becomes much contaminated with barren "country"), but because they open the ground more speedily. One good effect of their employment has been the enlargement of the main drifts, and consequent improved ventilation, and this has been especially benefited by the large amount of cool exhaust air set free by the machines. The greater number of machine drills hitherto have been employed in sinking, rising, or drifting, but there is a constant and growing tendency to employ them in stoping also.

Forty years ago much gunpowder was still used in the mines; to-day, after many experiments with compressed powder, cotton-powder, and other such compounds, and after nitro-glycerin had been tried and given up because of its danger, only such "high explosives" as dynamite, gelignite, and the like are used. These high explosives only came into use after much experimenting, by the Royal Cornwall Polytechnic Society in particular, but they have proved themselves very serviceable, especially in hard ground, and they are also found to be much safer in use than the old black powder.

Great improvements have been effected in the machines used for compressing the air employed in working the machine-drills; compound engines, compressing the air in successive stages, are now generally employed in the larger mines.

Compound engines, mostly of the tandem type, were introduced into several Cornish mines by Mr. Sims more than half a century ago, but with the low-pressure steam then employed did not recommend themselves, and so went out of use. A compound engine using high-pressure steam has been employed for years past in pumping at the Basset Mines for working the ordinary force pumps; of late many attempts have been made to introduce centrifugal pumps operated by electricity for draining the mines. A certain measure of success has attended these efforts, particularly at the Tywarnhaile Mines, and more recently at Wheal Vor; but it must be admitted that up to the present the Cornish system of pumping, the rods being operated by a simple vertical engine, single acting in the case of large installations, holds the field.

The use of electricity is spreading in the Cornish mines apart from pumping. At East Pool it has long been employed for surface traction, the mill being a mile or more away from the mine. At South Crofty it is employed for operating the new stamp mill; in several mines it supplies power to work pulverisers, buddles, and other dressing machines, and in this direction—as also in electric lighting—there is a large field for extension.

There have been great improvements in the engines used for winding during the past few years. It no longer takes thirty to forty minutes to raise a kibble of stuff from the bottom of the deeper mines, as it did at one time; skips running between guides are now common, cages bringing the ore-wagons direct to surface are employed in several mines, while the men are mostly brought up from below in shaft-gigs or special skips, so that the man-engine, once so great a boon and used in no fewer than twelve mines, can now only be seen in operation in the Levant Mine. For modern winding wire-ropes are universally used, and are practically indispensable. Accidents from its use are, indeed, exceedingly rare. Mr. Morgan's traversing engine, erected some years since for hoisting from Williams's Shaft at Dolcoath, will soon be at work again, but so far no proposals seem to have been made for using this remarkable engine anywhere else.

For signalling in shafts the old "knocker line" is still in use, and has its advantages. Indicators for the guidance of the engine-man are, of course, placed in the engine house in every case where men are raised, and in most other cases; overwinding is an extremely rare occurrence, such is the carefulness of the engine-man. The telephone was introduced in Wheal Eliza by Dr. Le Neve Foster many years ago for signalling from below, but it did not "catch on." It is, of course, used for ordinary business purposes in several of the mines.

The steam-boilers used in Cornwall are mostly of the Cornish or Lancashire type, and work at comparatively low pressures. The number of these boilers working above 60lb. is not very great, and those working at 100 or more could almost be counted on the fingers. Multitubular boilers, portable or semi-portable, are used in some instances where good water is obtainable, and particularly for winding, while the electrical pumping plant at Tywarnhaile is worked by engines which consume "suction gas."

Many improvements have been introduced in the treatment of ores; the ores treated in Cornwall now are almost exclusively of tin, copper ore being rare, while the working of iron, lead, and zinc ores has practically ceased.

The first crushing is generally done by stonebreakers of the Blake type, followed by stamps of the Cornish, California, or pneumatic type, the "rows" being finally reduced by some form of pulveriser. Self-feeders have not yet been used for the Cornish stamps, but they are always employed in connection with the California and pneumatic stamps. At Dolcoath powerful batteries of all three types can be seen regularly at work.

For dressing the crushed ore, while buddles are still very generally used at some stages, Wilfley, Buss, or other tables of the percussion type, or Frue vanners are employed in most of the larger mines. Hydraulic separators are mostly used to remove the slimes before feeding the pulp to the Wilfley and Buss tables, but in the case of the Frue vanner the slimes are generally removed for separate treatment at a later stage.

For slime treatment there is still nothing better known than the dead-frame, the ordinary round slime table, or the Acme table. The old-fashioned swinging rack for cleaning slime has practically disappeared, though it had some notable merits.

Most tin-ores need calcination before they can be cleaned for the market. In some of the smaller mines the old reverberatory oven is still in use, but in the larger mines the Brunton revolving calciner is always employed.

The calcination of tin-ores yields in some mines large quantities of "arsenic-soot," which is collected in long flues of masonry; this soot, at one time valueless or worse, is now an important by-product. It is handled by the ton as freely as sand, and apparently with equal impunity for cases of arsenic poisoning are far rarer in Cornwall than in London. Another important by-product in some mines is wolfram, which at one time was merely a deleterious component of the dressed tin, but is now profitably extracted at many of the mines, and in particular at Clitters United, East Pool, and South Crofty by means of the Wetherill magnetic separator. In this machine the powdered and thoroughly dried concentrates are carried slowly over electro-magnets on traversing belts. The magnets remove the slightly magnetic particles of wolfram, while the non-magnetic particles of cassiterite pass on and fall into a separate receptacle. The wolfram so separated in most cases still contains a considerable percentage of tin-oxide. At the mines mentioned this tin-wolfram product is "pickled" with dilute acid (aided by jets of steam at East Pool) in order to remove certain highly magnetic iron oxide components, which seriously interfere with the operation of the magnetic separator. A similar "pickling" was recommended by Dr. Richard Pearce forty years ago, and has occasionally been used for the removal of copper from calcined tin ores.

At Tynwarnhaile, and also at Dolcoath, the Elmore oil processes have been, or are being, introduced for the concentration of low-grade copper ores. The wet ore-pulp is mixed with oil and subjected to a partial vacuum, by which means the ore-particles are floated up from the waste as a sort of mineral scum, which is readily separated from the waste, and with much less loss than is the case by the methods hitherto employed.

Enough has been said in this hasty summary to show that the Cornish miner to-day, as in the past, is very ready to avail himself of such new methods and appliances as have a reasonable prospect of success, although it must be admitted that he is rather fond of letting other people experiment for his benefit.

J. H. COLLINS.

THE IRISH PEAT INDUSTRIES.[1]

ACCORDING to reports published in 1814 by the Bog Commissioners, Ireland possesses 3,028,000 acres of "peat bog," of which 1,648,000 acres form "available" or so-called "red" bog, and about 1,380,000 acres form "mountain peat soil." The "red bog" is mainly confined to the great central plain of the island, and the "mountain bog" to the counties of Wicklow, Donegal, Mayo, Galway, and Kerry. As the accompanying outline bog map (Fig. 1) shows, there are few portions of the island destitute of bog.

The slow but continuous reclamation of Irish bogs which has been going on for the past three hundred years is referred to in a work written, in 1645, by Dr.

[1] Abridged from the Economic Proceedings of the Royal Dublin Society, vol. i., part x. (July)

Gerard Boate. The method of reclamation practised in Ireland at the beginning of the seventeenth century, consisting as it did of draining the bogs and manuring the dried surface, was probably, owing to radical differences in detail between it and the Dutch fen reclamation process, of independent origin from the latter, which was introduced about the same time on the Continent at Groningen, in Holland, and at Emden, in East Frisia. At a later period—in the reign of William III.—the Dutch offered to introduce their system into Ireland upon condition of being allowed to establish a self-governing colony in the Queen's County.

The drainage and reclamation of the bogs have always been subjects of interest; the existence of so much unreclaimed land being a source of loss to the State, and its humidity being detrimental to the health of the community.

We find, for instance, a writer in 1660 recommending that "An Act of Parliament should be made that they who did not at such a time make some progress in draining their bogs should part with them to others that would," and about sixty-five years later an Act was passed

FIG. 1.—Outline bog map of Ireland.

by the Irish Parliament for the encouragement of the drainage of bogs.

Schemes for the drainage and reclamation by burning and manuring the surface of the bog, on the one hand, or by covering it with a layer of sand and manure after a due interval for subsidence, on the other, were published in 1814 in the reports of the Bog Commissioners. These reports described also the numerous successful plantations of trees in Irish bogs made during the eighteenth century. The engineers engaged in the work were of opinion that the bogs could be drained and converted into arable land without much expenditure of time or money.

It would be scarcely economic to attempt the reclamation of bogs the average depth of which is 25 feet, such as those in the central plain of Ireland, without first making a serious effort to utilise the "available" peat of the bogs. Apart from the large sum of 41,565*l.* expended in the years of the Bog Survey, there have been since that time smaller sums contributed by the State to the development of the peat industry. The Department of Agriculture, for example, has within the last few years spent upwards of 6317*l.* in experiments on the preparation of peat-moss litter and fuel. It employed the services of an expert to report upon the various Continental processes, and to select the machinery necessary for the carrying out of the experiments which were subsequently performed at Inny Junction, County Cavan, and at Castleconnell, County Limerick.

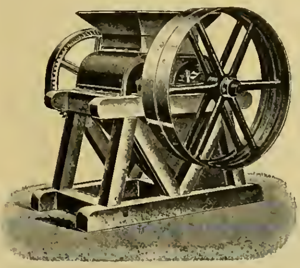

FIG. 2.—Dolberg's peat-moss litter dividing machine.

Within the past hundred years many attempts have been made in Ireland to utilise the peat supply. About the middle of the nineteenth century a turf-charcoal factory was established at Derrymullen by Rogers, but was, however, after a brief period of work, abandoned. A similar fate awaited the turf-distillation factory established in the year 1849 by Reece under the guidance of

FIG. 3.—Peat-moss litter baler, Umaras, co. Kildare.

Sir Robert Kane at Kilberry, near Athy. Although a bright future seemed to lie before this factory, which was the first of its kind in Europe, it was, after a few years' active work, closed by its directors. In 1863 a process for the manufacture of "sieve turf" was worked on a large scale for a short time in connection with the Creevelea Iron Works near Sligo. At Derrylea, near

Portarlington, in 1866, several thousand tons of press turf were made by a modification of the oldest known "dry-press" process—that of Gwynne, which was itself tried on a small scale in 1855 at Kilberry. Of historical interest also is the fact that, of "wet-press" processes, one of the oldest found in the literature of peat is that which was employed by Williams in 1844 at Cappoge, in the Bog of Allen.

In recent years there have been built in Ireland many peat-moss litter factories, such as those at Umaras, near Monasterevan, County Kildare; at Coolaney, County Sligo; at Maghery, County Tyrone; at Ferbane and Rahan, King's County; and at Inchicore and Ringsend, in Dublin. The peat paper factory at Celbridge, County Kildare, belonging to the Callendar Paper Company, has recently been closed. At Umaras and Maghery there are peat-fuel factories, and at Kilberry a fuel called "electro-peat" is manufactured. Quite recently experiments have been carried out at Carnlough, County Antrim, on the production of ammonia from peat, and the installation of a

FIG. 4.—Peat digester, peat paper factory, Celbridge, co. Kildare.

plant capable of producing 5000 tons of ammonium sulphate per annum is now being completed at a cost of 85,000*l*.

It is convenient to divide the peat industries into three classes, namely, the fibre, the fuel, and the distillation industries. In this paper the first, and probably the most important, class will be considered more fully. In the peat-moss litter districts of Ireland the peat is dug out of the bog in large sods, which are dried in the air and stored under cover to prevent the re-absorption of water. The air-dried peat is next disintegrated by the rotating circular saws contained in the body of a dividing machine (so-called wolf, Fig. 2), sifted free from mould, and compressed into bales by vertical knee-lever presses, such as that used at Umaras (Fig. 3). From the "wolf," which is placed on the ground floor of the factory, the divided peat is carried by elevators to the upper floor, where, after passage through a cylindrical sieve, it is delivered into the funnel-shaped mouth of the baler. The mould can at the same time be collected apart. It is exported in large quantities by the owner of one of the factories to southern countries for the preservation and packing of fruit and vegetables grown there.

Where a suitable canal system exists the peat-litter industry is successful, but where canals are not available the industry is crippled by the high rates of carriage charged by the railway companies.

The purified peat moss can be used for the preparation of peat molassine meal and for the manufacture of alcohol, but as the latter process can scarcely at the present time be carried on remuneratively it is not practised in Ireland.

The peat paper factory which was established in 1903 at Celbridge, and turned out large quantities of wrapping paper yearly, was unsuccessful. It was finally closed in December, 1905. The peat, brought on cars from a bog situated at a distance of several miles from Celbridge, was subjected to a preliminary treatment in a large spherical revolving digester (Fig. 4), from which it was conveyed by cars running on a small iron railway to the scarifying and beating machine, where it was converted into pulp. After passing through sand-traps, the unbleached pulp was delivered on to an endless band, by which it was brought between the revolving rollers of a paper-pressing machine. The band of paper thus formed was glazed and polished by vertical rollers.

The motive power of the factory was electricity, which was generated in a dynamo driven by a 200 horse-power turbine worked by water from the adjacent Liffey.

The brown wrapping paper sold by the company was of a strong texture, excellent quality, and contained about 66 per cent. of peat fibre. Considering, however, the large amount of material present in crude turf which is useless for the manufacture of paper, it will be readily seen that the preliminary treatment of the peat should be carried out in the immediate neighbourhood of the bog.

The accompanying illustrations from the author's "Reports upon the Irish Peat Industries," part i., are reproduced by the courtesy of the Royal Dublin Society.

HUGH RYAN.

ZOOLOGY AT THE BRITISH ASSOCIATION.

The Physical Basis of Inheritance.

ONE of the most interesting features of the programme of Section D was a discussion, jointly with Section K, on the physical basis of inheritance. In opening the debate, Prof. S. J. Hickson, F.R.S., dissented from Montgomery's view that the inherited characters are transmitted *solely* by the chromosomes. The principal piece of evidence which is quoted in support of this hypothesis is Boveri's experiment (1889) in which an enucleate echinoderm ovum of one species, fertilised by a spermatozoon of another species, produced a larva with purely paternal characters; but similar subsequent experiments have not always resulted in a larva with purely paternal characters. Confirmatory evidence of the theory is held to be afforded by (1) the constancy in the number of chromosomes in the somatic cells; (2) the reduction to half the normal number of chromosomes in the sexual cells; and (3) the presence of similar heterogeneous chromosomes in the sexual cells of certain Arthropods and their mutual conjugation during fertilisation. If the theory be true, it appears necessary to hold that the chromosomes maintain their individuality, but there is convincing evidence that in some animals this is not the case, *e.g.* in certain Rhizopoda (*e.g.* Pelomyxa), Suctoria (*e.g.* Ephelota, Dendrosoma), and Cœlenterates. Moreover, if it be true that the cytoplasm of conjugating cells is not concerned in the transmission of hereditary characters, it is difficult to account for the long duration of the period of conjugation in Infusoria and the cases of fertilised enucleate eggs which produced larvæ with maternal characters. Prof. Hickson suggested a possible explanation, viz. that where the characters are comparatively rigid, as in mammals, insects, and some other groups, they are aggregated in definite masses, and may be associated with the chromosomes, but where it is advantageous for the characters to remain more variable they are associated with the cytoplasm, as in the Protozoa and some Cœlenterates.

Prof. J. B. Farmer, F.R.S., said that although the chromosomes are probably not the actual bearers of the hereditary characters, they may produce their results by acting upon some specific substance in the protoplasm of the cell. He pointed out that the behaviour of the chromosomes in the heterotype division, preceding the formation of sexual cells, provides an arrangement for the sorting out of characters such as is shown to occur by breeding experiments. The chromosomes themselves consist of congeries of smaller entities—the chromomeres—which are probably very numerous; possibly it is these smaller entities which are associated with the hereditary characters. Such an assumption would answer the often raised objection that the characters exhibited by an organism are more numerous than the chromosomes. In any case, the heterotype division provides a mechanism for arranging these entities on a mathematical basis. The development of an organism on certain definite lines is the result of interaction of the nucleus and cytoplasm, and as there is no mechanism apparent in the cytoplasm for the sorting out of characters, while such is present in the nucleus, it seems reasonable to associate the latter with the carrying of the hereditary characters. Moreover, in many cases only the nucleus of the spermatozoon enters the egg during fertilisation, and yet the parental characters are conveyed.

Mr. R. C. Punnett pointed out that in the interpretation of the facts of heredity the student of genetics has been led to the conception of factors in the gametes upon which his unit characters are based. Between the postulated behaviour of these factors in segregation and the observed behaviour of the chromosomes in the divisions of the germ-cells there is a striking agreement. Nevertheless, certain cases of dihybridism offer phenomena pointing to the existence of gametic series in which the four types of gametes are produced, not in equal numbers, but in such ratios as 7 : 1 : 1 : 7 or 15 : 1 : 1 : 15. If the cytologist desires to regard the chromosomal elements as the physical basis of heredity, he must provide some scheme which will include these phenomena.

Prof. V. H. Blackman stated his belief in the chromatin as an active agent in the process of heredity. Boveri's work on the multiple fertilisation of echinoderm eggs seems to indicate that not only do the chromosomes carry the hereditary properties, but also that they are physiologically differentiated. The speaker suggested that in the protozoan nucleus there is a duplication or even a multiplication of the parts, and that it is not necessary for the whole nucleus to divide or for chromosomes to be evident; a portion of the nuclear substance pinched off may contain representatives of each of the characters.

Mr. R. P. Gregory pointed out that in all the somatic cells the division of the nucleus shows a certain form of symmetry, whereas just previous to the formation of gametes this symmetry is replaced by another—the heterotype division. From experiments in regeneration and vegetative propagation, it appears that all the characters are distributed throughout all the cells of the organism, whereas breeding experiments show that segregation takes place on the formation of gametes, one form of symmetry being replaced by another in precisely similar manner to that indicated by the study of the nucleus. It is impossible to believe that this is a mere coincidence.

Mr. A. D. Darbishire said he would only attempt to answer one question, viz., Are there any characters which depend for their manifestation on factors which exist in the cytoplasm? His observations on the starch grains in peas afford an affirmative answer. The difference between round and wrinkled peas depends largely on the nature of the starch grains. In round peas the grains are potato-shaped, in wrinkled peas they are round in contour and compound. In the hybrid the grain is intermediate between those of the parents in three respects:—(1) in contour; (2) in compoundness, about half the grains being simple and half compound; (3) in the number of pieces in the compound grains, which is usually three, rarely two (in non-hybrids it is six). As is well known, the formation of starch grains depends upon certain plastids produced, not by the nucleus, but from others previously existing in the cytoplasm.

Mr. L. Doncaster held that the maternal characters in the hybrid larvæ referred to by Prof. Hickson were only found in the very early stages, and could not properly be called hereditary characters. He suggested that the abnormal behaviour of the nucleus in the Protozoa might be associated with their great simplicity of organisation, no differentiation of chromosomes bearing hereditary characters having yet taken place.

Prof. M. M. Hartog said that the essential part of the chromosome in heredity appeared to be, not the chromatic elements, but the achromatic basis, a view advocated also by Boveri. He thought it was futile to attempt to exclude the cytoplasm from the genuine basis of heredity. With reference to the suggestion, made earlier in the discussion by Mr. C. C. Hurst, that cytologists should investigate the relations between the nucleus and the external characters of crosses, Prof. Hartog was inclined rather to request breeders to investigate certain forms exhibiting exceptional cell divisions. In at least two species of Tradescantia single chromosomes are often left out in the heterotype division of the pollen, and appear finally to be digested. In several species of Hemerocallis at the same stage the chromosomes are distributed into either three or four cells, and the pollen grains are consequently irregular in size, in number, and in the chromosomes they contain.

Prof. Hickson, in replying to the criticisms, regretted that there was not time to traverse them in detail. Referring to Wilson's work on the heterogeneous chromosome in the nucleus of the testis cells of *Anasa tristis*, he pointed out that Foote and Strobell deny the presence of such a chromosome. If, as was asserted during the discussion, specimens of this animal from some localities possess this chromosome while others from a different locality do not, that is a strong argument against the all-powerful influence of the chromosomes in regard to the hereditary characters.

The Experimental Study of Heredity.

Mr. R. C. Punnett illustrated his lecture on this subject by a series of actual examples, drawn chiefly from fowls and sweet-peas. He pointed out that the laws of heredity associated with the name of Mendel apply equally to plants and animals; the comb of the fowl, the stature of the sweet-pea, the colour of the stock, the hair of the rabbit, rust immunity in wheat, and some diseases in man, all conform to the same laws of heredity. Experimental work with animals may well lead to a solution of many problems in human disease; but, important as are the practical results, this study has a still greater importance in relation to our scientific conceptions, for it must radically affect our views of the process of evolution, the nature of mutation, and the physical basis of heredity.

Protozoa.

Mr. F. B. Rowley exhibited a series of models of Protozoa—Amœba, Vorticella, Paramœcium, Actinosphærium, and the parasite of human malaria in blood corpuscles—constructed chiefly of gelatin, which give an excellent idea of the appearance of these organisms in life.

Mr. H. B. Fantham discussed the classification of the Haplosporidia. He and Dr. Ridewood suggest the division of the group into two sections:—

(1) Polysporulea, in which the pansporoblast gives rise to nine or more spores, *e.g.* Rhinosporidium, Neurosporidium.

(2) Oligosporulea, in which the pansporoblast gives rise to a few (four) spores or to a single spore, *e.g.* Haplosporidium, Bertramia, Cœlosporidium.

The Movements of Spirochaetes.

Mr. Fantham pointed out that the nature of the movements of Spirochætes would serve as an aid in separating this genus from Spirillum. Knowledge of these movements would therefore be of value in connection with the vexed question of the nature of the organism of relapsing fever. Spirochætes, especially *S. anodontae*, with its pointed ends, usually move very rapidly, but in slowly moving specimens the organism can be seen to move forward while turning on its long axis. The motion can be resolved into two components:—(1) a vibratory motion of flexion of the body mainly for progression; (2) a spiral motion of the body as a whole due to the undulating membrane—a spirally wound lateral extension of the ectoplastic periplast bearing striations (the contractile myonemes). The body of a Spirillum bears flagella, and is more rigid than that of a Spirochæte in motion. The so-called flagellate (ciliate) stages of Spirochætes are merely due to the splitting off of myoneme fibrils from the undulating membrane during its rupture, resulting from violent contortions or approaching death.

Some Points in the Structure of the Larva of Lanice conchilega.

The Rev. G. A. Elrington described, in the pelagic larva of *Lanice conchilega*, a gland situated on the dorsal side of the œsophagus, and composed of a cluster of large pear-shaped cells, the thin ends of which converge to the orifice of the gland, which lies in the mid-dorsal line of the "neck" region. From its staining reactions it is evident that the gland is concerned in secreting the mucin of the gelatinous tube in which the larva is found enclosed. The gland, which is not present in the adult or in a young worm which was just beginning to form its sandy tube, is evidently a transitory structure, which persists only so long as the larva retains its transparent tube. In the pelagic larva there are three separate nephridia, there being no trace of the fusion characteristic of the nephridial apparatus of the adult.

Mr. Arnold T. Watson expressed the opinion that the gelatinous tube, in which the larva floats, not only serves as a protection, but is also the means of collecting food particles, which on being brought into contact with the outside of the tube adhere to it. In order to secure this food the larva from time to time partially emerges from one end of the tube and applies to its surface the ciliated groove which runs from end to end of its growing tentacles. Development of the organism is thus carried on to a stage further than would have been possible in the absence of solid food. By the time the animal settles down on the sea-bottom and begins to construct the membranous sand-covered tube inhabited by the adult, the mucus-secreting gland, being no longer required, disappears, and owing to its dorsal position does so without disturbing the formation of the permanent ventral glandular structures which produce the membranous basis of the tube of the adult.

The Development of Ophiothrix fragilis.

Prof. E. W. MacBride, F.R.S., described the early stages of development of this common British Ophiurid. Two sets of cultures were studied, the first obtained by fertilising the eggs artificially, the second by allowing the ripe male and female naturally to shed their reproductive products. In the first series, segmentation resulted in the formation of a morula, an invagination followed, and it then transpired that the interior cells were precociously formed mesenchyme. The cœlom appeared as a single vesicle at the apex of the gut. In the second series segmentation resulted in the formation of a thick-walled blastula, followed by a regular invagination. At the pole of the larva opposite the blastopore a great crest of vacuolated cells—serving as a float—was formed. (This crest was not seen in the larvæ of the first series.) The larva then assumed a triangular form, the cœlom appeared at the apex of the archenteron as a bilobed vesicle, and the crest slowly diminished in size. The cœlomic vesicle divided into right and left halves; of these, first the left, then the right, divided into anterior and posterior parts. Somewhat later, from the anterior portion of the vesicle of both sides a sac was budded off; that of the left side became five-lobed, and gave rise to the water-vascular system; that of the right side generally remained small, but sometimes also assumed the five-lobed form, showing that it is a rudimentary fellow of the water-vascular system. The larva of *Ophiothrix fragilis* affords final and convincing proof that the echinoderm larva possesses three somites, the middle one of which becomes, on the left side, the water-vascular system.

The differences in the early phases of development of the two series above described are probably attributable to the fact that the eggs withdrawn from the female and artificially fertilised were not quite ripe, and therefore not quite of the same chemical composition as those naturally shed. In certain features the development of the artificially fertilised eggs resembles that of *Ophiothrix brevis*, a species with shortened development, a fact which leads the author to ask if mutations may not be due to slight chemical differences in ova at the moment of fertilisation.

Sex in Crustacea, and the Nature of Hermaphroditism.

Mr. Geoffrey Smith's studies upon parasitic castration show that animals belonging to widely different phyla, but especially Crustacea, when attacked by various parasites, undergo an alteration in their sexual nature. At first the gonad in both sexes degenerates to a greater or less extent; the males assume in varying degrees the secondary sexual characters proper to the female, while those of the male practically disappear; the females, without assuming any male characters, suffer a certain amount of degeneration of the secondary characters, *e.g.* the ovigerous appendages. Finally, either on recovery from the parasite or during the degenerative process, the male may develop ova of large size in the testis, alongside mature spermatozoa. The females never produce spermatozoa in their ovaries. These results, which apply especially to the effects of the parasitic Rhizocephala upon the crabs they infect, show that hermaphroditism can be called forth by an external cause acting upon a sexually differentiated animal, and that it can only be called forth in the male, not in the female. A partial temporary hermaphroditism is assumed by other Crustacea (*e.g.* the crayfish, spider-crab, and Orchestia) at particular seasons when a period of growth, as opposed to one of reproduction, is being initiated. The conclusion that hermaphroditism is a property of the male sex, developed in response to altered conditions of metabolism, can be applied to this state as found normally in Cirripedes and parasitic Isopods, both of which lead a sessile, inactive existence when adult, and have their vegetative functions developed to a high degree. In the parasitic Isopods all the individuals are at first free-swimming males, which, on settling down to their parasitic life, develop the hitherto latent female part of their organisation. The presence in some Cirripedes of males which may degenerate completely, even in the larval stage, and other facts, suggest that all the individuals are primarily males and subsequently females.

Mr. F. A. Potts confirmed Mr. Smith's results from his study of the effects of Peltogaster on the hermit-crab, in which also the assumption of the character of the opposite sex is confined to the male. Especially interesting is the appearance, in parasitised males, of the tufts of hair modified for egg-bearing, and the testes in many cases contain ova.

Experiments on Seasonally Dimorphic Forms of African Lepidoptera.

Dr. F. A. Dixey stated that it is often found that the successive broods of Lepidoptera produced in the course of a year differ widely in appearance according to the meteorological conditions prevailing during their immature stages, the contrast being especially marked where there is a sharp distinction between the periods of rain and dry weather. Mr. Guy Marshall, working at Salisbury, in Mashonaland, has succeeded in showing that, by artificially varying the conditions to which the butterflies are exposed during their immature stages, it is possible to bring about in the midst of one season the emergence of a form which under natural conditions would only have been produced in the other. The period during which the animal is susceptible to climatic influences varies in different species, the critical stage being in some cases confined to the larval, in others to the pupal, condition. In one instance (*Belenois severina*) the effect of moisture combined with heat differs entirely from the effect of the former alone.

The Function of the Spiracles in Sharks and Rays.

Mr. A. D. Darbishire concludes that in the dog-fish water is drawn into the pharynx by way of the spiracles, and to some extent by the mouth, and is expelled through the gill clefts. In the skate the spiracles play a more important part, for when the animal is at rest all the water which enters the pharynx does so by way of the spiracles; none enters by the mouth. In *Rhina squatina* (the angel-fish) no movement of the spiracles is visible; there is a uniform current of water into the mouth and spiracles, and the water is driven out again through the gill slits by the undulations of the "gill covers."

The Systematic Position of Polypterus.

Mr. E. S. Goodrich pointed out that Polypterus and Calamoichthys, both from the rivers of tropical Africa, forming the order Polypterini, have no near relations among living fish. The presence of rhomboid ganoid scales, paired gular plates, a persistent spiracular gill cleft, true clavicles, a bilobed air-bladder, and a straight tail, form a combination unknown in any other order. Owing to their lobate pectoral fins, paired gulars, rhomboidal scales, outwardly diphycercal tail, and to a considerable resemblance in the disposition of the roofing cranial bones, Huxley (1861) placed the order Polypterini in the group Crossopterygii, in which it has been left by subsequent writers, associated with such extinct forms as Osteolepis and Holoptychius; but on comparing Polypterus with these fossils the resemblance is by no means close. The similarity in arrangement of the surface bones of the skull is only general, and such as may be found in most primitive Teleostomes. The scales of Polypterus and Osteolepis are of very different structure, those of the former being of the true ganoid type. The tail is not truly diphycercal, but of a modified heterocercal type, the notochord, in the young at any rate, being turned upwards (as shown by Budgett). In Actinopterygii there may occur a median ventral gular plate as well as two lateral series; two of the anterior plates of the lateral series may be more or less enlarged, as in Palæniscidæ; the paired plates of Polypterus may be the homologues of these plates of the Actinopterygii, and not of the more median plates of the Crossopterygii. The skeleton of the pelvic fin and girdle of Polypterus is much more actinopterygian than crossopterygian in structure. The resemblance of the fins of Polypterus to the lobate fins of the Crossopterygii was shown by Budgett to be superficial only. The relationship of Polypterus to the Actinopterygii is supported by a comparison of the structure of the scales and of the fins, by the presence of large solid otoliths in the ear, and the double nostrils on each side of the snout, while the brain, the alimentary canal with its pyloric cæcum, the kidneys and testes, the separate anus and urinogenital apertures, are also consistent with this view.

Colour Variations in the Skin of the Hamster.

Prof. Simroth (Leipzig) exhibited a series of skins of the hamster (*Cricetus frumentarius*), which is common in the cornfields of some parts of Germany, and especially in Thuringia. The usual coloration of the skin is grey along the back and black ventrally, these two being separated by a lateral reddish area, and there are three white or pale yellow patches at the sides of the head and breast. The skins, however, show great variations in coloration. In one series the red areas and then the white patches disappear, the upper side becomes grey, greyish-brown, and finally black, so that the whole skin is now black. In another series the under side becomes lighter, followed by a similar change on the upper side, leading finally to an albino, the rarest variation. The black specimens were first noticed during the hot summers some years ago. It is not yet clear whether these colour variations are to be attributed to climatic conditions or are atavistic.

Photographs of a Young Living Okapi.

Sir E. Ray Lankester, K.C.B., F.R.S., exhibited photographs of a living okapi taken by Signor Ribotti at Bambili, on the Welle River, in the Congo Free State. The animal is a young colt showing the striping of the upper part of the fore and hind legs and hind quarters, and the dark body colour, apparently as in the adult. It is worthy of note that this is the first time that a European has seen a living specimen of the okapi. Some doubt having been recently expressed as to whether okapi is the native name of the animal, Sir E. Ray Lankester remarked that he had shown the photographs and a portion of a skin to some of the African pygmies, now in London, who recognised them, and at once spoke of them under the name okapi.

Plankton Investigations off the Isle of Man.

Prof. Herdman gave an account of his plankton investigations off Port Erin during April. These were undertaken with the object of testing different kinds of open and closing tow-nets, and of gaining information regarding the detailed distribution of the organisms according to locality, depth, and date. Examples were given of very different results, quantitative and qualitative, obtained from quite similar nets hauled not far apart as regards both distance and time. Sudden variations in the vertical and horizontal distribution of the plankton were discussed, and the seasonal changes were also considered; obviously great care and much observation of the gatherings of organisms are required before these can be considered as adequate samples. Prof. Herdman concluded that our methods must be investigated before the attempt to investigate nature on a large scale can be made, and also that an intensive study of small, well-chosen areas is necessary before conclusions can be drawn with regard to relatively large regions such as the North Sea or the Atlantic Ocean.

Mr. W. E. Collinge traced the rise, and pleaded for the due recognition, of economic biology; Prof. Simroth gave an account of his pendulation theory in relation to geographical distribution; Mr. J. W. Jenkinson described his further experiments on the development of the frog; Mr. T. V. Hodgson pointed out the principal features of interest in the collections of Pycnogonids from several Antarctic expeditions; and Prof. R. J. Anderson detailed his observations on the thickness of the skull in Mammalia; but these papers cannot be well summarised in the space here available. J. H. ASHWORTH.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

THE physiological section has for several years devoted one morning to some subject of general interest. This policy was inaugurated at Cape Town by the discussion on the effect of climate upon health; it was followed up at York by one on the physiological minimum of rest for children, opened by Dr. T. D. Acland; and this year at Leicester by one on the physiological and therapeutical value of alcohol. The interest which this subject has aroused of late made it a particularly appropriate one, more especially as the matter has not been recently discussed in at all a dispassionate way. From this point of view the meeting at Leicester was all that could be desired, and perhaps the most remarkable feature in connection with it was the very narrow margin which separated those who took different views as to the value of alcohol.

The discussion was opened by Prof. Cushny, F.R.S., who reviewed the effect of alcohol on the various systems of the body, alluding especially to its very doubtful effect as a stimulant to the alimentary system, its effects upon the circulation, especially the heart, as recently worked out by Prof. Dixon, and its action upon the muscular nervous system and on the power of the body to resist toxic agents. In doing so he introduced some of the subsequent speakers. Dr. Rivers gave an extremely interesting account of the use of the ergograph in obtaining records of the effect of alcohol. It was very remarkable to see how great was the psychical element in ergograph tracings; this, indeed, was so marked that much the same effect could be obtained by giving a dose of alcohol and one which the patient thought was alcohol, or even one which merely excited his curiosity. Dr. Rivers has been able, in conjunction with Prof. Dixon, to administer considerable doses of alcohol in forms which were not recognisable, and in doing so he has found no certain beneficial effect on the power of performing muscular work. Some curves shown by Dr. Waller, F.R.S., were quite in harmony with this view. These results admittedly supported the contention put forward by Sir Victor Horsley, F.R.S., and Miss Sturge, that the ergograph gave results which were as yet too uncertain to yield a verdict which could be considered as final.

On one point there was unanimity, namely, that alcohol even in the smallest quantities was deleterious to the quality of mental work. This was insisted upon, not only by Sir Victor Horsley, but by Prof. Dixon, who took a much more optimistic view of the value of alcohol. Prof. Dixon especially considered it valuable in cases of cardiac collapse, on account of the readiness with which it appears to be absorbed and assimilated.

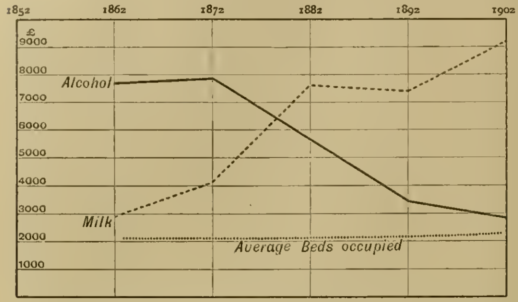

FIG. 1.—Diagram showing the gradual diminution during the past forty years in the administration of alcohol and the increase in the use of milk during the same period. The figures are summarised from the statistics of seven large London hospitals.

From the point of view of the use of alcohol in the treatment of disease, Sir Victor Horsley showed curves (Figs. 1 and 2) illustrating the departure from alcohol which has taken place in the last decade, not only in hospitals generally, but in hospitals for the treatment of fevers—a class of complaints in which alcohol was previously supposed to be especially beneficial.

Still dealing with the relation of alcohol to disease, Dr. Reid Hunt gave an account of the interesting experiments that he has been conducting which point conclusively to the fact that alcohol lowers the power of resistance of the body to a certain specific toxic body, acetonitryl.

Two points remain, the dose of alcohol which may be regarded as harmless, and the much-debated question of whether alcohol is a food. These points are closely connected. The impression left on the mind at the end of the discussion was that whether alcohol is or is not a food is largely a matter of definition. It seems certain, on the one hand, that it is oxidised in the body, yielding a corresponding amount of energy—in this sense it is a food. Such a definition includes many substances—morphia, for instance—which are clearly injurious. If alcohol is not only a "food" but "a useful food," it must be shown that it can be taken without injury to the organism in sufficient quantities to supply an appreciable proportion of the energy of the body. This has not yet been done.

Tuesday, August 6, was devoted to a discussion upon a much more technical subject, the value of perfusions. This was introduced by Prof. Schäfer, F.R.S., who gave an exact account of the best methods for perfusing the heart and the kidney. Others who took part in the discussion were Prof. Cushny, Dr. Alcock, Prof. Zuntz, and Mr. Barcroft. Perfusion has become so important a method in physiological and pharmacological research that some authoritative statement of its limitations would be useful. At present this may be approached in two ways: (1) by a discussion of the best fluids for the purpose, and here we may mention the work recently done at Oxford by Dr. Vernon, who advocated the addition of albumin to Ringer's solution; and (2) by an inquiry into the organs which seem to react most readily, when perfused, to the stimuli which normally produce functional activity. Along this line Mr. Barcroft tentatively put forward the thesis that those organs the coefficient of oxidation of which is lowest stand perfusion much better than others. Thus the heart and muscle react well when perfused, whilst the glandular structures appear incapable of full functional activity when irrigated with an artificial blood supply. Such a tissue as unstriated muscle, which probably has a lower coefficient of oxidation than any of the organs mentioned, will retain a considerable degree of functional activity if it be merely suspended in warm saline solution.

A very interesting discussion followed upon the presidential address. We need not further allude to the address itself, as it has already appeared in the columns of NATURE, than to say that the president's main thesis was that every practitioner should be trained in the quantitative administration of chloroform in surgical cases with an apparatus which delivered air containing a known percentage of the anæsthetic to the patient.

This view was very warmly supported by Sir Victor Horsley and Dr. Vernon Harcourt. Dr. Frederick Hewitt pointed out the difficulties which attended the administration of chloroform in this way, which consisted partly in the impracticability of having apparatus at hand in a great number of cases, and the difficulty in using them in cases where there was great personal idiosyncrasy in the patients. Prof. Waller made it clear, however, in a few words at the end that a person who had been instructed in quantitative ideas as to the administration of chloroform was in a better, not a worse, position to administer it without apparatus if need be, than the man who had only a rule-of-thumb knowledge. This view

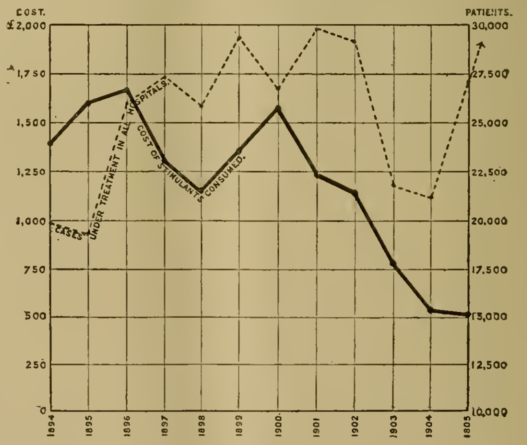

FIG. 2.—Metropolitan Asylum's Board Statistics. Diagram showing the fall in the administration of alcohol to fever patients during the years 1894 to 1905. The dotted line shows the number of patients beginning in 1894 with 20,000. The continuous black line shows the amount of money expended on alcohol beginning in 1894 with 1388*l.*, and falling to 515*l.* in 1905, although the number of patients in the hospitals that year was 27,162.

fairly represented that of the meeting, and it was supported by Prof. Schäfer, F.R.S., Prof. Gotch, F.R.S., and others.

The individual papers were perhaps fewer than is usually the case. Prof. Sherrington, F.R.S., added another to the series of communications on the coordination of reflex muscular movements in the spinal animal which has added so much to the interest of the British Association meetings in the last few years. Very beautiful examples were shown of graded reflex movements which took place in response to graded stimuli. His experiments throw a good deal of light upon the action of strychnine. This drug appears to cause an exaggeration of the rebound which takes place normally after reflex inhibition. The inhibition may be re-established by giving chloroform. Two practical points were brought out:—(1) that in many cases the physiological units of musculature do not correspond to the anatomical ones; and (2) that there is a portion of the gluteus maximus muscle which does not respond either to ordinary reflex stimulation or to strychnine.

Papers on the physiology of nerve were read by Dr. Alcock and Prof. Macdonald. Interesting in themselves, these communications were rendered doubly so by the fact that their writers take a diametrically opposite view of the nature of the nervous impulse.

Three reports were presented by committees; they dealt, respectively, with the metabolic balance sheet of the individual tissues, the ductless glands, and the effect of climate upon health. Their work evoked more interest than usual. The afternoon was spent in discussing the report of the committee of which Sir Lauder Brunton is chairman, and which is a very strong one. It has worked very hard in its efforts to produce a schedule for the collection of the necessary data for the comparison of the climatic conditions of various localities with the diseases which are prevalent in them. Along another line the committee has been greatly strengthened by the active interest of Prof. Zuntz, who came over to Leicester and gave an account of the work which is now being inaugurated in Berlin.

Prof. Zuntz is continuing the work which he and his collaborators carried on in the high Alps, and at the present time two travellers, Drs. Schilling and Jaffé, are making a corresponding set of observations upon themselves in Togo. It will be of great interest to compare the effects of hot climate with the positive results which were obtained upon the high Alps.

J. BARCROFT.

THE KINGSTON EARTHQUAKE.

THE official report on the Kingston earthquake, of January 14 last, by Mr. Maxwell Hall, contains, in addition to the customary compilation of accounts of time, duration and violence of the shock, some interesting records of the peculiar behaviour of the sea on the north coast of the island. At Annotto Bay and Port Maria the sea receded, about three or four minutes before the shock at Port Maria, at about the same time after it according to the account from Annotto Bay, the amount of the recession being equivalent to a vertical fall of from 12 feet to 20 feet; after the shock the sea returned in a wave which swept up the shore to 6 feet or 8 feet above its normal level. This phenomenon was only recorded at the two localities mentioned, a fact which points to its being probably due to movement of the land rather than to a sea wave. At the Kempshot Observatory, St. James, the masonry pier of the transit instrument, resting on solid rock, was found to have been disturbed, so that the west end of the axis was 32″ higher than the east end. In Kingston Harbour subsidence of the land was noticed along the shore-line, of more than 24 feet in places, but this appears to have been due to the shaking down of loose accumulations of recent deposits, as there is no indication of a permanent change of level in the centre of the harbour or on land except near the shore-line.

Beside the official report, we have received from Prof. Carmody, of Trinidad, a series of photographs taken in Kingston on the second and third day after the earthquake. Two of these are reproduced, which show the character of the damage done; this was greatest in the case of walls facing east, those facing north or south being generally uninjured. A noteworthy peculiarity was the fact that arched openings seem to have withstood the shock while

FIG. 1.—Railway station wall facing south.

the rest of the wall was destroyed; as there is no form of construction less suited than the arch to withstand the strains set up by an earthquake shock, this can only be

FIG. 2.—Typical north and south narrow street.

ascribed to the badness of material used for building, the arches having stood owing to the necessity for using better material and more skilled workmanship in their construction.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BY the will of the late Mr. A. H. Blount, lord of the manor of Orleton, Hereford, who died in London on June 17, Yale University will receive a bequest the value of which, after payment of duties, &c., will amount to about 80,000*l*.

THE new session of Birkbeck College, London, will be opened on Monday, September 30, when an address will be given by Mr. G. G. Chisholm. The laboratories will afterwards be open to inspection, and demonstrations will be given. There will be an annual exhibition of students' works on Friday, Saturday, and Monday, September 27, 28, and 30.

THE Department of Agriculture and Technical Instruction for Ireland will, next month, award not more than three commercial scholarships to young men having a sound general education and some commercial experience. The object of the scholarships is to afford facilities for the holders obtaining training in some higher institution, approved by the department, with a view to their employment as teachers of commercial subjects in Ireland. The scholarships are of the value of 100*l.* each, and are tenable for two years. Candidates must have been at least twenty-one years of age on September 1, and must fill in and return a certain form to the secretary of the department not later than September 25. The department also proposes to award three industrial scholarships to persons engaged in industries, such as the woollen, linen, leather, and tanning industries. The scholarships will be of the value of 80*l.* each, and may be renewed for a second or a third year at the discretion of the department.

The new buildings in Queen's College, Belfast, which are to be formally opened by Lord Kelvin on September 20, are for the purpose of affording increased accommodation in the departments of chemistry, physics, engineering, natural history and geology, physiology, pathology, medicine, and surgery. The chemical buildings are now completed by the erection of a large lecture room, a lecture preparation room, and a museum for chemical specimens. In physics there are new elementary and advanced laboratories, and in engineering a laboratory, a lecture room, and a drawing office. The additions to the natural history and geological departments include a laboratory for elementary classes in biology, a laboratory for geology and mineralogy, and rooms for advanced classes and private research in zoology and botany. The physiological department has been provided with three new laboratories, viz. for histology, chemical physiology, and experimental work, and the pathological department with private research rooms for the professor and his assistant, and a laboratory for advanced classes in bacteriology. The medical buildings have been extended by the addition of a class room, &c., specially designed for operative surgery. The cost of these extensions has been defrayed by private donations, with the assistance of a Government grant.

A medical department of the Board of Education has been established to advise and assist in the discharge of the new duties imposed on the Board by the Education (Administrative Provisions) Act in regard to the medical inspection of school children which local education authorities are required by that Act to carry out in England and Wales. The chief duties of the Board in this direction will consist in advising and supervising local education authorities as to the manner and degree in which those authorities carry out this medical inspection; in giving such directions as may be necessary regarding the frequency and method of such inspection in particular areas; and in considering and sanctioning such arrangements as may be proposed under the Act by individual authorities for attending to the health and physical condition of the children. The organisation and *personnel* of the Board's medical department are not yet fully determined; as a first step Dr. George Newman has been appointed chief medical officer of the Board. Dr. Alfred Eichholz, who has for nine years been on the Board's staff as medical inspector of schools, will also be appointed to the medical department, and further appointments will be made in due course. The Board intends in the autumn to issue a circular to local education authorities regarding their new duties in the matter of medical inspection of school children.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 9.—M. Henri Becquerel in the chair.—The contact phenomena of phonolitic trachyte from Griounot, Cantal: A. **Lacroix.**—Bi-secondary butylene chlorohydrin: Louis **Henry.** The secondary butyl alcohol, CH_3—CH_2—CH(OH)—CH_3, was prepared synthetically from ethylmagnesium bromide and aldehyde; this was converted into the secondary iodide, and from this, by the action of alcoholic potash, symmetrical dimethylethylene was prepared. The chlorohydrin results from the interaction of this hydrocarbon and hypochlorous acid. Its physical properties are given.—The resistance of the air: M. **Jouguet.**—Contribution to the study of the alloys of cobalt and tin: F. **Ducelliez.** The present note deals with alloys containing between 57 per cent. and 66 per cent. of tin. The alloys are probably formed of a mixture of CoSn and Co_3Sn_2.—Celestite from Mokattam: M. **Couyat.**—Parasitic phanerogamic plants and nitrates: Marcel **Mirande.** Parasitic phanerogams without chlorophyll cannot absorb nitrates from their hosts. The green hemiparasites vary, some being capable of absorbing nitrates from the host, others not.—Variation in the ramification of umbels: H. **Ricôme.**—The causes of the death of the young hippopotamus of the museum menagerie: E. L. **Trouessart.** The animal died from injuries to the head caused by the mother in repelling the young hippopotamus from the breast.—The culture of the turbot: R. **Anthony.**—The subterranean waters of the Basque country: E. A. **Martel.**

New South Wales.

Linnean Society, July 31.—Mr. A. H. Lucas, president, in the chair.—The geology of Newbridge, near Bathurst, N.S.W.: W. Noel **Benson.**—Revision of the Australian species of the genus Anthobosca (Hymenoptera: fam. Scoliidæ), with descriptions of new species: R. E. **Turner.** By careful comparison with exotic species in the British Museum collection, the author has convinced himself that the insects classed in the genus Anthobosca are the male sex of the insects usually known in Australia as Dimorphoptera (Sm.).—The Mollusca of the Mast Head Reef, Capricorn Group, Queensland, part ii.: C. **Hedley.** This part enumerates the Gastropoda collected on and around Mast Head. Thirty-seven new species are described and figured. The geographical range of shells previously only noted on the one part from Torres Strait, on the other from the neighbourhood of Sydney, is greatly enlarged. Altogether, two hundred and two mollusca are added to the known fauna of Queensland.

THE GEOLOGICAL SOCIETY OF LONDON.

The History of the Geological Society of London. By H. B. Woodward. Pp. xx+336; illustrated. (London: The Geological Society, 1907.) Price 7*s.* 6*d.* (to Fellows, 6*s.*).

The history of the Geological Society of London is rich in interest and instruction, as the society is unique in the extent of its influence on the science it was founded to promote. Geology had no chance of a satisfactory beginning, because of its immediate discovery of evidence inconsistent with the Mosaic account of Creation and the universality of Noah's deluge. Thus geology was driven at once into cosmogony, and started where it should have ended, and its immediate encroachment on the domain of dogma involved religious controversies that were not only tiresome, but demoralising. Classical and mediæval literature both contain some true descriptions of geological phenomena, but such observations were too occasional to influence the general trend of thought. The men who wrote the first general geological treatises, from Burnet's "Sacred Theory of the Earth" to Townsend, were essentially theologians, who failed owing to their application of spiritual laws to the natural world. The pioneers of geology were not free to choose their own ground and work on it at leisure; it was their misfortune rather than their fault that their views were often the illogical offspring of observations distorted by a cosmogonic squint. "A well-educated geognost" (a term then used as synonymous with geologist), according to Bakewell in 1813, "has lost the use of his own eyes."

This method did not suit the British mind, which, in the domain of natural science, preferred facts that could be verified by observation to the uncertain products of speculation. Mephistopheles, in Goethe's *Faust*, speaking as the evil genius of Continental science, sneers at the British respect for first-hand facts:—

> "Are Britons here? They travel far to trace
> Renowned battlefields and waterfalls."

The founders of British geology believed, above all things, in such field work, and most of them were interested in economic geology and were quite indifferent to cosmogony. Their studies were devoted to the distribution of soils, as by Lister in 1684, and the agricultural surveys begun by the Board of Agriculture in 1794; or to mining geology, such as the papers of Strachey of 1719 and 1725; while William Smith, engineer and surveyor, deplored "that the theory of geology was in possession of one class of men, the practice in another." Applied geology was, however, then of no general interest, and the science was judged by its contributions to cosmogony. It was prejudiced, according to Lyell, by "the imputation of being a dangerous, or at best but a visionary pursuit"; and it was the mission of the Geological Society to reform the methods of geological work so as to remove any justification for this reputation. Its founders were full of contempt for the vain wranglings between Neptunists and Plutonists, between naturalists and theologians, and it was their ambition to direct geological inquiry into useful channels and secure a foundation of positive knowledge, on which at some future date a geological system could be firmly based. This policy was proclaimed in 1811, when the society adopted as its motto a passage from Bacon, which recommended toil instead of talk. Its loyalty to this principle was remarked by Fitton in 1817, who, in an account of the society's transactions in the *Edinburgh Review*, said that they were limited to the record of "strict experiment or observation, at the expense of all hypothesis, or even of moderate theoretical speculation." According to Lyell, in 1832, the ideal of the founders was "to multiply and record observations, and patiently await the result at some future period . . .; and it was their favourite maxim that the time was not yet come for a general system of geology, but that all must be content for many years to be exclusively engaged in furnishing materials for future generalisations"; and he claimed for the society the credit of brilliant success as the reward of its consistency to that principle.

The Geological Society had two English predecessors, the Askesian Society and the British Mineralogical Society, founded respectively in 1796 and 1799, and amalgamated in 1806. The Geological Society dates from November 13, 1807, when a party of eleven men dining at the Freemasons' Tavern, according to one version (the diary of Wm. Allen), "instituted a Geological Society"; but according to another (a letter by Sir H. Davy) they established "a little talking Geological Dining Club." This misunderstanding led to conflict between those who held that the society should be a mere social dining club and should not encroach on the domain of the Royal Society by publication of important scientific work, and those who intended that the society should raise the status and advance the knowledge of geology by a strenuous, progressive policy. Scientific London had to face this problem, Is it better for each science to have its own society, or for all of them to unite into one great institution? Some of the leaders of the Royal Society thought that the inevitable competition and overlap between independent societies would be injurious; they proposed that the Geological Society should become a branch of the Royal Society, which was to have the right to publish in the Philosophical Transactions any papers it cared to select from those read before the Geological Society. The geologists, however, considered that scientific progress could be best be secured by independent societies working in friendly alliance. Their rejection of the federal policy was probably the wisest course, but it cost them the fellowship of Sir Joseph Banks and Sir Humphry Davy, who resigned as a protest against the alleged trespass on the sphere of the Royal Society.

The dinner, though part of the original plan, appears to have been always of secondary importance, and was soon abandoned to an independent geological dining club. The early meetings, however, consisted of dinner at 5 p.m., the reading of papers from seven to nine, after which often followed an informal assembly, wherein, soothed by smoke and stimulated by wine, discussion was prolonged until after midnight.

The Geological Society quickly justified its independence by raising the standard of scientific publication. It issued its Transactions on a scale of magnificence which the society makes no attempt to maintain. They were one of the finest scientific serials of their day, and the style in which the Government now issues the memoirs of our national Geological Survey is beggarly in comparison. The extravagance in illustration was possible owing to the lavish generosity of the members. Many of them were wealthy men, and they freely spent their money in promoting the objects of the society. Thus Warburton advanced 1000*l.* towards the preparation of Greenough's "Geological Map of England," and some of the members contributed an equal sum towards its publication. Most of the founders and early leaders of the society were men of distinction and influence; they were peers, members of Parliament, city merchants, and men of that professional class of which London is preeminently the home. According to Leonard Horner, the council of the society elected in 1816 "was a Council fit to govern the world."

The young society was at first exclusive, and did not represent the whole of British geology. It elected forty-two honorary members, but the list did not include William Smith. This strange omission is not clearly explained by the author, who hints that it may have been due to social prejudice. Possibly it was partly due to the fact that William Smith, in spite of the immense theoretical value of his work, was essentially an economic geologist, and he, like the two other prominent workers at applied geology, Farey and Bakewell, did not join the society. They may have regarded it as too academic, and the society may have regarded them as too commercial. On the other hand, Robert Jameson kept aloof because the society despised his high soaring flights. He was elected an honorary member in December, 1807, but that was before the publication of his "Elements of Geognosy," of which the preface is dated "The College, Edinburgh, January, 1808"; if this work, a statement of Wernerian geology, had been published a few months before, it should have cost him his honorary membership. His election did not apparently affect him, for he promptly founded the Wernerian Natural History Society at Edinburgh in 1808, perhaps in order to combat the grovelling geologists of London, and he does not appear ever to have joined the London society or taken any part in its proceedings. Was it ignorance or irony that led to the selection of the society as trustee of the Jameson fund, established to commemorate its greatest British protagonist?

The early exclusiveness of the society was due to its enthusiasm as well as to its defined policy. The election of new members had to be unanimous; absence from meetings was to be punished by fines; and no one could attend more than twice as a visitor. Although the society was also a dining club, its first ordinances were animated by the severe zeal of a star-chamber. The members were delightfully confident of their mission; according to the first constitution "all questions on which difference of opinion may arise shall be determined by ballot at the next ordinary meeting," and according to the author (p. 23) this rule appears to have been intended for the summary settlement of geological problems, and not of the society's business. But the society was too successful for such regulations, which were burst by the rapid growth in its roll of membership and the immense influence of its scientific achievements.

All this early history of the society and a summary of its work is now accessible in Mr. H. B. Woodward's monograph, which has been prepared for the centenary meeting to be held on September 26 to 28. The council is to be congratulated on having entrusted the work to an author who has an unrivalled knowledge of the literature of British stratigraphical geology, and is possessor of a rich store of traditional personal information. Mr. H. B. Woodward has been aided by many helpers. Amongst others, Sir Archibald Geikie and Prof. Bonney have read the proofs, Mr. Monckton has contributed an account of the medals, Mr. Herries has edited the reprint of the charter, and Prof. Garwood has arranged the excellent series of photographs. The author has compressed into 336 pages of fairly open print a condensed account of the work of the society, a guide to the available materials as to its history, summaries of the lives of the founders and chief early members, and instructive reprints or summaries of important discussions, one of which shows the reception accorded to Buckland's announcement of the former glaciation of the British Isles. Numerous appendices give lists of early fellows, of the presidents and the subjects of their annual addresses, of the council, the officers and officials, the awards of medals and funds, and reprint of the charter. The information is condensed, but apart from the appendices it is never dull; it is enlivened by racy stories and witty epigrams; the materials have been wisely selected, and presented with Mr. Woodward's usual literary skill.

The author's personality comes out in selection rather than in comment. He is perhaps too discreet, for he hints at explanations where a definite statement of his opinion would have been valuable. The course of the society has not always run smooth, and it is interesting to find that some of the modern criticisms are similar to those made at intervals through its life. A society with a strong policy and a definite ideal cannot expect unanimous approval, and its traditions have always been radical. It secured on incorporation an unusually liberal charter, and it has repeatedly been the pioneer in important reforms. Amongst other innovations was the admission of women to the meetings in 1860, an experiment abandoned, however, in 1863.

Mr. H. B. Woodward's history is worthy of its subject. He naturally devotes most attention to British stratigraphy, but one chapter might perhaps have been devoted to the society's contributions to foreign geology, so many of which are of first-class importance.

The author is gently sarcastic regarding the nomenclature of some modern palæontology published by the society. The artificial Linnean system was adequate for the biology of the eighteenth century, which was innocent of such principles as "heterogenetic homogeneity." The plastic terminology that is in process of development in correspondence with the variability of life has lost in simplicity, while it has gained in truth. Scientific names, like other words, must be allowed to change in meaning, even though the change may puzzle geologists as much as a lawyer is puzzled to define such common terms as mine or mineral. The author notes with apparent regret that a fossil should be called a "konincko-phyllid cyathophyllum"; but the Geological Society would be untrue to its inspiring traditions if it closed its journal to those whose living faith in evolution is much more than a mere verbal creed, and must be expected to influence all their practice. J. W. G.

ANCIENT BABYLONIAN LETTERS.

Late Babylonian Letters. By R. Campbell Thompson. Pp. xxxvi+226. (London: Luzac and Co., 1906.) Price 15*s.* net.

OF all the ancient written matter that has been discovered by modern archæological research and deciphered by the professors of languages long dead, perhaps the documents most interesting to the general reader are those which reveal to us the daily life of the people who wrote them thousands of years ago. These "human documents" are always interesting reading. Royal instructions, reports of generals or of astrologers, ministers or caravan-leaders, diplomatic correspondence, and last, but not least, the ordinary letters from one man to another, whether anent business or pleasure, have been during the last half-century recovered from the past, and are now supplementing in a most remarkable way the formal annals of the historians. From Egypt we have the famous "Tell el-Amarna Letters" of 1400 B.C., the correspondence of the time of the priest-kings (1000 B.C.) published by Spiegelberg, and the interesting series of Greek letters recovered from the sands of Oxyrrhynchus by Drs. Grenfell and Hunt, not to speak of the Coptic epistles of the monks of Deir el-Bahari in the seventh century A.D., translated by Crum and by Hall. From far Turkestan we have the wooden tablets inscribed in Kharoshthi characters, discovered by Dr. M. A. Stein, which tell us of the daily life of the Indian kingdom of Khotan in the flourishing days of Buddhism; and now Mr. R. C. Thompson (late of the British Museum), of the University of Chicago, has published an edition of a series of late Babylonian letters, being "transliterations and translations of a series of letters written in Babylonian cuneiform, chiefly during the reigns of Nabonidus, Cyrus, Cambyses, and Darius," *i.e.* from about 550 to 480 B.C. These letters are preserved in the British Museum, and the original cuneiform texts have been published by the Trustees.

The book is published by Messrs. Luzac and Co. in their admirably got-up "Semitic Text and Translation Series." Print, paper, and binding are good and appropriate. As a frontispiece Mr. Thompson gives an adaptation (with English text instead of Babylonian) of a remarkable Babylonian map of the world, which we recommend to the attention of Mr. Beazley for comparison with other ancient maps. We do not believe, by the way, that this map, with its restricted knowledge, really represents the world as known to the Babylonians of the sixth century B.C. It is obviously a copy of a far more ancient map, dating from the days when the Babylonian knew of but little beyond the limits of his own fens, which he conceived as an island surrounded by the waters of the Persian Gulf.

The perusal of these letters will be useful to the modern historian who is not content merely to recapitulate the annals of his ancient *confrères*, but wishes to give a picture of the civilisation of an ancient people. With the exception of an occasional royal epistle, such as the very interesting one of Ashurbanipal (No. 1, a century older than the rest) ordering the collection of tablets for the royal library at Nineveh, now in its entirety preserved on the shelves of the British Museum, these letters were written by the ordinary Babylonian "man in the street," the ordinary middle-class inhabitant of Babylon, and his wife. For the ladies of Babylon were as busy with the stilus as those of London are with the pen, and many of Mr. Thompson's collection were written by women. They relate to the usual round of life of a civilised people as led in an Oriental country. The letters of the modern inhabitants of Cairo, Baghdad, Lahore or Delhi must be very like them. Perhaps at Benares, rather, we might get their very counterparts. For in Babylonia, as in modern India, the temples of the gods and the business of the priests were a great factor in the city life, and a large proportion of these letters "is connected with the business of the great temple of the Sun-god at Sippar," with the landed property belonging to the temple, from which the priests drew their revenues, and with the arrangements for the temple-dues, which were often paid in kind. This is an ancient touch, which we should only find paralleled now in India and the Far East. An Oriental trait is the correspondence with regard to the transport of food, goods, materials for building, &c., by beasts. The back of a beast of burden was then, as now in the same country, the only means of transport. Babylonia has not progressed a step in the direction of the improvement of transport since the days when these letters were written; and the completion of the Baghdad Railway seems still far off!

Of the ordinary letters between man and man on matters of interest only to themselves Mr. Thompson gives many specimens. Travellers in a far country write to their friends asking for news, and upbraiding their faithless correspondents, for then, as now, "one had not time to write." Husbands indite model epistles to their wives, like one, highly commended by the editor, which reads :—

"By the grace of the gods I am well, as also is Bêl-iddin. See, I am sending a letter to Iddina-

Marduk, the son of Ikiša-apli, that he may give thee the *gur* of wheat. Be not remiss in the housework, but be careful; pray the gods on my behalf, and speedily let me have news of thee by the hand of some traveller."

And so forth. In conclusion, we may congratulate Mr. Thompson on his interesting book, and, for the necessary *amari aliquid*, warn him against indulging in rather too breezy translations, such as "Why, an't please thee, have I and my daughters to pass the time in thirst for a letter from thee? Rack thy brains (for an excuse and then) by Šamas, see why Bêl-uballit, an't please thee, hath taken away all my dates" (p. 175). Elsewhere (p. xxxii) Mr. Thompson presents an even more alarming version of the same epistle:—"Why, pray, am I and my daughters to pass the time thirsting for a letter from thee? Now, gather thy wits together, and then, by Šamaš, observe! Why, pray, hath Bêl-uballit taken away all my dates?" This style of translation is hardly sufficiently dignified, and is to be avoided. The lady Gagâ, who writes the letter to her father, was no doubt a very energetic female, but Mr. Thompson's version of her filial exhortation seems to us to be rather too energetic. The index and vocabulary at the end are very complete and useful.

PSYCHOLOGICAL SCIENCE.

Psychology—General Introduction. By Dr. C. H. Judd. Pp. xii+389. (New York: Charles Scrib-Price 7s. 6d. net.

The Major Symptoms of Hysteria. By Dr. Pierre Janet. Pp. x+345. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1907.) Price 7s. 6d. net.

THESE two books furnish yet one more proof—if further proof were needed at the present day—of the right of psychology to a place among the primary sciences. In Prof. Judd's book we have a concise and well-synthesised statement of the methods and principles of the science, in the form of a general introductory text-book; Dr. Pierre Janet shows the exclusive importance of those principles in the diagnosis and cure of a widespread disease.

Prof. Judd leaves his readers in no doubt as to his general standpoint or the guiding idea of his book. He develops his subject along the lines of "function" in contradistinction to "structure," and "objectivity" as opposed to the "subjectivity" of mere introspection, laying great stress throughout on "organisation" as the general explanation of mental products. In a well-worded preface he attempts to anticipate criticism by summarising the general principles of treatment which he has followed. Briefly they are: (1) "A functional view of mental life"; (2) the genetic method; (3) a coordination of physiological and psychological data; (4) an endeavour to make clear "the significance of ideation as a unique and final stage of evolution." These principles he follows faithfully in his book, the marked "objectivity" of treatment almost amounting to materialism in the earlier pages. Analysis of material conditions takes precedence of, and to a great extent supplants, introspective description of mental states; moreover, the absence of any definite discussion of the general relation of mind and matter tends to intensify this impression of materialism. But if such an illusion should arise in the reader's mind it is quickly dispelled by later chapters, more particularly by the chapter on "The Concept of the Self." The nature of this concept as ultimate and supreme for psychology, though admitting of a developmental history, is very well brought out. The chapter following this, on "Voluntary Choice," is rather disappointing.

Parts of the book are of outstanding excellence. The discussion of space-perception seems to the writer an ideal of what a treatment of this difficult subject should be The chapter headed "Experience and Expression" is also very good. It brings out well the importance of motor factors to the general structure of experience, not in the form of muscular *sensations*, as the first imperfect statements of the theory would have had one believe, but as forms of "motor organisation" in the central nervous system. In this chapter we have developed in greater fulness that central idea of organisation which dominates the whole book.

Two small points call for criticism. First on p. 97, to explain contrast effects as merely after-effects in the retina is surely a case of over-simplification. Undoubtedly the two classes of phenomena are closely connected, but the relation is more complicated than the text would have the reader believe. Secondly, what is called the Principle of Fusion (Association) on p. 223 should not be dismissed as self-evident and requiring no explanation.

On the whole, the book is an excellent treatment of the general principles of psychology, and may be confidently recommended to all earnest students of the science. It is a book that should be read more than once. On the title-page it is described as the first volume of "a series of text-books designed to introduce the student to the methods and principles of scientific psychology." We can only say that our experience of this volume encourages us to look forward with eagerness to the publication of the later volumes of the series.

Dr. Pierre Janet's book is a collection of fifteen lectures given in the medical school of Harvard University towards the end of last year. Much of the material, cases and explanations alike, is taken from previous publications of the author, as, *e.g.*, "Névroses et Idées fixes," "L'état mental des Hystériques," &c., but the form of exposition makes of it an independent scientific and literary achievement for which all who are interested in mental diseases will be thankful to its author. Prof. Janet is admittedly supreme in the domain of pathological psychology, and the present book will do still more to confirm that estimate of his position. His statement of the major symptoms of hysteria is no mere external classification. Taking somnambulism as the typical form of hysterical accidents, he shows with copious illustration and acute argument how such symptoms shade off into fugues, double personalities, convulsive attacks, contractures, paralysis, anæsthesias, &c., while exhibiting the same essential relations in all these various forms. By the time lecture xiii. is reached, the evidence is overwhelming as to the extent of hysterical symptoms and the ground of their relationship to one another. "Dissociation" and "suggestibility" are the words employed to describe the underlying mental state, and their exact meanings are very carefully and thoroughly worked out. The final outcome is a definition of hysteria, an enumeration of its direct and indirect stigmata, and incidentally a theory as to the nature of personal synthesis, with which this disease is so closely connected.

To medical practitioners and psychologists alike the work should be of supreme value. W. B.

THEORY AND PRACTICE OF LUBRICATION.

Lubrication and Lubricants. A Treatise on the Theory and Practice of Lubrication, and on the Nature, Properties, and Testing of Lubricants. By Leonard Archbutt and R. Mountford Deeley. Second edition, thoroughly revised and enlarged. Pp. xxxii+528. (London: C. Griffin and Co., Ltd., 1907.) Price 21s. net.

THIS work may be divided into two parts, which, in fact, have little connection with one another. The first is that which deals with the chemical and physical properties of lubricants generally, and will appeal more particularly to analytical chemists, to whom samples of lubricants are submitted for the purpose of estimating their commercial value. So far as one can judge, this part of the work is particularly clear; full directions are given for carrying out any of the tests, in order to obtain such things as the free acids. This will, however, hardly appeal to the average user of lubricants, as what he requires is some simple mechanical test which will, more or less, indicate the value of the oil. The second portion of the work deals with the mechanical testing of oil, and also the design and construction of bearings generally, together with the general theory of friction, as given in chapter iv. This is particularly well written, and gives the full theory of lubrication as developed by Osborne Reynolds, Goodman, and Towers, and will repay a careful study. An account is given of the various oil-testing machines as designed by Thurstan, Smith, and Goodman. Judging from our own experience, while these machines when extremely carefully handled give trustworthy results, one is never quite certain as to what is really being obtained; whether it is a test of the lubrication itself, of the materials forming the bearing, or of the condition of the bearing. We should be inclined to say that it would probably be a small part of each, and, moreover, it does not give much idea as to the value of the lubricant for continuous use, which is now the rule for engine work generally. Doubtless, owing to the great length of the book, some 500 pages, the authors have been unable to devote a large space to the design and lubrication of bearings, although they give much useful information as to the composition of bearing metals generally, and also the admissible loads. They do not, however, give the attention to forced lubrication which we consider it deserves. The whole tendency of modern engine practice, either with enclosed or open engines, is to substitute pressure lubrication for gravity, and this has entailed wholly different construction of bearings from those with the ordinary drip lubrication.

The large subject of ball and roller bearings is dismissed in some three pages, and, considering the importance and growing use of the ball bearing in large sizes, we think this type of bearing deserved fuller attention. The mechanical lubrication by means of sight-feed lubricators, which allows the attendant to regulate exactly the quantity of his oil, is well illustrated, and rightly so, because this method is found in practice very considerably to economise the oil supply. Splash lubrication, as used by Willans and by many motor-car engineers, is alluded to, but its defects as regards the oil working up into the motor cylinders are not pointed out, nor is it shown that this method of lubrication is fast being driven out in favour of a pressure system. The authors, in the chapter on gas-engine cylinder lubrication, give some interesting analyses of the deposit found in the cylinders, and point out that the deposit is not wholly of a carbonaceous nature, but contains quite a considerable portion of sulphur obtained from the gas. They also recommend the use of pure mineral oils, as against the mixture of a small quantity of a neutral fixed oil. This wholly agrees with our own experience, namely, that a pure mineral oil is the only one possible to use when the compression of the engine is in the neighbourhood of 200 lb. per square inch. It would almost appear as if the whole difficulty of running at very high compressions is to prevent deposits of carbon. The only way to overcome this is to use an oil which will entirely burn, and in very small quantities. All those who are interested in lubrication generally will welcome Messrs. Archbutt and Deeley's work, more especially those in a consultative position, but we fear that, owing to its length and the predominance of the chemical and physical side, it will not be of the service to engineers generally that a smaller and less scientific work would be, as it must be borne in mind that the great majority of those who have to use lubricants have neither the time nor inclination to make accurate chemical tests.

F. W. BURSTALL.

OUR BOOK SHELF.

The Savage South Seas. Painted by Norman H. Hardy. Described by E. Way Elkington. Pp. xii+211. (London: A. and C. Black, 1907.) Price 20s. net.

To those who know the parts of Melanesia which Mr. Norman Hardy pictures, or who, like the writer, have seen much of his work, this book will come as something of a disappointment; and this from no fault of the artist, who is generally successful in reproducing, not only the physiognomy, but the musculature and the tricks of movement of the folk whom he portrays. The truth is that the tone of the reproductions (apparently made by the three-colour process or one of its modifications) of Mr. Hardy's water-colour sketches leaves much to be desired; in many of the reproductions there is a darkening of the colour scheme, giving crepuscular and storm effects—where none are intended—to many of the landscapes, as plates 2 and 4. In the case of illustrations showing figures, the tone of the whole group may be so lowered that people, houses and utensils show up in scarcely differentiated tints of brown against a sky for the colour of which the writer knows no warrant (illustration 19).

But there are also many charming and realistic pictures, such as plates 3 and 33, though in the last the excellence of the drawing and colouring of the canoe and the figures seated therein is perhaps somewhat discounted by the excess of grey and brown in the landscape.

Plate 16 may be picked out for special praise. It gives a very real impression of the Rigo dubu, seen at midday, when the glare of the sun lightens the grey of its weather-beaten posts and renders the yellowish soil on which it stands almost white.

In spite, then, of defects of the kind mentioned, the illustrations of this book give a better idea of Melanesia than can be obtained by photographs or black and white drawings, and so the work must be pronounced a success. Mr. Hardy is also to be congratulated on the accuracy of his observation, for in so few instances are there ethnographical inaccuracies in the plates or their accompanying short descriptions that it may be useful to point out the chief of these in as far as they affect New Guinea. Probably no girl ever danced her way to "the dubu dance" flirting her petticoats the while, as is shown in the frontispiece. Kaivakuku masks do not exist among the Roro tribe, though they occur among the Waima and Kevori, both Roro-speaking tribes. The feather head-dresses of the girls (illustrations 14 and 15) are distinctly yellowish, not red as shown in the plates; indeed, red feathers are carefully excluded from this dancing head-dress, the parrots providing the feathers being subjected to special treatment in order that their feathers may be of the desired colour.

In this book the illustrations so far exceed the text in importance and quality that little need be said concerning the latter, which contains many inaccuracies and misprints, is written in poor English, and generally falls far below the level of other volumes contained in this series. C. G. S.

A Text-book on Hydraulics, including an Outline of the Theory of Turbines. By Prof. L. M. Hoskins. Pp. v+271. (London: Archibald Constable and Co., Ltd., 1907.) Price 10*s.* 6*d.* net.

THIS book is intended for the instruction of engineering students during their university or college course, who have already acquired a good practical knowledge of pure mathematics, and possess a fair elementary acquaintance with the principles of mechanics. After a short introductory chapter dealing with definitions and principles, followed by a chapter on hydrostatics, the flow of water through orifices under different conditions is considered, and Torricelli's theorem is stated, and instances of its application explained. Bernoulli's theorem, which the author calls the general equation of energy, and upon which he bases his explanations of the problems of the steady flow of liquids, and its applications, form the subject of the next four chapters. Various formulas for the flow of water in pipes under definite conditions are then deduced from the general equation of energy; whilst a separate chapter is devoted to a discussion of the methods of estimating the frictional loss of head in pipes.

In treating of uniform flow in open channels, the author, after referring to Chézy's formula, $v=c\sqrt{rs}$, as the basis for calculating the mean velocity, and alluding to Bazin's experiments for determining the influence of the nature of the surface and the shape of the channel in modifying c, deals fully with the well-known, general, empirical formula for c deduced by Ganguillet and Kutter from the measurements of flow in a wide range of channels, which is a function of the slope, the hydraulic radius, and a coefficient of roughness depending on the nature of the surface of the channel. To facilitate the adoption of this complex formula, a table is given of the values of c computed for a certain range of conditions, and also a graphic diagram from which they can be obtained by measurement. The more complicated question of non-uniform flow in open channels is next discussed, deduced in the first instance from the general equation of energy for streams of variable cross-section; and the portion relating to hydraulics is concluded by a consideration of the different methods, direct and indirect, by which the discharge of streams differing greatly in volume can be measured.

The theory of turbines forms the subject of the last seven chapters of the book, under the respective headings dynamic action of streams, theory of steady flow through rotating wheel, types of turbines and water wheels, theory of the impulse turbine, and of the reaction turbine, the tangential water wheel, and turbine pumps. The book terminates with three appendices, in which the general equation of energy is applied to the steady flow of gases, relative motion is explained, and tables of conversion factors are given. The subjects dealt with are elucidated by one hundred and thirty-seven simple diagrams in the text, and examples are added in almost every chapter relating to its contents, for the student to work out, to which the answers are appended. This book will be valuable in training engineering students possessing a fair knowledge of mathematics to solve any problems in hydraulics they are likely to meet with in practice, and it will also furnish them with an insight into the principles on which the working and efficiency of turbines are based.

Flora of Sussex, or a List of Flowering Plants and Ferns found in the County of Sussex. By Rev. F. H. Arnold. Pp. xxii+154. (London: Simpkin, Marshall and Co., Ltd.; Arundel and Horsham: Mitchell and Co, 1907.) Price 5*s.* net.

THIS is a new and revised edition of the flora, including phanerogams, pteridophytes, and Characeæ, brought out by the author in 1887. The principal changes will be found in the additions to the species and many new localities. The introduction is not altered except for the increase in the list of contributors, to which are added the names of Mr. C. E. Salmon, Mr. W. Whitwell, Rev. E. Ellman, and Rev. E. S. Marshall. The last-named has been a most energetic worker, especially in West Sussex, and several of the new species were first discovered by him. A complete revision will be noted for the species of Rubus, for which the localities are provided chiefly on the authority of Messrs. Salmon, Marshall, and Rogers, and also a revision of the genus Salicornia. Among the species added to the county list are *Epilobium Lamyi*, *Wolffia arrhiza*, *Utricularia neglecta*, *Chenopodium botryoides*, *Spartina Townsendi*, and *Spartina alterniflora*, first found by the author. Most of these species were previously known from adjacent counties, as noted in the appendix, where the list has escaped revision. The author was not fated to see the publication of this book, which will be welcomed by all systematic botanists sojourning in Sussex; a note saying that he dictated the preface on the very day that he was taken ill is added by his daughter, who has also prepared the three illustrations which are included.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Reconstruction of Diprotodon from the Callabonna Deposits, South Australia.

SOME years ago, under dates June 21 and June 28, 1894, NATURE contained a notice of an extensive deposit, at Lake Callabonna, South Australia, of fossil bones of Diprotodon, Phascolonus, various species of extinct kangaroos, and of a large struthious bird, since named *Genyornis newtoni*, in honour of the late lamented Prof. Newton, of Cambridge, and in recognition of much personal kindness received from him by the writer. Since that date various and more detailed references to some of the forms represented in this deposit have appeared in the Transactions and Memoirs of the Royal Society of South Australia; and now, at last, after a lapse of years, which may have seemed unnecessarily long to those unacquainted with all the circumstances of the case, we have lately completed at this museum a complete cast in plaster of the skeleton of *Diprotodon australis*. Some of your readers may be interested in the photograph of this cast which I now send you (Fig. 1), as well as in one which gives our idea of the reconstruction in the flesh of this marsupial (Fig. 2).

As has been previously mentioned in your columns and in the other publication referred to, the state in which the Callabonna fossils were originally found, and the injury which they suffered as the result of a long journey on camel back to the railway line, were such as to require the expenditure upon them of much detailed preparatory labour before they could be restored to a sound and enduring condition; but while the ultimate result has been quite satisfactory as regards the appendicular skeleton, there have been much greater difficulties, and not so completely a satisfactory result, in respect to the skull and vertebral column. In both these categories the bones were to a degree above all the others soft, friable, broken, and infiltrated with saline matter that was difficult to remove. In the skulls particularly, the constituent bones were both broken and greatly distorted. Those that had been found lying on their sides were laterally compressed to an extent that the whole cranial mass formed a flattened slab which in some instances did not exceed a few inches in thickness. In other cases the compression had occurred in a dorso-ventral direction with a like result of producing many fractures and much distortion of the proper relation of parts. Fortunately, the distortion has not affected every skull in the same way, so that in the construction of the cast it has been possible to utilise undisturbed parts of different skulls.

Nevertheless, even with the considerable mass of material available, both from Callabonna and from other localities, there were some parts of the skull which were never found in an intact condition, and it is in these respects that the cast is not to our satisfaction.

For the information of those who will, it is hoped, eventually possess a copy of this cast, it may be well now to mention those parts the correctness of which we cannot, unfortunately, for the above reasons guarantee. Coming under this category are the occipital region, with the exception of the condyles and the immediate boundaries of the neural foramen. In not a single skull from Callabonna or from elsewhere was this extensive region without such serious breakage and distortion as to render a faithful reproduction of its details impossible. Consequently, in our restoration we have followed as best we could the details of Owen's figure (Owen's "Fossil Mammals of Australia," Plate xix., Fig. 3). Then another part that was always greatly damaged was the anterior or malar pier of the zygomatic arch, the broken parts being generally telescoped; thus we are not quite satisfied that we have got this region as it should be, though in other respects the zygoma is correct. Also, as might be expected, the thin laminar edges of the lateral boundaries of the mesopterygoid fossa were always broken, so that we have been consequently devoid of objective guidance in their reconstruction.

For the vertebræ, many of which were also in a particularly fragmentary and friable condition, a set belonging to one animal which was numerically nearly complete was used as models. Where parts of these were deficient, as often occurred, they could generally be supplied by the corresponding segment from another animal, but not always so. We had no model for the neural spines of the sixth and seventh cervical vertebræ, which are thus parts added in conformity with what we conceive to be the serial plan of arrangement. Fourteen vertebræ bear ribs, and there are five of the lumbar series; four are fused to form the sacral mass, and there are nineteen separate segments in the tail. The ribs, with one exception, are those belonging to the vertebræ, but as most of them were considerably twisted or otherwise distorted, it was sometimes necessary that they should undergo the operation known to wheelwrights as "cutting and shutting" before they could be set properly both to their respective vertebræ and to one another.

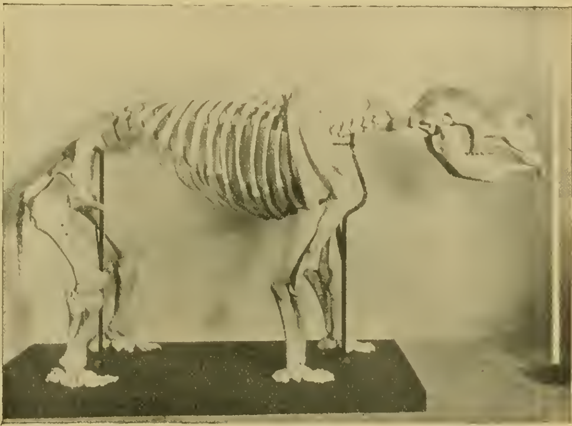

FIG. 1.—Plaster cast of the skeleton of *Diprotodon australis*.

As previously stated, the limb bones, from their fewer fractures and better texture, gave much less trouble in their restoration than those of the axial skeleton. Most of them belong to the same individual as the vertebræ, but some, in a damaged condition, have been replaced by other bones of suitable size. The peculiar feet, the structure of which was revealed by the Callabonna discovery, have been described (Memoirs Royal Society of South Australia, vol. i., part i.).

It is clear by reference to the bones of other skeletons in the Callabonna collection that the animal now represented was of medium size only, the height of the cast at the shoulder being 5 feet 6 inches, but unfortunately the skeletons of the very large individuals were much more incomplete than that which served as our model. I think it would be safe to place the height of the largest animals in life at 6 feet, or perhaps even a few inches more.

With regard to the restoration in the flesh, the photograph which I send you was made by my friend Mr. C. H. Angas, a skilful delineator of animals, with such help as we could give him from the anatomist's point of view. There can, I think, be little doubt that in its general build the Diprotodon had considerable resemblance to a gigantic wombat, and as such we have drawn him. Opinions may, however, differ as to our treatment of the muzzle. The huge overarching nasals, which greatly exaggerate the somewhat similar formation in the tapir, and the very massive bony internarial septum, must indicate some special, and probably some protuberant, development of the soft parts in this region. Bearing in mind the many cranial, as well as other skeletal, resemblances between Diprotodon and Macropus, we have consequently assigned to the former in our restoration a snout of the same type as that of the latter animal, but of greatly exaggerated size and prominence. In the case of the ears, we have compromised between the extremes of length of those organs as they occur in the kangaroos and wombats, with, however, a nearer approach to the former proportions. The result, on the whole, has been to make the head appear much more like that of a very massive and bulky kangaroo than of a wombat. In the original sketch we have presumed the animal to be covered with a very dark short fur of wombat type. For a setting we have delineated the Diprotodon amidst surroundings that represent some *present* characteristics of Central Australia. Thus in the background, to the left, is part of the white expanse of one of those large salt-encrusted clay pans of which Lake Callabonna, where the bones were found, is an example. In the distance beyond the lake is shown one of the flat-topped hills that are very characteristic of the "desert sandstone" region of the interior. The vegetation in the foreground is chiefly "saltbush" (Atriplex spp.), some species of which, together with allied plants, having apparently formed the principal food of the Diprotodon, just as these now supply the chief sustenance of the introduced Herbivora, while here and there is a trailing plant of "parakylia" (Claytonia spp.), so well known to travellers in the dry central regions for its moisture-holding properties.

I might add, though the information has already appeared in your columns, that a copy of this cast is in the possession of the Zoological Museum at Cambridge University, and that portions of it, together with some original bones, have been sent to the Natural History Department of the British Museum. Replicas of it have also been sent to the museums of Melbourne, Victoria, and of Perth, Western Australia.

FIG. 2.—Restoration of *Diprotodon australis*.

The Origin of Radium.

IN a communication published in NATURE of November 15, 1906, I described some experiments which had given results indicating the growth of radium in a preparation of thorium which had been previously precipitated in a solution of a uranium mineral. I had found from other experiments that the thorium after this treatment contained a radio-active body which did not decay appreciably in the course of several years. It was a simple matter to demonstrate that this active substance was not radium, uranium, or polonium, and I therefore assumed that it was actinium, since Debierne has stated (*C.R.*, cxxx., 906) that the chemical properties of actinium are similar to those of thorium, and since, moreover, an emanation which completely lost its activity in less than half a minute was evolved in small amounts from the oxides of the thorium treated in this manner. I therefore suggested that actinium was the parent of radium and the intermediate product between uranium and radium.

Rutherford has recently given an account (NATURE, June 6) of some experiments in the course of which a solution of actinium was successively precipitated with ammonium sulphide in order to remove the radium present. From the results obtained he concludes that the parent of radium is distinct from actinium, and is separated from the latter by precipitation with ammonium sulphide.

For the past ten months I have been continuing my experiments with the object of determining more definitely the properties and chemical behaviour of this elusive parent. The general manner of proceeding has been to obtain as complete a solution as possible of known weights of different uranium minerals. These solutions have been treated in the manner described in my earlier communication, with special precautions and modifications. The growth of radium in the solutions of the rare earths finally obtained was determined by measurements of the amount of radium emanation present at frequent intervals, and the rate of growth was calculated by an expression which took into account the rate of production of the emanation by the radium. The minerals used included carnotite, Joachimsthal pitchblende, gummite, uranophane, and a specimen of very pure uraninite from North Carolina containing only 0·03 per cent. of material insoluble in dilute nitric acid.

The space available in these columns will permit of only a brief mention of some of the more interesting results. In confirmation of Rutherford's statement it was found that the rate of production of radium was not influenced appreciably by the presence of radio-actinium and its products, which were completely absent from most of the solutions at the start. Continued observations of the growth of radium in the first solution prepared indicate that the rate of production of radium has been constant, within the limits of experimental error, for a period of more than 500 days.

I have attempted with one of my preparations to repeat the separation of the radium parent from actinium by the ammonium sulphide treatment which Rutherford has described. No separation could be detected when freshly prepared, pure ammonium sulphide was used. It was found that the radium parent can be quite completely separated from actinium by repeated precipitation with sodium thiosulphate under the conditions usual for the precipitation of thorium. In the case of a solution of the parent substance with thorium and other rare earths treated in this manner, less than 1 per cent. of the parent present remained in the filtrate, as was shown by the growth of radium in the two fractions obtained in this process. Since ammonium sulphide is always open to suspicion unless freshly prepared, and since on standing in loosely stoppered bottles it ultimately changes wholly into ammonium thiosulphate, it appears probable that the separation noticed by Rutherford was due to the latter reagent.

An interesting relation has been noticed between the growth of radium and the activity of the substances other than thorium in my solutions containing the radium parent. This proportionality is quite striking in those solutions containing the more completely purified salts. The activity of the substance present in these salts is comparatively high, and is about equal to the activity of the radium (itself) with which it is associated in the mineral. More significant still is the fact that this radioactive substance does not appear to possess any of the characteristic properties of the recognised radio-active elements. It is impossible that it is uranium, thorium, radium, or polonium. It has none of the properties that have been given as characteristic of actinium. About four-tenths of a gram of thorium oxide, containing an amount of this new body sufficient to give a leak of 500 divisions per minute in an α-ray electroscope, did not produce sufficient actinium emanation to permit its detection in another electroscope of greater sensitiveness. The thorium oxide had been prepared some weeks before by the gentle ignition of the oxalate, and was very porous. A strong current of air, about four litres per minute, was drawn over the preparation. There was no difficulty in measuring the thorium emanation evolved by this material under these conditions.

That the active substance is not actinium is also indicated by the fact that from a solution more than five months old no active substances other than thorium products could be separated by treatment with ammonia, by the formation of finely divided sulphur from sodium thiosulphate, or by the precipitation of considerable quantities of barium sulphate in the solution. The first process should have separated actinium X, and the two last should have separated radio-actinium had these products been present. The solution contained about 3 grams of thorium and a quantity of the new substance having an activity equal to that of about 35 grams of pure uranium.

Another important matter is the behaviour of the oxides obtained by strongly igniting the hydroxides precipitated by ammonia from a solution similar to the above. The activity of these oxides remains nearly constant for long periods, showing only a slight initial rise corresponding to the formation of thorium X in the thorium present. No rise corresponding to the formation of actinium X can be observed, but if actinium were present a separation of this product would be expected.

For these and certain other reasons I think that there is good cause for believing that uranium minerals contain an element emitting α rays, which is different from the other elements that have been identified, which produces no emanation, and which resembles thorium in its chemical properties. The activity of this element appears to be about the same as that of the radium (itself) with which it is associated in minerals. It is without doubt a product of uranium, and is probably the immediate parent of radium. It is very likely that this body is contained in Debierne's actinium preparations and in Giesel's "emanium" compounds, especially in the former, and its presence may perhaps explain the confusion which has resulted from Debierne's earlier assertions that actinium accompanied thorium as opposed to Giesel's positive statements to the contrary (*Chem. Berichte*, xl., 3011). The proportion of the total activity of a mineral due to the actinium present is very small, for the activity which can be attributed to actinium is less than 9 per cent. of the total.

The rate of disintegration of radium as determined from its growth in preparations similar to those described above, separated with great care from very pure North Carolina uraninite, indicates that the half-value period of this element is about 1900 years. It is hoped that certain experiments now in progress will make it possible to determine this factor with a satisfactory degree of certainty.
